Atmospheric gravity waves (AGWs) propagating upward from lower atmospheric sources play a dominant role in transportating and depositing energy and momentum from upper troposphere (UT) to lower mesosphere (LM). Particularly, in polar region, these effects of AGWs are well-known to strongly decelerate the polar night jet and drive large scale meridional circulation from the summer pole towards the winter pole. In addtion, it is suggested that considerations of the realistic propagation property of AGWs may largely improve a significant bias of climate model. Therefore, investigation of the activity of AGWs between UT and LM based on continuous observational studies can be regarded as one of important isuues.

The National Institute of Polar Research (NIPR) is leading a six year prioritized project of the Antarctic research observations since 2010. One of the sub-projects is entitled 'the global environmental change revealed through the Antarctic middle and upper atmosphere'. As a part of the sub-project, a Rayleigh/Raman lidar (RR lidar) was installed at Syowa, Antarctica (69S, 39E) in January, 2011. The operation has been conducted since February 2011 and the RR lidar has kept measuring temperature profiles continuously between approximately 10 and 80 km for almost 3 years.

The RR lidar system in Syowa can obtain photon count data for 4 channels simultaneously, and each data is recorded separately in binnary format. The data from 3 channeles, i.e., Raman (10-30km), Rayleigh-Low (20-65km), Rayleigh-High (30-80km), corresponding to differenet height ranges are used for estimations of temperature profiles from UT to LM. In oreder to estimate height continuous profiles of atmospheric temperature based on the 3 different channeles, we are examing the following analysis methods. (1) The temperature for Rayleigh-High and Rayleigh-Low channels estimated by solving the lidar equation can be assigned to temperature at an initial height for the lidar equation in Rayleigh-Low and Raman channels, respectively. (2) The initial heights for the lidar equation can be determined automatically taking into account time and height dependent shot noises due to background luminosity. (3) The error propagations from the initial height to lower heights are evaluated by assigning artificial temperature offset ranging from -50 to 50 K.

The height continuous temperature profiles between UT and LM obtained from improved analysis methods would allows us to investigate important scientific issues such as temporal and height variabilities of potential energy per unit mass of AGWs and the relationship between occurrence of Polar Stratospheric Clouds and background atmospheric temperature. In this presentation, we will report the detail of the analysis methods and future perspectives including open data base of temperature profiles.

Tunable resonance scattering lidar system for Antarctic observation: Current status

TSUDA, Takuo[1*] ; EJIRI, Mitsumu[1] ; NISHIYAMA, Takanori[1] ; ABO, Makoto[2] ; MATSUDA, Takashi[1] ; KAWAHARA, Takuya[3] ; NAKAMURA, Takuji[1]

[1]National Institute of Polar Research, [2]Graduate School of System Design, Tokyo Metropolitan University, [3]Faculty of Engineering, Shinshu University

We are developing a new resonance scattering lidar system to be installed at Syowa Station (69S, 39E) in Antarctica. For the new lidar system, we have employed a tunable alexandrite laser covering the resonance scattering wavelengths of two neutral species, which are atomic potassium (K, 770.11 nm) and atomic iron (Fe, 386.10 nm), and two ion species, which are calcium ion (Ca^+, 393.48 nm) and aurorally excited nitrogen ion ($N_2{}^+$, 390.30 nm, 391.08 nm). Thus the tunable resonance scattering lidar system will provide information on the mesosphere and lower thermosphere as well as the ionosphere. Using the tunable lidar and co-located other instruments, we will conduct a comprehensive ground-based observation of the low, middle, and upper atmosphere above Syowa Station. This unique observation is expected to make important contribution to studies on the atmospheric vertical coupling process and the neutral and charged particle interaction. In this presentation, we report current status of the tunable lidar system in development and test observations at National Institute of Polar Research in Tachikawa, Japan.

Doppler-free spectroscopy experiments for the Antarctic Potassium resonant lidar

KAWAHARA, Takuya[1] ; TSUDA, Takuo[2*] ; NISHIYAMA, Takanori[2] ; EJIRI, Mitsumu[2] ; ABO, Makoto[3] ; NAKAMURA, Takuji[2]

[1]Faculty of Engineering, Shinshu University, [2]National Institute Polar Research, [3]System Design, Tokyo Metropolitan University

The National Institute of Polar Research (NIPR) is leading a six year prioritized project of the Antarctic research observations since 2010. One of the sub-projects is entitled ”the global environmental change revealed through the Antarctic middle and upper atmosphere”. Profiling dynamical parameters such as temperature and wind, as well as minor constituents is the key component of observations in this project, together with long-term observations using existent various instruments in Syowa, the Antarctic (39E, 69S). As one of the instruments in this project, a new resonance scattering lidar system with tunable wavelengths is developed to be installed and operated at the Syowa Station. The lidar transmitter is based on injection-seeded, pulsed alexandrite laser for 768-788 nm (fundamental wavelengths) and a second-harmonic generation (SHG) unit for 384-394 nm (second harmonic wavelengths). In order to tune the seeder laser to absolute Potassium resonance line, Doppler-free spectroscopy with a Potassium cell is crucial. The measurement was done at NIPR and the Doppler-free spectrum was recorded with 0.005 pm wavelength resolution. Three absorptions spaced with 0.05pm at the cross-over wavelength were clearly measured. In this talk, details of the experiment will be shown.

Development of a 3D sodium lidar: synchronous experimentation and validation

MURANAKA, Wataru[1*] ; KAWAHARA, Taku d[2] ; NOZAWA, Satonori[3]

[1]GSI, Shinshu University, [2]Faculty of Engineering, Shinshu University, [3]STE Lab., Nagoya University

Shinshu University, Nagoya University and RIKEN developed an all solid-state, high-power Na lidar for the temperature/wind measurements in the MLT region over EISCAT radar site in Tromso (69 N), Norway. Current observation is five-direction mode applied to the fixed direction such as vertical and 30 degree tilted to the north, south, east and west from the vertical.

We are now updating the lidar to multi-direction system which has never been done with resonant lidars. The transmission system uses two mirrors with electric rotary stages to emit laser light to any direction of the sky. Receiver system uses a telescope controlled by a PC. The coordination of the telescope is done with direction of so me blight stars. This repeatability pointing to the same direction is 5.3 mrad.

In this talk, we will discuss the experimental results of the synchronized experiments with the laser direction and telescope field-of-view.

Analysis of the factors of seasonal variation of the thermosphere-mesosphere NO observed at Syowa Station

UEMURA, Miku[1] ; ISONO, Yasuko[1] ; MIZUNO, Akira[1] ; NAGAHAMA, Tomoo[1] ; EJIRI, Mitsumu K.[2] ; TSUTSUMI, Masaki[2] ; NAKAMURA, Takuji[2*]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]National Institute of Polar Research

When high-energy particles such as solar protons and energetic electrons fall down to the earth's atmosphere, the nitrogen oxides (NO, NO2) are increased in the mesosphere and the upper stratosphere in the polar regions (e.g. Lopez-Puertas et al. 2005). In collaboration with the National Institute of Polar Research, Nagoya University Solar-Terrestrial Environment Laboratory installed a millimeter-wave spectroscopic radiometer at Syowa Station in Antarctica. We have conducted continuous observation of the NO spectrum since January 2012. The NO column density derived from this observation shows a seasonal variation that the NO column density increases up to about 1.7×10^{15} cm^{-2} in winter and decreases down to about 0.5×10^{15} cm^{-2} in summer. In order to understand the mechanism of the seasonal variation, we compared it with seasonal variation of CO vertical distribution in thermosphere-mesosphere and the length of sunshine hours at Syowa Station. Since CO photochemical lifetime is longer than or equal to the horizontal and vertical transport in the thermosphere and the stratosphere, CO can be considered as a good tracer of atmospheric transport. We used CO data obtained by AULA / MLS (Version3.3).

The CO volume mixing ratio in a latitude range of 65 S-75 S and an altitude range of 0.1-0.01 hPa shows a tendency that the mixing ratio increased in winter and decreased in summer. The peak altitude of the mixing ratio changed from upper altitude to lower altitude during winter, suggesting downward transport of the atmosphere. The commencements of the increment of the NO column density and the CO mixing ratio were almost coincident, but the temporal variation patterns of NO and CO did not agree well with each other especially in the decrement phase. On the other hand, the temporal variation pattern of the NO column density and the length of night time showed good correlation throughout the period during which the NO enhancement was significant. Thus the variation of the NO column density in the lower thermosphere-mesosphere is considered to be caused by both the descending of the air mass and the photochemical process.

In this poster, we will present more detailed discussion on the relationship among the NO column density, CO mixing ratio, and length of the night time based on the dataset including the new data acquired this year.

Small spatial scale field aligned currents in middle and low latitudes as observed by the CHAMP satellite

NAKANISHI, Kunihito[1*] ; IYEMORI, Toshihiko[1] ; AOYAMA, Tadashi[1] ; LUHR, Hermann[2]

[1]Department of Geophysics, Graduate School of Science, Kyoto University, [2]GeoForschungsZentrum, GFZ, Potsdam, Germany

The magnetic field observation by the CHAMP satellite shows the ubiquitous existence of small scale (1-5 nT) magnetic fluctuations with period around a few tens seconds along the satellites. From characteristics of the amplitude and period, they can be interpreted as the spatial structure of small scale field-aligned currents generated by the ionospheric dynamo driven by atmospheric gravity waves propagating from the lower atmosphere. The mechanism is the following; first, the gravity waves generated by the lower atmospheric disturbance propagate to the ionosphere; the neutral winds oscillate, cause ionospheric dynamo and Pedersen and Hall currents flow; because the dynamo region is finite, the currents cause polarized electric fields; and the polarized electric fields propagate along the geomagnetic filed as Alfven waves accompanied by field-aligned currents, at the same time, the ionospheric currents divert to the filed aligned currents; finally the CHAMP satellite observes the spatial structure of the filed aligned currents generated in this way as a temporal change along the path, because the temporal variation of the gravity waves are slow enough, i.e., more than a few minutes, that is, that of field aligned current can be ignored and nearly constant for the satellite crossing the currents.

This time we analyze correlation relation of the two components perpendicular to the geomagnetic field to find the following tendencies. About the magnetic data at the observed point, 1) if inclination and declination are plus and plus respectively, a correlation coefficient tends to be minus; 2) if inclination and declination are plus and minus respectively, it tends to be plus; 3) if inclination and declination are minus and plus respectively, it tends to be plus; 4) if inclination and declination are minus and minus respectively, it tends to be minus.

We report the model of the current system consistent to the characteristics of the magnetic fluctuations including the tendency of the correlation relation.

Atmospheric origin of small-scale magnetic fluctuations as observed by CHAMP above the ionosphere

AOYAMA, Tadashi[1*] ; IYEMORI, Toshihiko[2] ; NAKANISHI, Kunihito[1]

[1]Graduate School of Science, Kyoto University, [2]Graduate School of Science, Kyoto University

We analyzed magnetic field data obtained by a LEO(Low Earth Orbit) satellite, CHAMP(altitude 300˜450 km), and found out the global distribution of the short-period(10˜40 s) and small-amplitude(0.1˜5 nT) magnetic fluctuations in middle and low latitudes. We have reported that these fluctuations are small-scale structure(˜100 km) of the field-aligned currents generated by dynamo action in the ionospheric E-layer and the dynamos are caused by the atmospheric gravity waves (horizontal scale is ˜100 km) because of the characteristics of geographical and seasonal dependence of their amplitude.

In this paper, we focus on the mesoscale meteorological events to clarify the atmospheric origin such as typhoon which is possible to generate atmospheric gravity waves, and compare with magnetic fluctuations as observed by the CHAMP satellite above the ionosphere. We trace from the location of CHAMP to each footpoint in the E-layer along geomagnetic field line, and then compared with meteorological phenomena beneath the footpoint.

As a result, we detected large amplitudes of geomagnetic fluctuation above typhoons.

Optimization of notification system for bright meteor signals by using wide angle images at multiple sites

IYONO, Atsushi[1*] ; WADA, Naoki[2]

[1]Dept. of Fundamental Science, Okayama university of Science, [2]Graduate School of Science, Okayama university of Science

1. Purpose and Background

The sky monitoring system by using wide angle images have been maintained until Nov. 2011 at Okayama University of Science. The CCD camera system provides the slow shutter images every 3 second, and they have been transferred simultaneously to data storage server via the Internet connection. This system enables to monitor the real time condition of the sky. In the obtained images, bright meteors and sometimes fire balls were registered. We have been developing our new system which can provide quick analysis results for meteor and fire ball at the moment of observations. In this report, we describe the new sensor systems of thermography and low frequency sounds to increase the detection efficiency of brighter meteors and fire balls.

2. System

In the sky monitor system, CCD camera with wide angle lens and image server system have been operated in 24 hours/day. The exposure of CCD cameras has been set to be 4 second. The acquired image data have been stored in PC system via the internet ftp command. 28,800 images(500MB data

size) are stored in each day. In offline mode, images are processed with contrast enhancement module, image differentiating and object detection module. To detect meteors and fire balls effectively, we activated the IR image seosors and low frequency sound sensors as well as imaging devices.

3. Development

Our purposes are that new analysis system for online processing of images, IR sensors and low frequency seonsors have been developed in order to provied the information of the arrival of meteor and fireballs, arrival directions and brightness profiles. We are going to present new system and analysis result in this reports

Measurement of propagation characteristics of MF band radio waves in lower ionosphere by S-310-40 sounding rocket

ISHISAKA, Keigo[1*] ; ITAYA, Keita[1] ; ASHIHARA, Yuki[2] ; ABE, Takumi[3] ; ENDO, Ken[4] ; KUMAMOTO, Atsushi[4]

[1]Toyama Prefectural University, [2]NARA National College of Technology, [3]ISAS/JAXA, [4]Tohoku University

The ionospheric D region is important in radio wave propagation because it absorbs energy from waves at MF, HF and VHF, and it reflects LF and VLF signals. Then D region is present only during daylight hours. Therefore, in the night-time, the MF band radio waves are propagated as far as an area where its radio waves cannot be propagated in the daytime. This reason why the radio waves cannot receive is that the D region is disappeared at night. However, the MF band radio waves that transmit from distant place have not been often received at the mid latitude in the night-time. In this time the sporadic E region cannot be observed by the ionogram. We guess that the D region appear in the lowest ionosphere like a daytime. To farther study the structure of the lowest ionosphere, we propose a method to measure the very low electron densities that occur at altitudes from 50 km to 90 km using the partial and perfect reflection characteristics of electromagnetic waves.

S-310-40 sounding rocket experiment was carried out at Uchinoura Space Center (USC) at 23:48 JST on 19 December, 2011. The purpose of this experiment is the investigation of characteristics of radio wave propagation in the ionosphere and the estimation of electron density structure in the lower ionosphere, when the intensity of radio wave measured on the ground will be attenuate at night-time. In order to measure the radio waves, a LF/MF band radio receiver (LMR) is installed on the sounding rocket. The LMR has measured the propagation characteristics of four radio waves at frequencies of 60 kHz (JJY signal from Haganeyama radio station), 405 kHz (NDB station from Minami-Daito), 666 kHz (NHK Osaka broadcasting station) and 873 kHz (NHK Kumamoto broadcasting station) in the region from the ground to the lower ionosphere. The LMR consists of a loop antenna, a pre-amplifier and a detector circuit. The loop antenna is set up in the nose cone, which is transparent to the LF/MF band radio waves, and is not deployed during the flight. Therefore, the LMR can measure the relative attenuation of radio waves from the ground up to the ionosphere. Furthermore the loop antenna consists of three loop antennas in order to measure three components of four radio waves. Then we can obtain the propagation directions of radio waves in the ionosphere directly.

A propagation vector can be obtained from the propagation characteristic of radio wave. It is possible to estimate electron density profile from a propagation vector, because the propagation vector is dependent on the electron density profile in the radio wave propagation region. We have estimated the electron density profile by the propagation vector. When the electron density profile estimated by the propagation vector was compared with the electron density profile measured with the Langmuir probe and the impedance probe onboard the S-310-40 sounding rocket, it was found that electron density becomes the maximum at an altitude of 104 km.

We show the results of propagation characteristics of radio waves in the ionosphere and explain the propagation vector of radio wave in the ionosphere. And the electron density profile in the ionosphere can be estimated by the propagation vector. We will show the result that it is investigated the influence the lowest ionosphere region has on a MF band radio wave in this study.

Measurement of LF Standard-Frequency Waves JJY along the track of Shirase during JARE55: Preliminary Report

KITAUCHI, Hideaki[1*] ; NOZAKI, Kenro[1] ; ITO, Hiroyuki[1] ; KONDO, Takumi[1] ; TSUCHIYA, Shigeru[1] ; IMAMURA, Kuniyasu[1] ; NAGATSUMA, Tsutomu[1]

[1]NICT

We developed a highly sensitive, reliable receiving system for the purpose of reception of low frequency (LF) radio waves. The system consists of digital lock-in amplifiers and crossed-loop antennas. Digital lock-in amplifier (DLA) employs phase-sensitive detection (PSD) of periodic signal multiplied by the input reference source of the known signal frequency. This makes it possible to realize very narrow bandpass filter around the reference frequency, detecting/measuring that of very weak signal even in noisy environment. The antenna, on the other hand, consists of orthogonally crossed, larger double loops (receivers R_X, R_Y) and smaller doubles (transmitters T_X, T_Y): the former receivers R_X, R_Y receive LF radio signals of x-, y-components, the latter transmitters T_X, T_Y transmit an instant, weak signal from each x-, y-component for self calibration purpose. The self calibration test is performed by transmitting a weak LF signal for an instant every an hour from the transmitter T_X, T_Y respectively, and receiving this signal from the receivers R_X, R_Y to obtain preassigned field strength. This test indicates if the receivers of the system are working properly and allows us to obtain reliable measurements.

We apply the receiving system to measure the field intensity and phase of the standard frequency and time signals (SFTS) JJY of LF 40 kHz and 60 kHz during the summer expedition of the 55th Japanese Antarctic Research Expedition (JARE), from November 2013 to April 2014. Figure 1 shows temporal evolution of the field intensities JJY 40 kHz (light blue dots) and 60 kHz (brown dots) as well as the self-calibrating radio signals. Our receiving system detects both the LF JJY radio signals even offshore Syowa Station, Antarctic, about 14,000 km away from those transmitting stations. Also the field intensities of the self calibration test show about a consistent preassigned value, assuring the measurements.

Velocity distribution of electrons generating plasma waves around the wake of an ionospheric sounding rocket

ENDO, Ken[1*] ; KUMAMOTO, Atsushi[1] ; KATOH, Yuto[1]

[1]Department of Geophysics, Graduate School of Science, Tohoku University

When a body moves in plasma at supersonic velocity, a rarefied plasma region called 'plasma wake' is formed behind the body. Wakes can develop behind a solar system body immersed in solar-wind plasma as well as behind spacecraft such as satellites and ionospheric sounding rockets. There are several studies which report plasma waves around the wakes of a satellite and of the moon. Although there are not so many studies which report plasma waves generated in association with the rocket wake, observational results from two rocket experiments performed in 1998 and 2012 have shown generation of plasma waves around the wake of a rocket. It is very important to reveal the generation process of plasma waves near the rocket wake for understanding the universal physics related to the interaction between streaming plasma and a non-magnetized body as well as for interpreting wave data obtained in rocket experiments more accurately.

Our analysis has revealed three kinds of plasma waves observed in the S-520-26 rocket experiment in 2012. They are likely to be electrostatic electron cyclotron harmonic (ESCH) waves, upper hybrid resonance (UHR) mode waves, and whistler mode waves. They have spin-phase dependence in characteristic manners. These results indicate that the plasma waves should be generated inhomogeneously around the rocket. We have performed numerical calculations of plasma dispersion relations by assuming anisotropic velocity distribution functions such as electron beam and temperature anisotropy. As a result, positive linear growth rates have been obtained in the wave number and frequency ranges of UHR mode waves and ESCH waves in addition to electrostatic whistler mode waves. Accordingly, there have to be electrons with some anisotropic velocity distribution functions which are equivalent to those we assumed in the calculations. However, we have to clarify what kind of velocity distribution can be generated around the actual wake through the interaction between a sounding rocket and ionopsheric plasma.

Singh et al. (1987) has performed a one-dimensional simulation of plasma entering a void region from the two sides using a Vlasov-Poisson code. They have found counterstreaming electron beams in the very near wake. However, their study concentrates on electrons on the wake axis and does not indicate distribution functions in other areas. Besides, temperature anisotropy could not be treated in their simulation because it is performed in one dimension in velocity space.

In order to investigate inhomogeneity of electron distribution functions around the rocket wake, we are developing a Vlasov-Poisson code with one-dimensional space and two-dimensional velocity space, which is redesigned from the simulation code used in Singh et al. (1987). In this simulation, we deal with cases that electrons and ions are filling in a void space. The time evolution can be understood as spatial distribution along the wake axis. The direction of one-dimensional space is along the geomagnetic fields, along which electrons and ions can move easily. The size of space is 10 m, which is divided into 1024 grids in the calculation.

In this presentation, we clarify the frequency range and spatial distribution of the plasma waves around the wake based on the analyses of S-520-26 rocket experiment data. We also discuss the velocity distribution of the electrons which can generate the plasma waves as observed. In addition, we report initial results of our simulation for investigating the velocity distribution of electrons around the wake.

Atmospheric Neutral Analyzer for mass-resolved velocity distribution measurements: Verification of mass analyzer

SHIMOYAMA, Manabu[1*] ; HAYASHI, Ayuko[1] ; ITO, Fumihiro[1] ; HIRAHARA, Masafumi[1]

[1]STEL, Nagoya University

In order to understand the temporal and spatial variability of the ionosphere-thermosphere system, simultaneous measurements of the composition and density of the neutral atmosphere and the velocity distribution of individual species are essential. However, most conventional types of instruments for neutral atmosphere lack the simultaneous capability of measuring neutral atmospheric velocity and resolving neutral mass.

We have designed the Atmospheric Neutral Analyzer (ANA) instrument to measure the detailed, mass-resolved 2-dimensional velocity distribution of neutral species, from which the corresponding density, mass composition, bulk velocity and temperature were derived. In this presentation, we will report the results from laboratory experiments for the performance verification on the prototype of mass analyzer along with the detailed and overall design determined by numerical simulation.

Observation of resonance scattering light of Lithium vapor under daytime and moonlight condition and neutral wind analys

KIHARA, Daiki[1*] ; KAKINAMI, Yoshihiro[1] ; YAMAMOTO, Masa-yuki[1] ; WATANABE, Shigeto[2] ; HARD, Lucas[3] ; LARSEN, Miguel[3] ; YAMAMOTO, Mamoru[4] ; HABU, Hiroto[5] ; ABE, Takumi[5]

1.Introduction

For the purpose of measurement of neutral atmospheric wind in lower thermosphere, we observed resonance scattering light of sunlit Lithium vapor released from a sounding rocket in the evening thermosphere in 2007 (e.g. Yamamoto et al., 2008). At that time, we successfully measured thermospheric neutral wind profile between 110 km and 400 km. In 2012, we observed resonance scattering light of sunlit Lithium at dawn, and estimated lower thermospheric neutral wind between 76 km and 127 km.

On July 4, 2013, a U.S.-Japan collaborative rocket experiment to observe neutral wind profile in daytime lower thermosphere with Lithium release was carried out at WFF (Wallops Flight Facility), NASA. A rocket to operate chemical release of Lithium was launched at 10:31:40 EDT (14:31:40 UTC). The rocket launched to southeastern direction released Lithium vapor three times between at about 90 km and 130 km altitude during the upleg, at about 40 km horizontally away from a ground-based observation site in WFF. Here we tried to observe of Lithium clouds from the ground-based and airborne observations with collaboration of Kochi University of Technology (KUT) and Clemson University.

On July 20, 2013, a rocket experiment to observe neutral wind profile in moonlit lower thermosphere with Lithium release was carried out at USC (Uchinoura Space Center), Japan. The S-520-27 rocket to operate chemical release of Lithium was launched at 23:57:00 JST and released Lithium vapor three times between at about 80 km and 120 km altitude during the downleg under the almost full moon condition (Moon age was 12). Here we tried to observe of Lithium clouds from 3 ground-based sites and an airplane.

2.Observations

Airborne observation of Lithium cloud was carried out under a condition with the sun at the backward direction while it flew to north-northeast at about 10 km (33,000 feet) altitude and at about 300 km away from the ground site at the southeastern direction. An observation site was set in WFF on ground. In order to detect the Lithium clouds in daytime skies with good S/N ratio, digital cameras (Canon EOS Kiss X4, Nikon D90) with 2 nm band pass filters (BPF) at 671 nm wavelength were used for all digital cameras. We installed three digital cameras in the aircraft NASA-8 and set two digital cameras on the ground site. A video camera (Watec, WAT-120N) with a 12 nm BPF was also used in the aircraft and on ground, respectively.

The Lithium clouds under moonlight condition was observed by using digital cameras, Watec, and cooled EM-CCD (BITRAN BQ-87EM) with 2 nm and 12 nm BPF from the JAXA airplane Hisyo as well as three ground-based observation sites (USC, Tanegashima and Muroto).

3.Results

A Lithium cloud under daytime sky condition was observed for about 25 minutes from the aircraft. The released Lithium vapor formed red clouds along the rocket trajectory just after the release. Afterwards, the Lithium trails were spread into complex shapes by strong wind shear in the altitude. We successfully observed Lithium clouds by the airborne observation.

A Lithium cloud under moonlight sky condition was observed for about 90 seconds from the aircraft and two ground sites.

4.Summary

We successfully observed 2 chemical releases of Lithium from the aircrafts and ground sites on July, 2013, in daytime and midnight. We succeeded the detection of resonance scattering light of Lithium vapor under daytime and moonlight sky condition in lower thermosphere. Owing to this experiment, we confirmed that we can measure altitude profile of the neutral atmospheric wind in lower thermosphere at almost all local time by using the chemical release of Lithium.

In this paper, we will discuss that the observed emission intensity of the resonance scattering light of Lithium vapor under daytime and moonlight sky condition in lower thermosphere, obtained results of the S/N ratio, preliminary results and problems of the neutral atmospheric wind measurement in daytime lower thermosphere.

Improvement of the method for estimating thermospheric temperature using small FPIs and evaluation of their temperatures

NAKAMURA, Yoshihiro[1*] ; SHIOKAWA, Kazuo[1] ; OTSUKA, Yuichi[1] ; OYAMA, Shin-ichiro[1] ; NOZAWA, Satonori[1]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

Fabry-Perot interferometer (FPI) is an instrument that can measure the temperature and wind velocity of the thermosphere from the ground through observation of airglow emission at a wavelength of 630.0nm. The Solar-Terrestrial Environment Laboratory (STEL), Nagoya University, has five FPIs as parts of the Optical Mesosphere Thermosphere Imagers. Two of those FPIs, possessing a large aperture etalon (diameter: 116mm), were installed at Shigaraki, Japan in 2000 and in Tromso, Norway, in 2009. The other three small FPIs, using 70-mm diameter etalons, were installed in Thailand, Indonesia, and Australia in 2010-2011. They use highly-sensitive cooled-CCD cameras with 1024-1024 pixels to obtain interference fringes. However, appropriate temperature has not been obtained from the interference fringes using these new small-aperture FPIs. In the present study we aimed to improve the procedure of temperature derivation using these small etalon FPIs, to evaluate the accuracy for obtained temperatures and to perform statistical analysis of the temperature data obtained for 2-3 years.

The FPIs scan the sky in north, south, east, and west directions repeatedly by rotating a light receiving mirror. We determined each center of the laser fringe and sky fringes for north, south, east, and west directions. Then we found that they are slightly a few pixels different depending on the mirror directions. This difference of fringe centers seems to be due to distortion of the optics body, which is caused by the motion of the heavy scanning mirror on top of the optics. Thus, we decided to determine the fringe center for each direction. After this revision, we could make a reliable temperature determination. In this presentation, we show these procedures of temperature derivation and relation between airglow intensity and standard deviations of obtained temperatures as accuracy of temperature derivation. We also discuss effects of the etalon gap drift due to changes in etalon temperature for accuracy of measured thermospheric temperatures and winds.

Statistical characteristics of MSTIDs observed by 630-nm airglow imager and HF-radar echoes at Paratunka, Russia

MINOURA, Takeshi[1*] ; SUZUKI, Shin[1] ; SHIOKAWA, Kazuo[1] ; OTSUKA, Yuichi[1] ; NISHITANI, Nozomu[1] ; HOSOKAWA, Keisuke[2]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Department of Communication Engineering and Informatics, University of Electro-Communications

Medium-scale traveling ionospheric disturbances (MSTIDs), which typically have a horizontal scale of 100-500 km and a period of ˜1 h, are frequently observed in the F region ionosphere at middle latitudes. To date, quite a few observations of MSTIDs have been carried out especially in the middle latitudes; they predominantly had a northwest-southeast, (northeast-southwest) frontal structure and propagated southwestward (northeastward) in the northern (southern) hemisphere, however their generation and propagation mechanisms are not clear yet. Suzuki et al. [2009] investigated two dimensional characteristics of a nighttime MSTID using the SuperDARN Hokkaido HF radar at Rikubetsu, (43.5 N, 143.6 E), Japan, and an OI 630-nm airglow imager located at Paratunka (53.0 N, 158.2 E), Russia, within the radar field of view (FOV). The Doppler velocities of MSTID echoes observed by the SuperDARN radar showed systematic polarity changes which were consistent with airglow intensity variations. The electric field estimated from the airglow and SuperDARN observations, however, seems to be improbable and the E-F coupling processes would be important to explain the inconsistency. We investigated statistical characteristics of nighttime MSTIDs. Based on the coordinated airglow and SuperDARN measurements from 2011 to 2013, we investigated the relation between the MSTID amplitudes in the 630-nm airglow intensity and the Doppler velocities of the FAI echoes associated with the MSTID pattern. This study may give an observational insight into the E-F coupling quantitatively.

In this presentation, we will report the statistics of the relation of the FAI echoes and airglow signatures of the observed MSTIDs (5 events), which showed spatially conjugation in the radar FOV.

Detection of ionospheric disturbances caused by the earthquake using HFD

TAKABOSHI, Kazuto[1*] ; NAKATA, Hiroyuki[1] ; TAKANO, Toshiaki[1] ; TOMIZAWA, Ichiro[2]

[1]Graduate shool of Engineering, Chiba University, [2]Center for Space Science and Radio Engineering,Univ. Electro-Comm

Many studies have reported that ionospheric disturbances occur after giant earthquakes. This is because the acoustic wave and/or atmospheric gravity wave are excited by the ground perturbations or tsunami. The HF Doppler observation is suitable for detection of ionospheric disturbances since this can observe ionospheric vertical drift from Doppler shift of radiowaves (5006 and 8006 kHz) transmitted from the Chofu campus of UEC. In this study, usng Doppler shift data of 5006 kHz, ionospheric disturbances associated with earthquakes are ditected. When Doppler shift is fluctuated intensely after propagation time of Rayleigh wave from the seismic center to the observation points, the fluctuation is determined as a disturbance associated with the earthquakes.

In 55 events of earthquakes (M≥6.0) occurred around Japan since 2003, fluctuations by earthquakes are detected in 14 events and the smallest magnitude is 6.4. No fluctuation is detected in some larger earthquakes than M6.4. Since the ionosphere is unstable at night, received frequency is disturbed and it is hard to determine the fluctuations caused by earthquake. In addition, the observation points are not always located near the seismic centers. When earthquakes occur near observation points at the daytime, it is expected that the fluctuations caused by earthquakes are observed even if the magnitudes of the earthquakes is smaller than M6.4.

We also examined the relationship between direction of fault and fluctuations of HFD data. Most of the earthquakes in Japan are reverse fault type. Because a hanging wall slides up in this type of an earthquake, it is expected that initial perturbation of a sound wave excided by the hanging wall is upward. Actually, in most of the events Doppler shifts are negative, which means that the ionosphere moves upward. Next we examined a normal-fault-type earthquake (Fukushima hama-dori earthquake, 2011/4/11), in which a hanging wall slips down. In this event, the epicenter is located at the east of Fukushima prefecture. Doppler data of three observation points (Iitate, Sugadaira, Kiso) are examined. In Iitate observatory, which is the closest to the epicenter, Doppler data shows that ionosphere moved only upward. On the contrary, in the other two points, Doppler data shows that ionosphere moved downward first and then upward, or upward first and then downward. Therefore, fluctuations of ionosphere can not be determined only by a type of fault. More detailed analysis using the seismometer is necessary.

Observations of seismo-traveling ionospheric disturbance during the 2011 Tohoku earthquake using HF Doppler

CHOU, Min-yang[1*] ; TSAI, Ho-fang[1] ; LIU, Jann-yenq[2]

[1]Department of Earth Science,National Cheng-Kung University,Taiwan, [2]Institute of Space Science, National Central University, Taiwan

This paper reports seismo-traveling ionospheric disturbances (STIDs) induced by the 11 March 2011 M9.0 Tohoku-oki earthquake and following pan-Pacific tsunami by two networks of HF (high-frequency) Doppler sounding systems in Japan and Taiwan. The Hilbert-Huang Transform (HHT) is applied to analyze Doppler frequency shifts (DFSs) detecting STIDs, while the time delay, circle, ray-tracing, and beam-forming methods are used to compute the propagation of the detected STIDs. Both STIDs induced by the Rayleigh waves and tsunami of the Tohoku-oki earthquake are detected and discussed.

Spectrum of the neutral atmospheric waces derived from a numerical simulation of an earthquake

SHIMIZU, Yuki[1*] ; NAKATA, Hiroyuki[1] ; TAKANO, Toshiaki[1] ; MATSUMURA, Mitsuru[2]

[1]Grad. School of Eng. , Chiba Univ., [2]Center for Space Science and Radio Engineering, University of Electro-Communications

It is important to examine the ionospheric disturbances excited by earthquakes, since this contributes to monitoring tsunamis from satellites. There are many reports of ionospheric disturbances occurred by giant earthquakes, such as the 2011 off the Pacific coast of Tohoku Earthquake. But characteristics of atmospheric disturbances, connecting the ionospheric disturbances with the ground and the sea surface, is not clarified because broad observation of the atmosphere in high resolution is difficult. In this study, calculating the spectra from the temporal variations of neutral atmospheric waves determined by a numerical simulation, we derived the features of the propagation of the atmospheric waves.

In this simulation, two dimensional model is used. The atmospheric perturbation is created by a vertical velocity assuming an upward motion of the sea surface or ground surface. Calculating the temporal variations of neutral density, we derived their spectra.

As a result, it is shown that behavior of atmospheric waves is different for the frequency. For a notable example, variations around 1 mHz propagate to high altitudes 450 km ˜500 km and long distance 800 km. On the other hand, variations around 10 mHz propagate almost the same distance in lower altitude of 300 km or less. In addition, variation at 4 mHz are located above the epicenter at 350 km. This causes the variation of GPS-TEC at 4 mHz associated with earthquakes that have ever been reported.

Ionospheric effects on the F region during the Sunrise for the annular solar eclipse over Taiwan on 21 May 2012

CHUO, Yu-jung[1*]

[1]Department of Information Technology, Ling Tung University

On 21 May (20:56, Universal Time; UT, on 20 May), 2012, an annular solar eclipse occurred, beginning at sunrise over southeast China and moving through Japan, sweeping across the northern Pacific Ocean, and completing its passage over the western United States at sunset on 20 May (02:49 UT, 21 May), 2012. We investigated the eclipse area in Taiwan, using an ionosonde and global positioning system (GPS) satellites measurements. The measurements of foF2, hmF2, bottomside scale height around the peak height (Hm), and slab thickness (B0) were collected at the ionosonde station at Chung-Li Observatory. In addition, we calculated the total electron content (TEC) to study the differences inside and outside the eclipse area, using 3 receivers located at Marzhu (denoted as MATZ), Hsinchu (TNML), and Henchun (HENC). The results showed that the foF2 values gradually decreased when the annularity began and reached a minimum level of approximately 2.0 MHz at 06:30 LT. The hmF2 immediately decreased and then increased during the annular eclipse period. The TEC variations also appeared to deplete in the path of the eclipse and opposite to the outside passing area. Further, the rate of change of the TEC values (dTEC/dt measured for 15 min) was examined to study the wave-like fluctuations. The scale height near the F2 layer peak height (Hm) also decreased and then increased during the eclipse period. To address the effects of the annular eclipse in the topside and bottomside ionosphere, this study provides a discussion of the variations between the topside and bottomside ionospheric parameters during the eclipse period.

Horizontal shapes of mid-latitude sporadic-E observed with GPS-TEC

MAEDA, Jun[1*] ; HEKI, Kosuke[1]

[1]Graduate school of Science, Hokkaido University.

The horizontal shapes of sporadic-E (Es) have remained uncovered due to the lack of effective observation methods. We use a dense array of Global Positioning System (GPS) receivers in Japan to map horizontal shapes of mid-latitude sporadic-E layers and explore their diversity. The spatial and temporal resolutions of the GPS array are ˜25 km (in horizontal) and 30 s, respectively, which is ideal for studying the horizontal shape and movement of sporadic-E. Sporadic-E can be identified as positive anomalies of total electron content (TEC) along the line of sight between a satellite and a ground-based GPS station.

The results of GPS-TEC observation, i.e., mapping of positive TEC anomaly caused by mid-latitude sporadic E are presented in this presentation with a special emphasis on latitudinal and temporal variations of horizontal shapes of Es-layers. We analyzed ˜100 Es events in 2010-2013 to examine the latitudinal dependence of Es frontal structures with three study areas at different latitudes near ionosondes, namely Sarobetsu (geographical latitude: 45.16 N), Kokubunji (35.71 N) and Yamagwa (31.20 N).

As a result, strong Es shares the large-scale frontal structure as a common shape regardless of the occurrence latitude and time (e.g., morning, afternoon, and the evening). The horizontal structures of large-scale fronts are typically elongated in east-west (E-W) with the length and width of ˜300 km and ˜30 km, respectively. However, lengths vary from 30 to 300 km by occasion. The alignment of frontal structures prefers E-W, ENE-WSW and NE-SW alignment with some exception of NW-SE and NNW-SSE aligned structures.

We will also discuss the possible mechanisms for formation, development, and movement of mid-latitude sporadic-E based on the results of our observations and proposed theories.

GPS-TEC observation using two-frequency software receiver

ASHIHARA, Yuki[1*] ; KOMATSU, Kazuki[1]

[1]Dept. of Electrical Engineering, Nara National College of Technology

Global Positioning System (GPS) is a high accuracy positioning system that uses radio waves transmitted from several GPS satellites. The carrier signals of GPS satellites, there are two frequencies of L1 (1575.42MHz) and L2 (1227.60MHz). In the ionospheric plasma, the refractive index depends on the electron density. In addition, since the plasma is dispersive medium, each of L1 and L2 waves has different refractive indexes. Therefore, it is occurred propagation delay time (phase difference) in between these signals.

GPS-TEC (GPS Total Electron Contents) is a method to obtain the total electron contents along the line of satellite (LOS) from the phase difference between these signals. GPS-TEC is very useful technique to observe ionospheric electron density, but two-frequency GPS receiver is very expensive. Therefore, GPS-TEC has calculated by using GEONET data in most cases in Japan.

In the informatics and communication field, software receiver is being widely for demodulating the baseband signal, as a background of higher performance of computers. In this study, we build a software GPS receiver system, and receive the two-frequency signals. And we will evaluate the GPS-TEC data obtained by this observation.

Total electron content observation by using GPS, QZSS and BeiDou

KINUGASA, Natsuki[1*] ; TAKAHASHI, Fujinobu[1]

[1]Yokohama National University

There are several methods for observation of total electron content (TEC). TEC can be obtained from the measurement of global navigation satellite system (GNSS) such as GPS. Recently, RNSS (regional navigation satellite system) has been developed in China and Japan. We are trying to use RNSS for TEC observation.

RNSS makes TEC observation stable since a satellite is tracked continuously for long time. It is of benefit to study of plasmasphere because the altitude is higher than GNSS. There is also drawback. Since the direction of vector from grand receiver to satellite is not so variable, it is hard to observe the horizontal electron density distribution of ionosphere. This problem can be solved by combining with measurements of RNSS and GNSS. That is called multi-GNSS.

TEC can be caluculated from the difference of delay between dual-frequency. The inter-frequency bias which remain in TEC measurement are required to estimated and removed. We will present model of ionospheric electron density distributionfor the bias estimation procedure. We have constructed the observation system for GPS, Japanese QZSS, and Chinese BeiDou in Yokohama National University. Various observational results will be shown and discussed.

Total Electron Content prediction model over Japan using an artificial neural network

NISHIOKA, Michi[1*] ; TSUGAWA, Takuya[1] ; MARUYAMA, Takashi[1] ; ISHII, Mamoru[1]

[1]National Institute of Information and Communications Technology

Forecasting Total Electron Content (TEC) is important for Space Weather; for predicting propagation delay of the radio waves in the ionosphere. Although several empirical and theoretical models have been developed, no model is available for forecasting TEC over Japan. Our purpose is to accomplish an operational TEC model over Japan using an artificial neutral network (ANN) technique which is developed by Maruyama [2007]. In our model, absolute TEC values for each day from 27^{o}N to 45^{o}N in latitude and 127^{o}E to 145^{o}E in longitude were projected on a two-dimension TEC map, that is, a local-time and latitudinal map. Then the time-latitudinal variation was fitted by using the surface harmonic function. The coefficients of the expansions were modeled by using a neural network technique. For the learning process, we used absolute TEC value from 1997 to 2013. The input parameters are proxies of the season, the solar activity, and the geomagnetic activity. Thus, daily two-dimensional TEC maps can be obtained for any day when the input parameters are provided. We used input parameters which are available in real-time by some institutes and achieved one-day TEC prediction over Japan.

Statistical Analyses of Ionospheric Storms Over 50 Years In Japan

NAKAMURA, Maho[1*] ; KAMOGAWA, Masashi[1]

[1]Dpt. of Phys., Tokyo Gakugei Univ.

Statistical analyses of the ionospheric storms over Japan are carried out based on the long-term observations over 50 years in Japan. While there are many types of ionospheric variations such as ionospheric storms, plasma bubbles, TIDs and so on, ionospheric storms are most large fluctuations of electron density in the ionosphere. In general, the increase of the electron density is termed positive storm and the decrease of it is termed negative storm [1]. The positive storms cause satellite-positioning errors due to the delay of radio propagation and negative storms cause HF radio communication outages due to lowering the maximum usable frequency. Because these two types of ionospheric storms shows different characteristics on the duration, scale, and the seasonal dependences, we analyzed ionospheric storm occurrences using critical frequency of the F2 layer; foF2 obtained from ionograms over 4 observation sites (Wakkanai, Kokubunji, Yamagawa, and Okinawa) operated by National Institute of Information and Communications Technology, Japan (NICT) [2]. We extracted ionospheric storms based on the differences between the daily observation values and the one-month median in Japan for more than 50 years. Extracted storms of each station will be analyzed by the occurrences, duration, seasonal dependence and geomagnetic variations.

Statistical analysis of the Speckle applying the ”Hinode” / XRT

YAMADA, Masanori[1*] ; NOZAWA, Satoshi[1] ; SHIMIZU, Toshifumi[2]

[1]Graduate School of Science and Engineering, Ibaraki University, [2]Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency (ISAS/JAXA)

“ When a charge-coupled device (CCD) image is taken, white noise will appear identically main CCD image. For examlpe, the trajectory of noise is watched like scar, small spot and snowstorm, which is call as spike, unwanted signal, and so on. In this study, noise is called “ Speckle ” . The speclke is due to the particle nature of photon when CCD is hitted by Solar Energitc Particle(SEP) or cosmic ray.
SEPs have high energy of 10 keV - 10 GeV, which are generated by solar flare, coronal mass ejection(CME). This reason is that SEP plays an important role in space weather. When SEPs with hige energy of GeV order will come to earth magnetosphere, low earth orbit (LEO) stellite would be damaged the potential of single events like SEPs effect.

For this reason, this study analyzed Hinode / X-Ray Telescope (XRT) images and detected speckles. Analysis period is from January 2011 to July 2013. As a result speckles were periodic fluctuations and significant increased, when on 00:04 UT March 7 2012, X5.4 Flare occurred.
Number of detected speckles had a time zone is 3 or 4 times as high as before the occurrence of the Flare. In addition periodic fluctuations are synchronized with orbital period. Moreover information of the satellite orbit indicates speckles increases over the High Latitude Zone (HLZ). Although this is suggested SEPs flow in HLZ, there is a region with high geomagnetic latitude, so speckles are caused by charged particles of non-SEPs.

This study reports on detailed consequence. Besides it looks at the correlations between decrease or increase in speckles and information of the satellite orbit or solar activity.

Seasonal-longitudinal dependence of the occurrence of equatorial plasma bubbles obserbed by ISS-IMAP

TAKAHASHI, Akira[1*] ; NAKATA, Hiroyuki[1] ; TAKANO, Toshiaki[1] ; SAITO, Akinori[2]

[1]Chiba University, [2]Kyoto University

Equatorial plasma bubbles (EPBs) are local depletions of the electron density in the ionosphere. Ionospheric irregularities are included in EPBs and cause radio signal scintillation. Recently, reseach on applying GNSS to Air Navigation System has progressed, therefore, it becomes more necessary to investigate the generation mechanism and the morphology of EPBs.

In this study, we analyzed seasonal-longitudinal dependence of the occurrence of EPBs using airglow-images obtained by ISS-IMAP (Ionosphere, Mesosphere, upper Atmosphere, and Plasmasphere mapping).In 630-nm airglow images, EPBs are visualized as black lines. 181 events are selected during 2012/09 - 2013/08. To calculate the longitudinal denpendence of occurence rate, we divide the ionosphere into 36 longitude bins, each 10 degrees wide. Since EPBs are observed at low and middle latitude, the total obserbation time is accumlated when |latitude| $<$30. We calculate the occurrence rate as the number of EPBs detected over the total observation time.

The occurrence rate is high at the African-Atlantic-American regeions in the equinoctial seasons. On the other hand, the occurance rate is also high at American-Pacific resions in summmer, which is not obtained in the previous study, Burke et al. [2004], in which EPBs are detected using plasma density data on DMSP satellite. The altitude of DMSP is 840 km, which is higher than the observation altitude of ISS-IMAP, that is about 250 km. Therefore, it is conceivable that the difference of occurrence rate of EPB is due to the altitude of the observations. This imply that ISS-IMAP observation could detect EPBs not developed to higher altitude.

Based on above, we will present seasonal-longitudinal variability of the Rayleigh-Taylor instability growth rate, contributing the development of EPBs using ionosphere model and other observational data.

A coherent modulation of pulsating aurora at Pc5 frequency

SAKA, Osuke[1*] ; HAYASHI, Kanji[2] ; KLIMUSHKIN, Dmitri[3] ; MAGER, Pavel[3]

[1]Office Geophysik, [2]U. Tokyo, [3]Russian Academy of Sciences

Ground and satellite magnetometer observations and all-sky video images revealed that the Pc5 pulsations that occurred in 17 January 1994 showed a wide distribution in longitude from Alaska, USA (0 MLT) to the Hudson bay, Canada (11 MLT) and in latitudes from 62N (L=4.5) to 70N (L=8.5).

Auroras in all-sky image were composed of field line resonance (FLR) in higher latitudes in 67-70N and pulsating aurora (PsA) in lower latitudes in 62-67N.
It is found that the PsA, FLR, and field magnitude at the geosynchronous altitudes were all oscillated coherently at Pc5 periodicities.

We conclude that the coherent modulation of FLR and PsA are attributable to toroidally and poloidally polarized Pc5 pulsations, respectively, generated by the polarization splitting of the Alfven spectrum by the finite plasma pressures.(1), (2).

Generation of pulsating aurora: Role of cold electron and electric field

SATO, Natsuo[1*] ; KADOKURA, Akira[1] ; TANAKA, Yoshimasa[1] ; NISHIYAMA, Takanori[1]

[1]National Institute of Polar Research

Pulsating auroras are common phenomena, which are observed universally during the recovery phase of substorm in the auroral and subauroral zones. But, even today, generation mechanism of fundamental characteristics of pulsating aurora, such as, their periodicity, their shapes, and their motion are not understood. Simultaneous observations onboard satellites and on the ground are important method to examine such fundamental characteristics of pulsating aurora. We examined some selected pulsating auroral events, which obtained onboard THEMIS spacecraft and the THEMIS ground-based all-sky camera network. THEMIS satellites were located in the post midnight sector near the equatorial plane in the magnetosphere. We found following signatures of particle, field and wave in the magnetosphere at the onset and during pulsating aurora; 1) All pulsating aurora associate with high-energy (>5 keV) electron flux enhancement, 2) Cold electron flux (<20 eV) and electric field intensity show QP (quasi-periodic) modulation in association with pulsating aurora, 3) and their QP modulation sometimes show one-to-one correspondence to QP modulation of ELF wave intensity, for both type of electromagnetic lower-band chorus wave and electrostatic ECH (electron cyclotron harmonic) wave, 4) But, not all pulsating aurora associate with ELF wave enhancement.

In this talk we focus on the event which THEMIS-A, D, E spacecraft crossed a clear boundary between strong pulsating auroral region and non-pulsating auroral region. In this strong pulsating auroral region, electric field, ULF-ELF (<300Hz) electric field waves, and cold electron flux are modulated in association with pulsating aurora, but the activity of lower-band chorus wave is very low or nothing. When the spacecraft entered into non-pulsating auroral region all of QP activity became quiet/stop. It is interesting to note that high-energy electron (>10 keV) flux was almost the same for both of the regions, but cold electron flux suddenly decreased and temperature suddenly increased when the spacecraft entered into non-pulsating auroral region. We will discuss the role of cold electron, electric field and ELF waves for the generation of pulsating aurora.

We investigate dynamic switching of arrival time difference between pulsating aurora intensity and chorus waves which were observed on 7 February 2013 at Athabasca in Canada (L=4.4), using a crossed-loop antenna and a narrow field-of-view EMCCD camera. Power spectra of pulsating auroral intensity and chorus wave intensity at 1.5-2.5 kHz show a same pulsation period at 0.1-0.15 Hz. Arrival time difference between pulsating aurora intensity and chorus waves are evaluated by using cross-correlation analysis. We found that two patterns of arrival time difference switches with a time scale of a few tens seconds. One pattern shows that electrons reached ionosphere later than the associated chorus waves with a delay time of 2 s, consistent with the theoretical value for south-going electrons reflected at the ionosphere in the southern hemisphere. The other pattern shows that electrons reached ionosphere earlier by 4.5 s than the associated chorus waves, consistent with the theoretical value for south-going chorus waves reflected at the ionosphere in the southern hemisphere. These results firstly show that interaction process of high-energy electrons and chorus waves are changing with a time scale of a few tens seconds.

Relativistic electron precipitations in association with diffuse aurora

KURITA, Satoshi[1*] ; KADOKURA, Akira[2] ; MIYOSHI, Yoshizumi[3] ; SATO, Yuka[2] ; MISAWA, Hiroaki[1] ; MORIOKA, Akira[3]

[1]Tohoku Univ., [2]National Institute for Polar Research, [3]STEL, Nagoya Univ.

It has been widely thought that diffuse auroras are generated by electron precipitations in the energy range from a few keV to tens keV. Recent simulation results based on the quasi-linear theory showed that the scattering by whistler-mode waves plays an important role in the production of precipitating electrons responsible for diffuse auroras. A test particle simulation on electron-whistler interactions shows that relativistic electrons can be scattered into the loss cone simultaneously with the electrons in the energy range from a few keV to tens keV. Thus, it is expected that relativistic electrons precipitate into the atmosphere in association with diffuse auroras if whistler-mode waves contribute to generation of diffuse auroras. To examine this hypothesis, we investigated conjugate observations of SAMPEX and the all sky camera at Syowa Station on the dawn side, where diffuse auroras are frequently observed. In this study, we show a case study that relativistic electron ($>$1 MeV) precipitations observed by SAMPEX are associated with the diffuse aurora observed at Syowa Station. The SAMPEX observation shows that the enhancement of precipitating relativistic electrons are well correlated with that of precipitating $>$150 keV electrons, indicating that electrons in the energy range from a few keV to 1 MeV precipitate into the atmosphere simultaneously. It is observational evidence that whistler mode waves contribute to generation of diffuse auroras.

Refilling of Plasmasphere

WATANABE, Shigeto[1*]

[1]Hokkaido University

Satellite observations have revealed that ions are heated in the ionospheric polar region and are flowing to the magnetosphere. The fluxes of H+, He+, and O+ are ˜1011 ions m-2 s-1, ˜1011 ions m-2 s-1, ˜1010 ions m-2 s-1, ˜1010 ions m-2 s-1 during the solar maximum and ˜1010 ions m-2 s-1, ˜109 ions m-2 s-1, ˜109 ions m-2 s-1 near the solar minimum condition, respectively. The large amount of ions, including heavy ions such as O+, contributes the refilling of plasmasphere and inner magnetosphere. The ions are formed often as conics / transversely accelerated ion in the topside polar ionosphere. To understand the refilling process, the refilling time scale and the effects to the structure and dynamics of plasmasphere and inner magnetosphere, we have developed a three dimensional model of Atmosphere ? Plasmasphere including Electrodynamics (APE model). The model calculates densities, velocities and temperatures for electron, O2+, N2+, NO+, O+, He+ and H+ at altitudes from 90 km to 10 Re and for N2, O2, O, He and H in the thermosphere, and electric fields in the ionosphere, plasmasphere and inner magnetosphere. We calculate also parallel and perpendicular components of ion and electron temperatures to include the effect of perpendicular heating of ion in the polar ionosphere. The results show clearly the importance of ion heating in the polar region for the structure of plasmasphere, the refilling and the response to the magnetic disturbance.

M/Q=2 Ion Cyclotron Whistlers Observed by Akebono

MATSUDA, Shoya[1*] ; KASAHARA, Yoshiya[1] ; GOTO, Yoshitaka[1]

[1]Kanazawa University

It is well known that lightning whistler wave is caused by lightning discharge, and propagates along geomagnetic field lines as R-mode plasma wave below several tens kHz. Ion cyclotron whistler wave, which is one of Electromagnetic Ion Cyclotron (EMIC) mode waves, has close relation to lightning whistler [1]. One of most important features is the lowest frequency of ion cyclotron whistler which denotes the local crossover frequency of the EMIC mode wave. R-mode lightning electron whistler is converted into L-mode ion cyclotron wave at local crossover frequency between electron whistler and ion cyclotron branches along the propagation path. Propagation characteristics of ion cyclotron whistler strongly depend on ion concentrations in plasma as well as nature of general EMIC waves. These facts suggest that we can estimate ion species and concentrations at observation point and/or along the propagation paths of the ion cyclotron whistlers.

Watanabe at al. [2] reported first observation of M/Q=2 ion cyclotron whistler measured by the ISIS-2 satellite. According to their analysis, M/Q=2 ion cyclotron whistlers were observed at an altitude region around 1,360 km. They suggested that these M/Q=2 ion cyclotron whistlers are caused by deuterons (D^+) from ionosphere of the Earth, and they named them ”deuteron whistlers”.

In the current study, we report M/Q=2 ion cyclotron whistlers observed by the Akebono satellite at an altitude region around 4,500 km, which is the highest altitude where M/Q=2 ion cyclotron whistlers were observed so far. We found that these events had obvious frequency gap near the cyclotron frequency at half of cyclotron frequency of H^+. Hence, these events are precious evidence that some amount of M/Q=2 ion exists in the inner magnetosphere.

In this paper, we study ion concentration in the inner magnetosphere estimated from crossover frequencies of ion cyclotron whistlers observed by Akebono. Recently, it is pointed out that wave-particle interaction is important process to control innermagnetospheric physics. Our results become prior information of future satellite mission such as ERG [3] in the inner magnetosphere and/or simulations such as ray tracing method.

Sub-packet structures in the EMIC triggered emission observed by the THEMIS probes

NAKAMURA, Satoko[1*] ; OMURA, Yoshiharu[2] ; SHOJI, Masafumi[3] ; NOSE, Masahito[4]

[1]Department of Geophysics, Graduate School of Science, Kyoto University, [2]Reserach Institute for Sustainable Humanosphere, Kyoto University, [3]Solar-Terrestrial Environment Laboratory, Nagoya University, [4]Graduate School of Science, Kyoto University

We analyse Electromagnetic Ion Cyclotron (EMIC) triggered emission by the data from the THEMIS probes. These phenomena have recently received much attention because of the possibility of their strong interaction with energetic particles in the inner magnetosphere in spite of their scarceness in observations[1,2,3]. For 1400-1445 UT on 9 September 2010, THEMIS A, D and E observed strong EMIC waves with rising tone emissions. The probes were located near the dayside magnetopause at 8 R_E of the radial distance from the Earth, 13 MLT, and a few degrees of the geomagnetic latitude. During this time interval, the geomagnetic field was very distorted by the variation in the solar wind. We assume these emissions were excited around minimum-B pockets in accordance with the magnetospheric compression. It is found the rising tone emissions comprise of some smaller rising tones, which are called ”sub-packet structures”[4]. We compare these observed sub-packet structures with the nonlinear wave growth theory developed by Omura et al. [5]. The observed relationship between the amplitudes and frequencies of the emissions are well explained by the theory, and it is also found that the threshold and optimum amplitudes for the nonlinear growth agree well with the observed dynamic spectra.

Statistical analysis of ionospheric Pi2 pulsations observed at mid and low latitude by the SuperDARN Hokkaido radar

TERAMOTO, Mariko[1*] ; NISHITANI, Nozomu[2]

[1]JAXA, ISAS, [2]Solar-Terrestrial Environment Laboratory, Nagoya University

Ultra-low-frequency waves with the periods of 40-150 s are categorized as Pi2 pulsations, which occur over a wide rage of latitude in the night side at substorm onsets. To identify the generation mechanism of Pi2 pulsations, a number of studies using different devices such as ground-based magnetometers and satellites have been carried out. These study provide spatial properties of Pi2 pulsations on the ground and in the inner magnetosphere and suggested that high- and mid-latitude Pi2 pulsations are associated with Alfven waves in the auroral region, while the cavity mode resonance established in the plasmasphere by the fast mode waves has been proposed as a possible Pi2 source at mid and low latitudes.

The interaction of Pi2 pulsations with the ionosphere creates current systems that modify the amplitude and spatial scale size of the waves. In order to construct a coherent view of Pi2 signals measured by ground-based magnetometers, radars and satellites, the effect of the ionosphere needs to be understood.

In present study, statistical studies of Pi2 pulsations in the ionosphere were performed with the SuperDARN Hokkaido radar at Rikubetsu (AACGM magnetic coordinates: 36.5○, 214.7○). The radar can observe the Doppler velocity of ionospheric plasma due to the electric field of Pi2 pulsations in the mid- and low-latitude ionosphere. We investigated the spatial characteristics of the similarity, amplitude ratio, and cross phase between Pi2 pulsations observed by the radar and a ground magnetometer Memanbetsu (MMB) which is located close to the radar site. We will present the results and discuss the interaction of Pi2 pulsations with the ionosphere.

Pi pulsations in the near-earth magnetotail at substorm onset

SAKURAI, Tohru[1*] ; KADOKURA, Akira[2] ; TANAKA, Yoshimasa[2] ; SATO, Natsuo[2]

[1]Tokai University, [2]National Institute of Polar Research

The THEMIS satellite observations showed that Pi 1 and Pi 2 period range oscillations of the magnetic and electric fields play an important role at a substorm onset in the near-Earth magnetotail. They associated energetic particle accelerations toward the inner magnetosphere. The energetic particle accelerations were observed with very similar oscillation signatures to the Pi 1 and Pi 2 period range oscillations observed in the magnetic and electric fields.. This observation suggests that the Pi 1 and Pi 2 period range oscillations might play an important role for contribution to the auroral particle accelerations at substorm onset in the near-Earth magnetotail . The examination has been done on a substorm event observed on 28 February, 2009 at a THEMIS GBO station, Kuujjuaq (KUUJ) (Mag. Lat.=66.89 N, Mag. Lon.=13.23 E, Mag. Midnight =4.15 UT, L-value = 6.4) in the west coast at the high latitude of the North America Continent. This substorm event was simultaneously observed in the near-Earth magnetotail by the three THEMIS satellites, THEMIS-A, -E, and ?D located in the midnight region at ˜8 Re, ˜8 Re and ˜11 Re, respectively. The data examined in this study are the magnetic field, all-sky images (ASI) and keograms (ASK) obtained at KUUJ and the satellite observations of the magnetic field, electric field, and the electron and ion energy spectra in the ESA peir, and peer data. The results show very interesting facts of the Pi 1 and Pi 2 period range oscillations in the magnetic field and auroral activities observed on the ground and their conjunctions of the magnetic, electric fields, and the associated accelerated particles in the near-Earth magnetotail. The implication of this work provides the importance of the Pi 1 and Pi 2 period range oscillations for controlling the substorm onset plasma processes in the near-Earth magnetotail.

Substorm onset process: Ignition of auroral acceleration and related substorm phases

MORIOKA, Akira[1*] ; MIYOSHI, Yoshizumi[2] ; KASABA, Yasumasa[3] ; SATO, Natsuo[4] ; KADOKURA, Akira[4] ; MISAWA, Hiroaki[1] ; MIYASHITA, Yukinaga[2]

[1]PPARC, Tohoku University, [2]STEL, Nagoya University, [3]Dep. of Gephys. Tohoku University, [4]NIPR

The substorm onset process was studied on the basis of the vertical evolution of auroral acceleration regions derived from auroral kilometric radiation (AKR) spectra and Pi pulsations on the ground. The field-aligned auroral acceleration at substorm onset demonstrated two distinct phases. Low-altitude acceleration (h˜3000-5000 km), which accompanied auroral initial brightening, pre-breakup Pi2, and direct current of ultra-low frequency (DC-ULF) pulsation, was first activated and played an important role (pre-condition) in the subsequent substorm expansion-phase onset. Pre-breakup Pi 2 is suggestive of the ballooning-mode wave generation, and negative decrease in DC-ULF suggests increasing field-aligned current (FAC). We called this stage the substorm initial phase. A few minutes after this initial phase onset, high-altitude acceleration, which accompanied auroral breakup and poleward expansion with breakup Pi 1 and Pi 2 pulsations, suddenly broke out in an altitude range from 8000-16000 km. Thus, substorm expansion onset originated in the magnetosphere-ionosphere (M-I) coupling region, i.e., substorm ignition in the M-I coupling region. It is suggested that current disruption and subsequent violent energy release from the tail region take place after this ignition. Statistical investigations revealed that about 65% of earthward flow bursts observed in the plasma sheet were accompanied by enhanced low-altitude AKR, suggesting that flow braking of bursts causes FAC and resulting low-altitude field-aligned acceleration in the M-I coupling region. On the basis of these observations, we propose a substorm onset scenario in which FAC that originated from the braking of plasma flow bursts first enhances low-altitude acceleration (substorm initial phase onset), and then the increasing FAC induces current-driven instability in the M-I coupling region, which leads to high-altitude acceleration and resulting substorm expansion-phase onset.

drivers of the magnetospheric convection

FUJITA, Shigeru[1*] ; TANAKA, Takashi[2]

[1]Meteorological College, [2]Kyushu University

We present here the role of the plasma bulk flow in generation of the magnetosphere-ionosphere convection. Traditionally, the magnetospheric convection is studied with the perpendicular flow because this flow is equivalent with the speed of migration of the magnetic field. For example, the perpendicular force balance equations are utilized in discussion of the dynamo generation ($E*J<0$) in the cusp-mantle region [Tanaka, 1995]. However, since the plasma kinetic energy flux and the internal energy flux are transported along the plasma bulk flow, it is evident that the plasma bulk flow should be considered in generation of the magnetospheric convection. In
addition, the global MHD simulation reveals that the plasmas are accelerated into the cusp from the magnetosheath along the magnetic field. Thus, the plasma bulk flow transports energy into the magnetosphere.

At first, we discuss the dynamo in the cusp-mantle region based on the full set of physical principles (mass conservation, momentum conservation, and energy conservation). As a result, the load in the lower-latitude side of the cusp is invoked by plasma compression due to sudden deceleration of the field-aligned flow from the magnetosheath. The adiabatic assumption invokes pressure enhancement associated with plasma compression. Thus, energy should be supplied to compensate increase in the plasma pressure. As the kinetic energy is much smaller than the electromagnetic energy in the magnetosphere, the electromagnetic energy is converted to the thermal energy. Therefore, the load appears in the lower-latitude side of the cusp. On the other hand, in the cusp-mantle region, plasmas are squeezed with the field-aligned flow toward the lobe region. This yields plasma rarefaction, which eventually invokes energy conversion from the thermal energy to the electromagnetic energy. Thus, the dynamo appears. This process is also explained in terms of the slow mode expansion fan in the cusp-mantle region.

Next, we define an unique magnetospheric energy convection in the dayside magnetosphere. It is noted that the Poynting flux activated in the cusp-mantle region is transported across the dayside magnetosphere to the dayside magnetopause. The electromagnetic energy is totally deposited here. The deposited electromagnetic energy is converted into the thermal energy in the magnetopause. Then we need a mechanism of transporting this thermal energy elsewhere. The MHD simulation shows the thermal energy and the high-speed solar-wind kinetic energy are transported into the cusp from the magnetosheath. This flow goes to the mantle region. Then, the thermal energy transported from the magnetosheath via the cusp is partially converted into the electromagnetic energy in the cusp-mantle region. Finally, the loop of energy convection is completed.

The magnetospheric energy convection is unique because the energy convection and the mass convection show quite different behavior. On the other hand, in the normal fluid like the atmosphere, the energy convection is related to the mass convection in the atmospheric global circulation (convection).

Sudden pressure enhancement and tailward retreat in the near-Earth plasma sheet: THEMIS observation and MHD simulation

YAO, Yao[1*] ; EBIHARA, Yusuke[1] ; TANAKA, Takashi[2]

[1]Research Institute for Sustainable Humanosphere, Kyoto University, [2]SERC, Kyushu University

Plasma pressure enhancement is one of the drastic substorm-associated phenomena in the inner magnetosphere. In a substorm occurred on 1 March 2008, four of THEMIS (Time History of Events and Macroscale Interactions during Substorms) probes were almost aligned along the sun-Earth line, which was suitable for investigating spatial-temporal evolution of the near-Earth plasma sheet in a substorm. They observed a sudden increase in the plasma pressure at the inner probe (at ∼7.2 Re), followed by the outer probes (at ∼7.5, ∼8.3, and ∼10.4 Re), that is the high pressure region propagates tailward. Hereinafter, we call this sudden pressure enhancement (SPE). We compared the observations with simulation results of a global magnetohydrodynamics (MHD) simulation, and found a fairly good agreement between them in terms of the followings. (1) Tailward propagation of the SPE can be seen only at off-equator after the substorm onset. In the equatorial plane, an earthward propagation of the SPE precedes the tailward propagation. (2) Observations from the three inner probes show that the SPE consists of two enhancements. The first one is attributed to the convergence of bulk flow energy flux, namely flow braking. The latter one is due to the convergence of the thermal energy flux and subsequent inflation of the plasma sheet. (3) Plasma flow turned from the tailward-and-toward-the-equatorial-plane to earthward-and-away-from-the-equatorial plane near the onset from the simulation results. We discuss the spatial-temporal evolution of the plasma flow and the magnetic field during the substorm.

Evolution of theta aurora during strong positive IMF Bz and varying IMF By condition

OBARA, Takahiro[1*]

[1]PPARC, Tohoku University

Formation of the theta aurora, which appears under the condition of northward IMF and greater IMF magnitude, is investigated from the analysis of the numerical MHD simulation. The theta aurora is caused by the transient convection after a sign change of IMF By. This transient convection must include a replacement of lobe field lines from old IMF orienting fields, a rotation of plasma sheet to opposite inclination, and a reformation of ionospheric convection cells. In the midst of these reconfigurations, old and new convection system must coexist in the magnetosphere-ionosphere system. In this stage, the polar cap and tail lobes are continuously encroached by the new open field lines connected to the new IMF. Whereas magnetic field lines accumulated in new lobes tend to rotate the outer plasma sheet in the opposite direction, the old merging cell convection still continues to generate closed field lines that must return to dayside against the new lobe formation. As time progresses, the growth of new lobes results in the blocking of the return path toward dayside of closed field lines generated in the old merging cell to form the kink structure in the plasma sheet. Losing their return path, these closed field lines generated from old lobes accumulated on the night side. The theta aurora appears at the foot point of these accumulated closed field lines. In the presentation, we will demonstrate some observational results brought by satellites and ground based instruments, which support above mentioned hypothesis for theta aurora foramation.

Substorm Onset: Correlation between Ground and Space Observations

CHENG, Chio[1*] ; CHANG, T. F.[2]

[1]Plasma and Space Science Center, National Cheng Kung University, [2]Institute of Space and Plasma Sciences, National Cheng Kung University

The observations of substorm onset phenomena in the magnetosphere and ionosphere are examined to study their correlation and to understand the substorm onset mechanism. In particular, we examine the Pi2 wave structure, propagation, frequency and growth rate in the magnetosphere observed by the THEMIS satellites in the near-Earth plasma sheet and the structure and propagation of the substorm auroral onset arcs. We show the correlation between the substorm onset wave-like arcs and the Pi2 pulsations in terms of wave structure, propagation, and the exponential growth of arc intensity and Pi2 wave amplitude. In particular, the azimuthal mode numbers of the Pi2 waves and the wave-like arc structure are estimated to be ˜100-200. The correlation between the ground and space phenomena strongly supports the kinetic ballooning instability (KBI) as the cause of substorms. KBI is the most natural mechanism for explaining the unstable Pi2 waves in the strong cross-tail current region and the KBI parallel electric field can accelerate electrons along the magnetic field lines into the ionosphere to produce the substorm onset wave-like arcs.

Investigation of substorm triggering mechanism based on THEMIS data

MACHIDA, Shinobu[1*] ; MIYASHITA, Yukinaga[1] ; IEDA, Akimasa[1] ; ANGELOPOULOS, Vassilis[2] ; MCFADDEN, James P.[3]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]IGPP/EPSS, UCLA, [3]SSL, UC Berkeley

In this study, we show the result of superposed epoch analysis on the THEMIS probe data during the period from November, 2007 to April, 2009 by setting the origin of time axis to the substorm onset determined by Dr. Toshi Nishimura based on the THEMIS all sky imager (THEMS/ASI) data. We have restricted the time interval from t = -100 sec to t = 100 sec and the region to -7.5 >X(Re) >-23, and investigated various variations associated with substorm onset.

It was confirmed that earthward flows start at t = -60 sec in the region around X = -14 Re, and then they move toward the Earth. At t = 0, the dipolarization of the magnetic field starts at X ˜-10 Re, and simultaneously the magnetic reconnection starts at X ˜-20 Re. These variations support the validity of our Catapult Current Sheet Relaxation model for substorm onset.

Interestingly, the absolute value of dawnward plasma flow velocity |Vy|decreases in the plasma sheet and the plasma sheet boundary layer during the interval -20 <t(sec) <20. By analyzing individual event of |Vy|decrease, it was confirmed that the plasma flows turn from the duskward convective flows (Vy >0) to the dawnward flows (Vy <0) on average, associated with substorm onset, so that the value of Vy once becomes to zero around t = 0. This variation was found to be related to the deflection of the flows when they encounter with the Earth's dipole magnetic field as they approach to the Earth, which is the same reason already known to cause the tailward flows around X = -10 Re when the earthward flows reach that region.

Global MHD simulations of magnetosphere and 3-dimensional visualization

OGINO, Tatsuki[1*]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

A study on perpendicular and parallel current generation mechanism in the magnetosphere is important problems in interaction between the solar wind and earth's magnetosphere-ionosphere. Moreover, classification to fundamental MHD quantities and MHD modes is also essential for understandings of the mechanism. Thus we have executed a high resolution global 3D MHD simulation and a 3D graphic diagnostics.

As the solar wind and IMF becomes abnormal conditions, plasma turbulence are strongly excited near boundary layers in the magnetosphere. In the plasma sheet magnetic reconnection occurs in patchy and intermittent manner to produce streamer-like structure. At the magnetopause, more regular vortex train in association with current generation is formed for northward IMF.

Dayside reconnection occurs in patchy and intermittent manner to give seeds of plasma turbulence. As the results, complicated and strong vortex turbulence appears in flank magnetopause. We will demonstrate those phenomena from 3-dimensional visualization method of simulation results to discuss relationship between the currents and vortices in boundary layers. In particularly we will stress relationship among parallel and perpendicular components of vorticity and current, and also compressibility in order to understand the fundamental picture of magnetospheric dynamics. Moreover we will separate the fundamental MHD quantities to various MHD modes in the whole volume, which can make clear their roles on the vorticity and current generation mechanisms.

Two-spacecraft reconstruction of a three-dimensional magnetic flux rope at the Earth's magnetopause

HASEGAWA, Hiroshi[1*] ; SONNERUP, Bengt[2] ; ERIKSSON, Stefan[3] ; NAKAMURA, Takuma[4]

[1]Institute of Space and Astronautical Science, JAXA, [2]Dartmouth College, [3]University of Colorado, [4]Los Alamos National Laboratory

We present first results of a data analysis method, developed by Sonnerup and Hasegawa [2011], for reconstructing three-dimensional (3-D), magnetohydrostatic structures from data taken as two closely spaced satellites traverse the structures. The method is applied to a flux transfer event (FTE), which was encountered on 27 June 2007 by at least three (TH-C, TH-D, and TH-E) of the five THEMIS probes and was situated between two oppositely directed reconnection jets near the subsolar magnetopause under a southward interplanetary magnetic field condition. The recovered 3-D field indicates that a magnetic flux rope with a diameter of about 3000 km was embedded in the magnetopause. The FTE flux rope obviously had a significantly 3-D structure, because the 3-D field reconstructed from the data from TH-C and TH-D (separated by 390 km) better predicts magnetic field variations actually measured along the TH-E path than does the 2-D Grad-Shafranov reconstruction [Hau and Sonnerup, 1999] using the data from TH-C (which was closer to TH-E than TH-D and was at about 1000 km from TH-E). Such a 3-D nature suggests that reconnected field lines from the two reconnection sites may have been entangled in a complicated way through their interaction with each other. The generation process of the observed 3-D flux rope is discussed on the basis of the reconstruction results and anisotropy of observed electron pitch-angle distributions.

Auroral vortex, auroral surge, and vortical current in the ionosphere associated with the Pi2 pulsations

SAKA, Osuke[1*] ; HAYASHI, Kanji[2]

[1]Office Geophysik, [2]U. Tokyo

The auroral breakup event occurred at 0500UT 27 January 1986 in central Canada is studied using all-sky video image from two optical stations (GWR and SHM) and magnetometer data from three ground stations including the optical stations.

The spatiotemporal motion of the ionospheric vortical current explained the ground magnetometer data in the auroral zone. During the activation of the current vortex, auroras composed of the shear layers rotating clockwise and the auroral surge propagating westward were observed.

It is found that the auroral surge first appeared at the onset latitudes propagated poleward passing through the auroral vortex and became the poleward boundary aurora-surge (PBAS)(1).

Generation mechanism of steady-state field-aligned currents: A general theory in terms of plasma convection

WATANABE, Masakazu[1*]

[1]International Center for Space Weather Science and Education, Kyushu University, [2]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

It is well known that field-aligned currents (FACs) play an important role in that they transfer electromagnetic energy and momentum from the magnetosphere to the ionosphere. Recent global magnetohydrodynamic (MHD) simulations indicate that in almost all cases the pressure gradient force is the major driver of FACs [Tanaka, 2003, 2007]. The inertia force becomes appreciable only in very special cases such as the preliminary impulse (PI) in sudden commencements (SCs) [Fujita et al., 2003]. Thus the pressure gradient mechanism is working universally and represents the essence of the dynamical nature of the magnetosphere. What is less or not at all understood, however, is the role of plasma convection in FAC generation. One misconception is that plasma convection is irrelevant to pressure gradient-driven FACs. In fact, convection plays a vital role in energy conversion. This paper describes a general theory of steady-state FACs, with an emphasis on the importance of plasma convection. FACs are created and maintained through the following two processes that occur spatially contiguously with each other. (1) A ”dynamo” process in which plasma thermal energy is converted to electromagnetic energy. A magnetospheric dynamo is necessary in order to sustain a steady-state FAC system. This dynamo is generated by expanding plasma flow (div($\mathbf{v}$) $>$0) that is characterized by the slow mode in MHD waves. The wave normal is directed to the $-$ grad(B) direction, and the flow speed in the wave normal direction (the ”normal” component) becomes the phase speed of the slow mode wave. Slow mode disturbances do not associate FACs. (2) A process in which field-perpendicular currents transform into field-aligned currents. This process occurs by a mode conversion of the waves from slow to Alfvenic. If the pressure gradient has a component perpendicular to both the wave normal and the magnetic field (the ”tangential” component), it produces a magnetic tension and consequently excites Alfven mode disturbances. The flow speed in the wave normal direction becomes the phase speed of the Alfven mode wave. The Alfven mode is associated with tangential plasma flow, and consequently the plasma motion becomes rotational.

Multi-spacecraft analysis of tailward plasma flows in the near-Earth plasma sheet : THEMIS observations

OKAMOTO, Shunichi[1*] ; TAKADA, Taku[2]

[1]Kochi National of College of Technology Department of Electrical Engineering and Information Science, [2]Kochi National of College of Technology

In the near-Earth's plasma sheet, the magnetic field is abruptly dipolarized, associated with an aurora activity. In this region, most of plasma flows are earthward, while some are tailward. Although the candidate mechanism for such tailward flow is considered as rebound flows and/or a part of vortex flows, the quantitative occurrence rate is not fully understood. In this work, we selected events that THEMIS spacecraft observed tailward flows near the magnetic dipolarization region, and then categorized in flow patterns before the tailward flows. Based on the results, we statistically analyzed the categolized events, and estimated the space structure of tailward flows by multi-spacecraft analysis. Consequently, we show the occurrence rate of such rebound flows and the vortex flows.

Simultaneous observation of a field-aligned current by the JAXA QZS satellite and a MAGDAS ground observatory

TAKEUCHI, Yuuto[1] ; KAWANO, Hideaki[2*] ; HIGASHIO, Nana[3] ; MATSUMOTO, Haruhisa[3] ; BAISHEV, Dmitry G.[4] ; UOZUMI, Teiji[2] ; ABE, Shuji[2] ; YUMOTO, Kiyohumi[2] ; YOSHIKAWA, Akimasa[2] ; MAGDAS/CPMN, Group[2]

[1]Department of Earth and Planetary Sciences, Kyushu University, [2]International Center for Space Weather Science and Education, Kyushu University, [3]Japan Aerospace Exploration Agency, [4]Yu.G.Shafer Inst. of Cosmophysical Research and Aeronomy, Siberian Branch, Russian Academy of Sci.

In this paper we conduct a QZS-MAGDAS conjunction study of a field-aligned current (FAC). QZS (Quasi-Zenith Satellite) is operated by JAXA, and MAGDAS is the ground magnetometer network mainly operated by ICSWSE (International Center for Space Weather Science and Education), Kyushu Univ.

There have been only limited number of papers on satellite-ground conjunction studies of FACs, because satellites usually passes overhead at a ground observatory in a short time.
On the other hand, the footpoint of QZS stays near one ground point in Siberia, Russia, because the orbit of QZS is close to that of geosynchronous satellites on the Japanese meridian. Moreover, a few Siberian MAGDAS observatories exist near the QZS footpoint.

Another advantage of QZS is that, unlike geosynchronous satellites, QZS has 41deg inclination and 0.1deg eccentricity which enable QZS to stay for a long time at northern high latitudes in the magnetosphere; this high-latitude feature increases the detectability of FACs, because the FAC magnitude is in general smaller near the equator, i.e., the FAC source region in the magnetosphere. Thus, the pair of QZS and Siberian MAGDAS is expected to have more chances of simultaneously observing the same FAC than past satellite-ground pairs.

We have been searching for events in which, when QZS and a Siberian MAGDAS observatory were located near the same field line (calculated by the Tsyganenko 96 model), QZS and MAGDAS simultaneously observed transient magnetic field perturbations.

In this paper we present such an event observed by QZS and a Siberian MAGDAS observatory CHD (Chokurdakh). We have found that the transient magnetic perturbations of this event can be interpreted to have been generated by the motion of a local current circuit consisting of line FACs and an ionospheric current. More details will be presented at the meeting.

Comparison between particle environment around GEO from global MHD simulation and that from LANL satellite

NAGATSUMA, Tsutomu[1*] ; YAMAMOTO, Kazunori[1] ; KUBOTA, Yasubumi[1] ; TANAKA, Takashi[1]

[1]National Institute of Information and Communications Technology

Substorm injection is one of the important element of magnetospheric substorm, like auroral break up. Studying substorm injection is important to understand the physics of substorms. Also, substorm injection temporaly changes the particle environment around satellites at GEO. And dynamical variations of particle environment around GEO is one of the causes of satellite anomaly due to surface charging. We try to evaluate our magnetospheric global MHD simulation code by comparing output from global MHD code and LANL satellite particle data. Previous work has be done by Nakamura [2009]. We will examine the possibility of substorm injection prediction using global MHD simulation. Detailed comparison between simulation and observation will be shown in our presentation.

Energy dispersion and trajectory of particles injected from the magnetotail in magnetospheric quiet conditions

YAMAUCHI, Satoko[1*] ; NAGAI, Tsugunobu[2]

[1]Tokyo Institute of Technology, [2]Tokyo Insutitute of Technology

Particle injection is sudden enhancement in flux of energetic charged particles, commonly observed at geosynchronous orbit ($6.6R_E$), and associated with magnetospheric substorms. Since 2007, dispersive particle injections have been observed in the further dawnside of the magnetosphere ($>10R_E$) than geosynchronous orbit in quiet conditions with the spacecraft Geotail and THEMIS. Although only electron injections are observed in most cases, both electron and ion injections are observed in some cases. The injected population displays energy dispersion in which more energetic particles arrive at a given location earlier than less energetic particles. This dispersion occurs because of energy dependence of particle drift in the magnetospheric magnetic field. In order to investigate the time delay, we have calculated electron trajectories in the inner magnetosphere. We assume that the magnetospheric magnetic field is a simple dipole and the magnetospheric electric field is sum of a convection electric field and a corotation electric field, and obtain the particle trajectories in the equatorial plane using particle drift velocity. We find that the time delay is related to the intensity of the convection electric field. The simulations and observations show that electrons drift from the nightside through the dawnside to the dayside while ions drift from the nightside through the duskside to dayside. However, in the range given by the dipole field, it is not possible to explain the energy dispersion as observed. The shape of the magnetic field is different from the magnetic dipole in the magnetic tail region because the magnetosphere is stretched by the solar wind. In order to provide a more realistic magnetic field model in the magnetosphere, we use the Tsyganenko model that is an empirical magnetic field model of the magnetosphere. In this study, multi-satellite observations and test particle simulations are carried out to explore mechanisms in energization and transport of electrons in the quiet magnetosphere.

Time development of the Dipolarization Front and its interactions with the dipole-field region obtained by 2-1/2 dimensi

UCHINO, Hirotoshi[1*] ; MACHIDA, Shinobu[2]

[1]Earth and Planetary Sciences Graduate School of Schience, Kyoto University, [2]Solar-Terrestrial Environment Laboratory, Nagoya University

Bursty bulk flows with increasing B_z (northward component of the magnetic field), which are caused by magnetic reconnections in the magnetotail, are called Dipolarization Front (DF). Under the picture of the Near Earth Neutral Line model, which is one of the models explaining the triggering of substorms, the compression of the dipole region by DF and the pileup of DF itself around the near-Earth plasma sheet boundary cause a wide increase of B_z in the night magnetosphere. Although there are many observational studies of DFs by spacecraft, there are no full-particle simulations that examine the case in which the DF approaches to the dipole region.

In this context, we have performed two-dimensional full-particle simulations for the initial magnetic configuration which is akin to Earth's dipole magnetic field together with a stretched magnetic field by the thin current sheet. We have generated the magnetic reconnection and earthward plasma flows accompanied by B_z, and examined the time development of the flows and the interactions with Earth's dipole-field.

In our simulations, a minimal region of the northward magnetic field where B_z does not increase have been formed between the dipole region and flux pileup region, different from the common picture of Dipolarization. The reason of this can be considered as follows; (1) the earthward flows transport and accumulate the plasmas of the current sheet around the near-Earth plasma sheet boundary, (2) the pressure of the accumulated plasmas decelerate the flow, (3) B_z piles up in the tailward of the boundary. This result is different from the common effect of the DF that it broadly increases B_z in the night side of the magnetosphere. Because of the two-dimensionality in our simulations, the accumulated plasmas cannot leave in the Y-direction (eastward), producing such characteristic region. We also discuss on the structure of the particle flow velocity and particle density distributions near the DF by comparing with observational results.

3D Full kinetic simulations of plasma flow interaction with meso- and micro-scale magnetic dipoles

USUI, Hideyuki[1*] ; ASHIDA, Yasumasa[2] ; SHINOHARA, Iku[3] ; NAKAMURA, Masao[4] ; YAMAKAWA, Hiroshi[2] ; MIYAKE, Yohei[1]

[1]Graduate school of system engineering, Kobe University, [2]Research Institute for Sustainable Humanosphere, [3]Japan Aerospace Exploration Agency/Institute of Space and Astronautical Science, [4]Osaka Prefecture University

Plasma flow response to a magnetic dipole and the resulting formation of a magnetosphere depends on the intensity of the magnetic moment of the dipole. In this study, we examined plasma flow interactions with a magnetic dipole which is much smaller than the Earth's intrinsic magnetic dipole by performing three-dimensional full Particle-In-Cell simulations. The size of a magnetic dipole immersed in a plasma flow is characterized by distance L from its center at which the equilibrium is satisfied between the pressure of the magnetic field of the dipole and that of the plasma flow. In the Earth's magnetosphere, L implies the magnetopause location. We particularly focused on meso- and micro-scale magnetic dipoles in which L is comparable to and smaller than the gyroradius of ions in the flow. In the meso-scale case, ions kinetics should be dominantly considered while electrons whose gyroradius is sufficiently small can be treated as fluid. In the micro-scale, however, electrons as well as ions should be treated particles because L becomes small and the electron kinetics cannot be ignored either. Our interest is in the formation of current layer at the magnetosphere boundary in the both scales. Corresponding to the formation of a magnetosphere, the boundary current also depends on the size of the magnetosphere.

In the meso-scale case, the boundary current is dominated by the electron diamagnetic current at the large density gradient found at the distance of L. This signature is similar to the case of the Earth's magnetosphere. In the micro-scale case, however, the trajectories of ions and electrons gyration play an important role to determine the boundary current. Since the ion's gyroradius is larger than L, charge separation between ions and electrons occurs in the upstream region. As particles approach to the inner dipole, the electron gyroradius becomes small and electron drift motion becomes dominant. It is also confirmed that static electric field caused by the charge separation affect the plasma dynamics and the resulting current flow.

Estimation of the plasma sheet thickness in the Mercury's magnetosphere from the MESSENGER observations: IMF dependence

MORIMOTO, Yuya[1*] ; TAKADA, Taku[2]

[1]Kochi National College of Technology Department of Electrical Engineering and Information Science, [2]Kochi National College of Technology

Only two of spacecraft arrived at the Mercury until now: NASA's MESSENGER which went into orbit around Mercury in 2011 and Mariner 10 which investigated Mercury for two years from 1974. Although the Mercury's magnetosphere was first found by the Mariner 10, the magnetosphere has not been quantitatively understood. With the observations of magnetic field, we deduced the thickness of the plasma sheet and examined its dependence on the IMF (Interplanetary Magnetic Field) As a result, the plasma sheet thickness is estimated as 0.12-0.19 R_M during the northward IMF, and 0.02-0.08 R_M during the southward IMF. Bi-polar magnetic field signatures, which can be associated with the plasma flow in the plasma sheet, are observed both during northward and southward IMF. We then discuss the substorm-related phenomena in the Mercury's plasma sheet.

Problems of DC Probe Measurement onBoard Mini/Microsatellite

OYAMA, Koichiro[1*]

[1]Plasma and Space Science Center, National Cheng Kung Universoty,Taiwan, [2]International Center for Space Weather Study and Education

DC Langmuir probe is one of the key instruments to study ionosphere by satellite. It needs a counter electrode whose conductive surface are is at least 1000 times larger than that of surface area of the electrode. This requirement is usually fulfilled for large satellites which have been launched so far for ionosphere study. Now we are jumping into an era to use tiny satellites. Then we will encounter serious problems for DC Langmuir probe measurements. Conductive surface area of the satellite becomes much less than 1000 times, or even equal to the surface area of electrode. As a result, measurement of electron density becomes unreliable, because potential of the electrode with respect to the satellite (counter electrode) cannot reach ambient plasma potential where electron density is calculated. For the worst case, DC Langmuir probe is in double probe region, where the maximum current is controlled by ion current. An electronics needs to measure low current. although to measure the low current is not impossible with low frequency response. Another more serious problem is contamination of electrode as well satellite surface. To avoid the effect of contamination, probe bias of DC Langmuir probe need to be swept with about 10 Hz. These two factors make it possible to use DC Langmuir probe, because to measure low current with high frequency is not possible. We review problems which raises for the ionosphere measurement by small satellite, and propose one solution to avoid these problems to accomplish accurate measurements. The data which have been used here are the contribution of three students, G. S. Jiang, W. H. Chen, and Y. W. Hsu, Plasma and Space Science Center, National Cheng Kung University,Taiwan.

Development of Miniaturized Plasma Wave Receiver using ASIC

ZUSHI, Takahiro[1*] ; HANGYO, Kensuke[1] ; ONISHI, Keisuke[1] ; KOJIMA, Hirotsugu[1] ; YAMAKAWA, Hiroshi[1]

[1]Research Institute for Sustainable for Humanosphere

Plasma waves are an important physical phenomenon for understanding the electromagnetic environments in space. The plasma wave receiver is roughly divided into two types: a waveform receiver and a spectrum analyzer. Spectrum analyzer provides the frequency spectrums with low noises and high frequency resolution. On the other hand, waveform receiver provides the waveform. Though the waveform has more noise than the spectrum provided by the spectrum analyzer, only the waveform has phase information of a plasma wave. Thus it play a complementary role. However, these plasma wave receivers occupy a large amount of space because of its analog circuits, so a late scientific satellite has only a kind of plasma wave receiver. We have developed miniaturized waveform capture (WFC), a kind of waveform receiver, and sweep frequency analyzer (SFA), a kind of spectrum analyzer, using ASIC (Application Specific Integrated Circuit). We realized 6ch WFC in a chip of 5 mm x 5 mm. We execute experiment expose this chip to radiation. We find that though radiation influence WFC component, especially switched capacitor filter, our WFC fit for the space radiation environment. The SFA has fine frequency resolution, but its time resolution is poor. We propose a new kind of SFA combined with FFT. It has an improved time resolution without losing time resolution. We have developed analog circuits in the new SFA using ASIC technology. Furthermore, we propose the multipoint plasma wave observation system that consisted of some sensor probes using these miniaturized plasma wave receiver. We plan the sounding rocket experiment for performance test of this sensor probe.

Development of a wide-field X-ray imaging spectrometer for solar system exploration

EZOE, Yuichiro[1*]

[1]Tokyo Metropolitan University

We present our development of a wide-field X-ray imaging spectrometer for solar system exploration. In the past decade or so, various types of X-ray emission have been discovered in the solar system (Bhardwaj et al., 2007, Planet. Space, Sci., Ezoe et al., 2011, Adv. Space, Res.). These X-rays are often associated with energetic particles in planetary magnetosphere and neutrals in planetary atmosphere and cometary coma. Therefore, X-ray observations of solar system objects will lead to better understanding of solar system environments and astrophysical phenomena.

For this purpose, we are developing a wide-field X-ray imaging spectrometer for future exploration missions such as GEO-X (Ezoe et al. 2014, Space Sci. Symposium) and JMO (Sasaki et al. 2011, EPSC-DPS). This instrument is composed of an ultra light-weight X-ray telescope and a low-power radiation-hard semiconductor pixel sensor. The telescope covers a wide field of view of ~4 deg in diameter in 0.3–2 keV with the angular resolution of <5 arcmin. It uses sidewalls of etched holes through thin 4-inch silicon wafers for X-ray mirrors (Ezoe et al., 2010, Mircosys. Tehc.). The detector covers a wide area of ~20 x 20 mm^2 with a ~300 x 300 um^2 pixel. It is an active pixel sensor developed by MPE and PNsensor (Strueder et al., 2010, SPIE). Compared to X-ray CCDs, this type is more radiation hard and allows higher frame time less than 1 ms. This instrument can satisfy stringent resource constraints in the exploration missions. The mass, size, and power are estimated to be ~10 kg, ~30 cm cubic, and ~10 W, respectively. Multiple units of this instrument are considered for GEO-X to achieve a wider field of view, while one unit will meet science requirements of JMO. In this presentation, we will describe design, fabrication, and performance of the instrument components and future prospects.

ENA Imaging On board the DESTINY Mission

BRANDT, Pontus[1*] ; MITCHELL, Donald[1] ; WESTLAKE, Joseph[1] ; KEIKA, Kunihiro[2]

[1]The Johns Hopkins University Applied Physics Laboratory, [2]Solar-Terrestrial Environment Laboratory, Nagoya University

Energetic Neutral Atom (ENA) imaging is a technique that enables remote imaging of space plasma and neutral clouds. Several current space-borne missions including Cassini, IMAGE, TWINS, Chandrayaan-1, IBEX, and several future missions such as JUICE make use of ENA imaging to investigate magnetospheric plasma acceleration and evolution; structure and acceleration mechanisms in the boundary between the heliosphere and the interstellar medium; and surface and atmosphere interactions (terrestrial upper atmosphere, terrestrial moon, the Galilean moons, and Titan).

Demonstration and Experiment for Space Technology and INterplanetary voYage (DESTINY; See Kawakatsu et al., this conference) is an innovative technology demonstration mission that is being proposed to JAXA with a low-thrust increase of the apogee of an equatorial orbit, followed by a lunar swing-by, and finally an insertion in to a halo orbit around the Sun-Earth L2 point. This trajectory provides a historical opportunity to perform ENA imaging of the two following compelling targets.

- **The terrestrial magnetosphere:** the equatorial vantage point will offer the first compound view of how ions flow out from the polar ionospheres, , plasma stagnation at the sub-solar magnetopause, ion energization in the plasmasheet out to about 20 R_E and the subsequent heating and earthward transport that forms the terrestrial ring current.

- **The boundary between the heliosphere and the interstellar medium:** the NASA/IBEX and Cassini missions have revealed a global pattern and possibly dynamics that are believed to originate from ions charge exchanging in the heliosheath. A multitude of compelling science questions have arisen from the combined analysis of these two data sets that have demonstrated that ENA imaging is perhaps the only tool capable of remotely probing the global structure and acceleration processes in this important region.

The key to observing these targets in a new light that goes beyond previous missions is the ability to image with high angular and energy resolution, with a wide field of view (FOV) that can image large portions of the regions simultaneously. In this presentation we discuss a concept of an ENA camera to perform imaging from DESTINY. The ENA camera design is capable of imaging ENAs in the $\leq$1keV - 100 keV range with an angular resolution down to 2 degrees and an energy resolution down to 20%. The current design has a FOV of 120x90 degrees, which dramatically increases the duty cycle over single-telescope detectors on spinning platforms.

A compact, broad-beam, low-energy, LED-based, UV photoelectron source for the calibration of plasma analysers.

BEDINGTON, Robert[1*] ; SAITO, Yoshifumi[1]

[1]Solar System Science Division, Institute of Space and Astronautical Science, JAXA

Electrostatic electron analyser instruments are used to make in-situ measurements of space plasmas and are typically designed to detect electrons with energies from a few eV to a few tens of keV. To make optimal use of such instruments, a complete calibration is performed in a laboratory vacuum chamber before flight. An electron source and a moveable stage are used so that the instrument response can be characterised at every relevant electron energy and beam direction. For an ideal calibration, the source should be a uniform, collimated electron beam of controllable energy and flux, which is sufficiently broad in diameter to cover the entrance aperture of the electron analyser instrument being tested.

Various sources are used for such purposes, including radioactive beta-emitters and thermionic emission guns — although the former have fixed flux and are broad-band in energy, and the latter are expensive and produce only a narrow beam with limited energy ranges and limited dynamical control. To produce a broad, uniform, highly-controllable, long-lifetime, monoenergetic beam, UV photoelectron sources are generally preferable. These consist of a UV light source which illuminates a photocathode causing it to release photoelectrons. These electrons, which are released with negligible kinetic energy, are accelerated toward a high transmission grid by an electric field. The source can thus be as wide as the grid and the photocathode, as spatially uniform as the light that falls on the photocathode, and as collimated and monoenergetic as the photocathode and grid are flat and parallel (and thus the E field uniform). The electron flux can be adjusted by adjusting the UV lamp intensity, and the electron energy can be varied by adjusting the strength of the grid-photocathode E-field.

Traditionally the UV photons are created using gas discharge lamps (e.g. mercury, xenon, deuterium), however these typically have poor dynamical control, can create large amounts of background light and are bulky and inefficient. In recent years however, advances in solid-state technologies have enabled increasingly powerful, efficient and affordable LEDs of various UV wavelengths. Accordingly this has enabled compact, low-power, UV-stimulated electron sources that can have intensities that vary between 10 to 10^{-9} electrons cm^{-2} s^{-1}.

To meet the requirements for calibrating the electron analysers for the SCOPE (cross Scale COupling in Plasma universE) mission, a 9cm beam diameter, UV photoelectron source of this nature has been built and is being tested. Weighing approximately 1.5kg (excluding power supplies) and consisting of rugged, low cost components it can be mounted inside the vacuum chamber with great flexibility, including on a motorised translation stage.

The SCOPE mission requires several FESA (Fast Electron energy Spectrum Analyser) instruments for 10eV to 30keV electrons and several EISA (Electron Ion Spectrum Analyser) instruments for 10eV to 20keV electrons and ions. The first duty of the new electron source is the testing of prototype developments for the EISA instrument: namely measuring the electron transmission properties of carbon foil and assessing the secondary electron emission performance of candidate dynode materials

Characterization of Exoplanets with High Contrast Instruments

KAWAHARA, Hajime[1*]

[1]Department of Earth and Planetary Science, The University of Tokyo

Small exoplanets in the habitable zone (HZ) have been recently discovered by Kepler spacecraft and by ground-based radial velocity surveys. Now one of most interesting issues in this field is how to characterize them. In this presentation, I review our approaches to develop the instruments of direct imaging for the Thirty Meter Telescope (TMT) and other ground-based telescopes. These instruments aim to detect exoplanets in the HZ around late-type stars. I show that the search for the oxygen 1.27 micron bands as a biomarker is promising with the ground-based direct imaging (Kawahara+12 ApJ). I also show that the combination of extreme adaptive optics and coronaraphs for the direct imaging is also valuable for other characterization of exoplanets, for instance, for detection of exoplanetary molecules in close-in planets.

Hydrogen and helium atoms are the main constituents of the outermost region of the earth's atmosphere. These atoms resonantly scatter solar ultraviolet radiation causing an ultraviolet glow in this region, called geocorona. Hydrogen Lyman alpha radiation (121.567 nm) is the brightest. To date, various observations of the geocorona have been made. The geocorona comprises three main particle populations: ballistic, escaping, and satellite. Escaping particles are present at all altitudes, and they become particularly dominant at higher altitudes. In previous observations, the geocorona was identified to extend to an altitude of about 20R_E. The geocoronal distribution reveals asymmetries from day to night, dawn to dusk, and north to south. Recently, abrupt temporary increases (from 6% to 17%) in the total number of hydrogen atoms in the spherical shell from a geocentric distance of 3R_E to 8R_E have been recorded during several observed geomagnetic storms.

Past exploration of the geocorona has mainly been obtained from earth orbiters. Therefore, several low altitude (˜8R_E) observations have been made. On the other hand, in order to obtain the geocoronal distribution at high altitude, it is necessary to observe the geocorona from the outside in. However, there have been very few such observations (only Mariner 5, Apollo 16, and Nozomi). Among them, only Apollo 16 obtained an image. However, the observational FOV was about 10R_E.

In this study, we are developing a LAICA (geocoronal hydrogen Lyman Alpha Imaging CAmera) which will go onboard the very small deep space explorer PROCYON that will escape the earth and navigate interplanetary space. From such an explorer, our equipment can perform wide FOV (more than 25R_E) imaging of the geocoronal distribution. The first observation will be conducted one week after the launch for a period of one or two weeks. Subsequently, observations will continue for about three months. These observations will be conducted in higher temporal resolutions than that obtained from earth orbiters. The prototype of the LAICA has now been manufactured for testing and verification. And the flight model will have been completed by May. This presentation will show the development status.

Langmuir probe(LP) is a widely used instrument for measuring electron density and temperature on satellites and rockets. Recently pico- and nano- satellites have become more popular, when the surface area of satellite is similar to the probe, the effects on LP measurement due to limited satellite surface area need to be considered, and these effects may cause LP measurement inaccurate. We have investigated the effect of satellite surface area, satellite and probe contamination and LP sweeping frequency in laboratory. Also we have found that the satellite and probe voltage will decrease when a large quantity of electrons are attracted by probe voltage and the contamination effect of satellite surface becomes major.

In summary, a solution to these problems is suggested.

[1]Institute of Space and Plasma Sciences, National Cheng Kung University, [2]Plasma and Space Science Center, National Cheng Kung University

The nano/micro-satellite becomes popular for the study of near earth environment. To measure the electron temperature (T_e) and electron density (N_e) in the ionosphere, we have developed the Electron Temperature and Density Probe (TeNeP). The TeNeP measures T_e and N_e based on principles of electron temperature probe (ETP) and planar impedance probe (IP). By combining systems of ETP and IP, T_e and N_e can be measured by one single probe. The TeNeP system has advantages not only as being small, light weighted and low power consumption that fulfills the needs of instruments onboard nano/micro-satellites. It also overcomes problems associated with electrode surface contamination and satellite/probe surface area ratio for DC Langmuir probes.

Development of the small probe system to measure plasma wave for the sounding rocket experiment

ONISHI, Keisuke[1*] ; ZUSHI, Takahiro[1] ; KOJIMA, Hirotsugu[1] ; YAMAKAWA, Hiroshi[1]

[1]Research Institute for Sustainable Humanosphere, Kyoto University

Plasma filling the space is very rarefied. Ions and electrons in space plasma don’t exchange their kinetic energy through their collision but through plasma waves. Hence observing plasma wave is essential for measuring space electromagnetic environment. We propose the multipoint plasma wave observation system that consisted of some sensor probes.

The present paper shows the achievements in designing the small sensor probe system which is dedicated to the sounding rocket experiment. The experiment is performance test of the small sensor probe which measures the standard wave in outer space. The necessary components for the small sensor probe are Li-Ion battery, wireless LAN device, plasma wave receiver, A/D converter, and CPU. All of them should be installed in the cubic body with an edge of 10 cm. Therefore, we chose one-chip microcomputers as wireless LAN device, A/D converter, and CPU. The wave receiver is miniaturized by designing the analog ASIC (Application Specific Integrated Circuit).

The wave receiver has the function of observing electromagnetic waves in the frequency up to 100 kHz and we want to take three-axis data at the same time. So, we should design A/D converter which has three simultaneous sampling and sampling frequency over 200 kHz to fulfill the sampling theorem.

We also designed other necessary systems, such as attitude sensor and wireless communication system with the sounding rocket.

The space plasma operation chamber (SPOC), a research facility designed to calibrate and test satellite/rocket-borne instruments and study space plasma processes, is constructed at NCKU in 2009. It is a cylindrical chamber of 2m in diameter and 3m in length. Plasma is produced by two back-diffusion type sources installed at the center of both chamber sides. The sources produce ions of controllable drifting energy from a few ten to several hundred eV and density up to 10^6 cm^{-3}. These ions are neutralized by thermal electrons emitted from Nickel cathodes, and collide with neutral molecules in the chamber of pressure ~2.2×10^{-4} Torr, and a plasma environment with ion temperature ~300K and electron temperature ~1000-3000K is formed in the chamber. This paper presents measurement results of a retarding potential analyzer (RPA), an electron temperature and density probe (TeNeP) and a Langmuir probe installed on the 2-axis moving system in SPOC. The thermal and beam component ion energy distributions at different distances from the ion source and the electron temperature/density spatial distributions in the SPOC will be presented. The collision process of ions with neutral molecules will also be discussed.

Construction of a calibration system for developing space-borne particle analyzers

ITO, Fumihiro[1*] ; HIRAHARA, Masafumi[1] ; SHIMOYAMA, Manabu[1] ; HAYASHI, Ayuko[1] ; ISHIGURO, Keisuke[1] ; KOGISO, Shun[1]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

To study physical phenomena in the terrestrial/planetary ionosphere and magnetosphere, it is essential to consider effects of ionized particles and neutral particles which influence each other. For detailed investigations, in-situ observations by spacecraft are required. So we have been developing space-borne particle analyzers for planetary atmospheres with new technologies. As developing these analyzers, it is necessary to construct an appropriate calibration system for them.

For the calibration, we set the analyzer in a vacuum chamber, and irradiate an ion beam towards it, and investigate its response. We have already been constructing a calibration system (ion beam line) which can irradiate an ion beam of which energy per charge range is from 10keV/charge to 150keV/charge. It is necessary, however, for the system to irradiate a suprathermal ion beam of several tens eV/charge. Particularly the system provides the other species of atomic ion beams: H^+, He^+, O^+, N^+, Ar^+, over the energy per charge range from 10eV/charge to 10keV/charge in addition to the other species of molecular ions like $N_2{}^+$, $O_2{}^+$, $CO_2{}^+$. We have been constructed a new beam line which can irradiate an ion beam of which energy per charge range is from 10eV/charge to 10keV/charge. Eventually, we will construct a calibration system which can control each beam line integratedly. In this paper, we report the development of the suprathermal ion beam line.

The suprathermal ion beam line is mainly composed of six parts: (a) ion source, (b) electromagnetic ion mass spectrometer, (c) beam expander, (d) main acceleration, (e) vacuum chamber, (f) multi-axial turntable. In the ion source, introduced gases form a gas cylinder are ionized by thermal electrons emitted from filaments. The ionized particles are initially accelerated and discriminated by the electromagnetic ion mass spectrometer. The discriminated ion beam is expanded by electrostatic 2D raster scanning, and is parallelized through the deceleration and acceleration in the beam expander. The ion beam is accelerated or decelerated for the specific energy in the main acceleration. The analyzer is set on the turntable in the chamber. Incident angles of the beam are controlled by changing the elevation and azimuth of the turntable system. We can control the beam property to change parameters: (1) thermal electrons flux and its acceleration voltage, (2) pre-acceleration voltage for ionized particles, (3) strength of the magnetic field of the electromagnet, (4) raster scanning and parallelized electric field for enlarging the beam cross-section uniformly, (5) main acceleration/deceleration voltage, (6) elevation and azimuth of the turntable system. We have also been developing a system which can control them centrally and remotely by using a computer. As interfaces, we use wireless LAN, RS-232, and USB and make programs with LabVIEW. We have added a monitoring and alert system for multipoint vacuum components.

So far, we have constructed the system expect for the turntable system and can irradiate a specific energy beam which is expanded and parallelized sufficiently. We set up a MCP measurement system to measure the beam intensity and cross-section profile. We will present the updated status of calibration system and the beam properties in this paper.

[1]ISAS, [2]Nagoya University

ERG (Exploration of energization and Radiation in Geospace) is a geospace exploration spacecraft, which is planned to be launched in FY2015. The mission goal is to understand the radiation belt dynamics especially during space storms. The key of this mission is the observations of electrons and ions in medium-energy range (10-200 keV), since these particles excite various electromagnetic waves (e.g., EMIC waves, magnetosonic waves, and whistler waves), which are believed to play significant roles in the relativistic electron acceleration and loss. Engineering models (EMs) of medium energy electron analyser and ion mass spectrometer have been developed and their performances and tolerances are tested. We report the results of these verification tests on EMs.

The results in the initial operation of the Neutral Mass and Velocity Spectrometer (NMS) onboard the CASSIOPE satellite

KURIHARA, Junichi[1*] ; HAYAKAWA, Hajime[2] ; KOIZUMI-KURIHARA, Yoshiko[2]

[1]Graduate School of Science, Hokkaido Univeristy, [2]The Institute of Space and Astronautical Science/Japan Aerospace Exploration Agency

We report on the results in the initial operation of the Neutral Mass and Velocity Spectrometer (NMS) instrument that is one of the Enhanced Polar Outflow Probe (e-POP) mission payloads onboard the CASSIOPE satellite. The scientific objective of the e-POP mission is to explore the escape of plasma from the polar ionosphere and the escape of neutral particles from the upper atmosphere and their interactions. The NMS instrument is expected to contribute toward a quantitative understanding of occurrence morphology of neutral particles with non-thermal velocity distributions. Therefore, NMS was developed based on a new principle, which is different from previous satellite-borne neutral mass spectrometers. The NMS instrument has an entrance aperture for incoming neutral particles is perpendicular to the ram direction of the satellite in order to take in neutral particles using the satellite velocity of 7-8 km/s. The NMS instrument consists of three parts: an ionization part, a detection part, and data processing part. The ionization part has an electrostatic thermionic electron gun to ionize the neutral particles by the electron beam. In the detection part, the ionized neutral particles are perpendicularly accelerated by the electric field for the Time of Flight (TOF) mass spectrometry, and the two-dimensional positions are detected with a Microchannel Plate (MCP) and a resistive anode. The two-dimensional position detection provides the relative velocities of neutral particles with a certain mass and the original velocity distribution is derived by subtracting the satellite velocity from the relative velocities.

In the initial operation of the satellite, though the NMS instrument had nothing wrong in the status, it was found that charged particles a few orders of magnitude more than expected were detected if the electron gun was off. At present, we suppose this can be caused by the incident neutral particles ionized by collisions with internal surfaces of the instrument. The influence of the collision in the velocity distribution measurement and the results of the analysis in the routine operation are discussed in this paper.

Development and evaluation of the drive system of InSb imager mounted on infrared cameras for Jovian aurora

NOGUCHI, Eriko[1*] ; KOTANI, Koji[2] ; SAKANOI, Takeshi[1] ; KAGITANI, Masato[1] ; ICHIKAWA, Takashi[3]

[1]Geophys., Graduate School of Science, Tohoku Univ., [2]Electronics, Graduate School of Engineering, Tohoku Univ., [3]Astronomy, Graduate School of Science, Tohoku Univ.

In Tohoku University, infrared observation system is being developed for self-owned 60cm telescope. The purpose of this research is to develop a driving system of a Focal Plane Array (FPA) mounted on both an infrared camera and Echelle spectrometer and to evaluate observation possibility for various specific objects by establishing a method to determine adequate operating conditions based on detailed evaluation and analysis of a FPA.

First, from the previous researches, we estimated the required S/N to reveal the variation of some specific Jovian objects. In the case of H3+ aurora, the required S/N and the limit imaging time are 15 and 15s, respectively. For H2 aurora, they are 5 and 1200s. For equatorial temperature field, they are 5 and 7200s. Based on these, we showed the noise indicator, is composed of an upper limit of read noise and leakage current of FPA to realize the required S/N, considering the emission from a telescope and terrestrial atmosphere, and object.

Next, based on the driving mechanism of the FPA: CRC463(Raytheon) used in this research, we revealed that adequate bias is under -3.0V:Vdet, and over -4.0V :Vdduc. In this condition, Full Well(FW) is increased from 0.02V to 0.4V when bias(Vdet-Vdduc) is set at 0.6V, and we succeeded in the imaging of halogen lamp. And, we made improvements as follows.1. Increasing of conductivity of thermal path in the IR camera. This successfully decreased the temperature near FPA from 45K to 20K, resulting in the decrease of both the leakage current from 17,145e/s to 200e/s and the read noise from 453e$_{rms}$ to 320e$_{rms}$.2. Verifying the specific problem on CRC463, and we suggested new driving sequence based on frame to frame control. This resulted in the decrease in the read noise (to 200e$_{rms}$). This made it possible to precisely evaluate the performance of this system.3. Improving bias circuit in FPA driving system. The noise in output was reduced, resulting in the decrease of read noise (to 90e$_{rms}$).

Thanks to the above, it became possible to evaluate the performance parameters of FPA by Photon Transfer Curve method. As the result, in the case of 0.6V bias, DSNU and PRNU were evaluated as 38 ‰ and 16 ‰, respectively. In addition, leakage current, FW and system gain were 200e/s, 133,000e, and 10.9e/DN. We confirmed that the quantum efficiency is 0.85. We also evaluated the NEDT. With a 2.3μm filter and incident flux of 400K of blackbody, the NEDT reaches 45mK, is the equivalent performance compared to the third generation FPAs. As well, the performance parameters of our system other than the leakage current are equivalent to those of the NASA's IRTF system using the same FPA.

And, we evaluated the bias dependences on FW, leakage current and system gain. Using the results, we established the method to determine the adequate bias setting to realize the maximum S/N for specific object. As a result, following estimations were obtained. Using this FPA driving system, H3+ aurora can be observed at the maximum S/N=30 when the bias and exposure time are set at 0.5V and 15s. In the case of H2 aurora, the maximum S/N is 3.14 after binning, when the bias and imaging time are 0.4V and 1200s, respectively. Obtained S/N is below the requirement. It is needed to decrease leakage current under 81e/s. The case of temperature field, the maximum S/N is 52.7 with accumulating 28times, when total imaging time is 7200s, and the bias is set at 0.4V. To decrease accumulating times, bias should be set at 0.9V. If the leakage current will be under 100e/s, the S/N will be over 40 with an accumulation.

In summary, we developed FPA driving system for IR observation instrument mounted on telescope of Tohoku University for planetary observation. We evaluated the performance in detail, and developed the method to determine the adequate bias conditions for each observational object. Decreasing the leakage current is the remaining issue since it is two orders of magnitude larger than the FPA ' s specification.

A study for candidate scientific instruments for DESTINY

IWATA, Takahiro[1*] ; KAWAKATSU, Yasuhiro[1]

[1]Institute of Space and Astronautical Science, JAXA

DESTINY (Demonstration and Experiment of Space Technology for Interplanetary Voyage) aims to demonstrate new technologies of high energy orbit insertion, large scale ion engine, ultra light-mass solar panel, etc., which will be useful for deep-space mission by Epsilon launch vehicles. DESTINY has possibility to equip scientific mission instruments when system design makes the margin of the resource. DESTINY can conduct scientific observations for a half to one year on the Halo orbit of solar-terrestrial Lagrange 2 (L2) point. If conditions permit, DESTINY will leave L2 Halo orbit, and transfer to the next destination. Potential scientific topics include in-situ observation and remote sensing from L2 for, such as, plasma, energetic particles, and the magnetosphere in the plasma sheet of terrestrial magnetosphere. It is considered to be useful for the pilot observations for future infrared, gamma-ray, and cosmic-ray space astronomical telescope. It is probable to observe and monitor Near Earth Objects (NEO), inter-planetary and inter-stellar dust. It is also valuable to observe ultra-violet and X-ray emission from planetary phenomena. The mass allocated for the instruments is, however, currently estimated as in the range of between a few and ten kilograms. DESTINY will play roles as pilot experiments for these full-scale observations.

BepiColombo Euro-Japan Joint mission to Mercury: MMO Project Status update

HAYAKAWA, Hajime[1*] ; MAEJIMA, Hironori[1] ; BEPICOLOMBO, Project team[1]

[1]ISAS/JAXA

BepiColombo is a ESA-JAXA joint mission to Mercury with the aim to understand the process of planetary formation and evolution in the hottest part of the proto-planetary nebula as well as to understand similarities and differences between the magnetospheres of Mercury and Earth.

The baseline mission consists of two spacecraft, i.e. the Mercury Planetary Orbiter (MPO) and the Mercury Magnetospheric Orbiter (MMO). JAXA is responsible for the development and operation of MMO, while ESA is responsible for the development and operation of MPO as well as the launch, transport, and the insertion of two spacecraft into their dedicated orbits.

MMO is designed as a spin-stabilized spacecraft to be placed in a 400 km x 12000 km polar orbit. The spacecraft will accommodate instruments mostly dedicated to the study of the magnetic field, waves, and particles near Mercury. While MPO is designed as a 3-axis stabilized spacecraft to be placed in a 400km x 1500 km polar orbit. Both spacecraft will be in same orbital plane.

Critical Design Review(CDR) for MMO project is completed in November 2011 while ESA Spacecraft CDR is completed in Novemver 2013. MMO stand alone FM AIV is started from September 2012 and expected to be finished on this autumn. MMO FM will be transported to ESA/ESTEC to attend stack level (MCS) final AIV. BepiColombo is expected to be launched in 2016 summer.

10th BepiColombo science working team (SWT) meeting, which discusses science related matters, was held on September 2013 at Lapland. In this paper, we will report the latest information of BepiColommbo MMO project status.

Magnetic Cleanliness of BepiColombo MMO

MATSUOKA, Ayako[1*] ; NAKAZAWA, Satoru[2]

[1]ISAS/JAXA, [2]JSPEC/JAXA

In the terrestrial planets, Earth and Mercury has the intrinsic dipole magnetic field. The Mercury magnetic moment is relatively smaller than that of Earth; the magnetic field intensity on the Mercury surface is about 1 percent of that on the earth surface. Therefore the Mercury magnetospheric condition is significantly affected by the variation in the solar wind, and varies with the short period. The magnetic field around Mercury and its nature has been studied by MESSENGER which was launched by NASA and arrived at Mercury in 2011. However, because the magnetic field around Mercury is summation of the intrinsic and external origin, and MESSENGER always has the perigee in the north hemisphere, the Mercury intrinsic magnetic moment has not been determined accurately. BepiColombo is planed to be launched in 2016 and arrive at Mercury in January 2024. It consists of two satellites, MMO built by JAXA, and MPO by ESA, which will observe together the magnetic field around Mercury. BepiColombo has advantages to determine the accurate magnetic moment, which is one of the major scientific target of the BepiColombo project. The orbit shape is not biased, and the measurement at two locations enables to separate the intrinsic field and the external contribution. For the accurate measurement of the magnetic field, it is very important to suppress the magnetic noise generated by the components installed on the satellite. In the phase of the development of the satellite, the design of the every component was examined not to cause the magnetic noise which would degrade the magnetic field measurement. During the manufacturing period, components were controlled not to be magnetized. The means of the magnetic cleanliness of MMO and the result of the system EMC test, where the magnetic moment of MMO was measured, are reported.

Surface flows of Jupiter and Saturn are characterized by the broad prograde zonal jets around the equator and the narrow alternating zonal jets in mid- and high-latitudes. It is not yet clear whether those surface jets are the result of fluid motions in the ”shallow” weather layer, or they are produced by convective motions in the ”deep” region. ”Shallow” models consider atmospheric motions driven by the solar differential heating and the intrinsic heat flow from the deeper region under the assumption of hydrostatic balance in the vertical direction as a result of the thin atmospheric layer compared with the radius of the planet. These models can produce narrow alternating jets in mid- and high-latitudes, while the equatorial jets are not necessarily prograde. On the other hand, ”deep” models, which describe thermal convection in rapidly rotating spherical shells whose thickness is comparable to the radius of the planet, can produce equatorial prograde flows easily, while it seems to be difficult to generate alternating jets in mid- and high-latitudes.

Recently, Heimpel and Aurnou (2007) proposed thin spherical shell models and show that the equatorial prograde zonal jets and alternating zonal jets in mid- and high-latitudes can be produced simultaneously when the Rayleigh number is sufficiently large and convection becomes active even inside the tangent cylinder. However, they assume eight-fold symmetry in the longitudinal direction and calculate fluid motion only in the one-eighth sector of the whole spherical shell. Such artificial limitation of the computational domain may influence on the structure of the global flow field. For example, zonal flows may not develop efficiently due to the insufficient upward cascade of two-dimensional turbulence, or stability of mean zonal flows may change with the domain size in the longitudinal direction. In the present study, we perform numerical simulations of thermal convection in the whole thin spherical shell domain while coarse spatial resolution and slow rotation rate compared to Heimpel and Aurnou (2007) are used due to the limit of computational resources.

We consider Boussinesq fluid in a spherical shell rotating with constant angular velocity. The non-dimensionalized governing equations consist of equations of continuity, motion, and temperature. The non-dimensional parameters appearing in the governing equations, the Prandtl number, the Ekman number, the modified Rayleigh number, and the radius ratio, are fixed to 0.1, 10^{-4}, 0.05, and 0.75, respectively. The initial condition of the velocity field is state of rest and that of the temperature field is conductive state with random temperature perturbations. After time integration for 35000 rotation period, kinetic energy is saturated and statistically steady state seems to establish. Obtained velocity field satisfies Taylor-Proudman theorem; it is almost uniform in the direction of the rotation axis. An equatorial prograde surface zonal jet emerges in the region outside the tangent cylinder. In the inside of the tangent cylinder, the surface zonal flows are retrograde, but eastward spike features appear near the tangent cylinder in low latitudes. Correspondingly, coherent small scale convective motions exist in these latitudinal zones. It is expected that these convective motions excite topographic Rossby waves which remove westward angular momentum from these zones, producing eastward spike features. This mechanism may explain the origin of the strong thin jet at about 25 degrees north observed on the surface of Jupiter.

Numerical modeling of Cloud-level Convection in Venus Atmosphere

SUGIYAMA, Ko-ichiro[1*] ; KAWABATA, Takuya[2] ; ODAKA, Masatsugu[2] ; NAKAJIMA, Kensuke[2] ; ISHIWATARI, Masaki[3]

[1]ISAS/JAXA, [2]Department of Cosmosciences, Graduate School of Science, Hokkaido University, [3]Graduate school of Science, Kobe University

Cellular convection has long been thought to occur in the cloud layer of Venus, because some evidences for convection are obtained from radio occultation and spacecrafts data. However, the convective structure in the cloud layer is still unclear. Some numerical studies are performed to examine convective structure of the cloud layer (Baker et al., 1998, 2000, Imamura et al., 2014), but the domain of the model atmosphere in their numerical experiment is two-dimensional. In this presentation, we perform three-dimensional numerical calculation of convection using the same settings of Baker et al. (1998) in order to investigate a possible three-dimensional structure of convection in the cloud layer in statistically steady state.

The numerical model used in this paper is a cloud resolving model that is mainly used to simulate moist convection in Jupiter's atmosphere (Sugiyama et al., 2009, 2011, 2014), but condensation and chemical reaction are not considered in this experiment. The same sub-grid turbulence and radiation processes of Baker et al. (1998) are included in our model. The settings of the experiment are also based on those of Baker et al. (1998). In these settings, the altitudes of the lower and upper boundaries are 40 km and 60 km levels, respectively, and the layer between 48 km level and 55 km level is almost neutral.

The vertical motion obtained in our numerical experiment is characterized by wide, weak, warm updrafts and narrow, strong, cold downdrafts. This qualitative characteristic of convective motion is consistent with that obtained in Baker et al. (1998). The maximum velocity of downdrafts is about 10 m/s, while the mean vertical velocity is about 3 m/s. The downdrafts are driven by the cooling caused by the turbulent diffusion above the neutral layer and thermal flux at the upper boundary. The horizontal cell size is about 20 km, which is somewhat smaller than that of observed typical cloud-top cells in ultraviolet images; the sizes of the observed cells are typically 100-200 km and in some cases a few tens of kilometers across.

Convectively-generated gravity waves on Mars and their influence on the upper atmosphere

WATANABE, Ayuka[1] ; IMAMURA, Takeshi[2*] ; MAEJIMA, Yasumitsu[3]

[1]Department of Earth and Planetary Science, The University of Tokyo, [2]Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency, [3]Meteorological Research Institute, Japan Meteorological Agency

Gravity waves in the Martian atmosphere have been identified through various observations. The sources of the waves are still unclear, although topographically-generated gravity waves have been studied using regional models and incorporated into Mars GCMs with parameterizations. Here we investigate convective generation of gravity waves on Mars using a two-dimensional regional model based on the non-hydrostatic meteorological model CReSS. The heating source of the convection model is considered a horizontally-uniform heating of the atmosphere near the surface by sunlight and a localized heating caused by absorption of sunlight by dust clouds. The results show that tntense convection is generated as a result of a thin atmosphere, leading to generation of short-period, large-phase velocity (both in horizontal and vertical) waves. Such waves can reach high altitudes without serious dissipation; the horizontal wavelengths and the amplitudes of the gravity waves reproduced in the lower thermosphere are consistent with the density fluctuations measured during aerobraking experiments. The waves attain saturation amplitudes above ˜80 km altitude.

We further investigated the properties of vertical propagation and dissipation in the thermosphere using linear wave solutions based on the wave parameters observed in the convection experiment. Gravity waves reaching the thermosphere are damped by molecular diffusion and heat the atmosphere. The vertical profile of the heating rate shows two maxima: the lower one is located near the altitude where the amplitude peaks, and is generated by the sensible heat flux divergence, and the upper one is generated by the viscous dissipation of kinetic energy. These heating rates are comparable to other dominant processes such as EUV heating.

Mars 2020 rover is planned to launch by NASA in 2020, as the almost same package of the Mars Science Laboratory (named Curiosity after its successful landing in August 2012). The announcement of opportunity (AO) for scientific/technology payloads to be onboard the NASA Mars 2020 rover was called for to the scientists community in world wide in September 2013. Here, we introduce our proposed instrument designed for electromagnetic (EM) and acoustic wave (AW) measurements that have never been operated on Mars.

Low-frequency EM and AW are important for monitoring atmospheric events because of their long-distant propagating characteristics more than 1000 km. Electrical discharges could be a hazard for instruments and future human activities on Mars, hence it should be treated as one of the strategic knowledge gaps (SKGs) for future missions. Our concept is that combining EM and AW measurements, precise distance information of dust storms and/or dust devils can be obtained by using two independent velocities of light (c) and sound (Cs) because discharges could be generated by electro-static processes in low-pressure dusty atmosphere and the process also generates shock waves in acoustic/infrasonic pressure wave range. Moreover, wind roaring sound, shock waves by meteors entries, and operational sounds by rover itself will be recorded as the world first ”Martian sound.”

Our EM and AW detection system consists of antennae, microphones, and common receiver circuits with on-board software. For E-field detection, a legacy monopole of 10 cm will be used as a vertical antenna. Two orthogonal loop antennae should be applied for B-field with direction-finding system. However, instead of pop-up devices, these 3 antennae will be compressed into a fixed 10 cm cubic antenna to be equipped on rover surface. Although a legacy receiver circuit can be used, we can minimize it into a postcard size by applying a newly-developed chip device. Analyses of EM and AW for monitoring discharges can be operated by on-board software to reduce data volume. Similar software is used in GLIMS operated on JEM-Kibo/ISS, where only the most significant events will be sent to the Earth in priority basis.

EM sensing in the Martian atmosphere is significant for the future human exploration on Mars. Although the environment on Martian surface is too severe to survive even in fair climate condition, human activities on Mars is obviously dangerous especially when it is under the storm-like condition. Thus, dust devils on Martian surface are significant for the future human exploration, especially, electrostatic discharge events could be serious hazards for astronauts as well as for Martian base facilities. However, the EM condition on the Martian surface has never been measured in detail. Hence, we consider the remote-sensing of the dust devils and discharge events from a single site on Mars with simple sensors could be a potential instrumentation.

Here, as a proposal to the NASA 2020 AO, we introduce one of the most promising remote-sensing methods for dust devils and discharge events by using a combination of EM and AW. According to its rarefied atmospheric pressure condition on Martian surface, about 1/100 of the Earth’s surface, dust particles can easily be flown up by surface wind then could effectively produce charged particles by convection. Based on previous studies on the Earth, such charged particles possibly produce discharge events. Drastic changes in EM fields can be observed even at far-distant observatory, more than 1000 km away from the exact coordinates of discharges. AW also could be a remote-sensing method when there exists the atmosphere. Especially, low frequency AW less than 1 Hz can propagate for long distance more than 100 km even in the rarefied atmosphere. If we use two independent velocities of light (for EM) and sound (for AW), we can identify source coordinates of every discharge events within a few tenth km.

Observation of a few months temporal variability of UV brightness in Venus with Pirka telescope

IMAI, Masataka[1*] ; TAKAHASHI, Yukihiro[1] ; WATANABE, Shigeto[1] ; WATANABE, Makoto[1]

[1]Department of Cosmosciences, Graduate School of Science, Hokkaido University

The superrotation, which is a phenomenon that Venusian atmosphere moves westward at a velocity 60 times faster than the planetary rotation, is a unique atmospheric system of Venus. There are several theories to explain what drive the superrotation, but it is still unknown. Yamamoto and Tanaka (1997) suggested that the Kelvin wave in equator and the Rossby wave in mid-latitude, which propagating at an altitude of 70 km or higher, play an important role in the driving of the superrotation. They also suggested that the Kelvin and Rossby wave forms the Y-feature when they balanced. The Y-feature is the bright and dark pattern in UV range, and it has a planetary scale. From the Pioneer Venus spacecraft observation, it was revealed that the propagation and the distribution of UV features cause variation in several time scales [Del Genio and Rossow, 1982, 1990], but it has not been understood which dynamical processes determine these time scales. In our study, we focused on about 2-month brightness variation. That variation seems to be strongly associated with the Rossby wave because there is inverse correlation between low-latitude and mid-latitude, suggesting the existence of quasi-barotropic eddy. After the Pioneer Venus mission, there were no further observations to reveal the mechanism of the 2-month variation.

In this study, we observed the Venusian UV brightness variation as a function of latitude and time. We carried out the ground-based observations with Multi-Spectral Imager (MSI) onboard the Pirka telescope. The Pirka 1.6 m telescope, owned and operated by the graduate school of science in Hokkaido University, is primarily dedicated to the observations of solar planets. Using this system, we can monitor the planetary scale UV-features ($\sim$ 5,000 km) in Venus atmosphere over 8 hours in a day at 365 nm wavelength. In 2013, we carried out about 2 months total observations from mid-Aug. to mid-Nov.

There was a problem to estimate the absolute brightness variation because we observed Venus in the daytime and the correction of the extinction of the Earth's atmosphere had some difficulty. To investigate the brightness variation, we perform additional procedure for each image that we normalize the brightness in each latitudinal band with the mean brightness in 70^{o}N-70^{o}S area. Our results showed two types of UV feature. One showed the strong periodicity in both of equatorial region and mid-latitude and it also had the symmetric structure between northern and southern hemisphere. The other one did not show the strong periodicity and had the symmetric structure. We suppose that the Y-feature does not always exist and the balance of the Kelvin and Rossby wave might be lost when the periodicity and the symmetry disappear. From our observations, it seems to take more than 2 months to return from the asymmetric phase to symmetric phase. Additionally, we found that 2-month variation of brightness in each latitudinal band showed weak inverse correlation between both hemispheres like a seesaw. Such inverse correlation was not seen in the past Pioneer Venus observation. In this paper, we discuss the dynamical state of Venus during our observations and show further observation plans.

Spatiotemporal variations of brightness temperatures in the middle atmosphere of Venus revealed by Subaru/COMICS

SATO, Takao M.[1*] ; SAGAWA, Hideo[2] ; KOUYAMA, Toru[3] ; IMAMURA, Takeshi[1] ; SATOH, Takehiko[1]

The middle atmosphere (60-100 km altitudes) of Venus plays an important role in determining its own environment. Venus is completely shrouded by a curtain of dense clouds (50-70 km) with total optical thickness of 20-40 at visible wavelengths. The upper sulfuric acid (H_2SO_4) clouds reflect ˜76% of the incident solar radiation back to space (Crisp and Titov, 1997). More than 70% of the solar energy absorbed by Venus is deposited at altitudes higher than 64 km mainly due to absorption of unknown UV absorbers mixed in the upper cloud (Tomasko et al., 1980, 1985). This horizontally and vertically unusual heating in the cloud layer excites the thermal tides, which are the key process to understand the atmospheric super-rotation. In order to elucidate this mysterious atmospheric phenomenon, it is fundamental to investigate horizontal and vertical thermal structure in the middle atmosphere.

We conducted Venus observations at three mid-infrared wavelengths (8.66, 11.34, and 12.84 micron) with the Cooled Mid-Infrared Camera and Spectrometer (COMICS), mounted on the 8.2-m Subaru Telescope, during the period of October 25-29, 2007 (UT). Thermal radiations at these wavelengths (brightness temperature: 230-240 K) are most sensitive to altitudes of ˜70 km. The angular diameter of Venus and the solar phase angle (Earth-Venus-Sun angle) at the observation period were ˜25 arcsec and ˜90 deg (i.e., both the dayside and nightside hemispheres were observed), respectively. The spatial resolution of the observed images, which was determined by astronomical seeing, was ˜200 km for the sub-observer point. This was the first time that such high spatially-resolved images had been obtained at mid-infrared wavelengths (Mitsuyama et al., 2008).

From images at 8.66 micron, we obtained three important findings. First, the brightness temperatures at cloud top altitudes (˜70 km) in north high-latitudes seemed to be synchronized with those in south ones during the period, which implies that the rotational speeds of them were nearly identical in both high-latitudes. Such atmospheric synchronization has not been reported by any previous mid-infrared ground-based (Diner et al., 1982; Orton et al., 1991) and spacecraft (Taylor et al., 1980; Zasova et al., 2007) observations mainly because of low spatial resolution and tilt of Venus' north pole toward the Earth, and of restricted distribution of sounding, respectively. Second, the center-to-limb curves (dayside and nightside) showed a day-night asymmetry across the morning terminator except that those on October 25 were nearly symmetric. The magnitude of this asymmetry was variable from one day to the next. Such day-night asymmetric features would result from the differences of temperature and/or cloud optical thickness. Finally, there were some streaky and patchy patterns in the whole disk after high-pass filtering. These patterns, typical amplitude of which was ˜0.5 K, varied from day to day. It is worth noting that streaky patterns obtained on October 28 were similar to a well-known horizontal Y-shape structure seen in UV. The above three findings were commonly seen at the other wavelengths.

In this talk, we show the observational results and discuss what kind of atmospheric parameters are responsible for the anomalous features of planetary scale center-to-limb curves through radiative transfer calculations.

Energy spectra of atmospheric motions simulated by a high-resolution general circulation model of Venus

KASHIMURA, Hiroki[1*] ; SUGIMOTO, Norihiko[2] ; TAKAGI, Masahiro[3] ; OHFUCHI, Wataru[4] ; ENOMOTO, Takeshi[5] ; TAKAHASHI, Yoshiyuki O.[6] ; HAYASHI, Yoshi-yuki[6]

[1]ISAS, [2]Keio Univ., [3]Kyoto Sangyo Univ., [4]JAMSTEC, [5]DPRI, Kyoto Univ., [6]CPS/Kobe Univ.

The dynamics of the Venus atmosphere is unclear because of the lack of observational data. Many researchers have developed General Circulation models (GCM) for the Venus atmosphere and have attempted to simulate atmospheric motions of Venus. Because the planetary rotation period of Venus is much longer than the Earth, long-term integrations are needed for the solution to achieve a statistically steady state. Therefore, the simulations have been performed by low-resolution ($\sim$ T21; i.e., about 5.6 deg x 5.6 deg grids) models. We have developed a simplified Venus version of the AFES (Atmospheric GCM for the Earth Simulator) (Sugimoto et al. 2012) and performed a very high-resolution simulation. In this paper, we report and discuss kinetic energy spectra obtained from the high-resolution simulation.

The dynamical core of AFES is descretized by the spectral method in horizontal. The model resolution is T159 (i.e., about 0.75 deg x 0.75 deg grids) and L120 (Δz is about 1 km). In the model, the atmosphere is dry and forced by the solar heating with the diurnal change and Newtonian cooling that relaxes the temperature to the zonally uniform basic temperature which has a virtual static stability of Venus with almost neutral layers. To prevent numerical instability, the biharmonic hyper-diffusion is included with 0.01 days of e-folding time for the truncation wavenumber. The coefficient of the vertical eddy diffusion is 0.15 m^2 s^{-1}. A sponge layer is set above 80 km to prevent the reflection of waves. The dry convective adjustment scheme is used to avoid statically unstable state. A fast zonal wind in a solid-body rotation and the temperature field that balances (gradient wind balance) with the zonal wind are given as the initial state. Time-integrations are performed until the solution achieves a statistically steady state.

We calculate the horizontal kinetic energy per unit mass per unit wavenumber from the spectral coefficients of the vertical vorticity and horizontal diffusion (Koshyk & Hamilton 2001). The energy decreases by –5/3 power law in a range from wavenumber 4 to 45. Both in lower and higher wavenumber sides, the energy shows higher decreasing rate.

A feature of the energy spectral of aircraft observations (Nastrom & Gage 1985) and high-resolution GCM calculation of the Earth (Takahashi et al. 2006) is that the energy decreases by –3 power law in low-wavenumber range (n $<$80) and by –5/3 power law in higher range. Terasaki et al. (2011) have reported that the –3 power law in synoptic scale is due to Rossby waves and the –5/3 power law in the mesoscales is due to gravity waves. The energy spectrum that we have obtained shows –5/3 power law in the wavenumber range lower than the Earth cases. This implies that the gravity waves may dominant even in scales of several thousand kilometers in the Venus atmosphere. A reason for the Rossby wave not being dominant in these scales may be the slow planetary rotation. The effect of the hyper-diffusion may appear in the range near the truncation wavenumber.

[Acknowledgement] This study was conducted under the joint research project of the Earth Simulator Center with title “Simulations of Atmospheric General Circulations of Earth-like Planets by AFES.”

Microphysical properties of Venusian upper hazes observed with an Imaging-Polarimetry system " HOPS "

ENOMOTO, Takayuki[1*] ; SATOH, Takehiko[2] ; NAKATANI, Yoshikazu[3] ; SATO, Takao M.[1] ; HOSOUCHI, Mayu[4] ; NAKAKUSHI, Takashi[5]

[1]SOKENDAI, [2]ISAS/JAXA, [3]Kyoto University, [4]University of Tokyo, [5]Wakayama University

The high albedo of Venus is due to optically very thick main cloud deck which covers the whole planet. The small particles (hazes) which were distributed above the main cloud deck were discovered by the observations from Pioneer Venus Orbiter (PVO) which arrived at Venus in December 1978. Kawabata et al. [1980] found, from the data of Orbiter Cloud Photopolarimeter (OCPP) onboard PVO, that abundant sub-micrometer sized particles " hazes " were distributed above the main cloud deck mostly in polar regions. The optical thickness of the haze layer was reported to reduce during the PVO mission period [Sato et al., 1996]. Coincidently, decrease of the SO_2 abundance was also reported [Esposito, 1985]. After the PVO mission, however, the variation of the optical depth of the hazes has not been studied, so it is not clear what this correlation means for the generation and maintenance of hazes and whether a similar correlation between them exist today. Our study provides the latest information about the microphysical properties of hazes by ground-based monitoring observations which have not been done since PVO.

To monitor the distribution of the Venusian upper hazes, we developed an imaging-polarimetry system " HOPS " (Hida Optical Polarimetry System) and performed observations by attaching it to the 65cm refracting telescope at Hida Observatory of Kyoto University. As HOPS provides spatially resolved polarization map, polarization in an arbitrary area can later be obtained just by summing up the corresponding pixels for comparison with previous measurements. This is the biggest advantage of imaging polarimetry against the aperture measurements. HOPS is a " two beam type " polarimetry instrument which enables high accurate measurements against variable atmospheric conditions. The effect of variable atmospheric transparency, non-uniformity of sensitivities over the CCD pixels and different throughputs of two beams can be corrected through arithmetic operations in image processing.

The observations were carried out at solar phase angles around 39deg. (Jul., 2013), 56deg. (Aug., 2013), 58deg. (Oct., 2012), 85deg. (Aug., 2012) and 129 deg. (May, 2012) at 4 selective wave lengths 438nm (B), 546nm (G), 650nm (R) and 930nm (IR); G and IR data can be compared with similar wavelength data of PVO/OCPP. We averaged observed degree of linear polarization over the polar regions (latitudes higher than 60 deg.) and compared with the report of PVO. A clear difference is seen in IR data. The neutral point of our data is found to be at around 75 deg. while the point of PVO/OCPP is around 40 deg. This difference may indicate the different situation of the distribution and size parameters of hazes.

To analyze the obtained polarization data, we developed a radiative transfer calculation code using Adding?Doubling method with the Stokes parameters fully treated [de Haan et al., 1987, Hovenier et al., 2004]. It is possible to analyze three wavelengths IR, R, and G neglecting the Rayleigh scattering effect because Rayleigh scattering cross-sections for IR, R G and B are about 0.21, 0.083, 0.041, 0.0096μm^2 while Mie scattering cross-sections for a main cloud particle are the order of 7μm^2. We treated haze particle effective radius r_{eff} and optical depth τ_h as free parameters, respectively. The effective variance of hazes was fixed to 0.18 and parameters for main cloud layer were taken from Hansen and Hovenier [1974]. Single scattering albedos were assumed to be 1 for both haze and cloud layers. The resultant parameters for northern and southern polar region are r_{eff} = 0.22, 0.20μm, τ_h = 0.09, 0.05 at IR, respectively. The optical depth is smaller compared with the initial observations of PVO τ_h = 0.25 but comparable with those observed during the declining phase. Such declination of the abundance of SO_2 is also observed by Venus Express orbiter [Marcq et al., 2012], so our results are consistent with the report of the correlation with it.

Estimation of wind at the cloud top of Venus

IKEGAWA, Shinichi[1*] ; TAKESHI, Horinouchi[2]

[1]Graduate School of Environmental Science, Hokkaido University, [2]Faculty of Environmental Earth Science, Hokkaido University

A number of theories have been proposed to explain the formation of the super-rotation in the Venus atmosphere. Among them, we focused on the Gierasch mechanism. To validate the mechanism, it is required to investigate the horizontal momentum transport by eddies with an accuracy sufficient to resolve the eddies with scales smaller than several thousand kilometers. In this study, we used the ultraviolet images from Venus Monitoring Camera (VMC) onboard ESA's Venus Express. The VMC data have some random and coherent noises, so the simple cross-correlation methods used in previous studies do not necessarily provide an high accuracy. Here, we suggest a new and robust method to estimate wind velocity vectors accurately by using multiple images, thereby reducing the effect of noises. The accuracy of its results is estimated statistically. The results are also examined from the dynamical point of views. Contrary to conventional expectation, the magnitude of horizontal wind divergence has similar magnitude to its rotation on the horizontal scale of several thousand kilometers. It is discussed how the results are explained.

Studying the Venusian atmosphere on the 2012 transit of Venus

KANAO, Miho[1*] ; NAKAMURA, Masato[1] ; SHIMIZU, Toshifumi[1] ; IMAMURA, Takeshi[1]

[1]ISAS/JAXA

The solar satellite Hinode observed the transit of Venus on June 5-6th 2012. The solar optical telescope (SOT) observed the dark Venus disk against the bright solar surface. The images were acquired continuously for the wavelength of 396.8, 430.5 450.4, 555.0, 668.4 nm with unprecedented spatial scale (∼0.3 arcsec).

The purpose is the derivation of the latitudinal and vertical distribution of the cloud particle, SO2 and SO from the transmittance for considering the global dynamics. We calculated the transmittance normalized by the unattenuated solar intensity after the data correction processes including the removal of the solar limn darkening and the calibration for the plate scale.

The altitude as the transmittance of 0.5 (∼90 km) in the Venus atmosphere has the slant toward the equator. The difference is 9.1 km in the evening and 6.1 km in the morning. In the equatorial region (latitude $\leq$ 40 degree), the fluctuation of the altitude is observed. The amplitude for the wavelength shorter than 400 nm is a few times larger than that of 430.5 nm. We would show the consideration to explain the longitudinal distribution of the altitude of the Venus disk.

Keywords: planetary atmosphere, the transit of Venus

To understand the influences of the activities of the central star on the middle atmospheres of the surrounding terrestrial planets, we have performed millimeter-wave-band monitoring of the atmospheres of Venus and Mars by using a 10-m radio telescope called SPART (solar planetary atmosphere research telescope). The telescope employs highly sensitive superconducting SIS mixer receivers in the 100- and 200-GHz bands for the front-end and a commercially available FFT spectrometer (1-GHz bandwidth and 67-kHz resolution) for the back-end. Millimeter-wave-band heterodyne sensing is a powerful technique that can be utilized to trace the abundance and vertical distribution of minor constituents in a planetary middle atmosphere.

In 2011, we began observations of the middle atmospheres of Venus and Mars in the 100-GHz band. In 2012, the telescope had problems with the azimuth gear, motor, and synchro-to-digital converter unit, which resulted in a pause in telescope operation. In 2013, we repaired these problems and resumed the substantive operation test. We are currently restarting double-band full remote monitoring of the spectral lines of minor constituents such as ^{12}CO J=2-1 at 230 GHz, ^{13}CO J=2-1 at 220 GHz, and ^{12}CO J=1-0 at 115 GHz toward Venus and Mars. This season, the apparent diameter of Venus is greater than the beam size at the 200-GHz band (35 arcsec.). We adopted position switching and on-the-fly modes for 100- and 200-GHz-band observations, respectively. The latter two-dimensional mapping allows us to cover the entire disk of Venus. The retrieved CO abundance variation is compared with the data of high-energy particles, X-rays, solar wind velocity/density, and other measured parameters. The data are associated with flare, coronal mass ejection, and solar proton events.

In this conference, the current status of the SPART project and the millimeter-wave-band monitoring will be presented.

Observation of a wave structure of stratospheric haze in Jupiter's polar regions by the ground based telescope

GOUDA, Yuya[1*] ; TAKAHASHI, Yukihiro[1] ; WATANABE, Makoto[1]

[1]Department of Cosmosciences, Graduate School of Science, Hokkaido University

Stratospheric haze formed by aerosol particles covers both polar regions in Jupiter. It has been reported based on the imaging using a methane band filter at 889 nm that the stratospheric haze can be measured. They show bright cap structures covering polar regions and the edge of the cap shows a wave structure spreading in longitudinal direction. This structure can be seen more clearly in the Jupiter's south pole than the north pole, and wave is clear at a latitude of about 67 S [Sanchez-Lavega, 2008].

Jupiter's polar areas have been investigated by the Hubble Space Telescope (HST) from 1994 to 1999 and the Cassini ISS in 2000. This wave structure is known to exist for several years in Jupiter's both polar regions. These observations suggested that this wave structure is caused by planetary Rossby waves because this wave structure presents for a longer period and moves westward relative to the background flow. However, the origin and mechanism keeping to this wave structure, the vertical structure of the wave, change of the propagation velocity of the wave in the short time scale, and north-south asymmetry of the wave structure are unclear so far, because of lack of the observations in short time scale (monthly scale). We have carried out the monthly monitoring of Jupiter from 2011 to 2014 with the 1.6 m Pirka telescope of Hokkaido University.

In this paper, we show results of our observations of the wave structure in Jupiter's polar region. We found a north-south asymmetry of the wave structure in the polar areas. The wave structure at 67 N spread to 42 N in the northern hemisphere, however it does not so in the southern one. In addition, we found that the wave structure has varied in the vertical direction a bit between altitude of 361 mbar and 750 mbar.

Observing Jupiter with an infrared camera NIIHAMA

SATOH, Takehiko[1*] ; YONEDA, Mizuki[2] ; KAGITANI, Masato[2] ; KUHN, Jeff[3]

[1]Japan Aerospace Exploration Agency, [2]Tohoku University, [3]University of Hawaii

An infrared camera, NIIHAMA (1024x1024 pixels, PtSi array sensor), is attached to the SOLAR-C telescope (45-cm diameter off-axis Gregorian reflector) atop Haleakara in December 2013 and is now observing Jupiter.

NIIHAMA's 6-position wheel houses Dark, J, H, K, 3.4-micron (for Jupiter's H_3^+ aurora) and 2.26-micron (for Venus night-side IR emission) filters. The primary target of this project is to monitor the brightness of Jupiter's aurora simultaneously with SPRINT-A/HISAKI and other telescopes. However, due to smaller aperture of telescope, rather low quantum efficiency of PtSi sensor, etc., Jupiter's aurora has not yet been imaged so far. On the other hand, the satellite Io while in Jupiter's shadow was observed in K band, and the night-side IR emission of Venus was successfully imaged in 2.26-micron filter. We report the result of first-light observations and also discuss improvement and observing plans in near future.

Self-driven auroral acceleration process at Jupiter captured by continuous monitoring of Hisaki satellite with HST

KIMURA, Tomoki[1*] ; TAO, Chihiro[3] ; BADMAN, Sarah[2] ; YOSHIOKA, Kazuo[1] ; MURAKAMI, Go[1] ; YAMAZAKI, Atsushi[1] ; TSUCHIYA, Fuminori[4] ; FUJIMOTO, Masaki[1]

Two possible drivers have been proposed for planetary auroral acceleration processes: magnetosphere-solar wind interaction referred to as an 'external driver' and shear flow of magnetospheric plasma around a planet referred to as an 'internal driver'. Recent observations of Jupiter's aurora indicated significant responses of auroral intensity and morphology to the solar wind. These results are suggestive of the 'external driver' for Jupiter. On the other hand, there have not been reported dynamics of the 'internal driver' for Jupiter yet which should be essential because of Jupiter's fast rotation and internal plasma source Io. Here we firstly report dynamics of the 'internal driver' based on long-term continuous observation of extreme ultraviolet (EUV) aurora by Hisaki satellite. The long-term variations in EUV aurora are compared with solar wind extrapolated from Earth's orbit by numerical simulation. We found dramatical brightening and decay of EUV aurora during the solar wind quiet period. The brightening occurs once every a few days followed by sudden decay with a timescale less than a half of rotation (˜5 hours), which is significantly faster than the solar wind daily variations. Highly-resolved auroral imaging by Hubble Space Telescope captured expansion of diffuse aurora down to latitudes of Io's footprint aurora during the brightening. These observations are indicative of hot plasma deeply injected into the inner magnetosphere around Io's orbit independently from the solar wind, followed by rapid energy dissipation through auroral emissions and possibly other radiation and/or chemical processes.

Characteristics of O+ velocity distributions at Venus and ion acceleration mechanisms: ASPERA-4 observations

MASUNAGA, Kei[1*] ; FUTAANA, Yoshifumi[2] ; TERADA, Naoki[3]

[1]STEL, Nagoya Univ., [2]Swedish Institute of Space Physics, [3]Grad. Sch. of Sci., Tohoku Univ.

O^+ ion velocity distributions for high energy O^+ beams ($>$100 eV) around Venus are statistically studied. The study shows that O^+ acceleration is controlled by the local convection electric field produced by the local proton and local magnetic field. In the magnetosheath, velocity distributions show a trend that perpendicular velocity component shifts from initial phase of the ring distribution to the local proton velocity. This indicates that gyro motions of the pickup ion immediately collapse after pickup and the ions are incorporated into the local proton flow. The pickup ions only escape through the $+E_L$ hemisphere. In the dayside induced magnetosphere in the $+E_L$ hemisphere, measurements show a scattered velocity distribution of O^+. This velocity distribution has two ion components depending on whether their gyro radius is larger or not than the scale of the induced magnetosphere. For O^+ ions with small gyro radius ($<$500 km), the O^+ velocity distribution appears on the middle phase of the ring distribution. On the other hand for the O^+ ions with a large gyro radius ($>$500 km), the O^+ velocity distribution is similar to the one in the magnetosheath. This means that in the induced magnetosphere two types of ions are mixed up: pickup ions subject to the E x B drift and ions moving with the local proton bulk velocity. Since both ion components flow tailward, they are convected toward the nightside. In the nightside of the induced magneto- sphere, velocity distribution shows initial and last phase of the ring distributions and parallel beam (3D ring distribution). This suggests that ion pickup occurs at the center of the plasma sheet. There is no evidence of an electric potential in the plasma sheet because the O^+ parallel beam velocity is larger than the parallel velocity component of the local proton. Our result suggests that the local convection condition is rather important to discuss ion acceleration mechanisms at Venus than the solar wind condition.

Characteristics of boundary layer between the magnetosheath and Martian ionosphere during solar wind penetration events

MATSUNAGA, Kazunari[1*] ; SEKI, Kanako[1] ; HARA, Takuya[1] ; BRAIN, David A.[2] ; LUNDIN, Rickard[3] ; FUTAANA, Yoshifumi[4] ; BARABASH, Stas[4]

Deceleration of the solar wind due to the mass loading by planetary heavy ions forms the magnetic pile-up region around unmagnetized planets such as Mars and Venus. The Martian magnetic pile-up region diverts shocked solar wind plasma around the planet at altitudes typically in excess of 800 km [e.g., Vignes et al., 2000]. Mars Global Surveyor (MGS) measurements have shown, on one hand, that shocked solar wind (magnetosheath) plasma occasionally penetrates into much lower altitudes ($\sim$400km) [e.g., Brain et al., 2005; Crider et al., 2005]. Our previous statistical study of these solar wind penetration events using MGS magnetic field and electron observations revealed that both solar wind dynamic pressure (Psw) and the orientation of the interplanetary magnetic field (IMF) control the occurrence of the events. However, MGS cannot observe the solar wind regions due to its orbital design.

In this study, we focused on the simultaneous observation of the penetration events by MGS and Mars Express (MEX). MEX possess the ion mass analyzer (IMA) and electron spectrometer (ELS), which are parts of plasma packages of ASPERA-3. MEX partly observed the solar wind region, since the orbit of MEX is elliptical orbit. We can thus obtain the solar wind density and velocity from MEX data. Among the simultaneous observation data by MEX and MGS, we identified 46 simultaneous observation events of the solar wind penetration. We divided the 46 events into the low Psw ($\leq\sim$4nPa) and high Psw ($\geq\sim$4nPa) events. The solar wind penetration event on January 20, 2005 is observed during the high Psw periods, while the event on February 20, 2005 is during the low Psw periods. We investigated characteristics of the boundary layers between the magnetosheath and the ionosphere. We found that the electron flux shows a gradual decrease in the boundary in the high Psw event. On the one hand, intermittent appearance of both the magnetosheath plasma and the ionosphere plasma in the boundary is during the low Psw event. The signature of the boundary layer resembles with the K-H instability signature seen in LLBL (low-latitude boundary layer) in the Earth's magnetotail [e.g., Hasegawa et al., 2006]. We also report the results of statistical analysis of 46 simultaneous observation events.

Effects of ion-ion collisions on vertical distribution of CO2+ in Martian ionosphere based on multi-fluid MHD simulation

KOYAMA, Kyohei[1*] ; SEKI, Kanako[1] ; TERADA, Naoki[2] ; TERADA, Kaori[2]

[1]Solar-Terrestrial Environment Laboratory, NAGOYA University, [2]Graduate School of Science, Tohoku University

Comparison of the mass fraction of CO2 and N2 with regard to the total mass of each terrestrial planet suggests importance of the atmospheric escape to space in Martian atmospheric evolution [Chassefiere et al., 2006]. It has been considered that heavy CO_2^+ ions are difficult to escape based on known atmospheric escape processes. Observations of a large amount of CO_2^+ ion escape by the Mars Express thus challenged the existing escape processes. Vertical distribution of CO_2^+ density in the ionosphere is one of important factors that determine the rate of CO_2^+ escape. Chemical reactions in ionosphere have been implemented in previous studies using multi-species MHD simulations [e.g., Ma et al., 2004; Terada et al., 2009]. The velocity difference between ion fluid cannot be reproduced by the multi-species MHD approximation. On one hand, the importance of vertical transport in the upper ionosphere (>300km altitude) was pointed out by some ionospheric models [Fox and Hac, 2009]. Multi-fluid MHD code [e.g., Najib et al., 2011] can solve such ion-species dependent velocity.

In this study, we developed a multi-fluid MHD simulation code. Our code includes ion-ion collisions in order to investigate their effects on the vertical distribution of CO_2^+ density in the Martian ionosphere. Three cases of the simulation runs are carried out: Multi-fluid MHD with ion-ion collision (Case1), multi-fluid MHD without ion-ion collision (Case2), and all ion species have the same vertical velocity corresponding to multi-species approximation (Case3). We compared the results after each simulation run reached to a quasi-steady state. The CO_2^+ density at altitude 460 km were turned out to be 82, 190, and 11 cm^{-3}, respectively for the Cases 1-3. The results suggest that inclusion of ion-ion collision is important to reproduce the realistic CO_2^+ transport from lower to upper ionosphere.

Temporal variability of exospheric sodium density

KAMEDA, Shingo[1*] ; FUSEGAWA, Ayaka[1] ; KAGITANI, Masato[2] ; YONEDA, Mizuki[2]

[1]Rikkyo University, [2]Tohoku University

Mercury's atmosphere is very thin and it is also called "surface-bounded exosphere". In the detected species, e.g., H, He, O, Na, Mg, K, and Ca, Na emission (NaD) is the brightest and has been most frequently observed. Solar-photon-stimulated desorption, sputtering by impacting solar particles, and meteoroid vaporization are considered to be the source processes of Mercury's sodium. However, the primary process among these three processes is unclear as yet. The resonance scattering constitutes exospheric emission. The NaD emission is well suited for study by ground-based observations because of its high intensity. Past observations have shown that the temporal variation and north-south asymmetry of intensity of sodium emission.

We have observed Mercury sodium exosphere at the Haleakala Observatory in Hawaii since April 2011. The observations were performed using a 40 cm Schmidt-Cassegrain telescope, a high-dispersion spectrograph, and a CCD camera. We determined the temporal variation of the sodium density using the observational data. It is possible that the temporal variation of the sodium density is caused by variation of solar wind magnetic field if solar wind ion sputtering is the primary source process of Mercury exosphere. To verify this assumption, we checked the temporal variation of solar wind magnetic field observed by MESSENGER, and then we compared these variations with our observational result.

In this presentation, we show our observational results and discuss the dominant source process.

Study of heavy ion dynamics in the Mercury's magnetosphere with offset dipole

YAGI, Manabu[1*] ; SEKI, Kanako[2] ; MATSUMOTO, Yosuke[3] ; DELCOURT, Dominique[4] ; LEBLANC, Francois[4]

[1]Tohoku Univ., [2]Nagoya Univ., [3]Chiba Univ., [4]CNRS

From Mariner 10 and MESSENGER observations, Mercury's magnetosphere is thought to be a miniature of the Earth's magnetosphere. While these two magnetospheres have several characteristics in common, some critical differences are also evident. First, there is no atmospheric layer, but only tenuous exosphere. Second, the kinetic effects of heavy ions might not be negligible because Mercury's magnetosphere is relatively small compared to the large Larmor radii. Trajectory tracings is one of the dominant methods to estimate the kinetic effect of heavy ions which originate the exosphere, though the results of the simulation are quite sensitive to the electric and magnetic field. Hence, it is important to provide a realistic field model in the trajectory tracings. In order to construct a large scale structure, we developed a MHD simulation code, and adopted to the global simulation of Mercury's magnetosphere. We performed four solar wind conditions of the northward IMF, and the results showed that the global configurations such as the location of magnetopause depend heavily on the dynamic pressure, while the solar wind electric field contributes little to the magnetospheric configuration. On the other hand, the results of statistical trajectory tracings of exospheric sodium ions depend not only on the dynamic pressure but also on the solar wind electric field. In the results, we identified two efficient acceleration processes and formation of the 'sodium ring' which is formed by the accelerated ions drifting around the planet by magnetic gradient of the dipole field. When the solar wind dynamic pressure is low, acceleration by magnetospheric convection is efficient in the vicinity of Mercury. When the dynamic pressure is high, entry of the accelerated ions picked-up in the magnetosheath into the magnetosphere becomes dominant. The entry point of sodium ions changes due to the variation of the solar wind electric field, which causes a difference in the sodium ring's shape for the same solar wind dynamic pressure cases. Recent observation by MESSENGER revealed the weaker dipole field of Mercury than the past estimation based on Mariner 10 as well as large offset of dipole which could change the global configuration of Mercury's magnetosphere and behavior of sodium ions. In the presentation, we will also discuss the ongoing simulation including the above configuration of intrinsic magnetic field of Mercury especially focus on how will this affect the acceleration mechanisms.

Structure and time variability of Io plasma torus observed by EXCEED onboard the HISAKI satellite

TSUCHIYA, Fuminori[1*] ; YOSHIKAWA, Ichiro[2] ; YOSHIOKA, Kazuo[3] ; KIMURA, Tomoki[3] ; YAMAZAKI, Atsushi[3] ; MURAKAMI, Go[3] ; KAGITANI, Masato[1] ; TERADA, Naoki[1] ; KASABA, Yasumasa[1] ; SAKANOI, Takeshi[1]

[1]Tohoku University, [2]The University of Tokyo, [3]ISAS/JAXA

Spatial distribution and time variability of emission lines of sulfur ions in Io plasma torus (IPT) measured by EUV spectrograph (EXCEED) onboard the HISAKI satellite are presented. The satellite has been launched on 14 Sep. 2013 and begun regular observation of IPT and Jupiter's UV aurora since middle of Dec. and it will continue until the end of Feb. A wide slit whose designed field of view (FOV) is 400 x 140 arcsec was chosen to measure both radial and latitudinal distributions of IPT. Jupiter's north aurora was guided at the center of FOV and its spectrum was simultaneously observed. Averaged spatial distribution of sulfur emission lines is consistent with previous observations. Looking at the time variability of IPT, new features were found from the EXCEED observation. The most surprising one is periodic variation synchronized with Io's orbital period. The variations in dawn and dusk sides were out-of-phase, suggesting the bright region is co-rotating with Io. The amplitude of the periodic variation is larger than those of well-known Jupiter's rotation periodicities in shorter wavelength and becomes smaller as increasing wavelength. The wavelength dependence suggests significant electron heating and/or hot electron production processes associated with Io. Another noticeable feature is long-term change in dawn-dusk asymmetry of the emission intensity which had not been reported so far. The asymmetry has been assumed to be a proxy of large scale dawn-to-dusk electric field generated in Jovian magnetotail and the origin of the variation observed will be discussed in detail. Sporadic change in the emission intensity of IPT associated with the aurora brightening event is expected to investigate in detail with the EXCEED observation to reveal energy transport process between inner and middle/outer magnetospheres. The expected event has not been detected so far and further continuous observation will be expected to resolve this issue.

Major ions in Io plasma torus have many allowed transition lines in the EUV and their radiation easily escapes to become observable from outside the region. In other words, Jovian inner magnetosphere is able to be monitored by the EUV spectral observation remotely. Moreover, with the atomic database which provides the cross sections to the ambient electron, transition probabilities, and these temperature dependence, EUV observations can be a very important diagnostic of ion densities, electron density, and its temperature.

The EUV spectroscope EXCEED on the Hisaki spacecraft has started to observe the Jovian magnetosphere from the Earth orbit since the end of 2013. The spacecraft is dedicated for the solar system planets so that all the observation window is spared for planetary science. The spectral range is from 52 to 148 nm and its resolution is 0.3 nm with one of the narrowest slit. The field of view is 400 arc-seconds which corresponds to around 18 RJ. Therefore, it can observe whole region of Io plasma torus at one time. Moreover, it can achieve better spatial resolution than 1 RJ. It is the first time to get a whole spectral images of Io plasma torus in the EUV with such a high performance instrument. In this presentation, we will show the first results of EXCEED observation with its high spectral resolution slit for Io plasma torus.

Dust-plasma interaction in Saturn's inner magnetosphere and its magnetosphere-ionosphere coupling

SAKAI, Shotaro[1*] ; WATANABE, Shigeto[1]

[1]Dep. Cosmosciences, Hokkaido University

We investigated the magnetosphere-ionosphere coupling with a dust-plasma interaction in Saturn's inner magnetosphere by using a modeling of ionosphere and inner magnetosphere. From our previous model, it was revealed that the magnetospheric ion velocity was significantly reduced by the electric fields generated by the ion-dust collisions when the dust density is high and the thickness of dust distribution is large. It was consistent with observations when the dust density is larger than ~10^5 m^{-3} for ionospheric conductivity of 1 S. An average electron density of Saturn's ionosphere obtained from radio occultations by Cassini spacecraft was ~10^{10} m^{-3} at 2000 km where density had a peak and gradually decreased with the increasing altitude. The density was ~10^8 m^{-3} at 10000 km. Plasma densities calculated by models also were similar to the observations and the topside temperature is ~650 K. However, electron densities from those models were calculated at the altitudes below 4000 km.

We estimated the ionospheric Pedersen conductivity from the plasma densities, and the plasma temperatures and velocities by using a magnetohydrodynamics model. We used the magnetospheric plasma temperature, which was 2 eV, as a boundary condition to investigate the magnetospheric influences. The plasma density was about 10^9 m^{-3} at the altitude of 1200 km, and it decreased to about 10^7 m^{-3} at the altitude of 10000 km. Below 10000 km altitudes the light ion has the upward velocity, while heavy ions have zero or downward velocity at low altitudes. This might be due to the difference of mass. The electron temperature increased to 20000 K at the altitude of 10000 km due to the heat flow from the inner magnetosphere. The electron temperature was about 2000 K at the altitude of 1000 km, and the collision and joule heating were contributing to the temperature below 2000 km. The peak density changed between about 10^8 and 10^{10} m^{-3} during one Saturn's day, and the electron density decreased with increasing the altitude. On the other hand, the electron temperature didn't depend on the local time. The Pedersen conductivity was the maximum 0.77 S on day time and the minimum 0.30 S on dawn time. The Pedersen conductivity strongly depends on the ionospheric plasma density.

We estimated the magnetospheric ion velocity by using the calculated conductivity. The Pedersen conductivity was the largest value at L = 3 and it decreased with the increase of the distance from Saturn. The conductivity changed in local time. The maximum was on the day time and the minimum was on the dawn time. The calculated ion velocity decreases from the co-rotation speed outside 3.5 R_S. The ion velocity was 60-80% of the co-rotation speed in the inner magnetosphere. The ion velocity was smaller than the co-rotation speed since the magnetospheric electric field is smaller than the co-rotational electric field when the current due to the ion-dust collision flows in the inner magnetosphere. The ion velocity strongly depended on the local time since the conductivity also depended on the local time. It is suggested that the dispersion of the observed speeds could show the dependence of local time. The ion velocity is fast during the solar irradiation since the Pedersen conductivity is large, while it becomes slow after the sunset because of the small conductivity.

The magnetosphere-ionosphere coupling is significantly important for the dust-plasma interaction. It is impossible to understand the dust-plasma interaction in Saturn's inner magnetosphere without understanding of the Saturn's ionosphere, since the magnetosphere and ionosphere is intimately-connected.

Relation between Kronian magnetospheric convection and auroral emission from MHD simulation with solar wind data observe

FUKAZAWA, Keiichiro[1*] ; WALKER, Raymond J.[2] ; ERIKSSON, Stefan[3]

[1]Research Institute for Information Technology, Kyushu University, [2]UCLA, IGPP, [3]Laboratory for Atmospheric and Space Physics, University of Colorado at Boulder

In a series of our simulation studies we have reported that vortices formed at Saturn's dawn magnetopause in simulations when IMF was northward. We interpreted these vortices as resulting from the Kelvin Helmholtz (K-H) instability. In addition, thanks to the recent developments of computer performance, we have been able to perform the high resolution global MHD simulations of the Kronian magnetosphere. In these simulations we obtained the signature of the field-aligned currents from the K-H vortices in Saturn's auroral ionosphere and found small patchy regions of upward field-aligned current which may be related to auroral emissions. These patchy aurorae resembling our results have been reported from Cassini observations.

In our previous simulations we used the constant and simple solar wind conditions to understand the basic behavior of Kronian magnetosphere. In this study we have used Cassini observations of the solar wind upstream of Saturn to drive a simulation. Using these solar wind data we simulated the Kronian magnetosphere from 2008-02-12/14:00:31 to 2008-02-13/01:59:31 when the Hubble Space Telescope (HST) observed the Kronian UV auroral emissions. In these solar wind conditions there are several enhancement of the solar wind dynamic pressure (shock) and polarity reversal in the IMF components.

From these simulation the shape and convection of Kronian magnetosphere dynamically changed according to the variation of dynamic pressure and IMF directions. As the results, layered convection formed between the corotation region and magnetopause. Furthermore these convection interacted each other, then the large vortex configurations appeared. The calculated configuration of field aligned currents from the simulation also showed the layered and patchy distributions. In addition the upward field aligned current appeared in the dawn side mainly which resembles the configuration of auroral emission by HST.

Study of dynamics of the Jovian magnetosphere-II: energy transportation process to the inner magnetosphere

MIZUGUCHI, Takahiro[1*] ; MISAWA, Hiroaki[1] ; TSUCHIYA, Fuminori[1] ; OBARA, Takahiro[1] ; KASAHARA, Satoshi[2]

[1]Planetary Plasma and Atmospheric Research Center, Graduate School of Science, Tohoku University, [2]Institute of Space and Astronautical Science/ Japan Aerospace Exploration Agency

We have researched response of the Jovian inner magnetosphere to the substorm-like event which occurred in the night side of the middle/outer magnetosphere. The transport of magnetic flux tube is one of important issues in the global dynamics of the Jovian magnetosphere [Kivelson et al., 2005]. The magnetic flux tubes are carried outward from the Io plasma torus with the slowly outflowing plasma. As they move outward, alternative flux tubes should be returned to the torus through rapid inflow of lower-dense flux tubes. Goal of this study is to reveal the role of the substorm-like event in the transport of magnetic flux tube in the Jovian magnetosphere.

In this study, substorm-like events were identified by using the in-situ observation data obtained by the Plasma Wave Subsystems (PWS), Energetic Particle Detector (EPD) and Magnetometer (MAG) onboard the Galileo orbiter. X-lines where the substorm-like events are thought to start were located at around 60-80 RJ [Woch et al., 2002]. Narrowband KilOMetric radiation (nKOM) which was remotely observed by PWS was used to find response of the inner magnetosphere to the substorm-like event. The source of nKOM is suggested to be located at the outer edge of the Io torus (8-10 RJ) (Reiner et al., 1993).

In the preceding studies, Louarn et al. (2001) reported nKOM correlated with inward flow burst during Jovian substorm-like event reported by Woch et al.(1998) and Krupp et al.(1998). The report implies that the generation mechanism of nKOM relate with the return of magnetic flux tube to inner magnetosphere. However, it has not been revealed well yet how inner and outer magnetospheres couple each other during substorm-like event.

On the other hand, Dubyagin et al.(2011) reported about deeply penetrating flow burst at the terrestrial magnetosphere. They reported that an inward flow burst penetrated into the inner magnetosphere when its entropy was less than that of the inner magnetosphere, while flow burst did not penetrated when its entropy was larger than that of the inner magnetosphere.

We have analyzed Jupiter's several inward flow events which are expected to relate with tail reconnection and nKOM radiation by using the data obtained by Galileo. We also have applied Dubyagin's entropy analysis method to Jupiter's cases in order to reveal that how reconnection event at the outer magnetosphere couple with the inner magnetosphere.

In this presentation, we will show preliminary results on relations of Jovian substorm-like event and phenomena of inner magnetosphere.

Jupiter's decametric Io-C modulation lanes observed by LWA1 (2)

IMAI, Kazumasa[1*] ; SHIMANOUCHI, Yoshiaki[1] ; CLARKE, Tracy[2] ; HIGGINS, Charles A.[3] ; IMAI, Masafumi[4]

[1]Kochi National College of Technology, [2]Naval Research Laboratory, [3]Middle Tennessee State University, [4]Kyoto University

The Long Wavelength Array (LWA) is a low-frequency radio telescope designed to produce high-sensitivity, high-resolution images in the frequency range of 10-88 MHz. The Long Wavelength Array Station 1 (LWA1) is the first LWA station completed in April 2011, and is located near the VLA site in New Mexico, USA. LWA1 consists of a 256 element array, operating as a single-station telescope. Each LWA1 beam provides dual orthogonal linear polarizations such that it is possible to reconstruct the full Stokes parameters for each tuning. The first Jupiter radio observation using LWA1 was made by Tracy Clarke (PI) from December, 2011. The initial analyses of Io-A/C, Io-B, and Io-D event, show many spectral features such as S-bursts, narrow-band events (N-bursts), as well as modulation lanes and Faraday lanes.

The modulation lanes in Jupiter's decametric radiation, which were discovered by Riihimaa [1968], are groups of sloping parallel strips of alternately increased and decreased intensity in the dynamic spectral plots. We present LWA1 observations of modulations lanes detected across a Jovian decametric Io-C burst that contains both right hand circular and left hand circular emission. The modulation lanes cross both handedness of polarization, suggesting that the emissions may be coming from the same hemisphere. These results add important information regarding the emission mechanism of Jupiter's decametric emissions.

Observations of Polarization of Auroral Kilometric Radiation by KAGUYA and its Lunar Occultations

HASHIMOTO, Kozo[1*] ; GOTO, Yoshitaka[2] ; UDA, Kazuaki[2] ; KASAHARA, Yoshiya[2] ; ONO, Takayuki[3]

[1]Professor Emeritus, Kyoto University, [2]Kanazawa University, [3]Tohoku University

In KAGUYA (SELENE) LRS[1], WFC-H[2] observes wave spectra in 1kHz-1,000kHz and various plasma waves like Auroral Kilometric Radiation (AKR), electron plasma waves, and broadband electrostatic waves have been observed. This system can observe wave polarizations by two pairs of dipole antennas. We have analyzed the AKR polarizations.

Kaguya moves behind the Moon every rotation. The occultations of AKR radiated from the Earth occur. Such occultation observation by the 32 channel burst receiver of lunar orbiter RAE2 was reported in [3,4]. The polarizations were not measured then. The polarization of AKR is defined with respect to the magnetic field from a view point of plasma waves. On the other hand, the polarization is observed with respect to the propagation direction. Both polarizations depend on the source hemisphere. When only one hemisphere can be seen due to the occultation, the source hemisphere is identified and the polarization can be measured correctly. This result is also useful when both hemispheres are seen after the occultation. We show the results and their interpretations.

Study of the Venus' upper haze

TAKAGI, Seiko[1*] ; ARNAUD, Mahieux[2] ; VALERIE, Wilquet[2] ; ANNCARINE, Vandaele[2] ; IWAGAMI, Naomoto[1]

[1]Graduate School of Science,the Univ. of Tokyo, [2]Belgian Institute for Space Aeronomy

Venus is completely shrouded by a thick cloud deck floating at 45 – 70 km. The major material of the cloud deck is thought to be H_2SO_4 – H_2O droplets. The upper haze on Venus lies above the cloud layer surrounding the planet, ranging from the top of the cloud ($\sim$70 km) up to as high as 90 km. The upper haze particles with an effective radius of $\sim$0.25 μm was suggested from Pioneer Venus Orbiter (PV) measurements. The particles were most likely composed of sulfuric acid in terms of refractive index $\sim$1.45. The haze vertical optical thickness in the polar region at 365 nm was found to be 0.8 above the main cloud of 1 μm particles by PV measurements. By comparison, the optical thickness of the haze above the main cloud at low latitudes was found to be 0.06 [Kawabata et al., 1980]. Knibbe et al. (1998) and Braak et al. (2002) observed a gradual decrease of the haze particle column density during the PV mission. Braak et al. (2002) reported a correlation between the decrease of SO_2 abundance [Esposito et al., 1988; Na et al., 1990] and that of the polar haze optical thickness. However, it is unclear how haze are produced and composition of haze.

The upper layer detected (above the clouds) is characterized by a SO_2 mixing ratio increase with altitude from 85 to 105 km [Belyaev et al., 2012]. It shows a new source of SO_2 at high altitude. One possible source of SO_2 in the upper haze layer could be photo-dissociation of H_2SO_4 vapor resulting from evaporation of acid aerosol droplets. However, recent upper limit of H_2SO_4 from sub-mm ground-based observation makes this theory less likely [Sandor et al., 2012]. The cause of the phenomena given above is still controversial.

The Solar Occultation at InfraRed (SOIR) on board Venus Express (ESA) is designed to measure the atmospheric transmission at high altitudes (70 – 220 km) in the IR (2.2 – 4.3 μm) with high resolution by solar occultation. The SOIR data obtained in 2006 – 2009 are analyzed to examine the upper haze at altitude above 90 km. Vertical and latitudinal distribution of haze extinction, optical thickness and mixing ratio are calculated in using SOIR data statistically. Extinctions and optical thickness at low latitude are two times thicker than those of high latitude. One of the notable results is that mixing ratios increase at altitude above 90 km at both high and low latitudes. It is speculated that sources of haze are transported upward from under altitude 90 km and haze is produced at high altitude. From comparison with the vertical distributions of SO and SO_2 mixing ratios reported by Belyaev et al. (2012), it is speculated about the correlation between sulfuric compound and haze.

Observation of CO2-ice cloud in the Martian mesosphere by using PFS onboard Mars Express

SATO, Yuki[1*] ; KASABA, Yasumasa[1] ; MARCO, Giuranna[2] ; AOKI, Shohei[1] ; NAKAGAWA, Hiromu[1] ; KURODA, Takeshi[3]

[1]Planetary Atmosphere , TOHOKU University, [2]IAPS,INAF,Italy, [3]Planetary Plasma and Atmospheric Research Center , TOHOKU University

Almost all of constituent of martian atmosphere is CO2 (95%). It condenses at very high altitude (60˜100km) and become cloud. CO2-ice cloud have been observed by many instrument , but it was difficult to clearly judge whether observed cloud is made of CO2 or not. However OMEGA, visible and near-infrared imaging spectrometer onboard Mars Express, have provided the first spectroscopic identification of a cloud as being composed of CO2 (Montmessin et al, 2007) CO2-ice cloud has characteristic spectral feature emission peak at 4.26μm. Recent study reported that CO2-ice cloud distributes around equator in spring equinox to early summer and mid latitude in local autumn. (Maattanen et al,2010 , Montmessin et al,2007 2006, Clancy et al 2007) However, it is not clear about cloud feature (particle size or opacity).

We try to observe CO2-ice cloud using high spectral resolution instrument PFS, infrared fourier spectrometer onboard Mars Express. Strong point of PFS is that spectral resolution is ten times greater than that of OMEGA and We can see spectral feature of CO2-ice cloud (spike at 4.26μm) more clearly. Another point is that PFS and OMEGA observe almost the same point , so two instruments can observe CO2-ice cloud at the same time. For the first step, we check the data where OMEGA observed CO2-ice cloud (10 orbits) and found CO2-ice cloud like feature all of the 10 orbits. However emission peak appears at shorter wavelength (at 4.25 μm) . In order to judge whether this signal is real or not, we compared PFS spectra and OMEGA spectra observed at the same point. When PFS observe signal at 4.25μm , OMEGA also show strong signal at 4.26μm ,so we can say PFS signal is real. In some orbit, PFS observed different signal from that of OMEGA. It is double spike feature at 4.25μm and 4.28μm which OMEGA can not resolve. It is possible that double peak feature shows different cloud feature, for example, particle size.Now we are trying radiative transfer model and discuss how cloud spectral feature changes when we changes cloud parameter (size distribution, altitude, cloud opacity).

Numerical Modeling of Moist Convection in Giant planets

SUGIYAMA, Ko-ichiro[1*] ; NAKAJIMA, Kensuke[3] ; ODAKA, Masatsugu[2] ; KURAMOTO, Kiyoshi[2] ; HAYASHI, Yoshi-yuki[4]

[1]ISAS/JAXA, [2]Graduate school of Science, Kobe University, [3]Department of Cosmosciences, Graduate School of Science, Hokkaido University, [4]Graduate school of Science, Kobe University

It is now widely accepted that moist convection is a common phenomenon in giant planets atmosphere. The moist convection is thought to play an important role in determining the mean vertical structure of the atmosphere; the mean vertical profiles of temperature, condensed components, and condensible gases in the moist convection layer is thought to be maintained by the statistical contribution of a large number of clouds driven by internal and radiative heating/cooling over multiple cloud life cycles. However, the averaged structure of the giant planets atmosphere and its relationship to moist convection remain unclear. For the purpose of investigating the above problem, we developed a cloud resolving model and investigated a possible structure of moist convection layer in Jupiter ′ s atmosphere with using the model (Sugiyama et al., 2009, 2011, 2014). In this presentation, we perform two-dimensional calculations of moist convection and demonstrate a possible structure in the atmospheres of Saturn, Uranus, and Neptune.

The basic equation of the model is based on quasi-compressible system (Klemp and Wilhelmson, 1978). The cloud microphysics is implemented by using the terrestrial warm rain bulk parameterization that is used in Nakajima et al. (2000). We simplify the radiative process, instead of calculating it by the use of a radiative transfer model. The model atmosphere is subject to an externally given body cooling that is a substitute for radiative cooling. Because the vertical profile of net radiative heating is not observed in giant planets except Jupiter, the layer between 2 bar level and the tropopause, which corresponds to the observed cooling layer in Jupiter, is cooled. The body cooling rate is set to be 100 times larger than that observed in Jupiter ′ s atmosphere in order to save the CPU time required to achieve statistically steady states of the model atmosphere.

The domain extends 960 km in the horizontal direction. The vertical domains are 400 km for Saturn case and 600 km for Uranus case and Neptune case, which are based on the one-dimensional thermodynamical calculation (Sugiyama et al., 2006). The spatial resolution is 2 km in both the horizontal and the vertical directions. The temperature and pressure at the lower boundary is also based on the thermodynamical calculation. The initial temperature profile follows adiabatic from lower boundary to tropopause and is constant above the tropopause. The abundances of condensable gases used in the each calculation are taken at 0.1, 1, 3, and 10 times solar.

The results obtained in Saturn case with 1 times solar abundance of condensible gases are discussed below; the results of other planets and the dependency on the abundances of condensable gases will be demonstrated at the meeting. The major characteristic of vertical motion in the moist convection layer obtained in Saturn case is that downdrafts are stronger than updrafts; this characteristic is obviously different from that obtained in Jupiter case (Sugiyama et al., 2009). Sugiyama et al. (2009) demonstrates that the vertical motion in the moist convection layer of Jupiter is characterized by narrow, strong, cloudy updrafts and wide, weak, dry downdrafts. On the other hand, the characteristics of mean vertical structure are consistent with those obtained in Jupiter case. Due to the active transport associated with convection, considerable amounts of H_2O and NH_4SH cloud particles exist above the NH_3 condensation level, while the mixing ratios of all condensible gases decrease with height from the H_2O condensation level. The stable layer associated with the H_2O condensation level acts as a fairly strong barrier for vertical convective motion; the vertical profile of root mean square of vertical velocity has local minimum at this level.

Two dimensional numerical study on Venusian gravity waves by using mesoscale model

ANDO, Hiroki[1*] ; SUGIYAMA, Ko-ichiro[1] ; IMAMURA, Takeshi[1] ; ODAKA, Masatsugu[2] ; NAKAJIMA, Kensuke[3]

[1]ISAS/JAXA, [2]Hokkaido University, [3]Kyusyu University

Recently Venusian gravity waves are often observed. For example, Airglow measurements of O_2 found the gravity waves with horizontal wavelength of ∼100 km at 110 km altitude. UV images also detect gravity waves with the horizontal wavelength of 60-150 km at the cloud top level (70 km altitude). However, only a specific altitudes can be observed in these measurements, thus it is difficult to examine the propagation characteristics and momentum flux of waves. Radio occultation measurements also detect upward propagating waves from the vertical temperature profiles within the altitude range of 65-90 km and suggests that waves with the vertical wavelength of 5-10 km are dominant by the spectral analysis. However, horizontal resolution in this measurement is ∼200 km, then small scale gravity waves cannot be observed. Therefore, it is difficult to understand how these gravity waves have their influence on the Venusian atmosphere.

In this study we developed a new Venusian mesoscale model and examined the propagation characteristic of the waves. In the model, we simulated the generation and propagation of the waves including the convective motion in the Venusian cloud layer. We will make a presentation about the initial analysis results.

Temporal variations of Venus O2 night airglow using IRTF/CSHELL

OHTSUKI, Shoko[1*] ; IWAGAMI, Naomoto[2] ; ROBERT, Severine[3] ; SAGAWA, Hideo[4] ; KOUYAMA, Toru[5] ; SATO, Takao M.[6]

[1]Senshu University, [2]University of Tokyo, [3]Belgian Institute for Space Aeronomy, [4]National Institute of Information and Communications Technology, [5]Information Technology Research Institute, [6]Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency

Venus 1.27-micron O_2 night airglow is the indicator of the general circulation at about 95 km in Venus. Recent observations reported that the airglow emission showed the temporal variations with a period of a few hours and days [e.g. Ohtsuki et al., 2008; Gerard et al., 2008]. Such variations may be caused by the upward momentum transport and fluctuations by atmospheric waves. In recent years, the importance of planetary-scale waves on the general circulation of the Venus atmosphere has been recognized. Forbes and Konopliv [2007] suggested the propagation of planetary-scale waves originated in the cloud deck into the upper atmosphere. However, effects of planetary-scale waves on the Venus upper atmosphere have not been investigated yet.

We conducted 5-days monitoring observation of the airglow to detect the planetary-scale waves with IRTF/CSHELL from 11-15 July 2012, 3 and 5 February 2014. The 1.27-micron O_2 night airglow in the Venus atmosphere can pass through the Earth's atmosphere with a help of the Doppler shift. We obtained spectral image cubes at the wavelength of R-branch of the airglow band, which includes several rotational lines. In order to cover spectral information continuously, a slit drifted across Venus' nightside disk. The spatial resolution of the image is governed by seeing. The typical seeing was 0.6" to 1.5" in our observing run and corresponds to 200-450km at the center of Venus' disk. Under such conduction, we may detect airglow structures of small scales due to atmospheric waves; this is smaller than the region of enhanced airglow having a horizontal scale of ˜3000km. We can also derive the hemispherical distribution of the rotational temperature. To coincide with our observations, SOIR/Venus Express stellar occultations were conducted. We can try to compare our horizontal temperature map and vertical temperature profile from SOIR data.

In this presentation, we will show temporal variation of the airglow distributions in July 2012 and report a preliminary result of our new observations in February 2014.

Observing plan for planetary atmosphere using IR heterodyne spectroscopy in 2014

NAKAGAWA, Hiromu[1*] ; AOKI, Shohei[1] ; KASABA, Yasumasa[1] ; MURATA, Isao[1] ; SAGAWA, Hideo[2]

[1]Tohoku University, [2]National Institute of Information and Communications Technology

We propose a new developed infrared heterodyne instrument, called Mid-Infrared LAser Heterodyne Instrument (MILAHI), for our dedicated telescope at the top of Mt. Haleakala, Hawaii. It addresses the key physical/meteorological parameters, such as the atmospheric temperature profiles, abundance profiles of the atmospheric compositions and their isotopes, and wind velocity. The observational sensitivity of MILAHI is discussed in this paper. The scientific target of MILAHI is to understand highly variable phenomena in the planetary atmospheres. The nature of atmospheric activity in various time-scale will be investigated by continuous monitoring with our dedicated telescope, in order to increase our understanding of planetary atmospheric dynamics, photochemistry, and meteorology. New measurements with high spatial/spectral resolutions constrain the three-dimensional distributions of temperature and compositions. The D/H and other isotopic ratios, diagnostic of the terrestrial atmosphere evolution, will be accurately measured in H_2O and CO_2. The atmospheric chemistry will be studied by monitoring O_3, H_2O_2, H_2O, and HDO. Mapping of the H_2O isotopes reveal the mechanism of complex interaction between regolith-aerosols-atmosphere-polar caps on Mars. Direct measurements of wind velocity and temperature allow the first monitoring of the middle atmosphere oscillations to investigate the effects of the gravity waves from the lower atmosphere on the upper atmosphere for various seasons and dust loadings. A number of organics molecule bands in the mid-infrared regime will be accurately measured in planetary/cometary/stellar atmospheres. In addition to these interconnected objectives, serendipitous searches with our advantage of dedicated use for astronomical/atmospheric transient events which occur at frequent and unpredictable intervals (e.g. dust storm) will enhance our knowledge of the composition and dynamics of the astronomical sources.

Visual Orbit Design for the Next Mars Exploration Mission

OGURA, Satoshi[1] ; KAWAKATSU, Yasuhiro[1] ; MATSUOKA, Ayako[1] ; TAGUCHI, Makoto[2*]

[1]ISAS/JAXA, [2]Rikkyo University

In December, 2011, the working group concerned with the Japanese next Mars exploration mission began to study the use of orbiters to investigate the mechanisms of carbon dioxide and water escape from the Martian atmosphere, and the role played by the solar wind. This will be the successor to the first Japanese mission to Mars involving the NOZOMI spacecraft, and two different orbiters will be deployed around the planet. Orbiter-A will carry out in-situ observations of electric and magnetic fields, particles, plasma and the atmosphere at an altitude of about 100 km above the Martian surface. Orbiter-B will capture images of the escaping atmosphere and monitor solar-wind conditions. The mission life will be a Mars year. This paper describes a visual method for determining the orbits of both spacecraft, and presents examples of possible orbits.

The orbital constraints proposed by the working group are as follows.

Orbital constraints for Orbiter-A

A1. The periapsis altitude is around 150 km.

A2. The apoapsis altitude is between 5000 and 7000 km.

A3. The period during which periapsis occurs on the dayside of the planet is more than two thirds of the mission life.

Orbital constraints for Orbiter-B

B1. The apoapsis altitude is about 4-6 R_M.

B2. The period during which the orbiter is exposed to the solar wind is more than three quarters of the mission life.

B3. The period during which the orbiter can image the local time zone of 12-15 h at the planetary limb is more than three quarters of the mission life.

Orbital constraints for combined observations by both orbiters

C1. The number of times during which Orbiter-B is exposed to the solar wind and can also image Orbiter-A, whose solar zenith angle and altitude are less than 60 deg and about 300-800 km, respectively, is more than one hundred during the mission life.

C2. When C1 is satisfied, the angle between the line-of-sight of the imager onboard Orbiter-B and the velocity vector of Orbiter-A is within 90 ± 20 deg.

The orbital elements are obtained by solving the Lagrange planetary equations for a two-body boundary-value problem, taking only the J2 perturbation into account. Constraint A3 is chosen as an example for explaining the visual method of orbital design. The orbiter's longitude of ascending node and argument of periapsis in a Mars-Sun fixed coordinate system are taken as design variables, and the orbital constraint is used as an evaluation function. A contour map for a period in which periapsis occurs on the dayside is plotted in a coordinate system in which the longitude of ascending node and argument of periapsis are the X and Y axes, respectively. A mission profile is placed on the map, along which the changes in the longitude of ascending node and argument of periapsis during the mission period are plotted. The mission profile can be placed at anywhere on the map, since its shape can be kept almost constant by selecting an initial position determined by the position and direction of the spacecraft during Mars orbit insertion. By looking at the map, it then becomes easy to identify an appropriate initial point for the mission profile that maximizes the period during which periapsis occurs on the dayside.

By the method described above, it is possible to visually determine rough values for the longitude of ascending node and argument of periapsis that are suitable for the mission. This technique is also applicable to the general design of orbits around a planet by choosing a coordinate system appropriate for the given orbital constraints.

A Circumpolar Stratospheric Telescope for Observations of Planets ? FUJIN

MAEDA, Atsunori[1*] ; TAGUTI, Makoto[1] ; YOSIDA, Kazuya[2] ; SAKAMOTO, Yuji[2] ; NAKANO, Toshihiko[2] ; SHOJI, Yasuhiro[3] ; TAKAHASHI, Yukihiro[4] ; NAKAMOTO, Jumpei[4] ; IMAI, Masataka[4] ; WATANABE, Makoto[4] ; GODA, Yuki[5]

[1]College of Science, Rikkyo University, [2]Graduate School of engineering, Tohoku University, [3]JAXA/ISAS, [4]Graduate School of Science, Hokkaido University, [5]School of Science, Hokkaido University

It is important to conduct long-term continuous observations of time-dependent events in planetary atmospheres and plasmaspheres. The aim of the FUJIN project is to carry out continuous observations of planets using a telescope that is lifted by a balloon to the polar stratosphere. The FUJIN-1 experiment was organized at Taiki Aerospace Research Field in Taiki-cho, Hokkaido, Japan, from May to June 2013, but the experiment was canceled due to a failure found in the balloon operation system provided by JAXA. However, the results of various prelaunch ground tests clearly established the feasibility of the experiment.

We have recently begun organizing the FUJIN-2 experiment, in which scientific observations of planets will be conducted in the Arctic. Wind speed in the stratosphere is very low during April and May. The FUJIN-2 experiment will be conducted during this period in 2015 at ESRANGE in Kiruna, Sweden, since this is when Venus will be in the most favorable position for observations. The gondola will be recovered somewhere in the Scandinavian peninsula after one or two days of continuous observations.

In summer, an eastern circumpolar wind is dominant in the stratosphere. If a balloon is flown under these conditions, it will take a week to fly from Kiruna to Alaska and more than two weeks for it to fly back to Scandinavia along a constant-latitude path around the Earth. We are currently organizing another experiment (FUJIN-3) involving such a circumpolar flight that will be conducted in 2017 or later. The system used in FUJIN-2 will also be used for FUJIN-3, but with the inclusion of a high-sensitivity CCD camera and a liquid-crystal tunable filter. Venus, Jupiter, and Mercury will be the planets of interest for FUJIN-3. Moreover, a next-generation stratospheric telescope with a meter-class aperture, a mobile gondola to approach the center of the polar vortex, and a super-pressure balloon for year-round observations are being studied to upgrade the FUJIN system for future use.

Study of fast resistive magnetic reconnection in the upper atmosphere of Venus

SAKAMOTO, Hitoshi[1*] ; TERADA, Naoki[1]

[1]Graduate School of Science, Tohoku University

Although Venus has no intrinsic magnetic field, magnetic field exists in the upper atmosphere through the interaction of the solar wind. In the dayside ionosphere of Venus, small magnetic rope-like structures called 'flux ropes'were often observed when solar wind dynamic pressure was low. Pioneer Venus Orbiter (PVO) observed flux ropes on more than 40% of the orbits passing through the dayside lower ionosphere, and founds its occurrence rate maximizes at altitude170km [Elphic et al., 1983].

So far some models to generate flux ropes have been proposed (K-H instability [Wolff et al., 1980], nonlinearity associated with the Hall effect [Kleeorin et al., 1994]), but the generation mechanism is not yet understood. In this study, we propose a new model to generate flux ropes based on recently proposed fast resistive magnetic reconnection [Loureiro et al., 2007]. This fast resistive reconnection occurs in a very long Sweet-Parker (SP) current sheet. The growth rate in the linear stage is proportional to the one-quarter power of the Lundquist number, and the current sheet is unstable under the condition that the Lundquist number is more than 10 to the power of 4. According to MHD simulation results [Samtaney et al., 2009], a chain of plasmoids is formed after reconnection at many points in the current sheet. Such a chain structure is similar to flux ropes. In the dayside ionosphere of Venus, a very long current sheet can form, where the fast resistive magnetic reconnection occur. Therefore, we considered a model to generate flux ropes through the formation of a very long current sheet and subsequent fast resistive reconnection in the dayside ionosphere of Venus, and then examined its applicability. The outline of the generation model we propose in this study is as follows: First, the interplanetary magnetic field (IMF) carried by the solar wind penetrates into the dayside lower ionosphere when solar wind dynamic pressure is high. Then, the field reversal structure resulting from an IMF turning penetrates there, and a very long SP current sheet is created. Finally, flux ropes are generated through the fast resistive reconnection in the current sheet.

In order to examine the applicability of our model, we estimated the altitude profiles of the Lundquist number, the growth rate of the fast resistive reconnection, and the SP current sheets thickness by using the result of a hybrid simulation in the upper atmosphere of Venus [Terada et al., 2002]. From the profiles, we chose the altitudes corresponding to specific Lundquist numbers, and we consider that the fast resistive reconnection can occur if the following conditions are satisfied at the chosen altitudes. First one is that the fast resistive reconnection can grow sufficiently. Second one is that the SP current sheet thickness is larger than the observed flux rope radius [Elphic et al., 1983]. Consequently, we found that our model is applicable between near 170 km altitude (Lundquist number is 10 to the power of 5 at this altitude) and near 230 km altitude (Lundquist number is 10 to the power of 6 at this altitude). We will show the result of MHD simulation performed with the parameters at these applicable altitudes.

Estimation of the ion acceleration in the Ganymede polar magnetosphere by the Galileo spacecraft observation

WATANABE, Shinya[1*] ; KATOH, Yuto[1] ; KUMAMOTO, Atsushi[1] ; ONO, Takayuki[1] ; KURTH, William S.[2] ; HOSPODARSKY, George[2]

[1]Department of Geophysics, Graduate School of Science, Tohoku University, [2]Department of Physics and Astronomy, University of Iowa Iowa City, Iowa, USA.

Ganymede is one of the Jovian moons and is known as the only satellite that has an intrinsic magnetic field [Gurnett et al., 1996]. Since Ganymede is located in the Jovian magnetosphere, corotating magnetospheric plasma always blows toward Ganymede's magnetosphere [e.g. Kivelson et al., 1998]. Since the spatial scale of Ganymede's magnetosphere is comparable to the Larmor radius of magnetospheric ions, the characteristic plasma environment around Ganymede is formed due to the interaction between Ganymede's magnetosphere and Jovian magnetospheric plasma. Although previous studies discussed the morphology of Ganymede's magnetosphere and its plasma environment, most of them are still unknown and understanding of the interaction is necessary to reveal processes occurring in Ganymede's magnetosphere.

In the present study, we discuss the plasma environment observed in Ganymede's polar region by the Galileo spacecraft. First, we have identified Upper-Hybrid Resonance (UHR) frequency by the Plasma Wave Subsystem (PWS) and have analyzed the electron density at the point of observation. We have analyzed four Ganymede encounters including those on orbits G01 and G02 which have been analyzed in the previous study. Since the most dominant ion in Ganymede's magnetosphere is O+ [Vasyliunas and Eviatar, 2000], we assumed that the O+ density equals the electron density. Based on the results of this analysis, we have plotted the distribution of O+ density in the altitude range from 264 km to 5262 km and have revealed that the number density decreases rapidly with distance from Ganymede. Next, we have discussed the ion outflow from Ganymede's polar region. Based on the obtained distribution, we have found that the density distribution can be expressed by r^-5.98, where r is the distance from Ganymede. Assuming that the flux is conserved along the path of the ion outflow and that the cross section of the flux tube of outflow is proportional to r^2 and r^3, we have estimated that the ion velocity reaches 17.3 km/s and 14.5 km/s, respectively, at the distance of 500 km from Ganymede. This result is consistent with the previous study which suggested the outflow O+ velocity is 18 km/s from observations of the Galileo PLS instrument [Vasyliunas and Eviatar, 2000]. We also discuss candidate mechanisms for the ion outflow from Ganymede's polar region and report the current status of a simulation code which we are developing so as to discuss the outflow process quantitatively.

The extreme ultraviolet (EUV) telescope EXCEED (Extreme Ultraviolet Spectroscope for Exospheric Dynamics) onboard the Japan's small satellite HISAKI (SPRINT-A) will be launched in August 2013. The EXCEED instrument will observe tenuous gases and plasmas around the planets in the solar system (e.g., Mercury, Venus, Mars, Jupiter, and Saturn). One of the primary observation targets is Jupiter, whose magnetospheric plasma dynamics is dominated by planetary rotation. In the EUV range, a number of emission lines originate from plasmas distributed in Jupiter's inner magnetosphere. The EXCEED instrument is designed to have a wavelength range of 52-148 nm with a spectral resolution of 0.3-1.0 nm. The spectrograph slits have a field of view of 400 x 140 arc-seconds (maximum), and the attitude fluctuations are stabilized within 5 arc-seconds. The optics of the instrument consists of a primary mirror with a diameter of 20cm, a laminar type grating, and an EUV detector using microchannel plates (MCPs). The surfaces of the primary mirror and the grating are coated with CVD-SiC.

After the launch of the HISAKI satellite and the initial check out of the instrument for 2 months, we performed in-orbit calibrations of the EXCEED instrument by stellar observations. We observed the standard stars GD71, HZ2, and FEIGE110, and measured the absolute sensitivity and the spatial resolution of the EXCEED instrument. As a result, the absolute sensitivity was ˜1-2 cm^2 and the spatial resolution was ˜16 arc-seconds. In this presentation, we report the overview and initial results of the in-orbit calibration of EXCEED.

Coordinated observation of Io plasma torus using Hisaki/EXCEED and gourd-based telescopes

KAGITANI, Masato[1*] ; ANDREW, Steffl[2] ; BADMAN, Sarah[3]

[1]Tohoku university, [2]Southwest Research Institute, [3]University of Leicester

EXCEED is an EUV spectrograph onboard an earth-orbiting space telescope, Hisaki(SPRINT-A). One of the primal mission goal of Hisaki/EXCEED is to reveal radial transport of mass and energy in the Jovian magnetosphere. At the begging of January 2014, intense campaign observations of Jovian aurora and Io plasma torus were made using Hisaki/EXCEED, Hubble Space Telescope and other ground-based telescopes covering wavelength range from EUV through IR. We will present results of spectroscopic observation of Io plasma torus using the R.C. spectrograph attached to Kitt-Peak 4-meter telescope and an Echelle spectrograph attached to Haleakala 40-cm telescope.

The 4-meter R.C. Spectrograph was set up covering 550nm through 800nm which could successfully detect NaD (589nm), SIII 631.2nm, SII 671.6/673.1nm, and OII 731.9/733.0nm as well. A field-of-view was 98 arcseconds along the slit and the slit center was pointed at the dawn or dusk edge of the centrifugal equator. We could get 54 spectra from the observation during January 4th through 10th, 2014.

The Haleakala spectrograph is a high-resolution echelle spectrograh with an integrated field unit (IFU) which enables to capture 2-d distribution of [SII] 671.6/673.1nm emission with spectral resolution of 67000 over a field-of-view of 41” by 61”. The 40-cm telescope was observing Io plasma torus all over the night during the observing campaign period.

Based on preliminary analysis of the EUV spectrum from EXCEED/Hisaki, visible spectrum from Kitt-Peak 4-meter and Haleakala 40-cm, emission peaks of SIII and OII was located outward compared to the SII emission peak which is consistent with results from previous studies. More accurate analysis including pointing calibration and flux calibration are ongoing, the result will be presented at the meeting.

Coordinated observation of Jupiter thermosphere and radiation belt in January 2014

KITA, Hajime[1*] ; MISAWA, Hiroaki[1] ; TSUCHIYA, Fuminori[1] ; FUJISAWA, Shota[1] ; SAKANOI, Takeshi[1] ; KASABA, Yasumasa[1]

[1]Tohoku Univ.

In order to evaluate the solar UV/EUV heating effect on the Jovian radiation belt, we made coordinated observations for both temperature of the Jovian thermosphere using an infrared telescope and synchrotron radiation from the radiation belt (JSR) using a radio interferometer. JSR is the most effective probe for the dynamics of the Jovian radiation belt through remote sensing from the Earth. Recent intensive observations for JSR reveal short term variations of JSR with the time scale of days to weeks, but their causalities are not understood well. It is theoretically expected that the Jovian thermosphere is heated by solar UV/EUV radiation, and planetary atmospheric neutral wind is driven by solar UV/EUV heating. Then, induced dynamo electric field is mapped into the radiation belt and induces radial diffusion. From this scenario, the total flux density of JSR is expected to correlate with the solar UV/EUV flux.

Previous studies confirmed that the total flux density of JSR varied corresponding to the solar UV/EUV variations though it is unclear whether the temperature of the Jovian thermosphere actually varied during this event. The purpose of this study is to confirm whether sufficient solar UV/EUV heating occurs on the Jovian thermosphere and it actually causes variations of JSR total flux density. We made coordinated observations of the NASA Infra-Red Telescope Facility (IRTF) and the Giant Metrewave Radio Telescope (GMRT). From the infrared spectroscopic observations, we measured thermospheric temperature of H_3^+ ion. From the radio interferometer, we measured the total flux density and brightness distribution of JSR.

The IRTF is a 3 m infrared telescope located in Mauna Kea, Hawaii. The IRTF observations were made on Jan 3, 8, and 13 in 2014. We used the high spectral resolution spectrometer, CSHELL, and observed H_3^+ 3.9530 microns emission (Q(1,0)) and 3.4547 microns doublet emission (R(4,3) and R(4,4)). We assumed local thermodynamic equilibrium at the equatorial region and calculated thermospheric temperature from the two emission line ratio. The GMRT is a large radio interferometer located in India. The GMRT observations were made from Dec 31 to Jan 16 with a few days interval. The typical duration of observation time was 2 hours per day, and the observation frequency was 235 and 610 MHz. During this period, the SOHO satellite showed that the solar EUV flux increased from Dec 26, reached at the maximum flux on Jan 8, and then decreased to Jan 16. A preliminary analysis of the IRTF data showed that the temperature increased from Jan 3 to Jan 8, and decreased from Jan 8 to Jan 13. This is the first result that shows the temperature response of Jovian upper atmosphere to the solar UV/EUV heating. We will also introduce analyzed results of the GMRT data and discuss the relationship between Jovian thermosphere and radiation belt.

Data analysis of Jupiter's decametric radio emission observed by LWA1

SHIMANOUCHI, Yoshiaki[1*] ; IMAI, Kazumasa[1] ; CLARKE, Tracy[2] ; HIGGINS, Charles A.[3] ; IMAI, Masafumi[4]

[1]Kochi National College of Technology, [2]Naval Research Laboratory, [3]Middle Tennessee State University, [4]Kyoto University

We present new results in the study of Jupiter's decametric emission obtained using the newly commissioned Long Wavelength Array Station 1 (LWA1). The LWA1 is a low frequency radio array operating in the frequency band between 10 and 88 MHz. The array consists of 256 dual polarization dipole stands, and observations are possible with up to four simultaneous beams, each of which has two independent tuning frequencies. The LWA1 is well suited to studying details of Jovian phenomena due to its high sensitivity as well as high time and frequency resolution over a wide bandwidth. We present LWA1 observations and the developed data analysis software by using IDL. The observed Io-C dynamic spectrum on March 10, 2012 shows the modulation lanes of both left and right hand polarization components share the same lane structure. It indicates that the both left and right hand Io-C radiations are emitted from the southern hemisphere. And the locations of the radio sources along the Jupiter's magnetic field should be very close.

Long Term Variations of Jupiter's Auroral Radio Emissions - II

MISAWA, Hiroaki[1*] ; YONEDA, Mizuki[2] ; MORIOKA, Akira[1] ; TSUCHIYA, Fuminori[1] ; MIZUGUCHI, Takahiro[1]

[1]PPARC, Tohoku Univ., [2]PPARC, Tohoku Univ. / IFA, Univ. Hawaii

It is known that Jupiter's auroral radio emission (hereafter JAR) shows long term variations with the time scale of about a decade. The variations were first considered to be initiated by the solar activities in 1960's, however, longer term analyses in 1970's showed the variations relate with the Jovicentric declination of the earth (De). So far, their plausible causalities are considered to be brought by 1) De relating to amount of reachable rays to the earth, and 2) the geocentric declination of Jupiter relating to incidence angle of the radio wave to the terrestrial ionosphere. However, considering solar cycle dependence on the terrestrial auroral radio activity (e.g. Kumamoto et al., 2003), the solar activity control may not be negligible for the long term variations. Furthermore, we have not known well long term relationship between JAR and Jupiter's substorm-like process which may be controlled by Io's volcanic activity.

In order to assess the previously proposed causalities and the other effects, we have investigated occurrence features of JAR using the radio wave data observed outside the terrestrial ionosphere; i.e., by the WIND satellite after 1995. We have derived year-scale occurrence probabilities for 0.7 - 14 MHz around Jupiter's occultation periods, where the frequency range includes both Jupiter's decameter and hectometer radio emissions (so-called DAM and HOM, respectively). As the result, the yearly-scale occurrence probabilities show almost monotonous decrease from 1995 to 2005, then gradual increase after 2005, but change to somewhat complex nature with increase and decrease after 2009. The tendency is roughly similar for DAM and HOM, and also quite roughly similar for Io-related and non-Io-related DAMs. On the other hand, the JAR variation features do not seem to correspond to individual variation of De, solar activity and solar wind, but seem to somewhat correlate with those of Iogenic gas luminosity. These results imply that multiple causalities and/or Jupiter's internal process(es) control the long term variations.

Acknowledgements: We would greatly appreciate M. Kaiser and the WIND/WAVES team for providing the radio wave data.

Analysis of the PWV variations observed by a hyper-dense network of GNSS receivers prior to localized rainfall

IWAKI, Yuya[1] ; REALINI, Eugenio[1] ; TSUDA, Toshitaka[1*] ; SATO, Kazutoshi[1] ; OIGAWA, Masanori[1]

[1]RISH, Kyoto University

Sudden and localized heavy rainfall events are posing increasing danger to urban areas, not only for the generation of floods, but also for the possibility to trigger landslides and damage crucial infrastructures. Numerical weather prediction models need to be supported by observations with sufficiently high spatial resolution, in order to be able to successfully forecast such localized precipitation events. To this aim, a crucial parameter to be monitored is the amount of precipitable water vapor (PWV), as well as its spatial distribution over the area of interest, and its variation over time. The Global Positioning System (GPS), which is one of the Global Navigation Satellite Systems (GNSS) currently available, has been increasingly used not only for positioning, but also for the remote sensing of physical parameters useful in Earth sciences. The PWV, or integrated amount of water vapor along the zenith direction, can be estimated by GPS (or GNSS) meteorology, which is a method that associates the amount of water vapor to the tropospheric delays which affect the signals of positioning satellites.

We deployed a dual-frequency (DF) GNSS network around Uji campus of Kyoto University, Japan, with inter-station distances of about 1-2 km. By using this network, we built a basic system to observe PWV fluctuations occurring within a small horizontal scale (less than 10 km), which are then analyzed to identify possible precursors of local torrential rain. Results from two observation campaigns (executed in the summer of 2011 and 2012) to retrieve and study GPS-derived PWV showed that its difference from other meteorological instruments was at most 2 mm in RMSE. We analyzed the variations of PWV detected when localized heavy rain was observed on July 9 and 25, 2012. Both the averaged value and the variance of PWV among GNSS stations increased before a nearby meteorological radar detected the rain clouds. In the latter case, the relative value of PWV among stations was larger than 5 mm.

For turning this system into practical use, e.g. for supporting a heavy rain early warning system, real-time satellite orbit and clock products are required. To estimate and correct the error of predicted satellite clock information, we used stations from the existing nation-wide GPS network in Japan (GEONET), with long baselines (˜100 km). The difference between the real-time PWV and that obtained in post-processing by means of precise orbit and clock products was 1.5 mm in RMSE.

Furthermore, the cost-effective deployment of hyper-dense GNSS networks over urban areas would benefit from the usage of inexpensive single-frequency (SF) receivers. We implemented and tested a software application that estimates and interpolates the ionospheric delay from DF stations surrounding the hyper-dense network, in order to compensate SF observations for the effect of the ionosphere, according to a method called SEID (Satellite-specific Epoch-differenced Ionospheric Delay), which was originally developed at the GFZ in Potsdam, Germany. By applying SEID for SF PWV retrieval, the error in terms of PWV with respect to the DF solution was about 1.6 mm in RMSE. The PWV horizontal distribution obtained by SF analysis with this model could detect localized PWV inhomogeneity emerging prior to a rainfall which occurred within a small horizontal scale (less than 10 km).

PWV retrieval by radiosondes and GPS receivers in Indonesia: spatial and time variations associated to rain events

REALINI, Eugenio[1] ; SATO, Kazutoshi[2] ; TSUDA, Toshitaka[1*] ; SUSILO, .[3] ; MANIK, Timbul[4]

[1]RISH, Kyoto University, Japan, [2]RISH, Kyoto University, Japan - now at JAXA, Japan, [3]Indonesian Geospatial Information Agency (BIG), Indonesia, [4]National Institute of Aeronautics and Space (LAPAN), Indonesia

Flooding due to local convective rain is a serious problem in the urban area of Jakarta, Indonesia. However, accurate prediction of local heavy rainfall events by means of current mesoscale numerical prediction models is difficult, partly because of lacking meteorological observations in Indonesia. Spatial and time variations of water vapor over a given area are expected to increase before precipitation occurs, due to the accumulation of water vapor in the lower troposphere, followed by convective instability. A means to reliably and continuously monitor Precipitable Water Vapor (PWV) is needed in order to detect such variations before the formation of rain clouds. GPS meteorology, i.e. the retrieval of PWV above a GPS station of known coordinates, is a useful technique to achieve this objective. The GPS signal delay induced by tropospheric refractivity is related to the amount of water vapor along the slant path between each satellite and the receiver antenna, therefore each fixed GPS station can be effectively employed as a sensor that continuously monitors the PWV with high temporal resolution (down to few seconds). By deploying multiple GPS stations that concurrently estimate the amount of PWV at different locations within an area of interest, one can evaluate the spatial and time fluctuations of the water vapor field, and investigate their relation to rain events.

We conducted a PWV observation campaign from 23 July to 5 August 2010 by using five GPS receivers installed at four different locations in Jakarta and Bogor, on Java island, Indonesia. Radiosondes were launched three to four times a day, from a site co-located with two of the receivers, in order to validate the GPS-derived PWV data. The validation resulted in a root mean square error of 2-3 mm. The influence of atmospheric pressure and temperature on GPS-derived PWV can be significant, therefore it was evaluated by referring to ground pressure and temperature measured by weather stations, and radiosonde temperature profiles. A regular semi-diurnal pressure oscillation was observed, showing an amplitude ranging from 3 to 5 hPa, which corresponds to 1.1-1.8 mm in PWV. A temperature inversion layer was observed in the radiosonde profiles during the night, which resulted in an error of about 0.5 mm in the retrieved PWV.

During the campaign, there was a passage of precipitation clouds over western Java, moving southwestward from the Equator towards the Indian Ocean, from 26 to 29 July. A second precipitation event, with localized rain clouds near Bogor, occurred on 2 August. Both events were observed also by a C-band Doppler Radar, operated in Serpong by the Japan Agency for Marine-Earth Science and Technology (JAMSTEC) as part of the HARIMAU project. The highest value of GPS-derived PWV (about 68 mm) was observed on 27 July, coinciding with the first rainfall event. Spatial and time variations in the estimated PWV between the four sites were enhanced before both the analyzed rainfall events, on 27 July and 2 August. We thus suggest the possibility that the spatial and time inhomogeneity of PWV detected by a network of GPS receivers could be used to support the prediction of rainfall events.

A Dense Observation of the Tokyo Metropolitan Area Convective Study for Extreme Weather Resilient Cities (TOMACS)

SHOJI, Yoshinori[1*]

[1]Meteorological Research Institute

It is recognized that large cities with populations of several million people are inherently vulnerable to severe weather, such as torrential rainfall, lightning, and tornados. An increase in the occurrence of torrential rainfall and strong typhoons, which can be caused by global warming, can cause extensive damage to large cities (Ishihara, 2013). The number of days with thunderstorms has been increasing in Tokyo in recent years, and the requirement of an advanced monitoring and forecasting system for extreme weather is becoming greater.

An unprecedented dense observation campaign and relevant modeling and societal studies have been conducted since April 2010 by the National Research Institute for Earth Science and Disaster Prevention (NIED), Meteorological Research Institute (MRI), and more than 25 national institutions and universities in Japan that target local high-impact weather (LHIW) in the Tokyo metropolitan area. The objectives of the project, the Tokyo Metropolitan Area Convection Study for Extreme Weather Resilient Cities (TOMACS), include the 1) elucidation of the mechanism of LHIW in urban areas (e.g., local torrential rain, flash flood, strong wind, lightening), 2) improvement of nowcasting and forecasting techniques of LHIW, and 3) the implementation of high resolution weather information to end-users through social experiments.

One of the unique features of TOMACS is the utilization of dense meteorological instruments in the Tokyo Metropolitan area, which is one of the most urbanized areas in the world. Their objectives are to target the tropospheric environment, boundary layer, initiation of convections and the lifecycles of thunderstorms. For the study of the mechanism of LHIW, data are used from the advanced observational instruments owned by participating organizations (including X-band and C-band polarimetric radars, a Ku-band fast scanning radar, Doppler lidars, microwave radiometers, a network of Global Positioning Systems (GPS), radiosondes and unmanned aerial vehicles), which are currently deployed in the Tokyo metropolitan area in addition to the operational observation networks of the Japan Meteorological Agency (JMA) and the Ministry of Land, Infrastructure, Transport and Tourism (MILT) of Japan. The intensive operational period (IOP) of the observations was set to the summers of 2011, 2012 and 2013.

During the IOP, several LHIW events occurred and have been energetically studied. In this topic, we briefly overview the necessity of this study, observation system, and results obtained so far.

A case study on the local front prior to the cumulonimbus cloud and the verification of JMA-NHM simulation

NAGUMO, Nobuhiro[1*] ; YAMADA, Yoshinori[1] ; KAWABATA, Takuya[1] ; SATO, Eiichi[1]

[1]Meteorological Research Institute

The local fronts observed over the Kanto plain on July 23, 2013 have been analyzed that is the origin of the isolated cumulonimbus cloud in Tokyo metropolitan area and verified numerical simulation by JMA-NHM.

The local fronts and cumulonimbus cloud formation have been examined based on the data from dense observation network around Kanto plain including Doppler radar for Airport Weather (DRAW) at Haneda, Doppler lidar installed in Tokyo Institute of Technology (Ookayama Campus) and surface meteorological data by Japan Meteorological Agency (JMA). The verification of numerical simulation was based on the results of 500 m horizontal resolution of Japan Meteorological Agency Non-Hydrostatic Model (JMA-NHM). As the initial and boundary data, JMA Meso-analysis data of 15 UTC July 22, 2013 have been adopted. The first simulations have been done with 5 km resolution covering East Japan and then nesting of 1 km and 500 m resolution have been done covering a large part of Kanto Plain. The simulation of 500 m resolution has been analyzed for 10 hours from 02UTC July 22, 2013 and the boundary process is based on Deardorff (1980).

The formation of cumulonimbus clouds in Kanto plain is often explained by the convergence of southerly wind and easterly wind. The southerly warm moist wind flows from Sagami Bay and Tokyo Bay by high pressure system in the south of Japan or sea breeze. The easterly wind flows from Kashima Bay. However, in one case of on July 23, it was found that the trigger of cumulonimbus was convergence with two different directions of sea breeze fronts and in addition gust front also plays an important role. The daytime sea breeze front is formed along the Sagami and Tokyo Bay, has entered inland at 1 m/s approximately. Several isolated cumulonimbus clouds have been formed in the rear of sea breeze front and some of them have been lost later, to form a gust front. The spread speed of gust front was about 3 m/s. The sea breeze front that was located in front of the gust front turned the direction to northwest. This sea breeze front and original northeast direction of front from Tokyo Bay have formed the convergence over Tokyo metropolitan area.

On the other hand, numerical simulations have predicted the strong rainfall in the Kanto plain but not all precipitation have been expressed. Comparing JMA-NHM 500 m resolution simulation with DRAW at Haneda, the horizontal distribution of sea breeze front was close to the position of real position. The simulations also have expressed the isolated cumulonimbus rear of sea breeze front. But the gust front spreading was small to the real one.

Doppler lidar had identified the horizontal and vertical structure of these fronts. The simulated structure by JMA-NHM can be compared with Observation. The knowledge of the representation of simulation leads to improve forecast accuracy. We would like to go on to investigate the similarities or difference between simulation and observation of these front structures.

Numerical simulations using WRF model for reproducing localized delay signals derived from InSAR

KINOSHITA, Youhei[1*] ; FURUYA, Masato[1]

[1]Natural History Sciences, Hokkaido University

For elucidating the mechanism of meso-scale phenomena involving a phase change of water molecule, water vapor is one of the most important but poorly understood parameter in meteorology. Recently, the Global Navigation Satellite System (GNSS) are routinely used to provide near-real-time estimates of PWV (Foster et al., 2005) and to assimilate routine weather forecasts (e.g. Nakamura et al., 2004). However, the limitation using GNSS atmospheric delay for meteorology is its spatial resolution, for example about 20 km for the Japanese GNSS network (GEONET). Interferometric Synthetic Aperture Radar (InSAR) phase signals, which can detect surface deformations with high-spatial resolution, are affected by earth's atmosphere like GNSS. Therefore, InSAR can detect water vapor distribution with high spatial resolution without any surface deformation signals or other errors and thus is potentially useful for meteorological applications. In previous studies, Hanssen et al. (1999) showed the coincidence between water vapor signals detected by InSAR and spatial distributions of rainfall echo detected by a weather radar (WR), indicating the possibility of InSAR as a water vapor sensor. Kinoshita et al. (2013) showed the water vapor distribution during the heavy rain event using ALOS/PALSAR emergency observation data. They conducted the estimation of the three-dimensional (3D) water vapor distribution and performed numerical simulations by means of the Weather Research and Forecast (WRF) model, which could reproduce a convective system observed as a localized signal in the InSAR image. However, there were still few cases detecting localized water vapor signals with InSAR and few studies using InSAR for meteorological applications.

In our past presentations, we reported several case studies detecting localized water vapor signals associated with deep convective systems with InSAR derived from ALOS/PALSAR data (Kinoshita et al., JpGU 2013), some of which reached over 20 cm in the line-of-sight direction within 10 km square. Observed locations of these interferograms are at Niigata (two cases), Shizuoka, Kyoto, Saga and Miyazaki. These signals are equivalent to about 21 mm in the precipitable water vapor, and are higher than that around each signal. Each signal located at the very location of high rainfall intensity in the WR data, and is regarded as including few ionospheric effects because of the use of PALSAR data with descending orbit. Such localized signals strongly suggest the existence of developed convective systems at SAR observation time. However, it is difficult to elucidate mechanisms of phenomena that caused these localized signals.

In this study, we will perform numerical simulations using the WRF model for the purpose of investigate mechanisms of these phenomena and compare simulation results with derived InSAR data. At the presentation, we will show these results and discuss them.

Development and Observation of the Phased Array Radar at X band

USHIO, Tomoo[1*] ; SHIGEHARU, Shimamura[1] ; KIKUCHI, Hiroshi[1] ; WU, Ting[1] ; MEGA, Tomoaki[1] ; MIZUTANI, Fumihiko[2] ; WADA, Masakazu[2] ; SATOH, Shinsuke[3] ; IGUCHI, Toshio[3]

[1]Osaka University, [2]Toshiba, [3]NICT

A new Phased Array Radar (PAR) system for meteorological application has been developed by Toshiba Corporation and Osaka University under a grant of NICT, and installed in Osaka University, Japan last year. It is now well known that rapidly evolving severe weather phenomena (e.g., microbursts, severe thunderstorms, tornadoes) are a threat to our lives particularly in a densely populated area and the number of such phenomena tends to increase as a result of the global warming. Over the past decade, mechanically rotating radar systems at the C-band or S-band have been proved to be effective for weather surveillance especially in a wide area more than 100 km in range. However, rapidly evolving weather phenomena have temporal and spatial scales comparable to the resolution limit (-10 min. and -500m) of typical S-band or C-band radar systems, and cannot be fully resolved with these radar systems. In order to understand the fundamental process and dynamics of such fast changing weather phenomena, volumetric observations with both high temporal and spatial resolution are required. The phased array radar system developed has the unique capability of scanning the whole sky with 100m and 10 to 30 second resolution up to 60 km. The system adopts the digital beam forming technique for elevation scanning and mechanically rotates the array antenna in azimuth direction within 10 to 30 seconds. The radar transmits a broad beam of several degrees with 24 antenna elements and receives the back scattered signal with 128 elements digitizing at each elements. Then by digitally forming the beam in the signal processor, the fast scanning is realized. After the installation of the PAR system in Osaka University, the initial observation campaign was conducted in Osaka urban area with Ku-band Broad Band Radar (BBR) network, C-band weather radar, and lightning location system. The initial comparison with C band radar system shows that the developed PAR system can observe the behavior of the thunderstorm structure in much more detail than any other radar system. The observed high temporal resolution images of the severe thunderstorm are introduced, showing the potential capabilities of the PAR system. The correlation coefficient of the reflectivity in PAR with C band radar ranges from 0.6 to 0.9 as a function of the distance from the PAR.

Although the phased array radar system using the digital beam forming technique can estimate the 3 dimensional structure of the precipitation system within 10 to 30 seconds with 100 meter resolution, the observation results also shows the received signal was seriously contaminated by the relatively high received power from ground clutter and strong precipitation echoes through the side lobes of the transmitting beam. To avoid this problem, a beam forming technique using the MMSE (Minimum Mean Square Error) formulation was proposed and tested. This approach can adaptively mitigate the masking interference that results from the standard digital beam forming method in the vicinity of ground clutter and strong precipitation area. The proposed method is compared with the standard beam forming technique by applying to the huge raw IF signal data digitized at each 128 antenna elements. The results show that the proposed technique can correctly estimate the precipitation echo within a few dB even in the presence of a strong ground clutter that is more than 20 dB higher than the precipitation echo with 15 pulse repetition number. The MMSE based technique is shown to be superior to the standard DBF scenarios under the small number of pulse repetitions to achieve the rapid scanning.

Descending reflectivity core analysis by Ku-band radar

SATO, Eiichi[1*] ; KUSUNOKI, Kenichi[1] ; FUJIWARA, Chusei[1] ; SAITO, Sadao[1] ; SHOJI, Yoshinori[1]

[1]Meteorological Research Institute

In order to observe extreme weather such as localized heavy rainfall, tornado etc., we installed a Ku-band radar in Musashino-shi, Tokyo in 2011. Since the radar can create a 3D volume scan per minute, we expect that the data observed by the radar will contribute to understanding mechanisms of such phenomena.

In our research, we defined a cell as an area whose reflectivity is $\geq$ 25dBZ, and a core as a reflectivity peak in the cell. The procedures of the cell/core detection are as follows: 1) conversion from rθ data to xyz data, 2) cell detection by binarization and labeling, and 3) core detection by method of steepest descent(ascent).

In this presentation, results of an automatic cell/core detection algorithm will be shown.

Influence of urban heat excess on heavy rain environment

SUGAWARA, Hirofumi[1*] ; SEINO, Naoko[2] ; ODA, Ryoko[3]

[1]National Defense Academy, [2]Meteorological Research Institute, [3]Chiba Institute of Technology

There are several observed fact that cities give influence on the precipitation, or cumulus generation. However the mechanism of urban influence on precipitation is not clarified. There would be three physical processes. Buildings could form updraft through a roughness effect. Much heat excess from cars, air conditioners and asphalt roads could also form updraft. Urban aerosol can be a condensation nuclei and gives chance to form cloud, however too much nuclei should suppress cloud droplets growing.

This study focuses on the heat effect. We measured surface sensible heat flux in urban, suburban and rural areas, and evaluated the urban heat excess quantitatively. The resulted heat excess amount was used to in calculation of atmospheric stability index.

In the heat flux measurement, the eddy correlation method which should be the most reliable way of heat flux measurement was used at the rural and suburban site. At urban site, we used the scintillation method which has a advantage of larger scale of measurement (km scale) than that of the eddy correlation method (100 m scale). The reason for taking scintillation method at urban site is severe heterogeneity in urban area. Urban area is mosaic of buildings, roads, parks, bare soil on the school ground field, and sometimes rivers or channels. Scintillation method enable us to measure the area-averaged heat flux in the urban heterogeneity. We used a modified scintillation method which takes into account of surface unevenness by the buildings. We operated measurement site for three years and analyzed a hourly composite of 50 fine days in July. As a result, urban heat flux is largest followed by suburban and rural. The difference between urban and rural was 140 Wm-2 at noon time.

We evaluated CAPE index for each site. We used simple 1D model to calculate the change of temperature profile by the surface flux. The morning initial condition to calculate daytime growing of mixed layer was acquired from the sonde observation. We adopted same initial profile for urban, suburban and rural, and give observed surface heat flux for each. This way of analysis evaluates thermal influence of land-use on CAPE index. The CAPE at 1500 LST is largest in cities and the difference between rural and city is 15%.

OROGRAPHIC PRECIPITATION OBSERVATION IN JEJU ISLABD, KOREA (2012-2013)

LEE, Dong-in[1*]

[1]Department of Environmental Atmospheric Sciences, Pukyong National University

In summer monsoon season, a Korean Peninsula is influenced by several weather phenomena such as the Changma-front, typhoon, strong low pressure, and local heavy precipitation. Especially, the orography plays an important role in controlling the cloud formation, amount and precipitation distribution. To find out the precipitation development mechanism by orographic effect, we performed the intensive field observation around Mt. Halla in Jeju island (33.21 N and 126.32 E, width 78 km and length 35 km) which is located at the southern part of Korea with JNU (Jeju National University), KNU (Kyungpook National University), IJU (Inje University), KMA (Korea Meteorological Administration), and NIMR (National Institute of Meteorological Research). We installed and arranged the observational instruments such as, AWS, radiosonde (including mobile sonde and ship sonde), Parsivel, 2DVD, ultrasonic anemometer, and raingauge along the altitudes in Jeju island. Each disdrometer sites were located in straight line considering topography between two S-band Doppler radars. We analyzed synoptic condition by NCEP/NCAR reanalysis data and kinematic characteristics of precipitation by dual Doppler radar analysis using S-band radars in KMA.

In 2012 case, the Changma-front was located in the northern part of the Jeju island and the precipitation system passed from the southwest to the northeast. The accumulated precipitation (31.7 mm) was recorded at the site PR4 which was placed in the highest (H: 975 m). During the passage of precipitation, the south westerly wind ($>$12 m s^{-1}) with warm and humid air and the cold (lower layer) and warm advection (upper layer) were observed. From the microphysical analyses, PR2 (windward side, H: 571 m) and PR6 (leeward side, H: 324 m) sites indicated high rain rate about 60 to 75 mm hr^{-1} by orographic effect.

In 2013 case, the Changma-front located in the center of Jeju island and precipitation system passed from the southwest to northeast. The warm advection in lower layer and cold advection in upper layer were observed by radiosonde analyses, relatively. Strong southwesterly winds were blown with moist environment in surface layer. By the wind field analysis, convergence in west and divergence in east were existed and updraft in Jeju island and downdraft in ocean area, relatively. High number concentration at PR4, 5 and PR8 were shown with small size raindrops (less than 2 mm), however large size raindrops (lager than 6 mm) were distributed at PR7(northeast in island) and PR9(southwest in island).

Characteristics of distribution and preceding surface conditions of cumulonimbus clouds appeared on Kofu Basin on a calm

SANO, Tetsuya[1*] ; SUETSUGI, Tadashi[1] ; OISHI, Satoru[2]

[1]International Reserch Center for River Basin Environment, University of Yamanashi, [2]Research Center for Urban Safety and Security, Kobe University

On a calm summer day, cumulonimbus clouds often appear on complex terrains with the thermal induced local circulations. The appearance of such cumulonimbus clouds on a basin is not so frequent ordinarily. Once a cumulonimbus cloud appears on a basin, it often brings much rainfall in a short time, which becomes triggers of weather related disaster in urban city on a basin. However, the characteristics of the generation of cumulonimbus clouds on a basin and the conditions in a basin preceding the generation of them have not been known enough. In this study, for the example of above situation, we analyze the distribution of the appearance of cumulonimbus clouds on Kofu Basin and the conditions in Kofu Basin preceding the appearance of them.

The days of the appearances of cumulonimbus clouds on Kofu basin in a calm day confirmed by the observation of X-MP radar of University of Yamanashi (UYR) were 8 days out of 1 July to 30 September on 2012. Although the number of the events was limited, they brought large rainfall amount of 20 to 30 mm in an hour. The positions of the appearance concentrated from center to eastern side on Kofu Basin.

Before the appearance, south-southwesterly (SSW-ly) and southeasterly (SE-ly) surface wind was measured on western and eastern sides on Kofu Basin, respectively. When SSW-ly or SE-ly wind expanded to reach Kofu city that locates center of Kofu Basin, surface equivalent potential temperature (θe) increased. From The meso-scale objective analyzed data of Japan Meteorology Agency (JMA-MANAL) shows strong south-component wind with high-θe toward Kofu Basin from Suruga Bay through a valley connecting Suruga Bay to Kofu basin at the level of about 900 hPa. At the eastern side of Kofu Basin, strong east-component wind with high-θe crossing the mountains on the eastern side was appeared. Then, the south-component wind and the east-component wind formed horizontal convergence on Kofu basin. So, we consider that, the winds entering from the outer side of Kofu Basin, conditional instability intensified and horizontal convergence formed in Kofu Basin, which played a role as trigger of precipitating cell on Kofu Basin.

Transition to resilience to extreme weather ,high-resolution monitoring and international synergies

SCHERTZER, Daniel[1*] ; MAKI, Masayuki[2] ; TCHIGUIRINSKAIA, Ioulia[1]

[1]Ecole des Ponts ParisTech, U. Paris Est, [2]Research and Education Center for Natural Hazards, Kagoshima U.

Transition from high vulnerability to extreme weather to resilience is a major challenge for megacities in response to two main drivers: urban sprawling and climate change. The functioning of cities, particularly the large ones, should be observed, understood, simulated and monitored on much larger ranges of scales than usually done. This requires at first observations of many geophysical fields with an unprecedented resolution to achieve high-resolution monitoring. However, this also require an advanced understanding/modeling of the nonlocal interactions between large and small scales, e.g. between weather and climate scales.

Finally, this pleads in favor of methodological approaches across scales, rather than over very limited ranges of scales. Such methodologies aim in fact to quotient out non trivial symmetries and therefore should enable us to dig out the relevant information from otherwise under-exploited big data.

Such approaches have been often invoked, but barely achieved because they correspond to formidable tasks that require an unprecedented development of international cooperation on both advanced technologies and methodologies. We will illustrate these questions with examples of research and innovation programs on flood resilience which seem rather complementary across national boundaries but require nevertheless much stronger international synergies.

The effect of scaling anisotropy on weather extremes

FITTON, George[1*] ; TCHIGUIRINSKAIA, Ioulia[1] ; SCHERTZER, Daniel[1]

[1]Universite Paris Est, Ecole des Ponts ParisTech, LEESU, 6-8 avenue B. Pascal, Cite Descartes, 7745

Predicting extreme weather events in and around cities is far from straight forward. Even in a stable and unbounded atmosphere, crude numerical approximations of the Navier-Stokes equations are required for reasonable computation times. Hence, numerical simulations of the weather in and around cities become even more complex, and therefore require much coarser space and time scales to model both the macro weather and the complex boundary conditions created by buildings and other urban structures. Such models will severely underestimate extremes due to the necessary truncation of scales to deal with these additional complexities.

While progress in numerical simulation depends on the next fastest processor, measurement techniques on the other hand are becoming rapidly more and sophisticated. There appears however to be a gap forming in the ability to utilise the enormous datasets produced from new measurement techniques. This seems mainly due to outdated statistical methods that are used to make sense of these overwhelming databases.

In this study we propose a method, based on the structure function, that allows one to easily estimate the Levy index α of the wind. We show that due to the complex nature of a three-dimensional wind a rotated frame of reference is necessary in order to obtain a universal multifractal structure function exponent. We show that the angular dependency of the scaling exponent results in either an increase or decrease in dimension. This increase or decrease in dimension causes a first or second-order phase transition respectively. The kind of phase-transition that occurs is directly related to the generation of extremes of the wind.

The combination of this kind of analysis with the advancements in measurement techniques that are coming to light should allow for the better prediction of extreme weather events in and around cities.

The Impacts of extreme weather on urban water bodies

MEZEMATE, Yacine[1*] ; FITTON, George[1] ; TCHIGUIRINSKAIA, Ioulia[1] ; SCHERTZER, Daniel[1] ; BONHOMME, Celine[1] ; SOULIGNAC, Frederic[1] ; LEMAIRE, Bruno[1] ; VINCON LEITE, Brigitte[1]

[1]Universite Paris Est, Ecole des Ponts ParisTech, LEESU, Marne La Vallee, France

In the event of heavy rainfall, large amounts of storm water will carry roof runoff pollutants into urban lakes. This kind of discharge not only changes the dynamics of the lake (i.e. the mixing processes that occur) but also complicates ones ability to predict pollutant concentrations. Being able to quantify these changes in pollutant during and after extreme weather events is important for water quality management.

In the interest of understanding the impact of extreme weather events on water bodies, we set-up an Acoustic Doppler Current Profiler (ADCP) next to a storm water discharge point at the bottom of a shallow urban lake in Creteil, a region in Paris.

The ADCP is particularly useful for analysing the turbulent boundary-layer (TBL) during these extreme weather events as it is able to measure the 3D velocity, in 127 vertical cells, over 3 meters. This is a unique situation compared to the atmospheric boundary-layer where profilers are typically coarsely spaced in the vertical.

To analyse the TBL dynamics we look only at the scaling properties of the velocity field. If the velocity is scaling the log-log plot of the energy spectra will be linear in wavenumber (or frequency). The slope of the log-log plot of the spectra gives the spectral scaling exponent. Performing the analysis we find a spectral exponent close to -1. Dimensional arguments suggest that this exponent occurs when the energy flux becomes dependent on the friction velocity instead of the length scale; likely a result of the strong inflow during extreme rainfall events. The ADCP data allows us to observe a smooth transition from a free stream turbulent regime (-5/3) to a bounded-turbulent exponent (-1) through depth.

This kind of analysis suggests the possibility for a general scaling model of the TBL that can be used to predict the mixing of pollutants during and after extreme weather events.

A large data set of raindrop size distribution (DSD) measured by 2-Dimensional Video Distrometer (2DVD) on 12 locations in Japan is analyzed using the truncated modified gamma DSD model and the normalized gamma DSD model. The present study seeks to: 1) explore the general properties of DSD observed at Kanto, Hokuriku, Nagoya, Kinki and Kyushu in Japan; 2) find the governing parameters of DSD models in different geographycal and seasonal regime; 3) statistics of big drops occurrence and instrinsic shape of the DSD with extremely large drops; 4) find relationships between DSD parameters such as the shape and slope parameters, the generalized intercept parameter and volume-weighted mean diameter, and etc. The present study on stratistical analysis of DSD provide us information which is nesessary to understand big drop microphysics and precipitation.

A Social Experiments on Disaster Prevention by Using of the Advanced Weather Information

NAKATANI, Tsuyoshi[1*] ; SHOJI, Yoshinori[2] ; MISUMI, Ryohei[1] ; NAKAMURA, Isao[3] ; MAKI, Masayuki[4]

[1]National Research Institute for Earth Science and Disaster Prevention, [2]Dept. of Meteorological Satellite and Observation System Research, Meteorological Research Institute, [3]Toyo Univ., Faculty of Sociology, [4]ERCPD, Kagoshima Univ.

The National Research Institute for Earth Science and Disaster Prevention has been carried out the research project on Tokyo Metropolitan Area Convection Sturdy for Extreme Weather Resilient Cities(TOMACS) in cooperation with 25 research agencies, researchers of more than 100 people and disaster management personnel of local governments. In this project we have been working on the following three research subjects.

(1) Studies on extreme weather with dense meteorological observations
(2) Development of the extreme weather early detection and prediction system
(3) Social experiments on extreme weather resilient cities

The study fields by the social experiment are Rescue Services (Tokyo Fire Department), Risk management(Edogawa ward,Yokohama city, Fujisawa city, Minamiashigara city), Infrastructure(JR East,JR Central, Obayashi) and Education and life(Toyo univ., The Certified and Accredited Meteorologists of Japan). In the social experiments, the each participated institutions have studied on the effective use of advanced weather information into disaster prevention according to their purposes.

The objective of social experiments are to enable the continous use of advanced weather information through the fixing of the monitoring and prediction system of extreme weather.

And also to discuss the problems and issues revealed in the course of social experiment, and to summarize as creating resilient city in extreme weather towards relevant government ministries and agencies, local government, the general population.

In this paper, overview of the social experiments is briefly explained and issues for continue use of advanced weather information are reported through the reference to the case of Edogawa-Ward where the X-band MP radar rainfall information is providing to residents. Finally this project is supported by the Japan Science and Technology Agency and Ministry of Education, Culture, Sports, Science and Technology.

Analysis of meso-gamma-scale convection in tropical regions using GPS meteorology

MATSUDA, Takafumi[1*]

[1]Graduate School of Science, Kyoto University

In tropical regions such as Indonesia, strong wind with severe shower called squall occurs frequently, and has a large impact on residents in a rainy season. To predict accurately local heavy rain (occurring in a short time and in the range of a few km) is difficult today. Therefore, it is important to understand generation and development mechanism of the meso-γ-scale convection that leads to locally heavy rain.

”GPS meteorology” is a method to obtain the ”atmospheric information” such as water vapor from atmospheric delay of radio waves based on a satellite ”positioning error”. We can estimate precipitable water vapor (PWV: integrated amount of water vapor along the zenith direction) with a high time resolution by using this method. Occurrence of rainfall associated with the meso-γ-scale convection has good correlation with the spatial non-uniformity and temporal variation of PWV estimated by the GPS meteorology technique (GPS-PWV).

The purpose of this study is to find out the generation mechanism of meso-γ-scale convection in the tropics by focusing on the GPS-PWV.

We analyzed GPS-PWV, radiosonde and rainfall data obtained from the campaign which was conducted during the rainy season of 2013 in Bandung, Indonesia.

We carried out accuracy validation of GPS-PWV by analyzing the radiosonde data. As a result, the rainfall data showed that precipitation occurred often in the late afternoon together with an increase of PWV. Furthermore, we found the daily cycle of PWV showing minimum and maximum values in the morning and late afternoon, respectively. In addition, there is a difference in an altitude of more than 1000 m in each observation point. The difference has a severe influence on GPS-PWV. Therefore, it is need to correct altitude difference effect.

Development of high resolution spatio-temporal precipitation data using a network of polarimetric X-band radars in Japan

KIM, Yu-ra[1*] ; LEE, Dong-in[1] ; JEONG, Jong-hoon[1] ; MAKI, Masayuki[2]

[1]Department of Environmental Atmospheric Sciences, Pukyong National University, [2]Department of Research and Education Center for Natural Hazards, Kagoshima University

Localized convective precipitation develops rapidly in a very short time and is conducive to extreme local rainfall amount. The X-band polarimetric radar is useful to analyze the convective precipitation because it can provide us polarimetric radar parameters which are useful to understand microphysical process in the precipitation. However, the radar observation has some limitations in detecting initial stage of rapidly developing convective cell; the radar volume scan strategy adopted in operational radar is 5 minute interval which is not enough for measuring rapidly developing convective precipitation. To detect the early stage of convective cell, we developed the algorithm which is based on the interpolation method both in space and time. The algorithm reproduces higher resolution spatio-temporal volumetric data using the operational network of four X-band polarimetric radars. The mosaic of multiple radars could be benefit for increased sampling into a certain volume. In addition, different scan strategy at each radar also improve spatio-temporal resolution. The algorithm is applied to radar data of convective precipitations observed in Kanto area in 2012. The new volumetric data can recognize more detail about echo which developed rapidly and detect the first appearance of convective echo at upper layer. Early detection of convective precipitation at upper layer can be useful for nowcasting or very short-term forecasting.

An Ensemble Nowcasting of Rainfall over the Kanto Region, Japan

P.C., Shakti[1*] ; MISUMI, Ryohei[1] ; NAKATANI, Tsuyoshi[1] ; MAKI, Masayuki[2] ; SEED, Alan[3]

[1]National Research Institute for Earth Science and Disaster Prevention(NIED), Tsukuba, Japan, [2]Kagoshima University, Kagoshima, Japan, [3]Bureau of Meteorology, Melbourne, Australia

Every year weather-related disasters: extreme rainfall, landslides and flooding destroy livelihoods and damage economics somewhere on the planet. Recently, number of flash flooding is believed to be increasing specially in urban areas. It has being a great challenge to forecast flood warning and urban drainage management. Nowcasting of rainfall (very short-range forecasting) is an important tool to minimize or manage all these weather-related disasters since precipitation is the main input. Common practice to forecast heavy precipitation for hydrological application varies from 0-6 hr and there are different kinds of nowcasting based on different method.

Nowcasting of rainfall comprises the detailed description of the current weather along with forecasts obtained by extrapolation for a different time period ahead. In this study, we focus on ensemble nowcasting of rainfall. It refers to the fact that many forecasts are produced, with the rainfall areas moving at slightly different speeds, and with the small rainfall features represented by slightly different random statistics. By comparing these different nowcasting of rainfall, the forecaster can decide how likely a particular weather event will be. It gives a much better idea of what weather events may occur at a particular time. Short Term Ensemble Prediction System (STEPS), one of the most advanced Quantitative Precipitation Forecast (QPF) systems currently available is considered for nowcasting of rainfall. Japan Meteorological Agency (JMA) and X-band multi-parameter (MP) radar data were considered to produce an ensemble nowcasting of rainfall. First, JMA radar rainfall data of Kanto region was fixed to check the performance of STEPS. Skill scores showed that STEPS can give a good forecast for less than one hour. However, more uncertainties can be seen during the starting and ending of rain event. High resolution of data (MP data) also used in the STEPS under the default condition. Overall, an ensemble nowcasting of rainfall seems close with real time data, which could be interesting to use them in hydrological model.

X-band polarimetric radar and C-band conventional radar composite rainfall map with high spatio-temporal resolution

MAKI, Masayuki[1*] ; HIRANO, Kohin[2] ; P.C., Shakti[2] ; SCHERTZER, Daniel[3]

[1]Kagoshima University, [2]NIED, [3]Ecole des Ponts ParisTech, U. Paris-Est

Radar with shorter wavelength such as the X-band (3-cm) wavelength has several advantages compared to C- and S-band radar. First, X-band wavelength radar has high sensitivity of the specific differential phase of the rain rate. Second, it is possible to achieve finer spatial resolution more economically; for example, X-band wavelength radar can achieve a 1 degree beam width with a 2 m diameter parabolic antenna, while S-band needs a 7 m diameter antenna to achieve the same beam width. Third, due to advantage number two, X-band radar is easier to setup in mountainous areas, and at lower cost compared to S- and C-band wavelength radar. In Japan, success in the detection of torrential rainfall that occurred in Tokyo in 2008 triggered the deployment of 35 operational X-band polarimetric radars in major urban cities by MLIT. This radar network named XRAIN provides rainfall information with high spatio-temporal resolution. In US, the X-band polarimetric radar network is constructed in Dallas Fort Worth, which is a research and innovation network linking academic researchers, local stakeholders, and industry to address water issues as they relate to urban sustainability. In Europe, The project named RAINGAIN is ongoing to improve fine-scale measurement and prediction of rainfall and to enhance urban pluvial flood prediction. Activities include the implementation and use of advanced radar technologies (X Band) in Leuven, London, Paris, and Rotterdam. Although X-band polarimetric radar has the advantages mentioned above and used in hydrological applications, there are essential disadvantages. First, the maximum range is shorter than that of C-band and S-band radar; maximum ranges of 200km or 300km are easily obtained in case of C- and S- band radar, while that of X-band radar is limited to 30km-60km. Second, signal extinction area which is defined as the area where the received signal is below the receiver noise level occurs behind heavy rainfall areas. These disadvantages will be a fatal flaw when extremely heavy rainfalls occur. Authors have experience that the maximum observation range of X-band radar was shorter than 3km when heavy rainfall passed over the radar site. The present paper aims to develop an algorithm to overcome these disadvantages. The method is based on the C-band and X-band radar composite map which attains the 1 minute time resolution and 250m spatial resolution by the interpolation method. The algorithm is applied to the heavy rainfall case observed on 12-14 July, 2012 in northern Kyusyu, Japan. The algorithm is validated with surface raingauge network: the composite radar rainfall estimation agreed well with raingauge data.

Entropic Balance Theory and Variational Field Lagrangian Formalism

SASAKI, Yoshi kazu[1*]

[1]University of Oklahoma

The entropic balance theory has been applied with outstanding results to explain many important aspects of tornadic phenomena. The entropic balance theory was originally developed in variational formalism with Lagrangian appropriate for supercell storm and tornadic phenomena. The entropic balance theory shares the same foundation as, symbolically called with keywords, ”variational field Lagrangian formalism” in short ”variational formalism”. It is broadly used in inmodern physics, not only in classical mechanics, with Lagrangian density and action designed for each physical problem properly. The Clebsch transformation (equation) was developed in the classical variational formalism, but has not been used because of the unobservable and non-meteorological Lagrange multiplier.

The Lagrange multipliers appeared in the Clebsch transformation are analogous to the mathematical vector potential (and gauge field) of the theoretically found Aharonov-Bohm effect . Its experimental verification has been difficult and has not been made until two decades later. The Lagrange multipliers in the Clebsch transformation seem similar to the vector potential and gauge of electromagnetic field and in advanced physics disciplines.

The entropic balance condition is thus developed from the Clebsch transformation, changing the unobservable non-meteorological Lagrange multiplier to observable meteorological rotational flow velocity with entropy and making it applicable to tornadic phenomena.

Deterministic predictability of the most probable state and reformulation of variational data assimilation

TSUYUKI, Tadashi[1*]

[1]Meteorological Research Institute

Four-dimensional variational data assimilation (4DVar) and ensemble Kalman filter (EnKF) have been widely used for data assimilation in meteorology and oceanography. Since prior probability density functions (PDFs) used in 4DVar and EnKF are usually assumed to be Gaussian, those two methods may not work well for a strongly nonlinear system. Thus data assimilation with nonlinear systems or non-Gaussian PDFs is a challenge in geophysics. Theoretical study of the two methods for nonlinear systems may be expected to provide insight for further advancement of data assimilation. The present study addresses this issue by reformulating variational data assimilation.

A necessary condition for deterministic predictability may be that the forecast state starting from the most probable state at an initial time remains close to the most probable state at a forecast time. It is found from the Liouville equation that if the trace of the Jacobian matrix of a deterministic nonlinear system does not depend on the state variables (hereafter referred to as the trace condition), the mode of a PDF of the state variables evolves according to the governing equations of the system. A condition for the forecast state to be close to the mode of the PDF is derived under an assumption of small prediction error for general deterministic nonlinear systems. This condition depends on the sensitivity of the trace to an initial condition, the size of initial condition error, and the length of forecast lead time.

Since the dynamical cores of numerical models of the atmosphere and the ocean are based on fluid dynamics, it is interesting to examine whether the governing equations of fluid dynamics satisfy the trace condition. The trace of the Jacobian matrix is calculated for finite-dimensional analogs of several Eulerian equations of ideal fluids. It is readily found that the trace condition generally holds for unbounded fluids under periodic boundary conditions. It is shown that the trace condition also holds for the quasigeostrophic equations with rigid boundaries, the Boussinesq approximation with rigid boundaries, and the shallow water equations on a sphere, by expanding the state variables in eigenfunctions of the Laplacian operator or the curl operator. The shallow water equations in a channel and compressible fluid with top and bottom boundaries do not satisfy the trace condition due to divergence at the boundaries.

A new formulation of variational data assimilation is presented for deterministic nonlinear systems that satisfy the trace condition. Though the cost function in the new formulation takes the same form as the conventional one, it makes clear an advantage of 4DVar over EnKF. If the trace condition holds, the forecast state starting from the mode of the posterior PDF at the last analysis time is the mode of the prior PDF. In the new formulation, the logarithm of the prior PDF is expanded around the forecast state, and covariance globalization is introduced to take into account the global distribution of the prior PDF that may be non-Gaussian. A feasible method for the covariance globalization may be to replace the local covariance matrix at the mode with a forecast error covariance matrix taken from EnKF. It is proved that a non-Gaussian prior PDF that evolves according to the Liouville equation is implicitly used for assimilating observational data in 4DVar. Results from an assimilation experiment with a toy model suggest that 4DVar thus formulated outperforms EnKF if the global minimum of the cost function is found.

Finally, it is pointed out that enough observational data are necessary for variational data assimilation to work well for a deterministic nonlinear system that does not satisfy the trace condition. Otherwise, EnKF and ensemble prediction may be a better choice for data assimilation and prediction of the system.

Modal analysis of near-bank velocity profiles in a tidal river.

WELLS, John[1*] ; PHAN, Tuy[1] ; NGUYEN, Linh V.[1] ; SUSUKI, Yoshihiko[2] ; BONNER, James[3] ; ISLAM, Mohammad S.[3] ; KIRKEY, William D.[3]

[1]Ritsumeikan University, [2]Kyoto University, [3]Clarkson University

We apply two decompositions to long-beam velocities of a 600 kHz 3-beam Horizontal Acoustic Doppler Current Profiler (HADCP) at West Point on the Hudson River Estuary, so as to efficiently characterize the spatiotemporal variation of near-bank velocity. One main motivation is to test statistical tools with which to benchmark computations. The HADCP is deployed next to the USGS gauging station at West Point, some 100 km upriver from Manhattan, on the inner bank downstream of a sharp bend and its associated 40 m deep trough. We analyzed a time series of 1-minute averages from October 2011, out to 80 meters from the bank with 1 m bins.

The first decomposition we apply is Principal Component Analysis. The PCA generates an optimally convergent set of spatial eigenfunctions or ”principal components” (PC), with which are associated temporally-varying amplitudes called ”temporal coefficients”. The first principal component captures more than 96.3% of the variance in velocity measured along the three HADCP beams, while the second PC captures about 2%. There appears an asymmetry between ebb and flood, as seen clearly from a phase plot of the temporal coefficient of the first PC versus that of the second.

The second is Fourier-based Koopman Mode Decomposition, i.e. decomposition into harmonic averages of the measurement vector. KMD associates a spatial structure with each of a series of temporal frequencies. For Oct 2011, the semidiurnal mode captured 74.33% of the variance. KMD also quantifies the phase lags at different distances from the river bank (and between normal and tangential velocity). Phase lags of tangential velocity between 10 and 80 m from the bank were about 1 hour for the semidiurnal mode, and 2 hours for the first (with a period of about 6 hours.), and this difference grew to a factor of four when considering flow within 10 m.

Pathways of the North Pacific Intermediate Water identified through the tangent linear and adjoint codes of an OGCM

FUJII, Yosuke[1*] ; NAKANO, Toshiya[2] ; USUI, Norihisa[1] ; MATSUMOTO, Satoshi[2] ; TSUJINO, Hiroyuki[1] ; KAMACHI, Masafumi[1]

[1]Meteorological Research Institute, [2]Japan Meteorological Agency

We develops a strategy of tracing a target water mass, and applies it for analyzing the pathway of the North Pacific Intermediate Water (NPIW) from the subarctic gyre to the northwestern part of the subtropical gyre south of Japan in a simulation of an ocean general circulation model. This strategy estimates the pathway of the water mass that travels from an origin to a destination area during a specific period using a conservation property concerning tangent linear and adjoint models. In our analysis, a large fraction of the low salinity origin water mass of NPIW initially comes from the Okhotsk and Bering Seas, meets at the southeastern side of the Kuril Islands, and is advected to the Mixed Water Region (MWR) by the Oyashio current. It then enters into the Kuroshio Extension (KE) around the first KE ridge, and is advected eastward by the KE current. It, however, deviates southward from the KE axis around 158E over the Shatsky Rise, or around 170E on the western side of the Emperor Seamount Chain, and enters into the subtropical gyre. It is finally transported westward by the recirculation flow. This pathway corresponds well to the shortcut route of NPIW from MWR to the region south of Japan inferred from the analysis of the long-term freshening trend of NPIW observation.

Optimization of nested ocean circulation model by four dimensional variational data assimilation system

WAKAMATSU, Tsuyoshi[1*] ; ISHIKAWA, Yoichi[1]

[1]Japan Agency for Marine-Earth Science and Technology

Optimization of a regional ocean circulation model by a data assimilation system is achieved by estimating optimal initial condition and external forcing terms which include boundary values. In a nested regional data assimilation system, extracting maximum information from optimized outer model through these control variables is crucial to obtain optimal performance of the nested regional data assimilation system and many schemes were proposed in the atmospheric and oceanic data assimilation studies. In this presentation, the optimization schemes of a nested atmosphere and ocean circulation model by four dimensional variation data assimilation system are summarized in a unified framework. Their performance will be analyzed using observability matrix of a variational data assimilation system constructed on regional ocean circulation model surrounding Japan islands.

Estimated State of Ocean for Climate Research by Using a 4 Dimensional Variatinal approach

MASUDA, Shuhei[1*] ; DOI, Toshimasa[1] ; OSAFUNE, Satoshi[1] ; SUGIURA, Nozomi[1] ; ISHIKAWA, Yoichi[1] ; FUKUDA, Kazuyo[1]

[1]JAMSTEC

A 4-dimensional variational data assimilation system has been used to better define the 50-year global ocean state estimation for climate research. The synthesis of available observations and general circulation model with a pelagic ecosystem model based on nitrogen cycle yields a dynamically self-consistent dataset. Obtained ocean state estimation possibly has greater information than do models or data alone. In our 4D-VAR approach, optimized 4-dimensional analysis fields are sought by minimizing a cost function on the basis of adjoint method for physical parameters and Green's function approach for biogeochemical ones. The assimilated elements are temperature and salinity based on EN3 dataset provided by Met Office Hadley Centre, sea surface height anomaly form AVISO, nitrate from WOA05, and chlorophyll-a from WOA98 and SeaWiFS. We here present the properties of the analysis fields and some results of climate study by using this state estimation named ESTOC. This report implies that our synthesis scheme as a dynamical interpolation for sparse observations including bio-geochemical parameters is possibly promising and useful for " Integrated Earth System Analyses " .

The data assimilation systems have been developed for the initialization of the numerical weather forecasting, and applied for other fields in recent studies. In the area of ocean and climate research, there are several interesting studies to utilize the advantage of the many aspects of the data assimilation, in addition to the ”ocean weather forecasting”.

The atmosphere-ocean coupled data assimilation system using variational adjoint method is one of the unique systems, which is developed in JAMSTEC. The target of this system is the variability of seasonal to inter-annual scale so that the integrated dataset of the observation both in atmosphere and ocean are derived using variational adjoint method. The remarkable feature of the system is that the bulk coefficients are estimated as well as the initial condition of the oceanic fields since the lower boundary condition of the atmospheric model are very important for seasonal to inter-annual time scale. Recently, the marine ecosystem model are embedded into this system and seasonal forecasting not only for physical fields but also for biogeochemical fields are carried out.

For oceanic long-term reanalysis dataset, the interesting data assimilation systems are developed using variational adjoint method (Masuda et al., 2010). In this data assimilation system, strong constraint conditions are applied for entire assimilation period over 50 years, so that the derived dataset are consistent with the dynamics in ocean general circulation model. This means that the derived dataset satisfies the conservation rules and suitable for the 4-dimensional analysis of the heat and water fluxes. This advantage is also suitable for the analysis of the oceanic tracers and useful for the biogeochemical studies.

The data assimilation system for the marine ecosystem model is also notable issues. Since it is difficult to identify the optimal parameters in the marine ecosystem model, the parameter estimation studies are widely used. The realistic fields of the biogeochemical variables are successfully obtained by parameter estimation (Toyoda et al., 2013).

Development of an ensemble-based data assimilation system with a coupled atmosphere-ocean GCM

KOMORI, Nobumasa[1*] ; ENOMOTO, Takeshi[2] ; MIYOSHI, Takemasa[3] ; YAMAZAKI, Akira[1] ; TAGUCHI, Bunmei[1]

[1]Earth Simulator Center, JAMSTEC, [2]Disaster Prevention Research Institute, Kyoto University, [3]RIKEN Advanced Institute for Computational Science

To enhance the capability of the local ensemble transform Kalman filter (LETKF) with the Atmospheric general circulation model (GCM) for the Earth Simulator (AFES), a new system has been developed by replacing AFES with the Coupled atmosphere-ocean GCM for the Earth Simulator (CFES). An initial test of the prototype of the CFES-LETKF system has been completed successfully, assimilating atmospheric observational data (NCEP PREPBUFR archived at UCAR) every 6 hours to update the atmospheric variables, whereas the oceanic variables are kept unchanged throughout the assimilation procedure.

An experimental retrospective analysis-forecast cycle with the coupled system (CLERA-A) starts on August 1, 2008, and the atmospheric initial conditions (63 members) are taken from the second generation of AFES-LETKF experimental ensemble reanalysis (ALERA2). The ALERA2 analyses are also used as forcing of stand-alone 63-member ensemble simulations with the Ocean GCM for the Earth Simulator (EnOFES), from which the oceanic initial conditions for the CLERA-A are taken.

The ensemble spread of SST is larger in CLERA-A than in EnOFES, suggesting positive feedback between the ocean and the atmosphere. Although SST in CLERA-A suffers from the common biases among many coupled GCMs, the ensemble spreads of air temperature and specific humidity in the lower troposphere are larger in CLERA-A than in ALERA2. Thus replacement of AFES with CFES successfully contributes to mitigate an underestimation of the ensemble spread near the surface resulting from the single boundary condition for all ensemble members and the lack of atmosphere-ocean interaction.

In addition, the basin-scale structure of surface and subsurface ocean temperature in the tropical Pacific is well reconstructed from the ensemble correlation in CLERA-A but not in EnOFES. This suggests that use of a coupled GCM rather than an oceanic GCM could be important even for oceanic analysis with an ensemble-based data assimilation system.

Data assimilation experiment of water vapor data derived from a hyper-dense GNSS network using a nested LETKF system

OIGAWA, Masanori[1*] ; TSUDA, Toshitaka[1] ; REALINI, Eugenio[1] ; IWAKI, Yuya[1] ; SEKO, Hiromu[2] ; SHOJI, Yoshinori[2] ; SATO, Kazutoshi[3]

[1]Research Institute for Sustainable Humanosphere (RISH), Kyoto University, [2]Meteorological Research Institute (MRI), Japan Meteorological Agency (JMA), [3]Japan Aerospace Exploration Agency (JAXA)

Data assimilation of observation data with high spatial and temporal resolutions within a numerical weather prediction model is important, in order to provide it with accurate and detailed initial conditions, which generally result in improved forecast accuracy for localized heavy rainfall. Assimilation of water vapor data is especially important because water vapor has a powerful effect on the initiation and development of cumulonimbus clouds. Many assimilation studies reported on the significant and positive impact of assimilating GNSS (Global Navigation Satellite System) derived PWV (Precipitable Water Vapor) data, i.e. the vertically integrated water vapor amount, on the modification of the initial distributions of water vapor, as well as on the forecast accuracy of localized heavy rainfall. The Japan Meteorological Agency (JMA) routinely assimilates PWV data derived from the nationwide GNSS observation network (GEONET) operated by the Geospatial Information Authority of Japan (GSI), which has a horizontal resolution of about 20 km. It is expected, however, that the assimilation of PWV data with higher spatial resolution will be needed as the horizontal resolution of numerical models becomes higher. Therefore, we investigated the assimilation impact of high resolution PWV observations derived from a hyper-dense GNSS network with a horizontal resolution of about 1 km, which we installed near Uji campus of Kyoto University (Sato et al., 2013).

The data assimilation carried out in this report is based on a two-way nested Local Ensemble Transform Kalman Filter (LETKF) system (Seko et al., 2013). Experiments were performed involving a heavy rainfall event that occurred on 14 August 2012, which brought about 260 mm of accumulated rain amount in 6 hours. First, GEONET-derived PWV data were assimilated into an outer model, with horizontal resolution of 15 km. The analysis window and assimilation interval of this first experiment were 6 hours and 1 hour, respectively. Next, PWV data derived from the hyper-dense GNSS network were assimilated into an inner model, with horizontal resolution of 1.875 km. The analysis window and assimilation interval of this second experiment were 1 hour and 10 minutes, respectively. Surface observations and upper atmospheric sounding data used in operational analyses by JMA were also assimilated in both the experiments.

In an experiment without assimilation of any PWV data, the location of the reproduced rainfall region was shifted, and the precipitation intensity was lower, compared with the observation result. When GEONET-derived PWV were assimilated into the outer model and no PWV data were assimilated into the inner model, the location of the simulated rainfall system was improved, although there was no modification in precipitation intensity. When PWV derived from the hyper-dense GNSS network was assimilated into the inner model together with the assimilation of GEONET-derived PWV into the outer model, the precipitation intensity was also modified in addition to the modification of rainfall system location.

These results suggest the usefulness of assimilating high spatial resolution PWV data for heavy rainfall forecast. In the future, we are planning to investigate how the assimilation impact of high resolution PWV data will change depending on the number of observation points of the hyper-dense GNSS network. In this talk, assimilation results of slant water vapor data will also be reported, which is the accumulated water vapor amount along ray paths of radio signals from a receiver to GNSS satellites.

Data assimilation experiments of tropical cyclones with the NHM-LETKF

KUNII, Masaru[1*]

[1]Meteorological Research Institute

Intensity forecast of tropical cyclones (TCs) has still been a challenging task whereas TC track forecasts have constantly improved over the past several decades owing to advances in numerical weather prediction models as well as observational capabilities. This is partly due to the difficulties in TC initialization because TCs occur and remain almost throughout their existence over the ocean, where observational data have generally been scarce. In this study, TCVital observations are assimilated with an ensemble Kalman filtering, and their impacts are estimated by comparing with the conventional bogus assimilation scheme.

Tropical cyclone forecast using a hybrid EnKF-4DVar system

ITO, Kosuke[1*] ; KUNII, Masaru[2] ; KAWABATA, Takuya[2] ; SAITO, Kazuo[2] ; HONDA, Yuki[3]

[1]JAMSTEC, [2]MRI, [3]JMA

Analysis increment is dependent on the prescribed background error covariance **B** in addition to innovation and model dynamics that describes the development of perturbations. Traditionally, **B** is assumed to be static in time according to so-called NMC method. Following this method, the differences between pairs of forecasts valid at the same time, but having different lead times, are taken to represent the background error. While **B** in NMC method approximates the climatological background error covariance, recent studies have shown that the forecast skill of 4DVar is further enhanced by making flow-dependent **B** out of the perturbations in the ensemble-Kalman filter (EnKF) (Buehner et al. 2010). This system is referred to as Hybrid EnKF-4DVar. We have developed the meso Hybrid-4DVar system based on the meso 4DVar system (JNoVA) in the Japan Meteorological Agency since the improvements is thought to be more pronounced for severe impact weather such as tropical cyclones and heavy rainfall. In this presentation, we present a preliminary result for a forecast of tropical cyclone Talas (2011). Figure 1 shows the analysis increment of horizontal wind in the conventional 4DVar and hybrid EnKF-4DVar. The first guess of the zonal wind is overplotted. It shows a pseudo observation of wind field near the center of the tropical cyclone yields the analysis increment of a pair of cyclonic and anti-cyclonic circulations. It corresponds to a vortex displacement in the hybrid EnKF-4DVar system. In contrast, the analysis increment does not fit the structure of the tropical cyclone when using **B** based on the NMC method. It suggests that the hybrid EnKF-4DVar system reproduces the reasonable analysis increment with a little information.

Dual-Scale Neighboring Ensemble Variational Assimilation for a Cloud-Resolving Model

AONASHI, Kazumasa[1*]

[1]Meteorological Research Institute, Japan Meteorological Agency

1. Introduction

The purpose of the present study is to develop an Ensemble-based Variational Assimilation (EnVA) scheme with sampling error damping method for the Cloud-Resolving Model (CRM). This is because, in ensemble-based assimilation schemes for CRMs, sampling error is serious, in particular, for precipitation-related variables (precipitation rate, vertical wind speed) because they are confined in rainy areas.

2. Dual-Scale Neighboring Ensemble Variational Assimilation method

Based on the CRM ensemble forecast error analyses for various precipitation cases, we developed the sampling error damping method that consisted of a Neighboring Ensemble (NE) method and a dual scale separation of NE. The NE method approximated the forecast error correlation using NE members within a reduced-grid box (5 x 5 grids in the present study) based on the spectral localization assumption. In the dual scale separation, we divided the NE forecast error into large-scale portions (13 x 13 grid averages in the present study) and small-scale deviations so as to reflect the horizontal scale differences in forecast error between precipitation-related variables and others.

In order to introduce the sampling error damping method to the three-dimensional EnVA, we assumed that the EnVA analysis increments were subject to the dual scale NE forecast error subspace. In addition, we introduced a vertical reduce approximation using the primary Singular Value Decomposition (SVD) modes of the vertical cross correlation of the dual scale NE forecast error. Since the SVD modes were mutually independent, the three-dimensional cost function of EnVA resulted in that for the horizontal component of the analysis increment of the each SVD mode. Then, we horizontally diagonalized the background term of the cost function using the horizontal correlation of the NE forecast error. We used the conjugate gradient scheme to solve the nonlinear minimization of the cost function, and obtained the optimal analysis increment for the ensemble mean. Then, we calculated the analysis increments for ensemble members with the analysis error covariance at the reduced grids.

3. Results of OSSEs

In order to examine the EnVA scheme, we performed OSSEs for several meteorological disturbance cases. The results show that the NE method was successful in producing plausible analyses of precipitation-related variables from the simulated surface precipitation even for grid points where less than 20 % of the ensemble members forecasted precipitation, and that the dual scale separation of NE made spatial scale changes in analysis increments in correspondence with precipitation rates. The EnVA scheme was also successful in retrieving precipitation flags and precipitation profiles from the simulated multi-channel microwave brightness temperatures that were non-linear functions of various precipitation-related variables.

Decadal climate prediction using 4D-VAR data assimilation approach

MOCHIZUKI, Takashi[1*] ; ISHIKAWA, Yoichi[1] ; MASUDA, Shuhei[1] ; AWAJI, Toshiyuki[2]

[1]JAMSTEC, [2]Kyoto University

It is very recently that decadal climate prediction experiments have been carried out with initialization. As a first step in decadal prediction, simple initialization approaches have usually been used so far, particularly focusing on ocean states. An advanced initialization technique is a pressing concern toward further enhancing the decadal predictability by obtaining suitable atmospheric and oceanic initial conditions that are compatible with both the model and observations. Here, by employing a 4D-VAR data assimilation approach to initialize the atmosphere-ocean coupled climate model, we attempt to perform ensembles of decadal hindcast experiments in line with the CMIP5 protocol. We perform full-field initialization rather than anomaly initialization and assimilate the atmospheric states together with the ocean states. We can validate the predictive skills in the atmosphere and ocean temperature hindcasts in some areas and, roughly speaking, the spatial patterns of the hindcast skills are similar to those of the multi-model ensembles of the CMIP5 decadal hindcasts. While our assimilation system has been developed originally for the purpose of seasonal-to-interannual climate simulations and we use 9-month assimilation window in these experiments, the hindcast results suggest that the atmosphere and ocean states associated with low-frequency variations beyond annual timescales can also be effectively initialized through the iterations of the forward and backward runs of the 4D-VAR data assimilation.

Assimilation of TRMM-PR bright band heights

ENOMOTO, Takeshi[1*] ; YAMAMOTO, Munehisa[2]

[1]Disaster Prevention Research Institute, Kyoto University, [2]Graduate School of Science, Kyoto University

Bright band heights in TRMM PR 2A23 are assimilated as temperature observations. Bright bands are strong radio echo from the melting layer. Bright band heights are located several hundred m below the 0C isotherms (Harris et al. 2000). In the TRMM PR algorithms (Awaka et al 2009), bright band heights are computed as the nadir projection of the distance between the satellite and the Earth ellipsoid minus the distance between the bright band peaks. Although the 0C isotherms from reanalysis or operational analysis are required in detection of bright bands, bright band heights are direct observations. Because bright band heights are valuable information to complement sparse direct measurements over ocean, the analysis can be improve when assimilated. Satellite radiances are mainly used in cloud-free area and assimilation of water substances are not straightforward. By contrast, because bright bands are associated with stratiform clouds, bright band heights are easily assimilated as conventional data over cloudy regions.

The data assimilation system ALEDAS2 (Enomoto et al. 2013) used in this study is composed of the atmospheric general circulation model for the Earth Simulator (AFES) and the local ensemble transform Kalman filter (LETKF). The resolution of the model is T119L48 (1 degree horizontally and 48 levels vertically) and the ensemble size is 63. ALERA2 produced with this system is regarded as the control. Bright band observations are processed as follows. First, each record is regarded as a 0C temperature observation at 500 m above the bright band height. Second, in order to avoid excessive horizontal correlations and computational load, super-observations are produced by the average of observations within 0.5 degree radius linearly weighted with the distance and converted to the LETKF input format in the 1 h window.

The number of the original bright band heights in January 2010 is 2572986 and that of the super-observations is 61905. The super-observations are widely distributed in the tropics and subtropics between 35S and 35N. In the Northern Hemisphere bright bands are clustered along the 30N over ocean, indicating bright bands due to stratiform associated with cyclones along the storm track (Yamamoto et al. 2006). A few bright bands are detected in the horse latitudes between the equator and 25N. In the Southern Hemisphere bright bands are distributed in the tropical and subtropical convergence zones. ALEDAS2 uses the 7 h data window for each analysis time every 6 h. The number of temperature observations increases by a few percent in synoptic hours of 0 and 12 UTC, but by a factor of 1.5 or 2 at 6 and 18 UTC.

In a preliminary experiment from 0 UTC 3 January for 4 d, the analysis ensemble spread, a measure of the analysis error, is reduced by 0.51 Pa and 0.94 Pa over the globe and in the Souther Hemisphere (35S–0), respectively at 0 UTC 7 January. The root mean square of the analysis increment increases by 2.4 % and 5.9 % in the global domain and in the Souther Hemisphere (35S–0).

A Study on the Structure of Instability in the Mesosphere Using a High Resolution General Circulation Model

SATO, Kaoru[1] ; MASUDA, Akihiro[1*] ; OKAMOTO, Kota[1]

[1]Dept Earth & Planetary Sci., The University of Tokyo

It is well known that in the winter mesosphere, a necessary condition of barotropic and/or baroclinic instability, i.e., negative latitudinal gradient of potential vorticity (PV), is frequently satisfied. This study examines dynamical mechanism of the formation of such instability condition in boreal winter using high-resolution general circulation model data. This model does not include gravity wave (GW) parameterizations and hence all GWs are resolved, allowing us to analyze GWs directly. This is a strong advantage of our study because GWs are quite important for the momentum budget in the mesosphere. First, the 2-d TEM analysis was made. It is shown that the negative PV gradient is regarded as an enhanced PV maximum. This maximum is due to the poleward shift of the westerly jet in associated with strong EP-flux divergence caused by planetary waves from the troposphere. Strong GW drag slightly above the westerly jet shifts poleward as well, which can be understood by a selective GW-filtering mechanism. It seems that this GW-drag shift induces strong upwelling in the middle latitudes and adiabatically cools the middle mesosphere. Resultant enhanced static stability is the main cause of the PV maximum in the upper mesosphere. Because of the dominance of planetary waves during this event, this process may not be zonally uniform. Thus, the 3-d analysis was made using recent theoretical formula by Kinoshita and Sato (2013). As expected, the GW drag is distributed depending on the longitude. The zonal structure of PV maximum is consistent with the GW drag distribution. An interesting fact is that the spatial distribution of GW drag is not largely correlated with that of the zonal wind at the same level but highly correlated with that in the stratosphere. This result indicates that the mesosphere reflects the zonal structure of the stratosphere via the selective GW filtering.

Dynamical mechanism of multiple tropopause structure observed over Syowa Station

SHIBUYA, Ryosuke[1*] ; SATO, Kaoru[1]

[1]Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo

Multiple tropopauses which are determined following the definition by the World Meteorological Organization (WMO) were detected in winter at Syowa Station (69.0S, 39.6E). It is shown that the multiple tropopause structures were observed along with a descent of the first (i.e., lowest) tropopause five times in the autumn period from 1 April and 16 May 2013. A detailed analysis using data from the PANSY radar and radiosonde observations was performed for a typical case in 8-11.

The mechanism of the multiple tropopause structure was analyzed using the PANSY radar and radiosonde observations. It is shown that the multiple tropopause structure was regarded as strong temperature fluctuations with a vertical length of about 3 km. Moreover, it is seen that the temperature fluctuations were out of phase with vertical wind fluctuations observed by the PANSY radar by 90o. This feature is consistent with the linear inertia-gravity wave theory. Thus, it is likely that the multiple tropopause structure above the first tropopause was due to the temperature fluctuations associated with an inertia-gravity waves (IGW) having a vertical length of about 3 km. The hodograph analysis also indicates that the multiple tropopause structure above the first tropopause is due to a monochromatic IGW.

To examine the dynamical mechanism and there-dimensional structure of this phenomenon, a numerical simulation was performed by NICAM without using any gravity wave parameterization. The model simulation period is from 0000 UTC 7 April 2013 to 0000 UTC 12 April 2013.

A close look at the time-height cross section of the zonal wind velocity and the static stability over Syowa Station indicates that the multiple tropopause structures together with the descent of the first tropopauses and associated wind disturbances were successfully simulated. A polar front jet strongly meanders in the time period from 8 April to 10 April and a tropopause folding structure is developed near Syowa Station. This means that the descent of the first tropopause was likely caused by the passage of a developing tropopause folding over Syowa Station. The IGW parameters were also consistent with those estimated by the hodograph analysis using the PANSY radar data.

Next, possible sources of the IGWs observed over Syowa Station were examined using data from the NICAM simulation. As a result, it was shown that wave packets observed over Syowa Station include gravity waves both excited by the steep topographic effect and the spontaneous adjustment process.

This mechanism is quite different from mechanisms which previous studies examined in the monsoon region or midlatitude, which is closely related to stratosphere-troposphere exchange (e.g. Randel et al. 2007). It is suggested this enable us to interpret a part of a significant seasonal sensitivity in the poles discussed by Anel et al. (2008). The static stability in the winter lower stratosphere in the Antarctic is particularly weaker than in other latitudes (Gettleman et al., 2011). It is likely because ozone heating is absent due to polar night. Based on the radiosonde observations, Tomikawa et al. (2009) also shows that the static stability in the lower stratosphere over Syowa Station is minimized in April through July. Temperature fluctuations associated with gravity waves are observed as fluctuations of the static stability. Thus, when the background static stability is sufficiently weak such as in the polar lower stratosphere, the temperature fluctuations associated with gravity waves can make local minima of the static stability which are detected as thermal tropopauses. Therefore, it is likely that multiple tropopause events due to IGWs are considered to occur frequently in the Arctic / Atarctic region in winter.

Tropical non-migrating tides appearing in a high vertical resolution GCM

SAKAZAKI, Takatoshi[1*] ; SATO, Kaoru[2] ; KAWATANI, Yoshio[3] ; WATANABE, Shingo[3]

[1]Research Institute for Sustainable Humanosphere, Kyoto University, [2]Graduate School of Science, The University of Tokyo, [3]JAMSTEC

Atmospheric tides are global scale waves with periods that are harmonics of a solar day. They are primarily excited in the troposphere and the stratosphere, and then, propagate upward. Tides are generally classified into two components: migrating (Sun-synchronous) and non-migrating (non-Sun-synchronous) tides. Although migrating tides were examined by many previous studies, a much fewer studies considered non-migrating tides particularly in the troposphere and the stratosphere. The purpose of this study is to reveal the horizontal and vertical structure of non-migrating tides and its seasonal variations in the region from the troposphere to the mesosphere, as well as to clarify the underlying physical processes.

In this study, data from a high-resolution (T213L256) global spectral climate model (Watanabe et al., 2008) are analyzed. This model covers quite a wide height range from the ground surface to the upper mesosphere (80 km in altitude), enabling us to investigate the full tidal coupling between the lower and upper atmosphere. Also, the vertical resolution is ˜300 m in the vertical, which is almost sufficient to simulate realistic propagation and momentum deposition of gravity waves including tides. We compared the model data with data from COSMIC GPS-RO measurements and TIMED/SABER satellite measurements, and confirmed that the model captures the observed characteristics at least qualitatively.

In the model data, we clearly see that non-migrating tides are mainly excited over the two large continents: over Africa and South America. The excited tides are propagating three-dimensionally like internal inertia-gravity waves. During the propagation, tides with small wavenumbers are filtered out by background zonal wind (e.g., stratospheric semiannual oscillation (SAO)). Thus, both excitation and filtering processes are important for understanding the tidal variability.

Influence of topography onto the temperature variation around the tropical tropopause layer

KUBOKAWA, Hiroyasu[1*] ; FUJIWARA, Masatomo[2] ; NASUNO, Tomoe[3] ; MIURA, Hiroaki[4] ; YAMAMOTO, Masayuki[5] ; SATOH, Masaki[1]

The tropical tropopause layer (TTL) is a region where the tropospheric air passes through before entering the stratosphere. Since this region is very cold, the air from the troposphere is dehydrated around here. It is known the Kelvin wave around the TTL affects the big temperature variation and strong dehydration. We investigated the temperature variations around the TTL using the Nonhydrostatic Icosahedral Atmospheric Model (NICAM) on December 2006 (Miura et al. 2007). We found that the temperature variations associated with Kelvin waves are very large over the mountain regions. The amplitude is about 2-times larger than that over the ocean even on the same latitude. We think this result would be a new scientific discovery from simulations or finding of unknown biases of simulations. In this study, we investigate the influence of the topography on the temperature variations around the TTL using the NICAM, re-analysis, satellite, and radiosonde data. We used the Constellation Observing System for Meteorology, Ionosphere, and Climate (COSMIC) data as a satellite data in December, January and February from 2006 to 2010 in order to investigate the temperature variations. The large temperature variations (standard deviation) were found over the mountain regions. This result satisfies the 90% statistical significance level, but the number of data samples is a few. We investigated some reanalysis data having different horizontal resolutions. The standard deviations of the TTL temperature near mountains became large as the horizontal resolution of the model became high. We checked a reanalysis data of the Year of Tropical Convection (YOTC) data from ECMWF with a horizontal resolution of 0.125 degree. When Kelvin waves passed through over the Western Pacific, the amplitude of temperature was large about 2 K over the mountain regions. The power spectrum in the mountains between 7 days and 12 days was actually larger comparing with the ocean. We compared the two local radiosonde data in Jambi and Kototabang (near mountains region). We found that there was no clear difference of temperature variation. Although the temperature variations at Kototabang were slightly large, it is associated with local diurnal variations but not the wave activities. In this study, we found large temperature variation over the mountain in the observational data and numerical models. We would discuss present results and the possibility of this work.

Atmospheric gravity wave, which is generated by topography, convective activity, frontal system, jet, and/or so on, affects the formation of the basic state in the troposphere and middle atmosphere through wave convergence. It is difficult for a GCM (general circulation model) to explicitly simulate processes of generation, propagation and convergence of the gravity wave, and gravity wave drag scheme is often used in such a model. Watanabe et al. [2008] successfully simulated realistic gravity wave and basic state of the middle atmosphere using high resolution GCM (60 km in horizon and 300 m in vertical) without gravity wave drag scheme. However, propagation characteristics of the gravity wave cannot be appropriately simulated by the GCM based on the hydrostatic system, since dispersion relationship of the gravity wave is different between the hydrostatic and non-hydrostatic system. In addition, GCM cannot explicitly simulate convection, which is one of the source of the gravity wave.

We are constructing the middle-atmosphere version of the non-hydrostatic global atmospheric model, NICAM (Non-hydrostatic Icosahedral Atmospheric Model). Horizontal resolution of the NICAM is 220 km, 56 km, or 14 km. We adopt hybrid-z∗system as a vertical coordinate, in which the horizontal surface is almost flat in the middle atmosphere. Vertical level is located up to 80 km with the uniform interval in the middle atmosphere; the vertical interval is 2 km (61 layers), 1 km (91 layers), 500 m (162 layers), or 300 m (261 layers). We do not use gravity wave drag scheme and cumulus convection scheme. Other configurations are almost same as those in the standard NICAM, which is mainly used for the tropospheric research.

In this presentation, we will show initial results of the performance in the reproducibility of the basic state. Overall, zonal mean structure of the temperature and zonal wind are well simulated in both the troposphere and the middle atmosphere. Though axis of the polar night jet is biased poleward, it is somewhat improved as the vertical resolution is increased. Higher vertical resolution also brings better performance in the strength of the easterly jet in the summer hemisphere and in the QBO-like structure in the tropical lower stratosphere. In the winter hemisphere, cold bias is found around the pole in the upper stratosphere and the mesosphere, and too strong polar night jet is found. At present, the simulation tends to be numerically more unstable as the horizontal and/or vertical resolutions are increased. We will show the above points and wake up debate about the potential of the non-hydrostatic atmospheric model for future research of the whole atmosphere.

Physical interpretation on the mechanisms of spontaneous gravity wave radiation using the renormalization group method

YASUDA, Yuki[1*] ; SATO, Kaoru[1] ; SUGIMOTO, Norihiko[2]

[1]Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, [2]Department of Physics, Keio University

Gravity waves (GWs) are categorized into orographic ones and non-orographic ones. The mechanisms for non-orographic GW radiation are not clear, because the dynamics is quite nonlinear and complicated unlike orographic GWs. Recently it has been revealed that GWs are spontaneously radiated from an approximately-balanced flow, especially in the jet/front systems (e.g., O ' Sullivan and Dunkerton 1995). The balanced adjustment theory proposed by Plougonven and Zhang (2007) is considered to be the most likely to describe the spontaneous radiation. However, their theory does not give physical interpretations on GW sources and radiation mechanisms. In this study, we derived a new theory and made physical interpretations.

Using the renormalization group (RG) method (Chen et al. 1996), which is a singular perturbation method, the interaction between the vortical flow and the Doppler-shifted GWs which both have slow time-scales is formulated for the hydrostatic Boussinesq equations on the f plane. In general, the RG method enables us to extract slowly-varying components systematically and naturally from the system containing multiple timescale motions. The derived time evolution equations (RG equations, referred to as RGEs) describe the spontaneous radiation of GWs from the components slaved to the vortical flow through a quasi-resonance together with the GW radiation reaction on the large-scale vortical flow. The quasi-resonance occurs when the space and time scales of slaved components are comparable to those of GWs (quasi-resonance condition).

The RGEs are validated using numerical simulations of the vortex dipole by Japan Meteorological Agency Nonhydrostatic Model. The flow near the dipole center is quite strong due to the confluence, which is similar to a localized jet stream in the atmosphere. GW distribution obtained by the RGE integration accords well with the numerical simulation. This result supports the validity of our theory.

The main GW sources in the vortex dipole can be classified into two groups by using the RGEs. The GW sources in the first group are the slaved components produced by the horizontal divergence of acceleration of the vortical flow near the dipole center (Fig. A). The acceleration can be regarded as the sum of Coriolis and pressure gradient forces. This fact indicates that the GW sources express the horizontal compression of fluid. The horizontal compression can produce vertical motion, which radiates GWs when its space and time scales satisfy the quasi-resonance condition. This radiation mechanism corresponds to the velocity-variation mechanism proposed by Viúdez (2007).

The slaved component in the other group is mainly produced by the vortical flow over the deformed potential temperature surfaces (Fig. B). The deformation of potential temperature surfaces can be attributed to the Bernoulli effect due to the strong vortical flow near the dipole center. The vortical flow over the deformed potential surfaces can produce vertical motion, which radiates GWs when its space and time scales satisfy the quasi-resonance condition. In other words, the deformed potential temperature surfaces act like a mountain as in the radiation process of orographic GWs. This radiation mechanism corresponds to the mountain-wave-like mechanism proposed by McIntyre (2009).

QBO-like oscillation in a radiative-convective equilibrium state obtained with a two-dimensional moist convection model

YODEN, Shigeo[1*] ; BUI, Hoang-hai[2] ; NISHIMOTO, Eriko[1]

[1]Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, [2]Hanoi University of Science

Quasi-Biennial Oscillation (QBO) is a prominent internal variations in the equatorial stratosphere due to the interactions between a mean zonal wind and waves that propagate upward in the stratosphere. Over two decades ago, Held et al. (1993) investigated radiative-convective equilibrium states with a two-dimensional explicit moist convection model and obtained a QBO-like oscillation. Their model contains the fundamental dynamical processes of the QBO, though it is a highly-idealized two-dimensional model for a periodic domain without Coriolis effects. In this study, we re-examine the QBO-like oscillation found by H93 with a long enough integration period over two years, by using Advanced Research WRF Modeling System. We also investigate the sensitivity of the QBO-like oscillation in regards of different factors such as domain size, resolution and boundary conditions (e.g., prescribed zonal wind at the top and sea surface temperature).

The control experiment has a similar configuration to that of Held et al.; 640km domain width with a resolution of 5km, 130 vertical levels up to 26km. Convective parameterization is turned off in all simulations and only a cloud microphysics scheme is used. Other physics options are standard ones for short- and long-wave radiations, surface fluxes, planetary boundary layer, turbulence and diffusion, and Rayleigh damping near the top boundary. After spin up, the mean zonal wind shows a clear QBO-like oscillation with a period of 120.6 days. Unlike the observed QBO, the oscillation has a clear signal in the troposphere, in which moist convections dominate and gravity waves are generated. Such convectively generated gravity waves propagate into the stratosphere to produce the QBO-like oscillation in the stratosphere. On the other hand, intensity and propagation of organized convective systems, including zonal mean precipitation, are modulated in accordance with the oscillation of mean zonal wind in the troposphere.

Interannual changes of the semiannual oscillation induced by stratospheric sudden warming events

OHATA, Tsuyoshi[1*] ; IIDA, Chihiro[1] ; HIROOKA, Toshihiko[3] ; EGUCHI, Nawo[2]

[1]Graduate School of Science, Kyushu University, [2]Research Institute for Applied Mechanics, Kyushu University, [3]Faculty of Science, Kyushu University

The semiannual oscillation (SAO) is observed in circulation changes in the equatorial middle atmosphere, which consist of two separate maxima centered near the stratopause (SSAO) and the upper mesosphere (MSAO) with an approximate out-of-phase relathionship between the two [e.g., Andrews et al., 1987]. The SSAO has eastely and westerly maxima at solstices and equinoxes, respectively, while the MSAO shows an out-of-phase change with the SSAO. It is known that somewhat different consideration must be made between the SSAO and the MSAO for their forcing mechanisms, and it seems to be also true of their interannual changes. In this study, we make global gridpoint data for geopotential and temperature fields up to the mesopause level derived from Aura MLS data, to make dynamical analyses for equatorial zonal wind and temperature changes since August 2004 to present. It is found that the strength of both the SSAO and MSAO might be modulated by stratospheric sudden warming (SSW) events in boreal winter solstices. In the equatorial regions, enhanced poleward flows of the residual meridional circulation associated with SSW events lead to temperature perturbations consisting of a cooling in the stratosphere and a warming in the mesosphere. Such temperature perturbations may bring about opposite changes in the SSAO and the MSAO through the thermal wind balance at the equator, leading to their amplifications.

Recent variability and zonal asymmetry in upper troposphere and lower stratosphere observed with GPS radio occultation m

MEHTA, Sanjay[1*] ; TSUDA, Toshitaka[1] ; FUJIWARA, Masatomo[2] ; SCHMIDT, Torsten[3] ; VERNIER, Jean-paul[4]

[1]Research Institute for Sustainable Humanosphere (RISH), Kyoto University, Japan, [2]Faculty of Environmental Earth Science, Hokkaido University, Japan, [3]GFZ German Research Centre for Geosciences, Potsdam, Germany, [4]NASA Langley Research Center, Hampton, VA 23666, USA.

Tropical upper troposphere and lower stratosphere (UTLS) variability and zonal asymmetry are explored using global positioning system radio occultation (GPS-RO) measurements. GPS-RO offers global monitoring of fine structures of the UTLS temperature variability. GPS-RO continuous measurements from CHAMP (2001-2006) and COSMIC (2006-2013) for about 13 years allows us to study the interannual variability, trends (over the last decade) and its fine zonal structures. The warming of UTLS temperatures between 100 and 50 hPa, warming of tropopause and decrease in its height have been observed over the last decade. The possible reasons for such changes linking to the recent moderate volcanic eruptions and dynamical changes involving changes in sea surface temperature and Brewer Dobson circulation will discussed. The variability and structure observed in GPS-RO will be compared with existing conventional radiosonde and reanalysis datasets.

The role of the mid-latitude oceanic front in the ozone-induced climate change in the Southern Hemisphere

OGAWA, Fumiaki[1] ; OMRANI, Nour-eddine[2] ; NISHII, Kazuaki[1*] ; NAKAMURA, Hisashi[1] ; KEENLYSIDE, Noel[3]

[1]RCAST, University of Tokyo, [2]GEOMAR, University of Kiel, [3]Geophysical Institute, University of Bergen

The Southern Hemisphere Annular Mode (SAM) is the dominant mode of low-frequency atmospheric variability in the extratropical Southern Hemisphere, exerting substantial impacts on regional distributions of temperature and precipitation. Its multi-decadal trend in the troposphere observed in late 20th century has been related to the lower-stratospheric changes induced by the ozone depletion. Known as a manifestation of meridional shift of the eddy-driven polar-front jet (PFJ), which is collocated with the storm-track, the SAM variability may be sensitive to the near-surface baroclinicity associated with the midlatitude oceanic frontal zone.

In the present study, aqua-planet atmospheric general circulation model experiments are conducted with two different zonally symmetric profiles of sea-surface temperature (SST) whose frontal gradient in midlatitudes is retained or eliminated. A comparison of the tropospheric response to the assigned stratospheric ozone depletion between the two SST profiles reveals critical importance of the frontal SST gradient for the intensified stratospheric polar vortex, which is due to the ozone depletion, in triggering and keeping positive phase of the tropospheric SAM in late spring through summer.

We also reveal that the SAM trend in late 20th century simulated in CMIP3/5 models is sensitive to the position and intensity of the mid-latitude oceanic frontal zone. Specifically, a model that simulates the zonal-mean frontal zone at higher latitude tends to simulate the maximum positive trends in the zonal-mean westerlies and midlatitude precipitation also at higher latitudes than another model with the oceanic frontal zone at lower latitude. This relationship is more obvious in a subset of the models with the relatively strong oceanic fronts.

[1]EES, Hokkaido Univ., [2]RISH, Kyoto Univ., [3]Oxford Univ.

The global climate response to the eruptions of Mount Agung in 1963, El Chichón in 1982 and Mount Pinatubo in 1991 is investigated using 9 reanalysis datasets (ERA-40, ERA-Interim, JRA-25/JCDAS, JRA-55, MERRA, NCEP/NCAR, NCEP/DOE, NCEP-CFSR, and 20CR). Multiple linear regression is applied to the zonal and monthly mean time series of key dynamical variables by considering the components of linear trends, seasonal variations, the Quasi-Biennial Oscillation (QBO), solar cycle, and El Nino Southern Oscillation (ENSO). The residuals are used to define the volcanic signals. Latitude-altitude distributions of the volcanic signals and of the regression coefficients are compared and discussed among the different reanalyses. In response to the Mount Pinatubo eruption most reanalyses show statistically significant negative and positive temperature anomalies in the tropical troposphere and in the tropical lower stratosphere, respectively. The signals are similar for the El Chichón eruption, with a statistically insignificant tropospheric response. The response to the Mount Agung eruption is asymmetric about the equator with significant warming in the Southern Hemisphere midlatitude upper troposphere to lower stratosphere. This work is a contribution to the SPARC Reanalysis Intercomparison Project (S-RIP).

Simulation of stratospheric aerosol changes after the Pinatubo eruption

SEKIYA, Takashi[1*] ; SUDO, Kengo[1]

[1]Graduate School of Environmental Studies, Nagoya University

An explosive volcanic eruption can inject a large amount of SO_2 into the stratosphere, which is oxidized to form sulfate aerosol. Such aerosol has an impact on the Earth's radiative budget by enhancing back-scattering of the solar radiation, and causes stratospheric ozone depletion through heterogeneous chemical reactions. This study investigates spatiotemporal changes in the volcanic aerosol after the 1991 Pinatubo eruption. We particularly focus on impacts of (1) heating due to volcanic ash, (2) injection height, and (3) temporal evolution of the aerosol radius, on transport and distribution of the volcanic aerosol. We conducted a control simulation and three sensitivity simulations using the MIROC-ESM-CHEM chemistry — climate model. In the control simulation, 20 Mt of the SO_2 and 30 Mt of the ash were injected into the altitudes between 16 km and 18 km over the Mt. Pinatubo on June 15th 1991. The radius of stratospheric sulfate aerosol is prescribed by the data estimated from SAGE II in the control simulation. The first sensitivity simulation injected only the SO_2 into the altitudes between 16 km and 18 km. The second sensitivity simulation injected the SO_2 into the altitudes between 17 km and 26 km. In the third sensitivity simulation, the radius of the sulfate aerosol was fixed to 0.08 μm. The control simulation reproduced a general feature of the observed aerosol optical depth (AOD) derived from SAGE II and AVHRR, although the simulated residence time of the aerosol is longer than the observed one. The sensitivity simulations show the following: (1) heating due to the ash causes an anomalous upward and equatorward transport of the volcanic aerosol during 4 — 5 days after the eruption, (2) the SO_2 injection into the altitudes of 17 — 26 km does not represent the anomalous transport due to the heating which is caused by long-wave absorption of the ash , (3) the temporal evolution of the aerosol radius slightly facilitates the removal of the aerosol from the stratosphere.

Recent Results for Middle Atmospheric Sciences using Data from SMILES

SHIOTANI, Masato[1*]

[1]Research Institute for Sustainable Humanosphere, Kyoto University

The Superconducting Submillimeter-Wave Limb-Emission Sounder (SMILES) aboard the Japanese Experiment Module (JEM) of the International Space Station (ISS) made atmospheric measurements of minor species in the stratosphere and mesosphere for about six months from October 2009 to April 2010. Data for scientific community are now provided from DARTS (Data ARchives and Transmission System) of ISAS/JAXA (http://darts.isas.jaxa.jp/iss/smiles/). In this talk, we will present recent results from the SMILES measurements in association with middle atmospheric chemistry and dynamics. The main topics to be highlighted are as follows.

[Diurnal ozone variations in the stratosphere] The SMILES observations have revealed the global pattern of diurnal ozone variations throughout the stratosphere. The peak-to-peak difference in the stratospheric ozone mixing ratio reaches 8% over the course of a day, suggesting careful consideration when merging ozone data from different satellite measurements (Sakazaki et al., 2013).

[Ozonesonde bias suggested from comparisons with SMILES] The SMILES ozone data have been extensively compared with other satellite data sources (Imai et al., 2013a). Further comparisons of SMILES ozone profiles with those from ozonesondes show that the agreement was generally good, but at low latitudes the SMILES ozone data showed larger values than those at middle and high latitudes. To explain this bias, we examined an issue of the ozonesonde's response time, and found a negative bias in ozonesonde measurements more than 7% at 20 km in the equatorial latitude (Imai et al., 2013b).

[Mesospheric ozone variations during the solar eclipse] During the annular solar eclipse on 15 January 2010, SMILES successfully captured temporal changes in ozone concentration. We found that in the lower mesosphere ozone amounts get closer to the normal nighttime average, and the mechanism is detailed with use of an atmospheric chemistry box model (Imai et al., 2014).

Stratospheric ClO observation by JEM/SMILES

SUZUKI, Makoto[1*] ; MANAGO, Naohiro[2] ; MITSUDA, Chihiro[3] ; IMAI, Koji[1] ; OZEKI, Hiroyuki[4] ; SAKAZAKI, Takatoshi[5] ; SHIOTANI, Masato[5]

[1]JAXA/ISAS, [2]Chiba U./CEReS, [3]Fujitsu FIP.Corporation, [4]Faculty of Science, Toho University, [5]Kyoto U./RISH

SMILES operated on the ISS from Oct. 12, 2009 to Apr. 21, 2010. Since the detector (Superconductor-Insulator-Superconductor: SIS mixer) was cooled down to 4K, SMILES showed system noise figure, Tsys ˜250K, or spectral noise floor ˜0.4K, which gave one order better signal to noise ratio compared to previous sub-mm observations from space (Aura/MLS and Odin/SMR).

Aura/MLS have been measuring ClO with a 0.1 ppbv precision at 25-50km altitude. Theoretical precision of SMILES has been reported to be about 0.01 pptv at 30 km. This value can be verified from bin-width of histogram of nighttime ClO, which should be almost zero below 35km at the background atmosphere. We obtained actual bin-width, or ClO random error, to be 0.015 pptv, which is slightly larger than the theoretical value. It has been estimated that

the additional random error might come from IFOV pointing error, a priori pressure error, or baseline fitting error.

In tropical region (N10-S10), difference between day and night profiles was 792 pptv at 25km. This result agreed quite well with reproductive calculated value (nearby 80 pptv) by using Chemical Transport Model (SD-WACCM). On the other hand, in middle latitude (N30-50) during Mar. 13-25, 2010, SMILES value were 712 pptv at 22km, and 352 pptv at 19 km. These value were significantly larger that reported as 10 pptv by airplane and balloon observation in 1986. SMILES mid-latitude value is about 3-7 times higher than the past observation, however, agrees with reproductive calculated value like as tropical region. These discrepancy in the mid-latitude between SMILES and past observation can be explained partly by the historical increase of total Clx from 2.4 pptv in 1968 to the present value, ˜3.0 ppbv.

Correlation between O_3 and HCl in the lower stratosphere as observed by SMILES

SUGITA, Takafumi[1*] ; KASAI, Yasuko[2] ; TERAO, Yukio[1] ; HAYASHIDA, Sachiko[3] ; SAGAWA, Hideo[2] ; SUZUKI, Makoto[4] ; SHIOTANI, Masato[5]

[1]NIES, [2]NICT, [3]Nara Women's Univ., [4]JAXA, [5]Kyoto Univ.

Ozone (O_3) in the upper troposphere (UT) has an effect on radiative forcing. One of poorly constrained source of tropospheric O_3 is the stratosphere. Marcy et al. (Science, 2004) have suggested that measurements of HCl in the UT can be used to calculate how much O_3 was transported from the lower stratosphere (LS). Using the correlation between O_3 and HCl in the LS, a fraction of the source of the stratosphere has been quantified from measurements in the UT. To perform such a study, it is important to establish the O_3/HCl correlations in the LS. Here, we will present the O_3/HCl correlations as observed by the Superconducting Submillimeter-Wave Limb-Emission Sounder (SMILES) on board the International Space Station (ISS) (Kikuchi et al., JGR, 2010). We first focus on latitudes between 30^{o}S and 66^{o}S in periods of November 2009, February 2010, and April 2010, when SMILES mainly covered the Southern Hemisphere (S.H.). Both the slope and intercept of the O_3/HCl correlation in the S.H. Feb. are larger than those in Nov. (outside the Antarctic vortex). This is probably due to mixing of air inside and outside the Antarctic vortex, where the enhanced HCl values were observed only inside the vortex (The break-up of the vortex occurred in Dec. 2009 in the LS). Then, hemispheric contrasts in spring and fall will also be presented. In the S.H. Nov. (late spring), the slope is larger than that in the N.H. Apr. (30-66^{o}N). Also, in the S.H. Apr. (fall), the slope is larger than that in the N.H. Oct. (30-66^{o}N). Although, the reason for these larger slopes in the S.H. is not known, the O_3/HCl correlations obtained from SMILES give recent references for the mid to high latitude LS in both the hemispheres.

Reincrease of total columns of HCl and HF observed with FTIR at Tsukuba

MURATA, Isao[1*] ; NAKAJIMA, Hideaki[2] ; MORINO, Isamu[2] ; AKIYOSHI, Hideharu[2]

[1]Graduate School of Environmental Studies, Tohoku University, [2]National Institute for Environmental Studies

The vertical column densities of HCl and HF have been observed with high-resolution Fourier transform spectrometer at Tsukuba, Japan since 1998. SFIT1 spectral fitting program was used to derive the vertical column densities.

HCl and HF are the reservoir species of Chlorine and Fluorine, respectively. Chlorofluorocarbons are the main sources of both of them.

Daily averaged HCl column increased from 1999 to 2001, decreased from 2003 to 2006 and again increased after 2007. Daily averaged HF column increased from 1999 to 2002, level off from 2003 to 2006 and again increased after 2007. The trend fitting shows -1.8%/yr (2001-2006) and +1.0%/yr (2007-2013) for HCl, and +0.3%/yr (2001-2006) and +2.5%/yr (2007-2013) for HF.

The reason why HCl and HF increase again has not been investigated yet but this increase may lead to the delay of ozone recovery. One possible reason is the change of atmospheric circulation. Simulation result of chemical transport model with observed meteorological data (ERA-interim) shows stop of decrease of HCl at around 2008 while the result without observed meteorological data shows continuous decrease. Another possible reason is the increase in emissions of HCFCs and HFCs which increased the input of Cl and F to the stratosphere but there is no observational evidence.

The impact of altitude mis-estimation caused by Vaisala RS80 pressure bias on ozone and temperature profile data

INAI, Yoichi[1*] ; SHIOTANI, Masato[1] ; FUJIWARA, Masatomo[2] ; HASEBE, Fumio[2]

[1]RISH, Kyoto Univ., [2]EES, Hokkaido Univ.

Non-biased meteorological data are necessary for studies for detecting long-term climate change. Vaisala RS80 radiosonde is widely used for operational and scientific observations. It has been known, however, that the RS80 has pressure bias. The pressure bias affects height information of the profile in a traditional way where the geometric height (or geopotential height in some cases) is calculated from the hydrostatics equation. In addition, the pressure measurements affect the mixing ratio values of any chemical species because the calculation needs air pressure value. The RS80 pressure bias is estimated to be -0.3 $\pm$0.2 hPa, -0.4 $\pm$0.1 hPa, and -0.4 $\pm$0.1 hPa (1σ) at 20 km, 25 km, and 30 km, respectively from the observations using RS80 together with global positioning system (GPS) sensor in the Soundings of Ozone and Water in the Equatorial Region (SOWER) project during from December 2004 to January 2010. Since ozone mixing ratio and temperature are also measured simultaneously, the impact of the mis-estimated altitude on observed profiles of ozone and temperature was evaluated. The net biases of -1.3 $\pm$1.4%, -0.5 $\pm$0.7%, and 3.1 $\pm$1.9% (1σ) at 20 km, 25 km, and 30 km, respectively for ozone mixing ratio and that of -0.1 $\pm$0.2 K, -0.2 $\pm$0.3 K, and -0.4 $\pm$0.7 K (1σ) at 20 km, 25 km, and 30 km, respectively for temperature are estimated as impacts from RS80 pressure bias. Those ozone and temperature biases can result in artificial variation in the long-term meteorological records when there is a radiosonde change from or to RS80. Especially, sign-reversed biases of ozone and temperature appear as artificial variations when the instrument is changed from RS80 to non-pressure-biased radiosonde (for example GPS sonde).

Total ozone reduction over Rio Gallegos (Argentina) in November 2009 simulated by MIROC3.2 Chemical Transport Model

AKIYOSHI, Hideharu[1*] ; KADOWAKI, Masanao[1] ; NAKAMURA, Haruna[2] ; SUGITA, Takafumi[1] ; NAKAMURA, Tetsu[3] ; MIZUNO, Akira[4]

[1]NIES, [2]Fujitsu FIP, [3]Arctic Environment Research Center, NIPR, [4]STEL, Nagoya University

de Laat et al. (Geophys. Res. Lett., 2010) reported three weeks of reduced total ozone columns over the southern tip of South America in November 2009. The duration of the low total ozone was unusual for the regions. Ozone vertical profile measurements at Rio Gallegos, Argentina (51S, 69W) by ozone LIDAR suggest that the isentropic surfaces of 675K and 475K over Rio Gallegos was inside the Antarctic polar vortex around 13-14 November and 22-23 November respectively thus the low total ozone lasted for three weeks (Wolfram et al, 5th SPARC General Assembly, Queenstown, New Zealand, 2014). MIROC 3.2 Chemical Transport Model with a horizontal resolution of T42 (corresponding to 2.8 degree by 2.8 degree in grids) simulates this long term reduced total ozone over Rio Gallegos. The dynamical and chemical fields around the Antarctica in November 2009 are analyzed. Investigations of these fields for the other past years and comparisons with those in 2009 will be performed.

Relationship between total ozone and wave activities in Antarctic region

KADOWAKI, Masanao[1*] ; AKIYOSHI, Hideharu[1] ; YAMASHITA, Yousuke[1] ; NAKAMURA, Tetsu[2]

[1]National Institute for Environmental Studies, [2]Arctic Environment Research Center, National Institute of Polar Research

It is well known that the formation, development and inter-annual variation of the ozone hole are related to the dynamics in winter polar stratosphere. Stratospheric sudden warming was detected in the Southern Hemisphere in 2002 for the first time and then the ozone hole area (defined by the area inside 220DU) was reduced to less than 5 million square kilometers. A similar reduction of ozone hole was also simulated by CCSR/NIES CCM with CCMVal-REF2 scenario, in which the wave number 2 was unusually developed.

These suggest a possibility that ozone hole may suddenly be reduced in a specific year by the dynamics in the future, apart from the effect of the decrease in chlorine and bromine concentration in the atmosphere due to the halogen regulation. Thus, in order to speculate ozone hole trend and the variability in the course of the long-term climate change of the future, it is needed to clarify the relationship between wave activity and ozone hole in the past. Relationships among the ozone hole indices (maximum ozone hole area and minimum total ozone), wave activity and temperature in the Southern Hemisphere were investigated using observation data and chemical transport model output.

Interannual and intraseasonal variability of gravity waves revealed from high resolution AIRS observations

TSUCHIYA, Chikara[1] ; SATO, Kaoru[1*] ; ALEXANDER, M. joan[2] ; HOFFMANN, Lars[3]

[1]University of Tokyo, [2]NorthWest Research Associates, [3]Forschungszentrum Juelich

An analysis was made of high-resolution temperature data from satellite onboard Atmospheric Infrared Sounder (AIRS) over eight years from 2003/2004 to 2010/2011 to examine gravity wave (GW) characteristics around an altitude of 40 km in terms of the interannual and intraseasonal variability in austral summer (DJF). AIRS is a nadir-view instrument and sensitive to the temperature fluctuations with vertical wavelengths greater than 15 km. The S-transform was applied to the data series in both cross-track or along-track directions to estimate GW characteristics. First, the DJF-mean time series of GW amplitudes and precipitation were regressed to the sea surface temperature time series in NINO.3 region. It is shown that both GW amplitudes and precipitation are large to the northeast (southwest) of the South Pacific convergence zone (SPCZ) in the El Nino (La Nina) phase. Second, the intraseasonal variation of GWs were examined in terms of the Madden-Julian Oscillation (MJO). Ten-day-mean time series was examined as a function of the longitude for GW amplitudes and precipitation that were averaged over the latitudes of 0-20S. Large GW amplitudes are observed in association with the eastward migrating precipitation of MJO, which is more clearly described by a regression to the Real-time Multivariate MJO Index. Another interesting finding is that the GW amplitudes are significantly weak when the zonal wind at 100 hPa is eastward regardless of the precipitation amount. These results suggest that the interannual and intraseasonal variations of GWs in the subtropical middle stratosphere are modified largely by ENSO and MJO through the precipitation as GW sources and the zonal wind around the tropopause regulating GW vertical propagation.

Balloon-borne observations of lower stratospheric water vapor at the Antarctic Syowa Station

TOMIKAWA, Yoshihiro[1*] ; SATO, Kaoru[2] ; TSUTSUMI, Masaki[1] ; NAKAMURA, Takuji[1] ; HIRASAWA, Naohiko[1]

[1]National Institute of Polar Research, [2]The University of Tokyo

A variation of water vapor in the lower stratosphere has a large radiative forcing. It is considered that increase and decrease of lower stratospheric water vapor before and after 2000, respectively, altered the surface temperature trend by up to 30% in each period. However, since the water vapor content abruptly changes with height around the tropopause, it is hard to capture its variation exactly by satellite observations with a low vertical resolution. Many in-situ (i.e., balloon-borne and aircraft) observations with a high vertical resolution have been performed in low and middle latitudes, but few in the polar region. At the Antarctic Syowa Station (69.0S, 39.6E), three balloon-borne cryogenic frost-point hygrometer observations were performed in 2013 by the 54th Japanese Antarctic Research Expedition (JARE54), so that high precision and high vertical resolution data up to about a 25km altitude were obtained successfully. In this paper, a preliminary result of these observations is presented, and it will be discussed how important it is to continue the water vapor observation at Syowa Station.

Three dimensional structure of planetary wave activity from tropical to extratropical regions in ENSO

KINOSHITA, Takenari[1*] ; SATO, Kaoru[2] ; HITCHMAN, Matthew, H.[3]

[1]Ntnl. Inst. of Information Comm. Tech., Japan, [2]Graduate School of Science, The University of Tokyo, [3]University of Wisconsin, Madison

It is kwon that the distribution of extratropical column ozone is modulated with El Nino Southern Oscillation (ENSO) (Hitchman and Rogal 2010a, b). This modulation is recognized as the 10 ˜20 day-scale responses including ”Tropical convective outflow into the upper troposphere and lower stratosphere”, ”amplification of subtropical anticyclone associated with transport of low potential vorticity” and ”modulated synoptic scale disturbances in extratropical regions”. On the other hand, it is suggested that planetary scale disturbances influence the distribution of extratropical column ozone. However, this is yet to be identified. The present study examines the modulation of planetary wave activity associated with ENSO from upper troposphere to stratosphere using the formulae describing wave-mean interaction in three dimensions and analytical techniques derived by Kinoshita and Sato (2013a, 2013b) , Sato et al. (2013).

First, we use the ERA-Interim reanalysis data and focus from August to October. Based on the Ocean Nino Index by NOAA, 1991, 1997, 2002, 2004, 2006, 2009 are selected as El Nino seasons and 1998, 1999, 2000, 2007 are selected as La Nina seasons. The Planetary scale disturbances are defined as the waves with zonal wavenumbers 1 ˜3 and periods more than 30 days.

We calculated the three dimensional wave activity flux and its divergences associated with the planetary scale disturbances. The results show that the planetary wave activity is amplified around Asian monsoon regions in La Nina seasons and the planetary wave propagates from tropical upper troposphere to polar stratosphere. The planetary wave activity in El Nino seasons is weak in this region. On the other hand, in the eastern pacific regions, the planetary wave activity in El Nino seasons is amplified and the planetary wave propagates from tropical upper troposphere to polar stratosphere, while the activity in La Nina seasons is weak. It is suggested that the source of tropospheric planetary waves is different between tropical and polar regions in both seasons. We plan to calculate the three dimensional material transport associated with the planetary waves and compare the transport and that associated with the mechanism shown by Hitchman and Rogal (2010a, b).

A study of Antarctic ozone variation by using FORMOSAT-3/COSMIC observation

HSIAO, Chun-chieh[1] ; LIU, Jann-yenq[1*] ; YU, Shiann-jeng[1]

[1]National Space Organization

The Formosa Satellite 3, also named as the Constellation Observing System for Meteorology, Ionosphere, and Climate (abbreviated as FORMOSAT-3/COSMIC, F3/C), is a constellation of six micro-satellites, designed to monitor weather and space weather. The constellation was launched into an initial circular low-Earth orbit at an altitude of 512 km on 15 April 2006. The six micro-satellites have deployed to six mission obits at around 800 km altitude with 30-degrees separation in longitude for evenly distributed global coverage. The major payload onboard F3/C, GPS occultation experiment (GOX) instrument daily provides more than 2000 soundings of atmospheric vertical temperature profile. By binning radio occultation observations, the three-dimensional temperature structure can be obtained to monitor Antarctic temperature variation. Real-time measurements of vertical temperature structures over the Antarctic region are important for monitoring the formation of polar stratospheric clouds (PSCs) which is a critical factor in the ozone variation. On the other hand, the Ozone Monitoring Instrument (OMI) in the Aura mission observes for total ozone and other atmospheric parameters related to ozone chemistry and climate. The instrument observes Earth's backscattered radiation with a wide-field telescope feeding two imaging grating spectrometers. In this work, more than 5 years observation will be used to make a quantitative comparison of ozone and atmospheric temperature variation in Antarctic.

Interannual variations of stratospheric water vapor in microwave limb sounding observations and climate model simulation

KAWATANI, Yoshio[1*] ; JAE, Lee[3] ; HAMILTON, Kevin[2]

[1]JAMSTEC, [2]University of Maryland, [3]IPRC, Univ. Hawaii

Using the almost decade-long record of water vapor (H2O) measurements now available from the Microwave Limb Sounder (MLS) instrument on the NASA AURA satellite, the time-height structure of interannual variations in H2O content are investigated. The interannual anomalies display upward propagation below about 10 hPa in a manner analogous to the seasonal tape recorder, but at higher levels the anomalies in H2O appear to propagate downward. An explanation for this effect is sought by examining stratospheric water vapor in simulations of a fine horizontal and vertical resolution (T106L72) version of the MIROC-AGCM. This model is notable for its rather realistic simulation of the quasi-biennial oscillation (QBO) in the tropical stratosphere. The interannual anomlies in simulated stratospheric H2O display a similar propagation as seen in the MLS data. Further analysis shows that the upward propagation in the lower stratosphere is related to the mean advection of interannual water content anomalies induced by the QBO at the tropopause, while the downward propagation is due to the advection of the mean vertical gradient of water content by QBO's interannual fluctuations in the vertical wind. This conclusion is supported by additional experiments run with a modified MIROC that had a significantly different the mean vertical H2O gradient in the middle and upper stratosphere. Also analyzed are global warming simulations in both the MIROC model and in several other global models included in the recent Coupled Model Intercomparison Project 5 (CMIP5). The upward propagating interannual H2O variations are projected to become weaker in all these models because of a weakened QBO amplitude in the lowermost stratosphere.

Basic characteristics of forecast skill variations in JMA 1-month hindcast experiments

TAGUCHI, Masakazu[1*]

[1]Aichi University of Education

This study investigates basic characteristics of stratospheric predictability in the Northern Hemisphere using 1-month hindcast (HC) experiment data of the Japan Meteorological Agency for 1979-2009. We describe characteristics of forecast properties of spread, error (root mean square error), and anomaly correlation, contrasting the stratosphere and troposphere for different seasons, as well as explore the so-called spread-skill relationship for the winter stratosphere. We also examine the role of stratospheric sudden warmings (SSWs) in variations in the forecast skills. Our results show that for lead times shorter than about 10 to 15 days, the forecast skills of the HC data are higher on average and more variable in the stratosphere than in the troposphere especially for Northern winter. This is reflected in larger average and variability in predictable time limit, or characteristic time scale of useful predictions, for the winter stratosphere. We also reveal that the spread-skill relationship for the Northern winter stratosphere is characterized by the existence of notable outliers from their expected linear distribution; the outliers have markedly large errors, or low skills, for given spreads. Most of the outliers are contributed by HC sets initialized before observed major SSWs. Such HC data fail to reproduce the strength and/or shape of the stratospheric polar vortex including both onset and recovery phases of SSWs. The HC data tend to yield too strong vortex and shorter-than-average predictable limit.

The ozone depletion occurs not only in the Antarctic but also in the Arctic. A record Arctic ozone depletion which was comparable to the Antarctic ozone depletion occurred in 2011. The ozone depletion itself occurs inside the polar vortex. But the airmass from the inside of the polar vortex is spread to mid-latitude in spring after its breakup. The purpose of this study is to quantify the impact of Arctic ozone depletion on mid-latitude by comparing the amounts of ozone in mid-latitude airmasses before and after the breakup of the polar vortex.

Vertical profiles of O_3, HF and N_2O have been retrieved from infrared spectra observed with Fourier transform infrared spectrometers (FTIR) at Tsukuba and Rikubetsu using the SFIT2 spectral fitting program. Spectra observed from 2006 to 2013 for Tsukuba and from 1997 to 2008 for Rikubetsu were used in this analysis.

HF and N_2O can be used as a tracer of the transport, because they are chemically stable species in the lower stratosphere. O_3 and HF (or N_2O) usually show a high correlation in the lower stratosphere because both species are stable. But the correlation will be changed when ozone is chemically perturbed. Therefore, we examined the correlations of mixing ratios between O_3 and HF (or N_2O) in the mid-latitude airmasses before and after the breakup and determined the chemical loss amount of ozone at the observational sites.

Some chemical ozone losses were found at the altitudes of 19 km and 21 km from O_3-HF correlation. Chemical losses in total ozone were also found from O_3-HF correlation and O_3-N_2O correlation. Then, these observed chemical loss amounts of ozone were compared with the total chemical loss amounts of ozone in the Arctic derived from Japanese Meteorological Agency [2012], Pommereau et al. [2013] and Rex et al. [2013].

Positive correlations were found between the observed chemical loss amounts of ozone at the altitude of 21 km for Tsukuba and at the altitude of 19 km for Rikubetsu and the total chemical loss amounts of ozone in the Arctic. Observed chemical losses in total ozone for both Tsukuba and Rikubetsu also showed positive correlation with the total chemical loss amounts of ozone in the Arctic.

The half-maximum total ozone loss amounts of 15 DU for Tsukba and 20 DU for Rikubetsu were estimated from the correlations, which result in the increases of 6 % and 7% of UV radiation, respectively.

The first observation of ozone enhancement in the lowermost atmosphere over China from a spaceborne ultraviolet spectrom

HAYASHIDA, Sachiko[1*] ; YURIKO, Keyamura[1]

[1]Faculty of Science, Nara Women's University

This is the first report of observation from space using ultraviolet radiance for significant enhancement of ozone in the lowermost altitudes (0 to about 3000 m) over East and Central China. The recent retrieval products of the Ozone Monitoring Instrument (OMI) onboard EOS/Aura satellite revealed the spatiotemporal variation of the ozone distribution in the lowermost troposphere [Liu et al., ACP, 2010]. The ozone enhancement over East and Central China was clear in June and July every year, associated with enhancement of CO observed from Measurements Of Pollution In The Troposphere (MOPITT) and hotspots taken from MODerate resolution Imaging Spectroradiometer (MODIS). It suggests that considerable part of the enhancement can be attributed to the emissions of ozone precursors from residue burning after harvesting winter wheat in this area. Ozone enhancement was also observed in autumn and early winter over East and Central China every year, sometimes not accompanied by signals of burning, It implies that CO emissions from industrial activity, automobiles and coal burning for heating would affect on ozone production rather than biomass burning in winter.

The validity of the estimation of ozone origin by sectoral air mass classification verified with tracer-tagging simulati

NAGASHIMA, Tatsuya[1*] ; IKEDA, Ayaka[2] ; SUDO, Kengo[3] ; HAYASHIDA, Sachiko[2]

The air quality in East Asia has changed rapidly in recent years, especially region-wide transboundary air pollution is the main issue in the atmospheric environment in this region. Therefore, the solution to this issue is of great importance today in East Asia, and the scientific understanding of the structure about this region-wide scale air pollution is necessary. The sectoral air mass classification method has been used to estimate the origin of air pollutants in East Asia, and demonstrated the characteristics of air mass with different origins and extended the understanding of the structure of air pollution. However, this method has a problem to erroneously estimate the origin of air pollutant due to the simpleness of the method. Here, we validate of the estimation of ozone origin by sectoral air mass classification by using the tracer-tagging simulation done by a global chemical transport model (CTM). The analysis suggested that the origin of ozone estimated by these two different methods (sectoral air mass classification and tracer-tagging) generally agreed with each other in the warm season, but the two differ significantly in the cold season. The results suggested that the sectoral air mass classification method should consider the different threshold of residence time to separate the air mass into different origins.

M. Obukhov Institute of Atmospheric Physics, Russian Academy of Sciences, [10]Belarusian State University, [11]V. E. Zuev Institute of Atmospheric Optics, Siberian Branch of the Russian Academy of Sciences

We conducted long-term network observations using standardized Multi-Axis Differential optical absorption spectroscopy (MAX-DOAS) instruments in Russia and ASia (MADRAS) from 2007 onwards. At seven locations (Cape Hedo, Fukue, and Yokosuka in Japan, Hefei in China, Gwangju in Korea, and Tomsk and Zvenigorod in Russia) with different levels of pollution, we obtained 80,927 retrievals of tropospheric NO2 vertical column density (TropoNO2VCD) and aerosol optical depth (AOD). This large data set was used to analyze NO2 climatology systematically, including temporal variations from the seasonal to the diurnal scale. The results were compared with Ozone Monitoring Instrument (OMI) satellite observations and global model simulations. Two NO2 retrievals of OMI satellite data (NASA ver. 2.1 and Dutch OMI NO2 (DOMINO) ver. 2.0) generally showed close correlations with those derived from MAX-DOAS observations, but had low biases of ˜50%. The bias was distinct when NO2 was abundantly present near the surface and when the AOD was high, suggesting that the aerosol shielding effect could be important, especially for clean sites where the difference could not be attributed to the spatial inhomogeneity. Except for constant biases, the satellite observations showed nearly perfect seasonal agreement with MAX-DOAS observations, suggesting that the analysis of seasonal features of the satellite data were robust. A global chemical transport model, MIROC-ESM-CHEM, was validated for the first time with respect to background NO2 column densities during summer at Cape Hedo and Fukue in the clean marine atmosphere.

The degradation of volatile organic compounds (VOCs) results in the formation of ozone (O_3) and secondary organic aerosols (SOA) in the troposphere. This process consists of the oxidation of VOCs by hydroxyl radical (OH), O_3, and nitrate radical (NO_3). Detailed understanding of the VOC degradation mechanism is challenged by the co-existence of vast variety of VOC species in the atmosphere. However, investigations on ubiquitous oxidation intermediates, e.g., formaldehyde (HCHO) and glyoxal (CHOCHO), can help us to test and improve the current knowledge of the VOC sources and degradation pathways.

We installed one ground-based Multi-Axis Differential Optical Absorption Spectroscopy (MAX-DOAS) system in Meteorological Research Institute (MRI) located at Tsukuba, Japan (36.06N, 130.13E) in June 2010. In addition, two more systems were installed in Chiba University at Chiba, Japan (35.63N, 140.10E) in June and December 2012, respectively. Since then, we have retrieved lower-tropospheric vertical profile information for eight components; aerosol extinction coefficients at two wavelengths, 357 and 476 nm, and NO_2, HCHO, CHOCHO, H_2O, SO_2, and O_3 concentrations. For a detailed evaluation for the aerosol retrieval, which is a key step in the MAX-DOAS eight-component retrieval, simultaneous aerosol observations with the Cavity Ring-Down Spectroscopy (CRDS) and the sky radiometer were conducted at Tsukuba on October 5-18, 2010 and September 7-18, 2012. At Chiba, in addition to the comparison with sky radiometer data, a self-consistency test was performed by comparing results obtained from two MAX-DOAS systems operated at the same place. Through these detailed evaluations, our retrieval method was improved significantly, attaining excellent agreement with CRDS and sky radiometer data. On the basis of these efforts, seasonal and diurnal temporal variations in HCHO and CHOCHO concentrations retrieved from our MAX-DOAS system are discussed in this talk.

Development of an angle-resolved polar nephelometer and its application to non-spherical particles

NAKAGAWA, Maho[1*] ; SASAGO, Hiroshi[1] ; NAKAYAMA, Tomoki[1] ; MATSUMI, Yutaka[1] ; UEDA, Sayako[1]

Angular distribution of scattering is one of the important optical properties contributing to the radiation balance in the Earth's atmosphere. Therefore,accurate description of the single-scattering properties of aerosol particles is required. In addition, the angular distribution of scattering of individual aerosol particle provides useful information to determine its size, shape, and refractive index of particles.

We are developing a new polar nephelometer, which can measure angular distribution of the optical light scattered by an individual particle. Laser light at 532 nm from a 300 mW YAG laser was used as light source. The laser beam intersects with a stream of aerosol particles introduced with a sheath flow using a double pipe. There are 21 photodiode detectors arrayed in each plane, totaling 42.Detector apertures were placed to limit sensing angles and minimize background light scattered from walls.

In this system, angular distributions of scattering for an incident light polarized parallel and perpendicular to the scattering plane were measured simultaneously. In the experiments, particles were atomized using a nebulizer and dried using a diffusion dryer. Then, size of particle was selected using a Differential Mobility Analyzer (DMA) and Aerosol Particle Mass Analyzer (APM) and introduced into the polar nephelometer.

The performance of the system was tested by measuring angular distributions of scattering by gaseous molecules (HFC-134 and CO2) and spherical particles. Polystyrene latex sphere is non-light absorpbing spherical particle, while nigrosine are light-absorbing spherical particle. The measured scattering angular distribution was compared with the simulation result calculated from the Mie scattering theory considering detection efficiency and of scattering angle range of each detector.

As a result, the scattering angular distributions could be reproduced by the simulation results for PSL particles with diameters between 150 and 900 nm. The scattering angular distributions for nigrosine particles, were in good agreement with the theoretical curve calculated using a literature refractive index value, $n = 1.63 + 0.24\,i$. This result suggests that light absorbing particles is distinguishable by the scattering angle distribution measurement.

In order to examine the influence of the difference of the shape, we also performed measurements of the scattering angle distributions of non-spherical particles such as sodium chloride and soot particles. In the presentation, capabilities of the system to determine the shape and refractive index of particle will also be discussed.

Lidar With Multiple Field-Of-View Receiver To Determine Aerosol Size-Distribution

LIU, Yutong[1*] ; YABUKI, Masanori[1] ; TSUDA, Toshitaka[1]

[1]Research Institute for Sustainable Humanosphere, Kyoto University

Knowledge of aerosol size distribution is essential for human health studies, because small particles are able to penetrate lung tissues, thus increasing the risk of bronchitis or of lung diseases. Optical remote sensing techniques such as lidar are effective for monitoring aerosols with high temporal and spatial variations. Aerosol instruments that use light with UV, VIS, and near-IR wavelengths have been used to effectively detect particles with diameters comparable to the wavelength. However, to quantitatively estimate the shape of the particle number-size distribution, more information is required with respect to small particles in the size range of sub-micrometer and below.

Conventional lidar employs very small field-of-view (FOV) for profiling aerosol distribution, and thus simply detects single scatter in the direction opposite to that of incident light. Multiple scattered signals are influenced not only by aerosol distribution along the laser path, but also by the size of aerosols. In this study, depolarization UV lidar with a multiple FOV receiver was used for detecting such multiple scattering effects in order to obtain more quantitative information concerning particle-size distribution. Considering the advantage of high scattering cross section for small particles, we employ a UV laser of 266 nm or 355 nm. A program-controlled mechanical FOV selector is used for a receiver system that can change the FOV from 0.1 mrad to 12.4 mrad. In the presentation, we introduce a retrieval method for aerosol size distribution using this feature and show preliminary results from field measurements by the multiple FOV lidar.

Retrieval of decadal record on the deposition of particulate refractory carbon urban and remote sites in Japan

KANEYASU, Naoki[1*] ; MATSUMOTO, Kiyoshi[2] ; YAMAGUCHI, Takashi[3] ; AKIYAMA, Masayuki[3] ; NOGUCHI, Izumi[3] ; MURAO, Naoto[4] ; NISHIMOTO, Shunya[4] ; FUNAKI, Daisuke[5] ; TAKAKI, Satoshi[5]

[1]National Institute of Advanced Industrial Science and Technology, [2]University of Yamanashi, [3]Hokkaido Research Organization, [4]Graduate School of Engineering, Hokkaido University, [5]Shimane Prefectural Institute of Public Health and Environment Science

The atmospheric concentration of refractory carbonaceous aerosol (black carbon, or elemental carbon) concentration are used for the evaluation of their direct radiative forcing. In addition, the deposition of such light absorbing substances on the snow or ice surface will result in the increase of the positive radiative forcing at the surface level. Long-term record of deposition for such relative inert substances is expected to reflect the change in the regional emission strength.

However, the reported measurements of deposition to the ground surface are scarce. We thus have conducted the retrieval of decadal record on the deposition of refractory carbon at two sites in the northern Japan (Rishiri Island: a remote site, and Sapporo City: an urban site). At these sites, the environmental monitoring division of local government have been measurering the total deposition of water-soluble aerosol components in the collected water by use of deposition gauges. To remove insoluble particles from the collected water placed beneath the funnel, a membrane pre-filter is placed at the bottom of the funnel of these deposition gauges. Such pre-filters were stored for more than 18 years for Sapporo site. These can be regarded as the long-term record of the deposited water-insoluble aerosol components in the past, as those in ice-core samples collected in glaciers.

We re-suspend these water-insoluble components into the aqueous phase by dissolving the membrane filter (mixed cellulose acetate) by an organic solvent and re-filter the suspended particles through quartz fiber filters for the analysis of TOT refractory carbon. Before dissolved into organic solvent, carbonate in soil dust particles were removed by the 2N HCl with heat. Collection efficacy of quartz fiber filters were corrected by the amount of retained particulate carbon on the first and second filters placed in series.

The deposition flux of TOT-EC is lager in Sapporo, while that in Rishiri showed a large seasonal variation, in general. In Sapporo, the flux decreased greatly in 2010s compared to those in 1990s, probably due to the introduction of regulations for diesel exhaust emission in 2000s. In addition, the deposition sample has been collected in Oki Island since 2013 spring. The preliminary result for this site will also be shown in the presentation.

The main controlling factor of black carbon mass concentration in rainwater during 2010-2013 summer in East Asia

MORI, Tatsuhiro[1*] ; OHATA, Sho[1] ; KONDO, Yutaka[1] ; MOTEKI, Nobuhiro[1] ; MATSUI, Hitoshi[2] ; IWASAKI, Aya[3] ; TOMOYOSE, Nobutaka[3] ; KADENA, Hisashi[3]

[1]Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo, Japan, [2]Japan Agency for Marine-Earth Science and Technology, Tokyo, Japan, [3]Okinawa Prefectural Institute of Health and Environment

Black carbon (BC) particles are emitted into the atmosphere by incomplete combustion processes, and removed by precipitation. The measurements of BC mass concentration in rainwater improve the quantitative understanding of BC loss because wet deposition is the major sink of BC. We measured BC mass concentration in the air (M_{BC}) and in rainwater (C_{BC}) simultaneously at Cape Hedo on Okinawa Island, Japan, in the East China Sea, from April 2010 to March 2013 in order to understand C_{BC} in each rain event during 2010-2013 summer. The rainwater is collected by an automated wet-only sampler during a 24 period. Photo-absorption photometer with heated inlet (COSMOS) is used to measure M_{BC}. C_{BC} was measured by a system consisting of an ultrasonic nebulizer and a Single Soot Photometer (SP2).

It is often heavy rain by cumulonimbus cloud during summer in East Asia, so that M_{BC} an hour before raining is expected to be related to C_{BC}. However, the correlation between M_{BC} and C_{BC} in all rain events during 2010-2013 summer is not agreed (r^2 = 0.12). Then, we extracted the heavy rain events, which had positive convective available potential energy (CAPE). These extraction was performed with the National Centers for Environmental Prediction (NCEP) Final (FNL) Operational Global Analysis data every 6 hours. This result was that C_{BC} was correlated with M_{BC} (r^2 = 0.47).

In order to investigate if C_{BC} (Estimated C_{BC}) is explained with M_{BC} and the liquid water content, Estimated C_{BC} is verified by comparing the observed C_{BC}. The liquid water content is maximum at the equilibrium level (EL) by the condensation process theoretically if the total water mixing ratio is conserved in the air parcel. If BC in the parcel is active as cloud condensation nuclei (CCN) at lifted condensation level and removed by precipitation at EL, the equation of Estimated C_{BC} at EL is represented as Estimated C_{BC}=M_{BC}/(m_v∗WCR). m_v is the water vapor content an hour before raining at the ground level. Water condensation ratio (WCR) is the mass ratio of liquid water content to water vapor content, which is calculated with the NCEP reanalysis data. Compared with the observed C_{BC}, Estimated C_{BC} is correlated with the observed C_{BC} well (r^2 = 0.68). It suggests that Estimated C_{BC} is correctly represented as C_{BC} with M_{BC} and the most liquid water content at EL. The observed C_{BC} is three times higher than Estimated C_{BC} because the cloud droplets including BC particles might be collected during falling down.

Number size distribution of ambient aerosols at Cape Hedo, Okinawa and Fukue Island, Nagasaki

MIYOSHI, Takao[1*] ; TAKAMI, Akinori[1] ; IREI, Satoshi[1]

[1]NIES

[**Introduction**]

Recent drastic economical growth in the East Asian region has caused large emission of anthropogenic pollutants to the atmosphere. Some aerosols act as cloud condensation nuclei (CCN) and influence the global climate. There was a report that the higher ratio of inorganic aerosol to the sum of inorganic and organic aerosol and the larger particle size resulted in the higher ratio of CCN to condensation nuclei at the same water vapor supersaturation.

We have conducted field studies for chemical compositions of ambient aerosols at some locations in the East Asian region. In this work, measurement results of number size distribution of aerosols, which potentially influences cloud formation, are presented. Obtained data at two locations were analyzed for better understanding the spatial distribution of aerosol size in the region.

[**Observation**]

The number concentration was measured at Cape Hedo, Okinawa (lat 26.9^{o}N, long 128.3^{o}E) from 15 to 22 February 2012 and at Fukue Island, Nagasaki (lat 32.8^{o}N, long 128.7^{o}E) from 15 to 28 February 2013 using a Wide-Range Particle Spectrometer (WPS, MSP Corp.), which has a capability to measure a wide particle size range. The WPS consists of two main parts: a combination of a Differential Mobility Analyzer (DMA) and a Condensation Particle Counter (CPC) for particle measurement from 5 to 350 nm (or from 10 to 500 nm) and a Laser Particle Spectrometer (LPS) for measurement from 350 to 10000 nm.

Simultaneously, chemical compositions of ambient aerosols (ammonium, nitrate, sulfate, chloride and organics) were measured by a Quadrupole Aerosol Mass Spectrometers (Q-AMS, Aerodyne Research, Inc.) at Cape Hedo and an Aerosol Chemical Speciation Monitor (ACSM, Aerodyne Research, Inc.) at Fukue Island. At Fukue Island only, sulfur dioxide concentrations were also measured by an SO_2 analyzer (Model 43i, Nippon Thermo Co., Ltd.). Sulfur dioxide concentrations at Cape Hedo were monitored at Hedo Acid Deposition Monitoring Station (Ministry of the Environment).

[**Results and Discussion**]

The size distributions at Cape Hedo consistently had two peaks at 50 nm and 200 nm. On the other hand, those at Fukue Island varied. There were two peaks at 50 nm and 150 nm after 0:00 a.m. JST on 23 February 2013. Ambient aerosols at 150 nm were largest among the particles which were measured at Fukue Island. There was one peak at 15-25 nm after 12:00 p.m. JST on 24 February 2013 when the number concentration was over 100000 #/cm^3. The concentration was also high on 16 and 25 February 2013. The growth of nucleation mode particles was observed from noon to night of each day. We believed that these cases were new particle formation (NPF) events. Such a case was not observed at Cape Hedo.

The molar ratio of sulfur dioxide to the sum of sulfur dioxide and sulfate was studied at both monitoring sites during the observation period by a WPS. When NPF events occurred at Fukue Island, the ratio increased over 80%. On the other hand, the ratio at Cape Hedo was at most 60% even on 17 February 2012 when the transport time of air masses from China according to back trajectory analyses (NOAA HYSPLIT) was approximately one day. The transport time was as long as that to Fukue Island. It was inferred that enough gases such as sulfur dioxide to cause NPF were around Fukue Island and semi-volatile vapors which were newly generated by photochemical reactions condensed on pre-existing particles because the concentrations of gases were low and those of aerosols such as sulfate were high around Cape Hedo.

Continuous measurement of organic nitrates at Suzu, the Noto peninsula

SADANAGA, Yasuhiro[1*] ; TAKAJI, Ryo[1] ; ISHIYAMA, Ayana[1] ; MATSUKI, Atsushi[2] ; SATO, Keiichi[3] ; OSADA, Kazuo[4] ; BANDOW, Hiroshi[1]

[1]Osaka Prefecture University, [2]Kanazawa University, [3]Asia Center for Air Pollution Research, [4]Nagoya University

Peroxyacyl nitrates (PANs) and alkyl nitrates (ANs) act as one of the reservoirs of nitrogen oxides (NO_x) in the atmosphere. Since their lifetime is longer than that of NO_x, they can be transported over a long-distance and would be important as trans-boundary pollutants. In this research, continuous measurement system of total PANs and ANs in the troposphere has been developed by using a thermal dissociation / cavity attenuated phase shift spectroscopy (TD/CAPS) method. Both PANs and ANs are thermally decomposed to produce NO_2 and then NO_2 is measured by CAPS method. This system can observe PANs and ANs with high time resolution while this system cannot separate constituents of PANs and ANs. Total PANs and ANs can be measured separately by setting up decomposition lines at different temperatures.

Continuous field observations of PANs and ANs concentrations have been being carried out at NOTOGRO (NOTO Ground-based Research Observatory) supersite in Suzu, Noto Peninsula, since November 2012. NO_x, NO_y, total inorganic nitrate ($T.NO_3$), O_3 and CO concentrations have also been being observed at NOTOGRO.

NOy concentrations were in agreement with the sum of observed NO_y components (= NO_x + $T.NO_3$ + PANs + ANs) regardless of seasons. NO_x fractions were the highest in NO_y constituents. $T.NO_3$ fractions were small in winter and increased in spring. Opposite tendencies were observed for PANs fractions. These reflect that wet deposition of $T.NO_3$ is promoted in winter and temperature increasing accelerates decomposition of PANs.

Seasonal variations of both PANs and ANs concentrations showed spring maximum and summer minimum. From winter to spring, both PANs and ANs concentrations from Korea-China air mass origin were higher than those from the other air mass origins. On the other hand, both PANs and ANs concentrations were independent of air mass origins from spring to summer. These indicate that PANs and ANs concentrations in winter and spring are governed by long-range transport and local photochemical productions of PANs and ANs are relatively important from spring to summer. In addition, PANs and ANs diurnal variations being high and low in the daytime and nighttime, respectively, in spring and summer also imply the local photochemical productions of PANs and ANs.

Light absorption and morphological properties of soot-containing particle mixed with sulfate observed at Noto Peninsula

UEDA, Sayako[1*] ; NAKAYAMA, Tomoki[1] ; MATSUMI, Yutaka[1] ; TAKETANI, Fumikazu[2] ; ADACHI, Kouji[3] ; MATSUKI, Atsushi[4] ; IWAMOTO, Yoko[4] ; SADANAGA, Yasuhiro[5]

[1]STEL, Nagoya University, [2]JAMSTEC, [3]Meteorological Research Institute, [4]Kanazawa University, [5]Osaka Prefecture University

Black carbon (BC) in atmospheric soot particle is known as strongly absorber of visible spectrum solar radiation in the atmosphere. The coating materials on soot particle can enhance the magnitude of light absorption by the soot-containing particles, according to the coating conditions including composition, amount and morphology. Several studies have indicated that the estimation by assuming core-shell shaped particle and simple composition tends to estimate larger than that for the real soot-containing particles (Adachi et al., 2010; Lack and Cappa, 2010; Cappa et al., 2012). To elucidate the enhancement of light absorption of aged soot-containing particles and their relation with the individual particle condition, we made an observation for continental outflow at Noto Peninsula, Kanazawa, Japan, in spring 2013.

Atmospheric observations were conducted at NOTO Ground-base Research Observatory (NOTOGRO) in Suzu City, Kanazawa, Japan from April 17 to May 14 in 2014. Absorption and scattering coefficients at 405, 532, and 781 nm, and soot mass concentrations of PM1 particles were measured using the photoacoustic soot photometer (DMT, PASS-3) and a single-particle soot photometer (DMT, SP2), after passing through diffusion dryers and one of the heaters controlled at 25, 300, and 400 deg C every 10 min. Aerosol samples were collected using two-stage cascade impactors (50% cutoff diameters of the two stages were 1.5 um and 0.3 um) on carbon-coated nitrocellulose (collodion) films for individual analysis using a transmission electron microscope (TEM). Elemental compositions of individual particles were analysed for particles on second stage using an energy-dispersive X-ray spectrometer (EDS) used along with the TEM. Mixing states between non-volatile chain-like soot and volatile materials to high-density electron beam were identified by comparing photograph before and after EDS analysis.

Increase in BC light absorption due to coating was estimated by comparing absorption coefficients at 781 nm with and without heating (300 deg C). The increase in BC light absorption on average was 23$\pm$25%. The maximum values of the increase in BC light absorption ($>$40%) were observed in air mass condition that derived from around Shanghai across the East China Sea, based on backward air mass trajectory analysis. In the TEM sample obtained at the air mass, most of soot were found as internally-mixed particles, which were well-embeded into round-shaped sulphate. On the other hand, increase in light absorption estimated at 405 nm was usually less than that at 781 nm over the entire observation period. Particularly the increase in light absorption at 405 nm tended to be negative under air mass derived from around Japan or the Korean Peninsula. Because absorption at 405 nm is more affected from OC, the negative values might to be attributed to formation of brown carbon in thermo denuder. In TEM sample obtained when the increase in light absorption were negative at 405 nm and $<$25% at 781 nm, most of soot were also internally-mixed particles with sulphate. The differences with sample of air mass from Shanghai were that many soot-containing particles were irregular shape, and that carbonaceous residues other than soot were found in particles after irradiation of high electron beam. Our results suggest that the variation of increase in BC light absorption were attributed to morphology and mixing state with OC of internally mixed soot-containing particles.

Mixing state is one of the factors that determine the characteristic of aerosol particles, and it is important for evaluating their climatic impact. Until recently, summer time aerosol particles in the remote region of central Japan didn ' t attract much attention since human influence was considered minimal during the season. However, our measurement in the last few years showed that particle number concentrations in summer time were the highest in all seasons. In order to understand the characteristics of the summer time aerosols, we analyzed composition and mixing state of individual particles using transmission electron microscopy (TEM) coupled to energy dispersive W-ray spectrometer (EDX). We conducted quasi-daily sampling at research facility NOTOGRO (NOTO Ground-based Research Observatory) situated at tip of the Noto peninsula from 9th, Jun to 23rd, August. Samples collected during episodes of high aerosol loadings were selected and analyzed. Winds tend to transport air-mass from the Pacific Ocean to the sampling site in summer. However, we found that there were some other flow patterns including flow from the continent of Asia, associated with the high aerosol concentrations. Major composition of particles differed depending on the flow patterns. In addition, many particles were internally mixed, and organics were predominant in smaller diameter range, while sulfates were predominant in larger diameter range. Above results showed that, depending e.g. on the difference of the flow patterns, mixing state of aerosols observed in high concentrations in summer exhibit high temporal variability, and such mixing state are often unevenly distributed among different particle sizes.

New Particle Formation (NPF) of atmospheric aerosol particle is an important production process which increases the number concentration of the aerosol particles that would act as Cloud Condensation Nuclei and potentially affect the global climate. The measurement of number size distribution of atmospheric aerosol particles was conducted at the atmospheric observation site, NOTOGRO in Noto peninsula, from October 2012 to September 2013. We identified NPF events throughout the measurement period and this is the first year-round observation reported on the NPF events from coastal region of the Sea of Japan. NPF events tended to occur when Condensation Sink (CS) was relatively low. CS is a measure of the amount of preexisting particle concentration and depends on the particle size distribution. Comparing with meteorological parameters, NPF events were concentrated in daytime, which suggests interaction with solar radiation. However, precipitation preceding the event tended to trigger NPF events by lowering CS (i.e. preexisting particle concentration) especially in winter and summer. On the other hand, NPF events observed in autumn and spring tended to concentrate on days with particularly low relative humidity. Above results suggested that, the conditions favorable for the NPF event is closely related to the seasonal climatic features of the measurement region, that is, the winter monsoon in winter, the rainy season and typhoon in summer and anticyclones in autumn and spring.

Origin of atmospheric gaseous mercury using the Hg/CO ratio in pollution plume observed at Mt. Fuji Weather Station

NAGAFUCHI, Osamu[1*] ; YOKOTA, Kuriko[2] ; KATO, Syungo[3] ; OSAKA, Ken'ichi[1] ; NAKAZAWA, Koyomi[1] ; KOGA, Masaru[1] ; HISHIDA, Naoko[1] ; NISHIDA, Yuki[1]

[1]the University of Shiga Prefecture, [2]Toyohashi university of technology, [3]Tokyo Metropolitan University

Mercury (Hg) is a global pollutant, which is dispersed worldwide mainly is gaseous elemental form via long-range atmospheric transport. Due to the increasing fossil fuel consumptions and industrial emissions, Asia now contributes more than 50% of the global anthropogenic Hg emission with China being the largest atmospheric Hg emitter. Previous studies have demonstrated that the trans-Pacific Asian Hg export could impact North America. Therefore, we would like to study its transport mechanism in the free troposphere by monitoring atmospheric Hg concentrations at high elevation site in Japan. The sampling site is at the summit of Mt. Fuji Weather Station, which is 3,777 m above sea level.

Gaseous mercury and particulate mercury in the atmosphere were separately collected by using a mercury sampler developed by Kagaya et. al., (2007). A quartz filter (Palflex2000, Tokyo Dylec) was attached at the tip of a mercury absorbing tube in which amalgamated gold was impregnated, and the air was aspirated by an air pump through the filter and the mercury absorbing tube at a rate of 0.5L/min. Particulate mercury was filtered by the quartz filter and gaseous mercury was absorbed by the amalgamated gold in the tube. Both particulate and gaseous mercury were analyzed by an atomic absorbance spectrophotometer (Nippon Instruments, MA-2000) after vaporization by heating.

The mercury sampler was set in a place 5m or more away from the building at summit of Mt. Fuji (N35.21'.38", E138.43'39"). The sampling was performed from 11 to 18 August, 2008. The filer and the absorbing tube were changed with 12-24 hour-intervals.

Atmospheric mercury concentrations observed at summit of Mt. Fuji and Japan. High concentrations of both gaseous and particulate mercuries were observed at the summit of Mt. Fuji. Swartzendruber et al. reported the gaseous and particulate mercury concentrations in the free troposphere at the Mt. Bachelor as 1.54 and 0.0043 ng/m^3, respectively. Hans R. Friedli et al reported that gaseous elemental mercury were found in industrial plumes exiting China, Korea, and Japan ˜6.3ng/ m^3, ˜3ng/ m^3 and ˜3ng/ m^3, respectively. The higher atmospheric mercury concentrations at the summit of Mt. Fuji may imply that there is a specific pollution source in the East Asia. Because from the result of the back trajectory calculation, the air mass came from the China during this observation periods.

Clarification of lead (Pb) species and its formation mechanisms in coarse and fine aerosol particles using X-ray absorpt

SAKATA, Kohei[1*] ; SAKAGUCHI, Aya[1] ; TANIMIZU, Masaharu[2] ; TAKAHASHI, Yoshio[1]

[1]Graduate school of Science, Hiroshima University, [2]JAMSTEC

There are very few studies on chemical speciation and atmospheric chemistry of trace elements. Among the trace elements in the aerosol particles, lead(Pb) has long been measured due to the toxicity of this element. The measurement of Pb isotope ratios in aerosol particles has also been employed as a powerful tracer for air-mass transportation because Pb isotope ratios differ significantly depending on the emission area/source. However the speciation of Pb has not been clarified, although their solubility is important to estimate the health effects for human/animal body. Furthermore, Pb in the aerosol particle is the dominant source of Pb, which is used as oceanic circulation tracer, in the surface seawater. Thus, the speciation of Pb in the aerosol particle is one of the important issue. In this study, we attempted to determine the Pb species in aerosol samples using X-ray absorption fine structure (XAFS) analysis.

Size-fractionated aerosol particles were collected by a high-volume aerosol sampler with cascade impactor at Higashi-Hiroshima. Lead LIII-edge (absorption edge: 13.04 keV) X-ray absorption near-edge structure (XANES) spectra were recorded on SPring-8 on BL01B1 and at KEK PF-AR on NW10A to identify the Pb species. The analyzed sample-sets of size-fractionated aerosol particles are follows: Spring (Asian dust event), summer (two sample sets), fall, and winter (transboundary pollution event).

Lead species in size-fractionated aerosol particles are different between fine and coarse aerosol particles. In the fine aerosol particles, the dominant Pb species were two or three components, $PbSO_4$, $Pb(NO_3)_2$ and PbC_2O_4, in all seasons. That is, the seasonal variation of Pb species in the fine aerosol was not found. It is because the Pb species in the fine aerosol particles are formed by uniform chemical reaction with H_2SO_4, HNO_3 and oxalic acid in droplet through a year. Pb species in the coarse aerosol particles, except for on Asian dust event, were $2PbCO_3$-$Pb(OH)_2$, $Pb(NO_3)_2$ and PbC_2O_4. These $2PbCO_3$-$Pb(OH)_2$ and partial PbC_2O_4 were derived from road dust, and $Pb(NO_3)_2$ in coarse aerosol particles was formed by chemical reactions with HNO_3 on the surface of the particle. In Asian dust event, the coarse aerosol particles showed PbSiO3 as major Pb species, although other species, $2PbCO_3$-$Pb(OH)_2$ and PbC_2O_4, were also obtained. Thus we could found the clear seasonal variation in the coarse aerosol particles. These results will be able to estimate the accurate estimation of Pb solubility to the surface seawater.

CARIBIC is a flying observatory onboard a Lufthansa A340-600 aircraft that observes various atmospheric compounds at almost monthly intervals. In this study, we present spatial and temporal variations of methyl chloride (CH_3Cl) in the upper troposphere (UT) observed mainly by CARIBIC for the years 2005-2011. The CH_3Cl mixing ratio in the UT over Europe was higher than that observed at a European surface baseline station throughout the year, indicative of a persistent positive vertical gradient at NH mid latitudes. A series of flights over Africa and South Asia show that CH_3Cl mixing ratios increase toward tropical latitudes, and the observed UT CH_3Cl level over these two regions and the Atlantic was higher than that measured at remote surface sites. Strong emissions of CH_3Cl in the tropics combined with meridional air transport through the UT may explain such vertical and latitudinal gradients. Comparisons with carbon monoxide (CO) data indicate that non-combustion sources in the tropics dominantly contribute to forming the latitudinal gradient of CH_3Cl in the UT. We also observed elevated mixing ratios of CH_3Cl and CO in air influenced by biomass burning in South America and Africa, and the emission ratios derived for CH_3Cl to CO in those regions agree with previous observations. In contrast, correlations indicate a high CH_3Cl to CO ratio of 2.9 ± 0.5 ppt ppb^{-1} in the Asian summer monsoon anticyclone and domestic biofuel emissions in South Asia are inferred to be responsible. We estimated the CH_3Cl emission in South Asia to be 134 ± 23 Gg Cl yr^{-1}, which is higher than a previous estimate due to the higher CH_3Cl to CO ratio observed in this study.

Flattening of the equatorial bulge of annual mean APO observed in the Western Pacific during the 09/10 El Nino event

TOHJIMA, Yasunori[1*] ; MUKAI, Hitoshi[1] ; MACHIDA, Toshinobu[1] ; TERAO, Yukio[1] ; NOJIRI, Yukihiro[1]

[1]National Institute for Environmental Studies

A tracer known as **a**tmospheric **p**otential **o**xygen ($APO=O_2+1.1xCO_2$) has been proved to be useful to study air-sea gas exchange. Although both atmospheric CO_2 and O_2 concentrations are affected from the air-sea and air-land gas exchanges, APO mainly reflect the air-sea gas exchange because APO is invariant with respect to the land biotic gas exchanges (-1.1 in the definition represents the molar land biotic $-O_2$:C exchange ratio). To investigate the spatio-temporal variations in the APO over the Pacific region, we have been observing the atmospheric CO_2 and O_2 concentrations onboard commercial cargo ships sailing between Japan and US/Canada and Australia/New Zealand since December 2001. Our previous studies based on the shipboard flask measurements for 7-year period (2002-2008) revealed that the average latitudinal distribution of the annual-mean APO in the Western Pacific (from 40 deg. S to 50 deg. N) show a maximum near the equator and decreasing trends toward the mid-latitude in both hemisphere (Tohjima et al, 2012). This latitudinal distribution of the annual-mean APO is mainly attributed to the latitudinal differences in the air-sea gas exchange: outgassing fluxes around the equator and ingassing fluxes in the mid and high latitude. In the previous study, the equatorial bulge was robust and always observed during the 7-year period. However, the equatorial bulge disappeared and the latitudinal distribution was flattened especially in the Southern Hemisphere during the period from July 2009 to June 2010, when the most recent El Nino event occurred. Simulated APO based on an atmospheric transport model (NIES99) driven by a set of climatological oceanic O_2 and CO_2 fluxes also shows suppression of the equatorial bulge during El Nino periods, indicating that the atmospheric transport substantially contributes to the inter-annual change in the latitudinal distribution of the annual-mean APO. The simulated APO, however, cannot fully reconstruct the flattening of APO in the Southern Hemisphere. Thus, the suppression of the Eastern Pacific upwelling during the El Nino period might reduce O_2 and/or CO_2 outgassing around the equatorial ocean.

Separation of gross primary production and ecosystem respiration of a Japanese forest using atmospheric O2/N2 ratio

ISHIDOYA, Shigeyuki[1*] ; MURAYAMA, Shohei[1] ; KONDO, Hiroaki[1] ; SAIGUSA, Nobuko[2] ; KISHIMOTO, Ayaka[3] ; YAMAMOTO, Susumu[1]

[1]National Institute of Advanced Industrial Science and Technology (AIST), [2]National Institute for Environmental Studies, [3]National Institute for Agro-Environmental Sciences (NIAES)

The atmospheric O2/N2 ratio (δ(O2/N2)) has been observed globally since the early 1990s to elucidate the global CO2 budget (e.g. Manning and Keeling, 2006). To apply this method, the global average terrestrial biospheric O2:CO2 molar exchange ratio is needed. Keeling (1988) estimated the - O2:CO2 exchange ratio (hereafter referred to as ER) of 1.05 by surveying the results from various elemental abundance studies. Severinghaus (1995) revised the ER to be 1.10±0.05, which has been used for the global average terrestrial biospheric ER in recent studies. However, Seibt et al. (2004) and Ishidoya et al. (2013) observed the ER values associated with respiration and photosynthesis in forests and reported that the ER for net turbulent O2 and CO2 fluxes between the forest ecosystem and the atmosphere above the canopy (hereafter referred to as ER_F) could be different from 1.1 significantly, based on one-box canopy O2/CO2 budget model analyses. Moreover, the ER_F reported by Seibt et al. (2004) is quite different from that by Ishidoya et al. (2013); the former is larger than 1.1 and the latter is smaller than 1.0 under the condition of uptake of CO2 from the atmosphere to a forest. Therefore, direct observation of the ER_F at various forests is expected to validate the global average terrestrial biospheric ER. In addition, such the observation of the ER_F will lead to estimate the gross primary production (GPP) and the ecosystem respiration (RE) of the forest separately.

In this study, we present the average daily mean ER_F at Takayama deciduous broadleaf forest site in central Japan (36○09′ N, 137○25′ E, 1420 m a.s.l.; designated as TKY in the Asia Flux site code database) for the period May 24 – August 28, 2013, observed firstly based on an aerodynamic method (Yamamoto et al., 1999). The observed average daily mean ER_F is 0.79±0.08, which is not only smaller than 1.0 as predicted by Ishidoya et al. (2013) but also significantly smaller than the assumed global average terrestrial biospheric ER (1.10±0.05). We also separate the average daily mean NEP for the corresponding period observed by the eddy covariance method (Saigusa et al., 2005) into average daily mean GPP and RE, by using the observed average daily mean ER_F in this study as well as the ER_A (the ER for GPP) and ER_R (the ER for RE) at TKY reported by Ishidoya et al. (2013). Then, the separated average daily mean RE is compared with that estimated from an empirical function of air temperature (Saigusa et al., 2005) and the soil CO2 efflux observed using soil chamber experiments (Mo et al., 2005), to discuss the validity of the observed ER_F and its implication to the forest and global carbon cycle (Ishidoya et al., in manuscript in prep.).

Atmospheric mixing ratios of greenhouse gases at about 11 km altitude were analyzed from monthly air sampling aboard commercial airliner during the flights between Europe and Japan from April 2012 to August 2013. Compared to the subtropic, higher CH4 and SF6 mixing ratios, similar values of N2O, and larger seasonal changes of CO2 were found in the upper troposphere. CH4, N2O and SF6 in the lower stratosphere, above the tropopause up to 30 K in potential temperature, showed simultaneous increases from June to October, and faster decreases at higher altitudes from January to March. Mean age of the air in the lower stratosphere was estimated based on SF6 mixing ratios to be about 2 years in late spring and 1 year in autumn, suggesting stronger influences on the mixing ratios in the stratosphere from troposphere in summer.

Long-term changes of CH4 concentration and its carbon isotopic ratio in the lower stratosphere over Japan

SUGAWARA, Satoshi[1*] ; MORIMOTO, Shinji[2] ; UMEZAWA, Taku[3] ; AOKI, Shuji[2] ; NAKAZAWA, Takakiyo[2] ; ISHIDOYA, Shigeyuki[4] ; TOYODA, Sakae[5] ; HONDA, Hideyuki[6]

[1]Miyagi Univ. of Education, [2]CAOS, Tohoku Univ., [3]Max Planck Institute for Chemistry, [4]AIST, [5]Tokyo Institute of Technology, [6]ISAS/JAXA

It is expected that d13C of CH4 provides us with useful information not only about CH4 emissions from biogenic and abiogenic sources but also about its oxidation process in the atmosphere. Therefore, measurements of d13C have been carried out for the major CH4 sources as well as for the background atmosphere. However, the measurements are still insufficient for elucidating the CH4 cycle on the earth's surface. In the stratosphere, CH4 is destroyed by reactions with OH, O(1D) and Cl atom. These destruction processes play an important role in the stratospheric chemistry, but the respective contributions to the CH4 loss and their temporal changes have not been yet well understood quantitatively. Measurements of the isotopic ratios of the stratospheric CH4 are one of the most promising methods to detect possible change of the CH4 destruction processes in the stratosphere on the basis of the different isotopic fractionations occurring in the different reactions. However, only a few measurements have been made so far, due mainly to difficulty of collecting air samples in the stratosphere. Systematic collections of stratospheric air samples have been carried out over Japan since 1985 using a balloon-borne cryogenic sampler. We analyzed the air samples collected in the period of 1994-2010 for concentrations of CH4, N2O, CO2 and SF6, and d13C of CH4. In this study, we report the preliminary results of the long-term change of d13C of CH4 in the stratosphere. Almost linear and compact relationships between CH4 and N2O concentrations were found for the all observations in the different years. CH4 concentration and d13C also showed compact relationships in the lower stratosphere, although those in the mid-stratosphere were less correlated. The tight correlations between CH4 and N2O in spite of the different destruction processes suggest that the ratio of both destruction rates has been kept as almost constant during the transport process in the stratosphere. It is well known that tropospheric CH4 and N2O have been secularly increasing in the recent decades. Such increasing trends should have been propagated into the stratosphere, and the compact relationships between the stratospheric CH4 and N2O would change depending on their increase rates. To elucidate an inter-annual changes of the stratospheric CH4 and its d13C, we employed N2O-loss, instead of the N2O concentration, as an indicator of how the chemical reactions have proceeded during the stratospheric transport. The N2O-loss was calculated as a concentration difference between the tropical troposphere and the stratosphere by considering the mean age of air estimated from CO2 and SF6 concentrations. This procedure eliminates the effect of the secular N2O increase from the relationships between CH4 and N2O, and enables us to detect possible change in the stratospheric CH4. As a result, we found that the CH4 concentration increased at a rate of 4.5+-0.9 ppbv/year in the lower stratosphere during 16 years. This increase rate is consistent with those observed in the troposphere. The same technique was applied to the correlations between CH4 concentration and d13C, and we found no significant changes of d13C in the lower stratosphere. Considering the fact that d13C in the troposphere also does not show a clear trend in a recent decade, our result implies that the relative contributions of the CH4 destruction processes have been unchanged in the lower stratosphere over the observed period.

Laboratory biomass burning experiments to investigate the dependence of emissions of volatile organic compounds on burni

INOMATA, Satoshi[1*] ; TANIMOTO, Hiroshi[1] ; PAN, Xiaole[2] ; TAKETANI, Fumikazu[2] ; KOMAZAKI, Yuichi[2] ; MIYAKAWA, Takuma[2] ; KANAYA, Yugo[2]

[1]NIES, [2]JAMSTEC

Biomass burning is one of major sources of primary fine carbonaceous aerosols and organic compounds.[1] A field observation campaign in a rural area of the Yangtze River Delta, China, was carried out during the harvest season in June of 2010 and air masses of open crop residue burning were frequently observed. It was found that the emission ratios of elemental carbon (EC) and organic carbon (OC) to CO were enhanced during the biomass burning episodes compared with those in urban pollution.[2] In addition, oxygenated volatile organic compounds were predominantly emitted during the biomass burning.[3] To investigate the emission properties of aerosols and organic compounds under controlled conditions, we carried out biomass burning experiments in the laboratory. Two types of crop residues, wheat straws and oilseed rapes, which were actually burned during the campaign, were used as the sample. We will mainly show the dependence of the emission ratios of volatile organic compounds to CO on burning conditions and compare with the field observation.

Impact of VOC emission from gasoline cars on ozone formation

HIROYUKI, Yamada[1*] ; INOMATA, Satoshi[2] ; TANIMOTO, Hiroshi[2]

[1]National Traffic Safety and Environment Laboratory, [2]National Institute for Environmental Studies

Ozone has been known that it was produced by the atmospheric reactions of volatile organic compounds (VOC) and NOx. The impact of VOC on ozone formation varies species by species. Thus, to evaluate the ozone formation in atmosphere, discussion based of ozone formation potential (OFP) is important.

This study discussed VOC emission from gasoline vehicle with OFP. Usually it is though that main source of VOC from vehicles were tailpipe emissions, however our former study suggested that main source from gasoline cars is not tailpipe emissions but evaporative emissions. So in this study, addition to tailpipe emissions, OFP of evaporative emissions were measured.

Improvement of measurement system for organic nitrates produced in the mixture of VOC, NOx and O3

MATSUMOTO, Jun[1*]

[1]Faculty of Human Sciences, Waseda University

Organic nitrates, ONs, are important as an intermediate of secondary organic aerosols (SOAs). Additionally, the branching ratio between ONs and NO2 formation after the reactions of NO with peroxy radicals (RO2) are critical for tropospheric ozone formation. In this study, laboratory experiments were conducted for the reaction of VOCs/O3/NO mixture. After the reactor, total ONs were monitored by the thermal-desorption laser-induced fluorescence (TD-LIF) technique. At this time, an improved glass double-tube flow reactor was constructed. The inner tube (Pyrex, O.D. 10 mm, I.D. 8 mm) was for the O3 flow, and the outer (Pyrex, O.D. 150 mm, I.D. 143 mm, length 500 mm) was for the additional flow (VOC sample and NO) to reduce the wall loss of ozone at the edges of reactor. As a result, after the improvement of the reactor and its conditions, the sensitivity of formed ONs was three times as large as the previous system. The sensitivity was defined as the slope of the regression line between VOC concentration and ONs increment. Observed sensitivities for isoprene and limonene were 0.00085 and 0.013 ppbv/ppbv, respectively. Sensitivity for limonene was 15 times as large as that for isoprene. Meanwhile, the reaction rate constant of limonene with ozone is 16 times larger than that of isoprene with ozone. It was experimentally indicated that the initial reaction of VOCs with ozone be critical for production of organic nitrates. It was also confirmed that measurements of ONs produced in the mixture of VOC, NOx and O3 was promising. As a next step, RO2 productivity of initial reactions (VOC+O3) and branching ratio between ONs and NO2 formation will be explored to clarify characteristics of ONs production in detail.

Humidity dependence of extinction coefficients of secondary organic aerosols and its relation with chemical properties

NAKAYAMA, Tomoki[1*] ; MATSUMI, Yutaka[1] ; SATO, Kei[2] ; IMAMURA, Takashi[2]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]National Institute for Environmental Studies

Atmospheric aerosols scatter and absorb solar radiation, thereby influencing the Earth's radiation balance. Light extinction is the sum of scattering and absorption. The aerosol extinction coefficient depends on chemical composition, particle size, shape and mixing sate in addition to wavelength of light. The uptake of water by aerosol particles can change extinction coefficients by changing size and refractive index of particles. Therefore, the detailed understanding of the relative humidity (RH) dependence of the extinction coefficients is important to estimate the impact of aerosols on radiation balance. However, the RH dependence of optical properties for secondary organic aerosol (SOA) has not been studied in detail.

In this work, we have determined the RH dependence of extinction coefficients of the SOAs generated during (1) the photooxidation of toluene in the presence of NO_x and (2) the ozonolysis of α-pinene. The SOAs were generated in a 6 m_3 teflon coated stainless-steel chamber in the absence of seed particles. The RH dependence of aerosol extinction coefficients at 532 nm was measured using a custom-made cavity ring-down spectrometer (CRDS). The CRDS has two measurement cells, in which the RH were controlled at $<$10% and 80%, respectively. The size distributions and chemical compositions of the SOAs were also measured using a scanning mobility particle sizer (SMPS, TSI) and a time of flight aerosol mass spectrometer (ToF-AMS, Aerodyne), respectively.

The ratio of extinction coefficients measured under high RH condition (RH=80%) to those measured under dry condition, F(RH), were compared with the relative abundance of the ion signal m/z=44 measured by the ToF-AMS to total organic signal, f_{44}. The f_{44} factor is known as a maker of oxygenated species such as organic di-acids, poly-acids, oxo-acids, hydroxy-acids, and acyl peroxides. Small RH dependence of extinction coefficients was found for the α-pinene-SOA with F(RH) of about 1.05, but the F(RH) values for the toluene-SOA were increase up to 1.4-1.6 with increasing the f_{44}. Interestingly, the relationship between F(RH) and f_{44} for the toluene-SOAs did not depend on the initial NO_x concentrations. Our results suggest that the increase in hygroscopicity due to oxidation of the SOAs mainly contributes to the observed RH dependence of extinction coefficients for the toluene-SOA.

Aerosols have cooling effect on the earth, which is divided into direct and indirect effects. The direct effect is reflection of sunlight directly by aerosols, whereas the indirect effect is the reflection by clouds formed by the aid of aerosols working as cloud condensation nuclei (CCN). Oxalic acid is a main component of secondary organic aerosols and abundant in the atmosphere, which is formed by degradation of organic matters with longer carbon chain such as cyclic olefin. Oxalic acid is hygroscopic, which can work as CCN with indirect cooling effect. It has been estimated that the degree of cooling effect by the aerosols are equal to that of the warming effect of carbon dioxide (CO_2). However, there is large uncertainty in the estimation. In addition, it is suggested that oxalic acid may form insoluble metal-oxalate complexes and does not have the indirect cooling effect. Therefore, it is important to re-evaluate the cooling effect of aerosols for precise prediction of global warming. Although dicarboxylic acid including oxalic acid is decomposed into CO_2 by photolysis, oxalic acid is more abundant than the other dicarboxylic acids. It is possible that oxalic acid can be stabilized by forming metal-oxalate complexes. This study was aimed (i) to measure the concentration of metal-oxalate complexes in the atmosphere to contribute to precise prediction of global warming and (ii) to measure the half-life time to evaluate the stability of metal-oxalate complexes during photoreaction.

Size-fractionated aerosol samples were collected at Higashi-Hiroshima in winter (Dec., 2012-Jan., 2013), spring (April, 2013), and summer (July-Aug., 2013). The ratio of oxalic acid and total metal-oxalate complexes was estimated based on the X-ray absorption fine structure (XAFS) spectroscopy for zinc (Zn), lead (Pb), and calcium (Ca). Photolysis experiments were conducted by ultraviolet ray for oxalic acid, Zn complex, and magnesium (Mg) complex, while absorption spectra were measured to evaluate photoreactivity.

As a result, metal-oxalate complexes were found in finer particles. There was a positive correlation between the ratio of oxalate/nitrate and ratio of metal-oxalate complexes/total oxalate species. Therefore, it is considered that metal-oxalate complexes are formed by relative increase of oxalate for nitrate. Although concentration of total oxalate species was largest, the ratio of metal-oxalate complexes/total oxalate species was smallest in summer. Concentration of total oxalate species was higher than that of metal ions (Zn^{2+}, Pb^{2+}, and Ca^{2+}). Therefore, it is considered that the ratio of metal-oxalate complexes is smallest in summer.

This ratio was about 30% to 50% for each sample through the year. This result showed that the cooling effect of oxalic acid may be smaller than previous estimation.

As a result of photolysis experiments, half-life time of oxalic acid, Mg complex, and Zn complex is 19 min, 71 min, and 172 min, respectively. This result showed that photoreactivity of oxalic acid was decreased by forming metal-oxalate complexes. Compared to absorption spectra between oxalic acid and metal-oxalate complexes, absorbance was decreased by forming metal-oxalate complexes. Therefore, it is considered that the increase of half-life time may be caused by the decrease of absorbance by forming metal-oxalate complexes.

Volatility basis-set approach simulation of organic aerosol formation in East Asia

MATSUI, Hitoshi[1*] ; KOIKE, Makoto[2] ; KONDO, Yutaka[2] ; TAKAMI, Akinori[3] ; KANAYA, Yugo[1] ; TAKIGAWA, Masayuki[1]

[1]Japan Agency for Marine-Earth Science and Technology, [2]University of Tokyo, [3]National Institute for Environmental Studies

Organic aerosol (OA) accounts for a significant mass fraction of the submicron aerosols in the atmosphere, and it influences the Earth's climate either directly (by scattering/absorbing of solar radiation) or indirectly (by modifying cloud microphysical properties). Recent studies show that secondary OA accounts for a large fraction of OA globally. However, as secondary OA formation processes are very complicated, estimates of the secondary OA burden in the atmosphere and its impact on climate and human health remain highly uncertain compared with those of other aerosols such as inorganic species.

In this study, OA simulations using the volatility basis-set approach were made for East Asia and its outflow region. Model simulations were evaluated through comparisons with OA measured by aerosol mass spectrometers in and around Tokyo (at Komaba and Kisai in summer 2003 and 2004) and over the outflow region in East Asia (at Fukue and Hedo in spring 2009). The simulations with aging processes of organic vapors reasonably well reproduced mass concentrations, temporal variations, and formation efficiency of observed OA at all sites. As OA mass was severely underestimated in the simulations without the aging processes, the oxidations of organic vapors are essential for reasonable OA simulations over East Asia. By considering the aging processes, simulated OA concentrations considerably increased from 0.24 to 1.28 μg/m^3 in the boundary layer over the whole of East Asia. OA formed from the interaction of anthropogenic and biogenic sources was also enhanced by the aging processes. The fraction of controllable OA was estimated to be 87 % of total OA over the whole of East Asia, showing that most of the OA in our simulations formed anthropogenically (controllable). A large portion of biogenic secondary OA (78 % of biogenic secondary OA) formed through the influence of anthropogenic sources. The high fraction of controllable OA in our simulations is likely because anthropogenic emissions are dominant over East Asia and OA formation is enhanced by anthropogenic sources and their aging processes. Both the amounts (from 0.18 to 1.12 μg/m^3) and the fraction (from 75 % to 87 %) of controllable OA were increased by aging processes of organic vapors over East Asia.

Impacts of BVOCs changes on global atmospheric chemistry: off-line coupling of CHASER and VISIT

SUDO, Kengo[1*] ; ITO, Akihiko[2]

[1]Graduate School of Environmental Studies, Nagoya University, [2]National Institute of Environmental Studies

Biogenic volatile organic compound (BVOC) is one of important factors to control global atmospheric environment and climate change, affecting tropospheric chemistry which involves ozone production/loss, OH radical abundance (atmospheric oxidizing power), and global production of secondary organic aerosols (SOA). Emissions of BVOCs are basically determined by land ecosystem processes, but also tightly linked to climate factors (such as temperature and precipitation), atmospheric CO2 concentration, and deposition of nitrogen species. Therefore, a modelling framework to couple atmospheric chemistry with land ecosystem is needed for considering BVOCs changes and associated impacts. In this study, coupled simulation of global atmospheric chemistry and terrestrial ecosystem has been developed by combining atmospheric chemistry model CHASER (Sudo et al., 2002, 2007) and land ecosystem/trace gas emission model VISIT (Ito et al., 2008). The CHASER model, also developed in the framework of the MIROC earth system model (MIROC-ESM-CHEM), simulates detailed chemistry in the troposphere and stratosphere with an on-line aerosol simulation including SOA production. The VISIT model calculates terrestrial emissions of CO_2, CH_4, N_2O, and BVOCs. This paper focuses on isoprene as a proxy of BVOCs, and discusses the impacts of the past isoprene emission changes on global atmospheric chemistry using the CHASER model constrained with off-line input from the VISIT simulation. VISIT calculates an increase in global isoprene emissions from 420 to 520 TgC a^{-1} (24%) from the first half of the 20th century to 2011. As a response to this emission change, CHASER simulated a ˜2% increase in global ozone production causing ˜4% increases in ozone concentration in the tropical middle-upper troposphere. The model also showed that OH decreases by 5-10% in the most of NH due to the isoprene emission change, resulting in 2-4% decreases of CO in NH. Also, SOA is largely increased by more than 30% in the major part of the troposphere (especially in the tropics).

Emission of iodine molecule and iodine monoxide from frozen solutions containing iodide ion

OKUMURA, Masanori[1] ; YABUSHITA, Akihiro[1*]

[1]Kyoto University

Iodine oxides are receiving increasing attention in atmospheric chemistry, because it may contribute to ozone depletion and atmospheric particle formation in polar region. Iodine monoxide(IO) generates from the reaction of iodine atom with ozone. Iodine atoms may be formed by photolysis of iodine(I_2) or volatile iodocarbons, the main source of which is oceanic biogenic production. Emission processes from inorganic source are also being proposed, but they are so far unexplained. Iodine compounds were found above, below and within the sea ice of the Weddell Sea, and these measurements show the Weddell Sea as an iodine hotspot. But, the calculated fluxes from biological production of iodocarbons are too small to explain the observed atmospheric IO, and the modelled I_2 is also smaller than the observed I_2. This observation suggests there is an unidentified iodine source. One of the candidates is presumably an inorganic source. In this work, we studied the surface reaction between gaseous ozone and a frozen sodium iodide solution by using cavity ring-down spectroscopy to detect gaseous products, iodine, I_2(g) and an iodine monoxide radical, IO(g).

The I_2(g) and IO(g) emissions were observed during ozonolysis of liquid and frozen NaI aqueous solutions. The concentrations of NaI were typically 1 and 5 mM. The concentrations of flowing O_3(g) were (0.5-4.2)$\times 10^{15}$ molecules cm^{-3}. The observed products concentrations were $\sim 10^{11}$ molecules cm^{-3} for IO(g) and $\sim 10^{14}$ molecules cm^{-3} for I_2(g). The peak of I_2(g) emission was markedly enhanced on a frozen NaI aqueous solution more than that on a liquid at pH 2. The peak of IO(g) emission was also enhanced on a frozen solution under the same condition. The physical structures of the ice substrates supposedly play an important role in this enhancement. Iodide anions are expected to be excluded from ice matrix during freezing. This exclusion process leads to the formation of concentrated iodide anions at the air-ice interface. In fact, sea ice contains brine microchannels that permit transport of reactants over large distances. It was found that the amounts of I_2(g) and IO(g) produced depend on [NaI], I_2(g) production is markedly enhanced at pH $<$4, and I_2(g) emission is decreased with decreasing temperature of a frozen NaI solution. Acidification of the brine by atmospheric trace acids could potentially lead to low pH. These results imply that a surface reaction between gaseous ozone and frozen iodide could be responsible for the inorganic source of iodine.

Speciation of S and Ca species in aerosols with its relations to global cooling effects and processes of chemical reacti

MIYAMOTO, Chihiro[1*] ; YAMAKAWA, Yoshiaki[2] ; SAKATA, Kohei[2] ; MIYAHARA, Aya[2] ; SAKAGUCHI, Aya[2] ; SUGA, Hiroki[2] ; TAKEICHI, Yasuo[3] ; ONO, Kanta[3] ; TAKAHASHI, Yoshio[2]

[1]Faculty of Science, Hiroshima Univercity, [2]Graduate School of Science, Hiroshima Univercity, [3]Photon Factory, KEK

Speciation of particles in aerosols is necessary to interpret what effects each species in the aerosols can have on environment. For example, global cooling effect by aerosols influences earth's climatic change (IPCC, 2007). In particular, sulfate aerosols are known to cool the earth by forming cloud condensation nuclei (CCN) because of their high hygroscopicity, which induces indirect cooling effect. Because the hygroscopicity differs depending on the species, sulfate speciation in aerosols is important for the determination of the magnitude of the indirect cooling effect.

In this study, major ion concentrations in aerosol samples were measured by ion-chromatograpy. In addition, chemical species of calcium and sulfur in the each aerosol sample were determined using X-ray absorption near-edge structure (XANES) measured at BL-9A in Photon Factory, KEK. The speciation analyses can have some implications on the influence on the environment and the processes of chemical reaction of aerosols collected during several periods, such as (a) dust (Kosa) period (March 4-9, 2013), (b) the period with high PM2.5 concentration (Jan. 31-Feb. 1, 2013), and (c) the periods before and after (a) and (b).

Major ion concentration data showed that Ca^{2+} , which is originated from soil, and NO_3^- and SO_4^{2-}, which were from human activities, increased in the period (a) compared with those in the periods before and after the period (a). On the other hand, SO_4^{2-} and NH_4^+, which were emitted from human activities, increased in the period (b). In the period (a), it is considered that species originated from acids such as sulfate and nitrate which were incorporated into the particles increased in the samples whose aerodynamic diameter is over 1.0 um, because they have reacted with $CaCO_3$ which was increased by Kosa event. In addition, from the fitting of XANES spectra, it was found that gypsum with low hygroscopicity were the main sulfur species in the period (a), whereas NH_4HSO_4, $(NH_4)_2SO_4$, and hydrated sulfate with high hygroscopicity were main sulfur species in the period (b). Therefore, it is considered that when the concentration of PM2.5 increases, the indirect cooling effect can be large due to the large fraction of NH_4HSO_4, $(NH_4)_2SO_4$, and hydrated sulfat. On the other hand, the indirect cooling effect by sulfate aerosols can be smaller during the dust period due to the formation of non-hygroscopic gypsum by high amount of calcite in the atmosphere.

Using the results of calcium and sulfur speciation both in the bulk and at the surface by fluorescence and conversion-electron yield detection, respectively, in the XANES analyses, we can discuss how chemical reactions occur at the surface of aerosol particles in each period. The abundance ratios of gypsum, $CaCO_3$, and $Ca(NO_3)_2$ were different at the surface and the bulk. As a result, it was concluded that calcium species changes from gypsum, $Ca(NO_3)_2$, to $CaCO_3$ from the surface to the core of the calcite particle. This results showed that (i) sulfuric acid from the atmosphere forms insoluble gypsum at the surface of calcite, (ii) $Ca(NO_3)_2$, formed as a result of the reaction of nitric acid and calcite, exists in the middle part, and (iii) unreacted $CaCO_3$ remains in the core of the particle.

Properties of Fe-containing particles and structure of mineral particles in the mountain, urban, and marine atmosphere

MIKI, Yusuke[1*] ; UEDA, Sayako[2] ; MIURA, Kazuhiko[1] ; KATO, Hiroki[1] ; FURUTANI, Hiroshi[3] ; UEMATSU, Mitsuo[3]

[1]Tokyo University of Science, [2]Nagoya University, [3]University of Tokyo

Atmospheric aerosol particles play an important role in global material cycles and global climate by acting as an agent which transports materials over long distances. Iron (Fe) is an essential element for marine phytoplankton growth especially in high nutrient and low chlorophyll (HNLC) area. Long-range transportation of atmospheric aerosols from the continent and subsequent deposition is an important process to supply Fe to the ocean. The dry and wet depositions of aerosol particles depend on the particle size and the mixing states with water-soluble materials. In order to study the properties of Fe-containing particles and modification of individual particles, we collected aerosol particles at the top of Mt. Fuji, at Kagurazaka, Tokyo, and on the ship over the mid-latitude western North Pacific Ocean during the KH-12-1 (EqPOS) Leg 2 cruise of the R/V Hakuho Maru. We collected aerosol particles with a low pressure impactor. Collected particles were analyzed using a transmission electron microscopy (TEM) with a water dialysis method and an energy-dispersive X-ray (EDX) analysis. We chose the samples which were collected in the long-range transportation events from the continent on the basis of 5-day backward air trajectory analysis, number size distribution of aerosols measured by an optical particle counter (OPC), and the results of the TEM-EDX analysis.

Water-insoluble materials such as mineral dusts and industrial anthropogenic metals are main sources of Fe. This study focused on water-insoluble materials and performed the EDX analysis. In each sample, most of water-insoluble materials were internally mixed with water-soluble materials (internal mixed particles). The volume percent of the water-soluble materials in the mixed particles on a marine sample was higher than that of other samples, indicating that water-insoluble materials as well as Fe-containing particles were mixed with water-soluble materials during transportation.

Structures of some mineral particles were verified using the focused-ion-beam (FIB) technique. Particles larger than 5 μm collected on the Ti-plate were sliced into 200 nm in thickness. We performed selected-area electron diffraction (SAED) on the cross section of the sliced particles. On the basis of the diffraction patterns and EDX results, structures of the mineral particles were verified. $CaCl_2$ was found on the surface of the particle and bounded on $CaCO_3$, suggesting that $CO_3{}^{2-}$ was replaced by Cl^- ($CaCO_3$ + 2HCl $\longrightarrow$ $CaCl_2$ + CO_2 + H_2O). Fe was included in the particle. There is a possibility that changing insoluble $CaCO_3$ to soluble $CaCl_2$ changes the ability of cloud nuclei and/or ice nuclei and the solubility of Fe.

Source of atmospheric lead in Omura City, west Japan, tied to the source of mineral particles

SAITOH, Yu[1*] ; UMEZAWA, Yu[2] ; KAWAMOTO, Kazuaki[2] ; TANIMIZU, Masaharu[3] ; ISHIKAWA, Tsuyoshi[3]

[1]Center for Advanced Marine Core Research, Kochi University, [2]Graduate School of Fisheries Science and Environmental Studies, Nagasaki University, [3]Kochi Institute for Core Sample Research, JAMSTEC

Lead is one of the major environmental pollutants, which seriously harms human body. Atmospheric lead concentration has been suppressed in Japan after the forbiddance of leaded gasoline in 1970s. However, the cross-border air pollution is getting unable to disregard with industrial development in neighboring countries. Identifying the source of aerosol particles is essential in painting a precise picture of the cross-border air pollution. The northern part of the Kyushu Island is the most affected area of the cross-border pollution in Japan due to closeness to the continent. We conducted isotopic analysis of aerosol particle samples corrected with high temporal resolution, once per a few days, from June 2011 to August 2012 in Omura City in the north Kyushu. Pb isotope ratios of 1M-HCl soluble component (”leachate”) of the corrected particles indicate the direct source of anthropogenic lead, while Sr-Nd isotope ratios of the residual mineral component digested by concentrated HF-HNO_3 (”slilicate”) indicate the source area of the mineral particles. High resolution sampling allowed us to distinguish the sources much more sensitively than commonly adopted monthly order sampling.

Sr-Nd isotope ratios of silicates indicate that the main source area of mineral particles changes seasonally. They have local origin in summer, while they are derived from deserts in mid-west China in fall and winter, and those in west China in spring (Figure A). Pb isotope ratios of leachates are distinct when the source of mineral particles is the mid-west China (Figure B). The values suggest the influence of the Chinese lead ore deposits. On the other hand, Pb isotope ratios of leachates are indistinguishable between samples of local origin and those originated from west China. An additional character of samples of west China origin is high amount of Pb in leachate relative to that of mineral component. Anthropogenic lead may be easier to be entrained to wind when the mineral particles comes from mid-west China because the wind trajectory should be much lower in altitude than when particles come from further distant west China. Cross-border atmospheric Pb pollution is suggested more serious in fall and winter when wind trajectory is low than in spring when the westerly transports vast amount of mineral particles known as ”Kosa” from the deserts in west China.

Continental Asia has been recognized as one of the most important sources of atmospheric dust particles. Many investigators have pointed out the importance of the atmospheric processing of dust particles in the course of long-range transport. Such processing can potentially change their radiative properties and their ability to act as cloud condensation nuclei. Three major factors that govern the processing of dust particles are dust mineral composition, relative humidity and concentration of acidic gas species. These factors are considered to be closely related with the height at which dust particles are transported. However, there has been no report so far on the direct comparison of the morphology and chemical composition of individual dust particles in the free troposphere and in the planetary boundary layer in the event of a same dust outbreak.

The helicopter was employed as the airborne platform in this study. Aerosol particles were directly collected by aerosol impactor over Hakui city, Isikawa, Japan (36.9 N, 136.7 E) on March 19, 2013. Then, Dust event was observed western Japan by Japan Meteorological Agency. Morphology and elemental composition of the collected particles were later examined on individual basis under SEM-EDX (Scanning Electron Microscope equipped with Energy Dispersive X-ray spectrometry).

Atmospherically processed dust particles (with apparent morphological modification) were hardly found in the free troposphere. On the other hand, large fraction of dust particles was found modified in the planetary boundary layer, showing spherical outline. High proportion of Calcium and Magnesium were detected from the modified particles. Also, dust particles collected in the planetary boundary layer contained Sulfur in higher abundance.

It is suggested that the atmospheric conditions in the free troposphere are less favorable for the dust particles to be modified than in the planetary boundary layer, because the vertical supply of acidic gases and water vapor into free troposphere is generally limited by the temperature inversion layer.

We have measured PM 2.5 using soler panel and fuel cell system at Southern area of Yakushima island Japan.

In order to clarify the long-range transport of atmospheric pollutants in the East Asian regions, we have challenged the continuous observation at a mountainous area without the commercial power. Although, we are considered to be better the system with a solar battery, the pump was sometimes stopped for the brownout cause by the lack of insolation. Thereupon, we make an attempt the continuous observation of atmospheric pollutants using the combination of the solar and fuel battery. And thus we achieve the continuous observation of the atmospheric pollutants. Consequently, we will report new monitoring system.

Development of a method to measure the hygroscopicity of black carbon-containing particles

OHATA, Sho[1*] ; MOTEKI, Nobuhiro[1] ; SCHWARZ, Joshua P.[2] ; KONDO, Yutaka[1]

[1]Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, [2]Earth System Research Laboratory, National Oceanic and Atmospheric Administration

Black carbon (BC) aerosols are generated by the combustion of fossil fuels and biomass. During transport in the atmosphere, BC particles acquire ”coating materials” through the condensation of semi-volatile gaseous components, and coagulation with the other aerosols. Freshly emitted BC particles are generally hydrophobic, so the hygroscopicity of BC-containing particles is largely controlled by the composition and amount of coating materials. Although measurement of the hygroscopicity of ambient BC-containing particles is important to understand their cloud condensation nuclei activity and optical properties, measurement data are still quite limited (McMeeking et al, 2011; Liu et al. 2013). In this study, we present a modified single particle soot photometer (SP2) as a humidified-SP2 (hSP2), which quantifies the BC mass and the amount of coating material within individual aerosol particles, under controlled relative humidity (RH), by detecting both the laser-induced incandescence emitted and laser light scattered from each BC-containing particle. High time-resolved measurements of growth factor (GF: the ratio of wet particle diameter to dry diameter) and hygroscopicity parameter κ for BC-containing particles can be achieved by combining an aerosol particle mass analyzer (APM) or a standard SP2 with the newly developed hSP2.

We have tested the hSP2 in the laboratory using both homogeneous ammonium sulfate, and internally mixed particles of BC (fullerene soot) and ammonium sulfate. These particles were dried and classified by an APM and subsequently measured by the hSP2 between 60% and 90% RH. We assumed a core-shell geometry for the BC-containing particles, and took account of the reduction in refractive index of the coating materials due to their hygroscopic growth. Measured GFs of the laboratory-generated BC-containing particles agreed with GFs predicted by κ-Köhler theory to within measurement uncertainty, demonstrating the applicability of the hSP2 for ambient measurements.

An Empirical Correction Factor for Filter-based Photo-absorption Black Carbon Measurements

IRWIN, Martin[1*] ; KONDO, Yutaka[1] ; MOTEKI, Nobuhiro[1]

[1]The University of Tokyo

Long-term observations of black carbon (BC) aerosol provide important information regarding seasonal variations, emission source attribution, and regional distribution & transport. Filter-based BC measurement techniques such as the Continuous Soot Monitoring System (COSMOS) are particularly well suited to this application, due to their relative robustness and reliability. However, caution is required when determining the threshold transmittance, Tr_{thresh} (proportional to the time interval between filter changes), in order to ensure that acceptable measurement accuracy is maintained throughout the sampling period. We present a new, empirically derived transmittance-dependent correction factor used to interpret the response characteristics of filter-based aerosol absorption measurements performed by COSMOS. Simultaneous measurements of ambient BC aerosol mass (M_{BC}) were conducted in Tokyo, Japan, using two identical COSMOS instruments operated with different threshold transmittance, Tr_{thresh}, values, of 0.95 and 0.6. The derived values for M_{BC} were consistently underestimated by the COSMOS operating at lower Tr_{thresh}, as a function of decreasing filter transmittance. The 1-hour averaged values of M_{BC} were underestimated by around 10 %, incorporating measurements across the entire range of filter transmittance (1 - 0.6), with a maximum underestimation at around 17 % immediately preceding filter advancement (i.e. $Tr = \sim 0.60$), and a minimum of $\sim$1 % immediately following filter advancement (i.e. $Tr = \sim 1$). An empirical second-order correction factor was derived from these ambient measurements, and was applied to M_{BC} as a function of filter transmittance, resolving the instruments to within 2 %.

Furthermore, the operational performance of COSMOS was tested for a new quartz fibre filter (HEPA). A comparison of different filter types demonstrated a systematic overestimation of M_{BC} of around 6 - 8 % when using HEPA filters. A sensitivity study of a radiative transfer model indicated that this enhanced absorption was primarily a result of the increased thickness of the HEPA filter.

Ship-borne measurements of black carbon aerosols over northwestern Pacific and Bering Sea

MIYAKAWA, Takuma[1*] ; KANAYA, Yugo[1] ; TAKETANI, Fumikazu[1] ; PAN, Xiaole[1] ; KOMAZAKI, Yuichi[1]

[1]Japan Agency Marine-Earth Science and Technology

Black carbon (BC) aerosol can strongly absorb the solar radiation and act as cloud condensation nuclei depending on the mixing state. Therefore, BC abundance and mixing state are key physicochemical properties to estimate the radiative impacts of BC aerosols [1]. Measurements of BC aerosols over the area where BC concentrations are very low are still limited because of the lack of high-sensitivity analytical methods. Single Particles Soot Photometer (SP2), which has been developed by Droplet Measurement, Inc., allows us to quantify the BC mass of single BC-containing particle and measure the BC number/mass concentration even in ultra-clean air [2]. Here we report the concentrations and mixing state of BC-containing particles observed using a SP2 on the research vessel *Mirai* during the research cruise over the northwestern Pacific and Bering Sea (MR13-05 cruise, 8/12-26, 2013).

BC mass concentrations over the sea near Japan ($<145^0$E) were elevated to $\sim$200 ng m^{-3}, whereas they were less than $\sim$40 ng m^{-3} over the northwestern Pacific and Bering Sea. Mixing states as a function of BC-containing particles deduced from SP2 raw data were categorized into three types; bare/thinly coated (type1), thickly coated (type2), and non-core-shell (type3) BC. Over the northwestern Pacific and Bering Sea, the number fractions of type1-BC were ~ 0.13, whereas those of type2-BC were as high as 0.8. We also found the minor but significant presence of type3-BC ($\sim$4%) over the remote ocean.

High-m/z ion signal to total mass signal ratios measured for secondary organic aerosol using aerosol mass spectrometer

SATO, Kei[1*] ; FUJITANI, Yuji[1] ; TANABE, Kiyoshi[1] ; MORINO, Yu[1] ; FUSHIMI, Akihiro[1] ; TAKAMI, Akinori[1] ; IMAMURA, Takashi[1] ; HIKIDA, Toshihide[2] ; SHIMONO, Akio[2]

[1]NIES, [2]Shoreline Science Inc.

A volatility basis-set (VBS) model in which oligomerizations are taken into account has recently been tested for further improvements of conventional VBS models.[1)] In order to study the oligomerization rates during secondary organic aerosol (SOA) formation and the ratio of high-*m/z* ion to total SOA mass spectrum ion signal, SOA particles produced during laboratory chamber experiments were analyzed by using an Aerodyne aerosol mass spectrometer (AMS). Photooxidation of α-pinene, isoprene, toluene, and 1,3,5-trimethylbenzene (TMB) was investigated in the presence of NO_x. Ozonolysis of α-pinene and isoprene was also studied. A stainless steel tube was used as a collection tube for AMS. A mass spectrum measured for organic aerosol (OA) in the region *m/z* = 10 – 675 was divided into seven mass regions; the total signal of each mass region was studied as a function of time. Increase in the signal intensity was observed with increasing of the OA level in a region *m/z* <500. The oligomer signals increased up to substantial levels within one hour after nucleation. After substantial amounts of oligomers were produced, the ratio of the total signal of each mass region to total OA signal was constant. Next, the ratio of total mass signal in the region *m/z* $>m_1$ to total OA mass signal, ϕ, was determined:

ϕ = OA (*m/z* $>m_1$)/OA(total),
$m_1 = n\ m_C$ (OM/OC),

where n is the number of carbon atoms in SOA precursor, m_C is the carbon atomic mass, and OM/OC is organic matter to organic carbon mass ratio measured by AMS. The m_1 values of α-pinene, isoprene, toluene, and TMB were determined to be 217, 147, 180, and 204, respectively. We assumed that a contribution from monomer signals is low in a region *m/z* $>m_1$. Signals measured by electron ionization of AMS contain both the fragment and parent ions of organic compounds. Note that the value, ϕ, is an index of oligomer to total SOA ratio, but does not represent an absolute value of that ratio. The ϕ value of SOA from the same precursor decreased with increasing of SOA mass loading (Fig. 1), showing that oligomer formation is suppressed under high mass loading conditions. In a region 10 – 100 μg m^{-3}, the ϕ value of toluene SOA was the highest, whereas that of α-pinene SOA was the lowest. No apparent effect of oxidation method (photooxidation or ozonolysis) was observed.

Controlling factors of aerosol size distribution over East Asia

HASHIOKA, Hideaki[1*] ; SHIBANO, Yuki[1] ; MOTEKI, Nobuhiro[1] ; KITA, Kazuyuki[2] ; MATSUI, Hitoshi[3] ; KOIKE, Makoto[1] ; KONDO, Yutaka[1]

Aerosol is known for its direct and indirect effects on climate, with both effects having a larger uncertainty than other radiative forcing elements, such as carbon dioxide. Investigating ambient aerosol size distributions is an important factor in estimating radiative forcing effects, as aerosol size is a major contributing factor to both the aerosol direct and indirect effects.

Ambient aerosol size and spatial distributions are controlled by various processes; e.g. new particle formation, coagulation, transportation, and wet deposition. For this reason, in situ measurements and analyses based on such processes are essential. However, results from measurements with high time resolution and low detection limits (e.g. of aerosol diameter) are rare. In this research, we introduce measurements of the aerosol size distribution over East Asia using the ultra high sensitivity aerosol spectrometer (UHSAS), and have tried to analyze the results based on wet removal processes.

The UHSAS is an optical particle counter. With its 2 types of photon diode and its efficiency in collecting scattering light, the UHSAS can obtain measurements of aerosol diameter in a wide range (about 70 to 1500 nm). We improved the hardware and software of the UHSAS specifically for use in aircraft measurements, to improve time resolution data and the instrumental precision of measurements of aerosol number concentration and size distribution (assuming spherical particles with refractive index 1.52). In addition, we have installed a robust mass-flow controlling system to deal with the significant changes in pressure associated with aircraft measurements. Scattering light signals obtained from photon diodes are saved to an external storage medium, which aids us in distinguishing signal from noise. We also present results showing the successful estimation of the optics inside UHSAS, in order to obtain highly precise diameter information using known standard particles.

The aerosol radiative forcing in East Asia (A-Force 2013W) aircraft campaign was conducted from late February to early March. We obtained air samples in real time from a forward facing inlet outside of the aircraft, Air was sampled by a variety of instruments including the UHSAS in real-time from a forward facing inlet outside of the aircraft. Data from the UHSAS showed good consistency with other instruments. During the campaign, the mean size distribution shifted to smaller diameters with increasing altitude. The transport efficiency (TE) of BC, which describes the degree of the wet removal of BC (calculated from the carbon monoxide mixing ratio and BC mass concentration), also decreased with increasing altitude (i.e. strong wet removal tendency for higher altitude). As the TE became smaller, the mean size distribution also shifted to smaller diameters, independent of altitude. This shows that the TE is the dominant factor controlling the aerosol size distribution, rather than absolute altitude. When the TE is smaller, the size distribution shifted to smaller diameters; this is the first observation of the size-dependent wet removal of general aerosols based on Köhler theory. This dynamic state of aerosol size distribution observed by the UHSAS surely contributes to quantitative understanding of aerosol direct and indirect effects on climate.

Vertical profiles of aerosol size distribution in small forest within a western suburb of Tokyo

YABUKI, Masanori[1*] ; TAKAHASHI, Kenshi[1] ; TSUDA, Toshitaka[1] ; MATSUDA, Kazuhide[2]

[1]Research Institute for Sustainable Humanosphere, Kyoto University, [2]Tokyo University of Agriculture and Technology

Forests interact in a complex manner with the atmosphere by acting as sinks for many atmospheric pollutants and trace gases, and by emitting biogenic volatile organic compounds into the air. These constituents influence the atmospheric chemistry and composition, including aerosols related to cloud condensation nuclei (CCN). Aerosol chemical and physical properties vary both temporally and spatially owing to various atmospheric processes (e.g., scavenging, nucleation, evaporation, and condensation) during the dispersion and transportation of air mass within and above forest canopies.

In this paper, we report on the field observations conducted from a 30-m-high tower in a small forest at the Field Museum Tama Hills, an experimental forest of the Tokyo University of Agriculture and Technology, located in a western suburb of Tokyo, between July 27 and August 3, 2013. At this site, atmospheric aerosols were expected to include the particles both from natural and anthropogenic sources. Using five sampling inlets placed at altitudes ranging from 8 m to 30 m, we conducted altitude-resolved measurements of particle number size distributions in the size range of 10-5000 nm. Herein, we present an outline of the observation systems, as well as the preliminary results of variability of sub-micrometer and nano particles within and above the forest canopy.

Recently, fluorescence from suspended single particles has been employed to identify and classify the certain types of organic/biological particles. Bioaerosols, including bacteria and other particles derived from living organisms, may explain large unidentified fraction of organic aerosols and play important roles in the cloud formation. In this study, we employed a single-particle fluorescence sensor, WIBS-4, to understand the abundance of bioaerosol particles over the western Pacific.

We conducted ambient air measurements over the western Pacific at July 2011, 2012, and 2013 by R/V MIRAI cruise. In order to avoid analyzing the particles emitted by ship's funnel, we eliminated the data by the wind direction. In the cruises, the bioaerosol particles based on fluorescent pattern were in the range of 0.1-2 particles/cc over the western Pacific. In the presentation, we will compare ocean surface chlorophyll data with detected fluorescence particles.

Impact of the Kuroshio warm SST on low altitude clouds: Numerical model simulation with smoothed SST

ASANO, Naruhiko[1*] ; KOIKE, Makoto[1] ; MATSUI, Hitoshi[2] ; NAKAMURA, Hisashi[3]

[1]University of Tokyo, [2]Japan Agency for Marine-Earth Science and Technology, [3]RCAST, University of Tokyo

Along the Kuroshio ocean current, high sea surface temperature (SST) is maintained even in winter and a steep SST gradient is formed across the current. In winter and spring, cold northwesterly air often flows from the Asia continent into the East China Sea. Once this cold air reaches the Kuroshio warm current, a large temperature contrast between sea surface and surface air (SAT) causes the marine boundary layer unstable and affect low altitude cloud formation. The northwesterly wind also transports a large amount of anthropogenic aerosols to East China Sea. These aerosols work as cloud condensation nuclei (CCN) and they affect microphysical properties of clouds. Because the marine boundary layer stability affects aerosol activation to form cloud particles, the large contrast between SST and SAT over the Kuroshio can also affect the aerosol-cloud interaction as proposed by Koike et al. [2012].

In order to assess the impact of Kuroshio warm SST on low clouds, we made WRF model calculations for a period between 21 Mar and 30 Apr 2009. In addition to the control calculation, we made sensitivity calculations, in which artificially smoothed SST was given for a lower boundary condition. In this smoothed SST, the SST gradually decreases toward higher latitudes and the maximum along the Kuroshio current no longer exists.

In the control calculation, the monthly mean cloud fraction (frequency of cloud occurrence in April 2009) was high in the south of Kuroshio and had a steep north-south gradient, corresponding to the SST steep gradient. A monthly mean liquid water pass (LWP) was large along Kuroshio and small in East China Sea, although it enhanced when cyclones passed. As compared with the control calculation, both the cloud fraction and LWP decreased over the Kuroshio in smoothed-SST calculations, and their north-south gradients became gentler.

LWP differences between control and sensitivity calculations varied depending on the wind direction. In northerly wind conditions, the LWP decreased in warmer frank (downwind) of a SST front. Under calm and horizontally homogeneous wind conditions, water vapor transport convergence was relatively small over the Kuroshio and column-integrated water vapor increased mainly by evaporation from the sea surface. In such case, LWP decreased on the Kuroshio in sensitivity calculation. This suggests that warm SST associated with Kuroshio enhances the evaporation and contributes to increase LWP of low clouds.

Measurement of the hygroscopic growth factor distributions of aerosol particles and the mass spectra of single particles

KAWANA, Kaori[1*] ; NAKAYAMA, Tomoki[2] ; MOCHIDA, Michihiro[1]

[1]Graduate School of Environmental Studies, Nagoya University, [2]Solar-Terrestrial Environmental Laboratory, Nagoya University

Hygroscopicity is a property that relates to the lifetime, chemical reactivity and cloud condensation nucleus activity of atmospheric aerosol particles. The amount of water retained by the particles as a function of relative humidity (RH) is governed by the phase state and chemical composition. In this study, hygroscopic growth factor distributions of atmospheric aerosol particles and mass spectra of single particles selected by the growth factors were measured using a combination of hygroscopicity tandem differential mobility analyzer (HTDMA) and a high resolution time-of-flight aerosol mass spectrometer (AMS) in Nagoya.

The observation of urban aerosols was performed on Higashiyama campus of Nagoya University in June and July, 2013. After aerosols were passed through PM1 cyclone and dried in diffusion driers, 300 nm particles were selected in the first DMA of the HTDMA. The growth factor distributions of the particles were measured under humidified conditions (setting RH: 37%, 65%, and 87%). The measurements were performed in both humidification and dehumidification modes. The mass spectra of single particles with specific hygroscopic growth factors *g* (1.0 at setting RH of 37%; 1.0, 1.1, and 1.25 at setting RH of 65%; 1.0 and 1.5 at setting RH of 87%) were measured using the AMS. The size distributions of aerosol particles were measured separately. The concentrations of organic carbon and elemental carbon in parts of the study period were also obtained.

In the humidification mode, the averages of the growth factor distributions at setting RH of 37% and 65% did not show substantial hygroscopic growth in terms of mean *g* (1.00 and 1.02, respectively), and those at setting RH of 87% showed large mean *g* (1.48). In the dehumidification mode, mean *g* of the averages of the growth factor distributions at setting RH of 37% and 65% (1.07 and 1.18, respectively) were substantially larger than those in the humidification mode, suggesting the presence of metastable-state aqueous solutions in the particles. At setting RH of 87%, the mean *g* in the dehumidification mode was large (1.44) as in the case of the humidification mode. The mass spectra of single particles with specific *g* were extracted from the obtained data; the number of these spectra was 349.

CCN activity of aerosol and its relation to air mass origins: an analysis based on year-round observation at Noto, Japan

IWAMOTO, Yoko[1*] ; KINOUCHI, Kento[2] ; MATSUKI, Atsushi[1]

[1]Institute of Nature and Environmental Technology, Kanazawa University, [2]Graduate School of Natural Science and Technology, Kanazawa University

Atmospheric aerosols play an important role in controlling the earth ' s radiation balance and/or the hydrological system by acting as cloud condensation nuclei (CCN). For a quantitative evaluation of CCN characteristics in the East Asia, CCN activity of atmospheric aerosols in submicrometer size range were measured at Noto Ground-based Research Observatory (NOTOGRO), located at the tip of Noto peninsula, facing the Sea of Japan. The observation was conducted from October 2012 to September 2013, to investigate the seasonal variability in CCN activity of the atmospheric aerosols.

CCN efficiency spectra, where CCN number fraction is plotted against the diameter of aerosols, were obtained at four different supersaturation (SS) conditions (0.1%, 0.2%, 0.5% and 0.8%) by using a scanning mobility CCN analysis (SMCA) system (Moore et al., 2010). Hygroscopicity parameters kappa (Petters and Kreidenweis, 2007), which depends on the chemical composition of aerosols, were estimated through analyses of the CCN spectra. The bulk chemical composition of non-refractory submicrometer-sized aerosols was also measured by an aerosol chemical speciation monitor (ACSM). Seven-days backward trajectories at the height of 500 m above the sea level were calculated by using NOAA/HYSPLIT4 model.

The CCN activation diameters of the atmospheric aerosols were clearly larger than those of pure ammonium sulfate throughout the year. The mean kappa values ranged between those of pure ammonium sulfate (0.61) and several pure organic compounds (0 to 0.25). These evidences suggest that the atmospheric aerosols were mixture of ammonium sulfate and organics. The bulk chemical composition derived by ACSM also showed that organics, sulfate and ammonium were three major components throughout the observation period. The contribution of organics to the CCN activity of the atmospheric aerosols observed in this study was more apparent than those obtained in the previous studies in the East Asia. As most of the previous CCN studies in East Asia were conducted in the season significantly affected by Asian outflow of pollutants, current numerical models might overestimate CCN concentrations in the East Asia.

The mean kappa values were 0.30, 0.26, and 0.18 during the spring, autumn and summer, respectively. The difference in kappa values among the seasons might be caused by difference in air mass origin. Air masses to the NOTOGRO site came mainly from NW across the Sea of Japan during the autumn and spring, whereas air masses of Pacific origin, those passed over the Japan islands, prevailed in the summer. Relatively high kappa values were observed under the influence of continental polluted air masses with high sulfate concentration. On the other hand, organic aerosols derived by photochemical oxidation were dominant in summer, resulted in low kappa values. The variation in kappa values of organics with air mass origins will also be discussed.

Long-term observation of initial droplet growth of activated CCN at Noto peninsula, Japan

KINOUCHI, Kento[1*] ; IWAMOTO, Yoko[2] ; KAGAMI, Sara[3] ; MATSUKI, Atsushi[2]

[1]Graduate School of Natural Science & Technology, Kanazawa university, [2]Institute of Nature and Environmental Technology, Kanazawa university, [3]College of Science and Engineering, Kanazawa university

Atmospheric aerosols affect the climate indirectly by changing optical property and lifetime of clouds through their ability to act as cloud condensation nuclei (CCN). Size of cloud droplets is an important factor to consider in the climate predictions because it can influence cloud albedo and frequency of precipitation. Important factors controlling the growth of cloud droplets are; 1. water vapor supersaturation (SS), 2. CCN size and 3. CCN chemical composition. Chemical composition of aerosols is a very important factor controlling the initial droplets growth. Recent studies indicate that there is high mass fraction of organics in the CCN relevant particles, and the droplet growth kinetics following the activation of such organic containing CCN is not fully understood.

East Asia is regarded as one of the most aerosol (hence CCN) dense regions in the world, but long-term monitoring of CCN properties in this region is relatively scarce. In this study, we conducted in-site and year-round measurement of CCN activity of submicron aerosols and related cloud droplet growth kinetics at NOTOGRO (acronym for NOTO Ground-based Research Observatory) located Suzu city, Noto Peninsula. A CCN counter (CCNC, CCN-100, DMT) was operated at four different super-saturation conditions (SS=0.1%, 0.2%, 0.5%, 0.8%). The diameters of cloud droplets activated from ambient aerosols ($D_{ambient}$) were compared to those activated from ammonium sulfate (D_{AS}) which is regarded as representative inorganic CCN. In order to identify factors that can potentially influence the initial cloud droplet growth, simultaneously measured chemical composition of aerosols with an Aerosol Chemical Speciation Monitor (ACSM, Aerodyne Inc.).

The measurement result showed that $D_{ambient}$ was not significantly difference from D_{AS} under higher SS conditions (i.e. SS=0.5% and 0.8%) throughout all seasons. However, there are periods that droplet growth was inhibited under lower SS conditions (i.e. SS=0.1% and 0.2%) especially during spring and autumn. Therefore, it was suggested that droplet growth under lower SS condition was more sensitive to other factors (other than SS). Based on the ACSM results, chemical composition of CCN was mainly contributed by various organics, ammonium and sulfate during the entire measurement period. The periods with limited droplet growth coincided with the periods with high organic mass fraction, and the negative correlation was found between the cloud droplets' diameters and organic mass fraction within atmospheric aerosols in CCN relevant sizes. On the other hand, we did not observe significant fluctuation in the cloud droplet diameters in winter. The measurement site is under the strong influence of winter monsoon especially during winter and the chemical species comprising CCN that are carried to the site may be considerably different from other seasons.

Seasonal variations of peroxyacyl nitrates and alkyl nitrates concentration at Suzu, the Noto Peninsula

ISHIYAMA, Ayana[1*] ; TAKAJI, Ryo[1] ; SADANAGA, Yasuhiro[1] ; MATSUKI, Atsushi[2] ; SATO, Keiichi[3] ; OSADA, Kazuo[4] ; BANDOW, Hiroshi[1]

[1]Osaka Prefecture University, [2]Kanazawa University, [3]Asia Center for Air Pollution Research, [4]Nagoya University

NO_x emissions have been increasing in East Asia with recent remarkable economic progress. NO_x has relatively short lifetime and NO_x concentrations are governed by local NO_x emissions. On the other hand, descendant photochemical products of NO_x such as $T.NO_3$ (the sum of gaseous nitric acid and particulate nitrates), PANs (peroxyacyl nitrates) and ANs (alkyl nitrates) have longer lifetime than NO_x, so that they can be transported over a long-distance. In order to understand influences of the cross-border pollution, it is important to clarify the long-range transport of $T.NO_3$, PANs, and ANs.

We have been continuously observing several pollutants at NOTOGRO (Noto Ground-based Research Observatory) supersite in Suzu, the Noto Peninsula. NOTOGRO is located at 37.45N and 137.36E. NO_x were determined by an LED photolytic converter / NO-O_3 chemiluminescence method. NO_y and $T.NO_3$ were observed by a scrubber difference / NO-O_3 chemiluminescence method. CO was monitored by a non-dispersive infrared photometer. PANs and ANs were measured by a thermal dissociation / cavity attenuated phase shift spectroscopy method.

In this presentation, observational results and discussion from December, 2012 to July, 2013 are described, focusing on seasonal variations of PANs and ANs. The air mass origins arriving at Suzu were classified into the following four groups, Russia and North China (RC), Korea and Middle China (KC) and Japan (JP) and Sea (S) using backward trajectory analyses. From winter to spring, both PANs and ANs concentrations from KC were higher than those from the other air mass origins. From spring to summer, their concentrations were independent of air mass origins.

From winter to spring, the lifetimes of PANs and ANs are long because of low temperature and weak solar radiation. In addition, their in-situ photochemical generation rates are low, so that PANs and ANs concentrations in this season are governed by long-range transport. From spring to summer, the lifetimes of PANs and ANs become shorter and their photochemical production rates become higher, that is, local photochemical productions of PANs and ANs are relatively important. Diurnal variations of PANs and ANs also support these concentration variation factors. From winter to spring, no diurnal variations were observed. Meanwhile, PANs and ANs concentrations began to be higher and lower in the daytime and nighttime, respectively, from spring to summer.

Development of a continuous measurement system of PANs and alkyl nitrates in the atmosphere and observations at Suzu, th

TAKAJI, Ryo[1*] ; ISHIYAMA, Ayana[1] ; SADANAGA, Yasuhiro[1] ; MATSUKI, Atsushi[2] ; SATO, Keiichi[3] ; OSADA, Kazuo[4] ; BANDOW, Hiroshi[1]

[1]Osaka Prefecture University, [2]Kanazawa University, [3]Asia Center for Air Pollution Research, [4]Nagoya University

Peroxyacyl nitrates (PANs) and alkyl nitrates (ANs) are generated in the atmosphere by oxidation of NO_x in the presence of solar ultraviolet. They have a comparatively long lifetime, and are important as transboundary air pollutants. On the other hand, PANs and ANs act as the reservoirs of NO_x. In order to clarify transboundary pollution of nitrogen oxides, comprehensive measurements of total odd nitrogen species (NO_y), including PANs and ANs, are required. In this research, a continuous measurement system of total PANs and ANs has been developed by a thermal dissociation / cavity attenuated phase shift spectroscopy (TD/CAPS) method.

This instrument consists of heated quartz tubes to decompose PANs and ANs into NO_2, and a CAPS-NO_2 analyzer. This system has three intake lines; NO_2, PANs and ANs lines. The NO_2 line equip of a quartz tube without heating. The PANs and ANs line equip quartz tubes heated at 433 K and 633 K, respectively for thermally decomposing them into NO_2. Concentrations of NO_2, NO_2 + PANs and NO_2 + PANs + ANs can be obtained from the NO_2, PANs and ANs lines, respectively. These concentrations are sequentially measured by switching solenoid valves and then NO_2, PANs and ANs concentrations are obtained. Since a part of HNO_3 is pyrolyzed in the ANs line, annular denuder coated with NaCl to remove HNO_3 is set before the heated quartz tube in the ANs line. The decomposition efficiencies of PANs and ANs were calibrated to be 100 and 95%, respectively, for all kinds of PANs and ANs examined.

Continuous field observations of PANs and ANs have been being performed at NOTOGRO (Noto ground-based Research observatory) supersite in Suzu, the Noto Peninsula, since November 2012. Continuous measurements of NO_x, NO_y, T.NO_3 (the sum of gaseous nitric acid and particulate nitrate) O_3, and CO have also been being conducted. NO_y concentrations were in agreement with the sum of observed NO_y components (= NO_x + T.NO_3 + PANs + ANs) regardless of seasons. NO_x fractions were the highest in NO_y constituents. Fractions of T.NO_3 in January and February were lower than those in other months. This reflects that wet deposition of T.NO_3 would be accelerated in winter due to snowfall. On the other hand, PANs fractions in spring and summer were smaller than those in winter. This suggests that temperature increasing promotes decomposition of PANs.

On-line measurements of multiple alkanes by chemical ionization mass spectrometry using NO^+ as the reagent ion

INOMATA, Satoshi[1*] ; TANIMOTO, Hiroshi[1] ; YAMADA, Hiroyuki[2]

[1]NIES, [2]NTSEL

Proton transfer reaction mass spectrometry (PTR-MS) is a technique that allows for fast and sensitive measurement of volatile organic compounds (VOCs) at trace levels in air. Proton transfer is an example of chemical ionization: it enables soft ionization of chemical species that have a proton affinity (PA) higher than that of the reagent species (i.e., water):

H_3O^+ + VOC ->VOC?H^+ + H_2O (1)

Unlike gas chromatography, PTR-MS does not require any sample treatment such as drying and/or preconcentration, which makes possible quantitative measurement of alkenes (except ethylene), aromatics, and even oxygenated VOCs. However, the proton transfer in reaction (1) does not occur for alkanes because they have lower PAs than water. Very recently, a method to measure C_{12}-C_{18} alkanes using PTR-MS was demonstrated. They were, however, detected by a series of fragment ions with formula C_nH_{2n+1} and were detected not individually, but as an ensemble.

Reactions of alkanes with NO^+ have been investigated by selected ion flow tube mass spectrometry (SIFT-MS). It was reported that hydride ion transfer is a major channel in the reaction of alkanes (RH) with NO^+.

NO^+ + RH ->R^+ + HNO (2)

Recently, the PTR-MS instrument has been combined with switchable reagent ion capability, which allows for easy and fast switching between H_3O^+ and NO^+ (proton-transfer-reaction *plus* switchable reagent ion mass spectrometry (PTR + SRI-MS)).

In the present study, the detection properties of alkanes by PTR + SRI-MS are investigated. We confirmed that alkanes (RH) were usually detected as R^+ by PTR + SRI-MS using NO^+ as the reagent ion and detection sensitivities were comparable to those of aromatics observed by H_3O^+ ionization. We also demonstrated time-resolved measurements of C_4-C{16} alkanes in automotive exhaust during the Japanese JC08 transient cycle. It can be concluded that sensitive on-line measurement of multiple alkanes is possible by PTR + SRI-MS using NO^+ as the reagent ion.

Observation of formaldehyde and glyoxal variations by MAX-DOAS in Chiba and Tsukuba in 2013

CHIN, Sei[1*] ; NI, Wentao[1] ; IRIE, Hitoshi[1]

[1]Chiba university

BVOCs (Biogenic Volatile Organic Compounds) are plant-released organic chemicals that are volatile in air at normal ambient temperature and pressure. Reactions of BVOC in the atmosphere have a great influence on the OH abundance in the atmosphere. In addition, the reactions lead to the formation of ozone, which is not only adversely affecting plants and human health but also acting as a greenhouse gas. Furthermore, part of the products from the oxidation reaction of BVOCs forms aerosols, which play a critical role in cloud formation processes and radiation balance. Thus, BVOCs are deeply related with climate and air quality surrounding us. Recently, formaldehyde and glyoxal are recognized as important indicators of oxidations of BVOCs. However, their observations have been limited. In this study, we use the data got from MAX-DOAS to analysis the diurnal variation, seasonal variation of formaldehyde and glyoxal for the first time. And then we try to find the reason or the factors which makes the variations.

Figure1 shows the data of glyoxal concentration observed in China during 2013. To know the diurnal and seasonal variation, we calculated the average value of every hour in each month. We found the clearly pattern that the concentration of glyoxal is high during the day and summer. At noon of the summer, the concentration of glyoxal was increased to more than 0.105ppbv. We also found the same pattern in Tsukuba. In this study, we observed glyoxal and formaldehyde in the same time, and organize the data of Chiba and Tsukuba in 2013 and try to find the reason of the variation.

Development of a direct measurement system of photochemical ozone production rate in the troposphere

KAWASAKI, Shio[1*] ; SADANAGA, Yasuhiro[1] ; TANAKA, Yuki[1] ; KAJII, Yoshizumi[2] ; BANDOW, Hiroshi[1]

[1]Osaka Prefecture University, [2]Kyoto University

Recently, ozone concentrations in the troposphere have been rising in spite of a steady decrease in concentrations of ozone precursors such as NO_x and volatile organic compounds. Photochemical production processes of ozone are non-linear to concentrations of ozone precursors. In addition, ozone concentration variations are influenced by meteorological factors such as transport and deposition processes as well as photochemistry. It is useful that the meteorological and photochemical factors could be divided to discuss ozone concentration variations. In order to discuss only "photochemical" factors for ozone production, a direct measurement system of photochemical ozone production rate has been developed.

Ambient air is introduced into "reaction" and "reference" chambers. The reaction and reference chambers (171-mm inner diameter and 500-mm length) are made of quartz and Pyrex, respectively. Inner walls of both the chambers are coated with Teflon to avoid wall loss of ozone. An outer wall of the reference chamber is coated with a UV-cut film (50%-cutoff wavelength of 405 nm). In the reaction chamber, photochemical reactions proceed to generate ozone. On the other hand, ozone is not produced photochemically in the reference chamber. Air passed from the reaction and reference chambers is introduced into "NO-reaction" tubes to covert O_3 to NO_2 in the presence of a high concentration of NO, and then the air is introduced into an NO_2 measurement system by a laser-induced fluorescence technique. Increment of ozone (ΔO_3) is defined by the difference of NO_2 concentrations derived from the reaction chamber and those from reference chamber. The ozone production rate is obtained by dividing ΔO_3 by a mean residence time of air in the reaction chamber (τ). In this system, O_3 concentrations are not directly measured but NO_2 concentrations converted by the reaction of O_3 with excess NO are observed. This is because the photostationary states between NO_x and O_3 are different between in the reaction and reference chambers, and ozone concentrations vary apparently. The sum of ozone and NO_2 concentrations (abbreviated as PO) are kept in the different photostationary states, so that this instrument measures production rates of PO instead of those of ozone practically.

Important parameters in this system are (1) ultraviolet transmittance of the reaction and reference chambers, (2) τ, and (3) conversion efficiency of O_3 to NO_2 in the NO-reaction tube. For (1), we measured solar spectra at inside and outside of the chambers using a spectroradiometer. Almost a hundred % of solar UV was transmitted into the reaction chamber. A wall of the reference chamber cut off solar UV adequately. For (2), about 10 ppmv of pulsed NO_2 was added into the reaction chamber and temporal variations of LIF signals were measured. τ was calculated to be 22.1 ± 0.5 min using the temporal variation the signals. For (3), quantitative conversions of O_3 up to 160 ppbv by NO in the NO-reaction tube were confirmed under the excess NO condition 0.97 ppmv.

Transbounday ozone pollution from China to Japan; a case study

YURIKO, Keyamura[1*] ; HAYASHIDA, Sachiko[1]

[1]Faculty of Science, Nara Woman's University

These days, high concentrations of atmospheric ozone are often observed at the ground and/or in the lower troposphere over Japan, and transboundary ozone pollution from China would be one the possibility.

In this study we sampled highly concentrated ozone events observed at the ground and in the lower troposphere, and calculated backward trajectories hourly from the observation sites and compared the trajectories with the ozone map obtained by satellite measurement. The ozone lidar used here is the MRL (Meteorological Research Laboratory) ozone lidar [Nakazato et al.,Applied Optics, 2007], which has short wavelengths in UV and thus continuous day-and-night measurements are possible. We also utilized the surface ozone monitoring network organized by Ministry of Environment.

The ozone distribution maps at the lower troposphere were obtained by OMI ozone product provided by Liu et al.[ACP, 2010]. They retrieved ozone profiles from the ground up to about 60 km into 24 layers among which 3 layers are in the troposphere. The lowermost layer (24th layer) is corresponding to 0 ˜about 3 km.

From analysis mentioned above, we found some cases indicating clear evidence of transboundary pollution from China to Korea and Japan.

This study was supported by a Grant - in - Aid from the Green Network of Excellence, Environmental Information(GRENE - ei) program. And OMI data were provided by Dr. X.Liu and Dr. K.Chance, and Ozone - liar data were provided by Dr. M.Nakazato.

[1]Graduate School of Science and Engineering, Ibaraki University, [2]College of Science, Ibaraki University, [3]Center for Environmental Remote Sensing, Chiba University, [4]Faculty of Science, Nara Women's University, [5]Solar-Terrestrial Environment Laboratory, Nagoya University, [6]Meteorological Research Institute, [7]National Institute for Environmental Studies, [8]NASA Ames Research Center

The lower tropospheric ozone is a major component of photochemical oxidant which causes photochemical smog, adversely affecting human health and vegetation when it comes to high concentration. Therefore knowing their behavior as air pollution is an important. In recent years, contrary to the reduction of lower tropospheric ozone precursor gases, their amount is increasing. It has been suggested that the long-range transport of the lower tropospheric ozone from Asian Continent affects air quality in Japan and other wide areas. Remote sensing from a satellite is effective to observe such extensive/transboundary air pollution. However it has been quite difficult to measure the lower tropospheric ozone from satellite.

We have proposed that it can be evaluated with simultaneous measurement of solar backscattering spectra in the ultraviolet(UV) and visible(Vis) regions. Because the atmospheric Rayleigh scattering cross-section is much larger in UV than that in Vis, lower tropospheric light path length of the solar scattered radiation observed from space is significantly different in these two wavelength regions. This difference of light path enables us to detect the lower tropospheric ozone by the simultaneous measurement of UV and Vis solar backscattered spectra from space.

For the validation of this technique, we carried out aircraft experiments to validate this method over Tsukuba on 10th and 13rd September 2012. UV and Vis backscatter spectra were measured with two spectroscopes (Maya2000pro, Ocean Optics, USA) at two altitudes 2500 ft (760 m) and 25000 ft (7600 m). Simultaneously, ozone profile was measured with ozone monitors on-board the aircraft, with ozonesonde launched near Tsukuba, and the tropopheric ozone lidar. Because aerosol scattering may significantly affect the evaluation of the lower tropospheric ozone amount, in situ aerosol observation with the CRDS, PSAP, and PASS instruments and the lidar observation were carried out in the Meteorological Research Institute. From the aircraft, we observed solar scattered radiation from zenith, nadir and 20 degree oblique directions in ultraviolet(300 - 380nm wavelength) and visible(400 - 700nm wavelength) spectral range. Because the surface reflected light greatly contribute to the scattered light from nadir, especially in the visible spectral range, for accurately estimation of the ozone amount, it is particularly important to understand the surface reflection spectrum. In this experiment, ground reflection spectra at different surface conditions such as rice paddy, forest, urban, farm areas and so on were measured at a low altitude of 2500ft (760m). It is necessary to consider the effect of scattering near the aircraft to estimate the surface reflected light. We estimated it with SCIATRAN (Rozanov et al., 2005). Results of these observations will be presented at this session.

The Relationship between CO Concentration and Biomass Burning over the North China Plain

KAYABA, Satoko[1*] ; HAYASHIDA, Sachiko[1] ; ONO, Akiko[1]

[1]Faculty of Science, Nara Women's University

Carbon monoxide (CO) controls the greenhouse gasses (e.g., CH4, O3) indirectly through a chemical reactions. Therefore, CO is regarded as an indirect-greenhouse gas and thus it is important to understand its spatiotemporal variation.

Wang et al.,[JGR, 2002] suggested that the open crop residue burning in June over the North China Plain affects on CO concentration, and it was confirmed by field campaign at Mt.Tai and investigated by model simulations [Kanaya et al.,2013 and reference therein]. Besides, the recent rapid industrialization in China brought significant increase in emission of CO [Ohara et al., ACP, 2007].

In this study, we analyzed the relationship between fire outbreak and CO concentration over the North China Plain by using satellite data. The CO data are taken from Measurement Of Pollution In The Troposphere (MOPITT). We used the Version 5 product. The fires detected by satellite observations are expressed as the hotspot numbers that are derived from the MODIS thermal anomaly product [Takeuchi and Yasuoka, 2006], using the algorithm by [Giglio et al.RSE,2003]. Here we used the hotspot numbers as proxy of the fire detection index.

CO concentration in June increases accompanied by a large number of the hotspot counts, which is consistent as previous studies. On the other hand, CO concentration gradually increases in fall and winter with only few hotspot numbers. It implies that CO emissions are possibly from industrial activity, automobiles and coal burning for heating rather than biomass burning in fall and winter. In addition, the year-to-year variability of CO concentration in June and in fall and winter was different.

This study was supported by a Grant-in-Aid from the Green Network of Excellence, Environmental Information (GRENE-ei) program.

We started an international collaboration project on research of ozone/UV and aerosol in South America since 2013. This project is supported by Japan Science and Technology Agency (JST) and Japan International Cooperation Agency (JICA) under SATREPS program. The counterpart institutions are CEILAP (Laser Application Research Center) in Argentina and Magellan University in Chile. The major aims of this project are (1) to construct new aerosol lidar network in Chile and Argentina, (2) to consolidate the ozone monitoring capability at the South Patagonian Atmospheric Observatory (OAPA , 52S, 69W) in Rio Gallegos at the southern end of the South American continent. The new aerosol lidar network consists of 9 lidars. Six of them are Raman lidars and the other 3 are high-resolution lidars with an iodine filter. Eight lidars are distributed over Argentine territory to observe volcanic ashes from volcanos in Andes, Patagonian dust, and black carbon from Bolivia and Brazil. From the observatory in Rio Gallegos, we will make comprehensive observations of ozone by using a DIfferential Absorption Lidar (DIAL), millimeter-wave spectral radiometer, brewer spectrometer, and so on. In addition to the consolidation of observing network, we will develop data analysis and data distribution system to deliver the data to the relevant organizations in the both countries.

In the presentation, we will introduce the overview of this project and present a progress report after the first year.

Observations of horizontal distributions of air pollutants by MAX-DOAS

NI, Wentao[1*] ; IRIE, Hitoshi[1] ; CHEN, Cheng[1] ; TAKAMURA, Tamio[1] ; KHATRI, Pradeep[1]

[1]Chiba University

In June 2012 we set up a MAX-DOAS device in Chiba University and continuous observations have been conducted since then. The MAX-DOAS method measures the spectra of scattered sunlight in ultraviolet and visible regions at various elevation angles. By analyzing the measured spectra with a radiative transfer model and an inversion method, vertical distributions of aerosol and gas and their column amounts can be retrieved (Irie et al., 2008,2009, Vlemmix, 2010). In this study, firstly, we compared the aerosol optical depth measured by the MAX-DOAS to that measured by the sky radiometer. We found the consistency of differences between MAX-DOAS and sky radiometer AOD values are within 30%.Secondly, we set up two MAX-DOAS devices (machine No.1 and No.2) for simultaneous observations at the same place. For both devices, the wavelength regions of 460-490nm and338-370nm were analyzed with the DOAS method to derive the differential slant column densities (DSCDs) of O4.In order to quantify the effect of the systematic offset of the elevation angle in O4 DSCDs, we have biased the offset of elevation angles by +-0.5,+-1.0 degrees. Comparisons such as correlation analysis etc. show that the effect is insignificant as there is only 20% differences found in the O4 DSCD comparisons between two devices. Based on such a detailed error evaluation, since December 2013, we have directed the machine No.1 to north and No.2 to west to perform quantitative observations of horizontal-distribution of aerosols. Results will be discussed in this work.

Validation of GOSAT SWIR xCH4 using TCCON and Airborne Measurements

IWASAKI, Chisa[1*] ; HAYASHIDA, Sachiko[1] ; ONO, Akiko[1] ; MACHIDA, Toshinobu[2]

[1]Faculty of Science, Nara Women's University, [2]NIES

As methane (CH_4) is one of the most important Short-Lived Climate Pollutants (SLCPs), global monitoring of atmospheric CH_4 with enough accuracy is expected to estimate its sources and sinks. For measurements of global distribution of CO_2 and CH_4 concentration from space, the Greenhouse gases Observing SATellite (GOSAT) was launched in 2009, and has continued measurements up to the present. However, cloud interferes satellite observation. To understand CH_4 emission from a cloudy region, the selection of an adequate criterion of cloud screening, and validation of data quality are necessary.

In this study, we validate the GOSAT CH_4 products of the column-averaged dry-air mole fractions (xCH_4) derived from Short-Wavelength InfraRed (SWIR) radiation by comparing them with data of Total Carbon Column Observing Network (TCCON). Yoshida et al. (AMT, 2013) had already carried out the validation for the NIES product, but we extended the period and involved more TCCON sites; Yoshida et al. (2013) used data observed at the 13 TCCON sites from June, 2009 to December, 2012 and we used data at the 17 TCCON sites from June, 2009 to August, 2013. We found that the average difference between TCCON and GOSAT for the whole period is -6.0 $\pm$ 16.1 ppbv.

We also examined the appropriate cloud screening for xCH_4 product from RemoTeC-MACC. The product was obtained by using the "proxy method" by which we can obtain more data under cloudy conditions. In this study, we also tried to compare GOSAT data with aircraft measurements over Siberia and other areas.

Acknowledgements

Mixing ratios of greenhouse gases and related trace gases have been measured using chartered and commercial aircraft in the lower to upper troposphere (LT and UT) over Japan by Tohoku University. We present variations of CH_4 during 1988-2010. The analysis is aided by simulation results using an atmospheric chemistry transport model (i.e. ACTM). Tropospheric CH_4 over Japan shows altitude-dependent interannual and seasonal variations, reflecting differences in air mass origins at different altitudes. The long-term trend and interannual variation of CH_4 in the LT are consistent with previous reports of measurements at surface baseline stations in the northern hemisphere. However, those in the UT show excursions from those in the LT. In the UT, CH_4 mixing ratios show seasonal maximum in August due to efficient transport of air masses influenced by continental CH_4 sources, while LT CH_4 reaches its seasonal minimum during summer due to seasonally maximum chemical loss. Vertical profiles of the CH_4 mixing ratios also vary with season, reflecting the altitude-dependent seasonal cycles. In summer, transport of CH_4-rich air from Asian regions elevates UT CH_4 levels, forming the uniform vertical profile above the mid troposphere. On the other hand, CH_4 decreases nearly monotonically with altitude in winter-spring. The ACTM simulations with different emission scenarios reproduce general features of the tropospheric CH_4 variations over Japan. Tagged tracer simulations using the ACTM indicate substantial contributions of CH_4 sources in South Asia and East Asia to the summertime high CH_4 values observed in the UT. This suggests that our observation data over Japan are highly valuable for capturing CH_4 emission signals, particularly from the Asian continent.

Measurement of CO2 stable isotope ratio by mid-inferred laser absorption spectrometry; analysis of CO2 cycle in urban

YUBA, Akie[1*] ; TAKAHASHI, Kenshi[2] ; NAKAYAMA, Tomoki[1] ; MATSUMI, Yutaka[1]

[1]Solar-terrestrial environment laboratory, Nagoya university, [2]Research Institute for Sustainable Humanosphere, Kyoto University

CO_2 concentration has been increasing from the range of 275 ppmv (parts per million by volume) to 285 ppmv in the previous industrial period to about 400 ppmv in 2013. IPCC reported that CO_2 has the most effective on the positive radiative force. The insight of CO_2 emission and absorption flux helps us to estimate the variation of radiative forcing and atmospheric environment. CO_2 concentration changed with the anthropogenic and biogenic emission and absorption. The stable isotope ratio of CO_2 (δ^{13}C and δ^{18}O) is associated with the CO_2 source such as combustion and biogenic respiration. The contribution of each CO_2 source in the urban area was estimated by using the stable isotope ratio of CO_2.

We conducted the continuous measurement for CO_2 concentration and stable isotope ratio of CO_2 using the mid-inferred absorption spectrometry which can obtain CO_2 concentration and its isotope ratio with high time resolution. The water vapor and stable isotope ratios of water vapor (δD and δ^{18}O-H_2O) were measured to show the relationship between H_2O and CO_2 due to the isotopic exchange reaction. CO and NO_x concentrations were obtained as a tracer of anthropogenic emission. The measurement was conducted for two weeks in summer and winter. The seasonal variation of CO_2 source was shown according to the comparison of CO_2 concentration and stable isotope ratio. Especially, we focused on the contribution of biogenic process to CO_2 concentration variation in the urban area.

CO_2 concentration and stable isotope ratio of CO_2 in the summer showed the diurnal variation. On the other hand, those in the winter had no diurnal variation. CO_2 concentration variation in the winter was correlated with CO concentration variation. These results suppose that CO_2 concentration variation in the winter was mainly dominated by the anthropogenic emission and that in the summer was related with biogenic process as well as anthropogenic emission. We will discuss the relationship between stable isotope ratio and meteorological condition or water vapor isotope ratio to identify the detail of CO_2 source.

Temporal and spatial variations of Radon-222 in the western North Pacific

TSUBOI, Kazuhiro[1*] ; MATSUEDA, Hidekazu[1] ; SAWA, Yousuke[1] ; NIWA, Yosuke[1] ; MURAYAMA, Shohei[2]

[1]Meteorological Research Institute, [2]National Institute of Advanced Industrial Science and Technology

A new compact radon measuring system has been developed for high-resolution observation of low-level radon-222 (Rn) for the remote sites, in collaboration with the MRI and AIST. The Rn measuring system was installed at 4 stations of Minamitorishima (MNM), Yonagunijima (YON), Chichijima (CCJ) and Ryori (RYO) operated by Japan Meteorological Agency (JMA) since 2007 . The Rn measurements clearly show that distinct seasonal variations as well as frequent episodic events with Rn enhancement peaks on a synoptic scale are successfully captured at all 4 stations. Although the seasonal cycles depended on the stations, significant correlations between the Rn and other trace gases were found for the most of the synoptic-scale events, indicating a large impact of widespread pollutions from the East-Asian countries on the regional air quality over the western North Pacific.

Estimation of Several Kilometer Scale PWV Distribution using GNSS Slant Path Delay for Monitoring of Cumulus Convection

SHOJI, Yoshinori[1*]

[1]Meteorological Research Institute

A procedure for estimating precipitable water vapor (PWV) distribution around each ground-based station of the global navigation satellite system (GNSS) on a scale of several kilometers is presented. This procedure utilizes the difference between zenith total delay above a GNSS station and zenith mapped slant path delay (SPD). By assuming an exponential distribution for the horizontal water vapor gradient, this difference can be used to estimate the PWV gradient in each SPD direction. Shoji (2013) proposed the WVI index, which is defined as the standard deviation of the PWV_{SPD}. The retrieved PWV gradient in this study can be regarded as another utilization of PWV_{SPD}. In the WVI index, ray path direction data is not utilized. The PWV gradient proposed in this paper utilizes both the deviation of PWVSPD and information on its direction.

The procedure was tested for an estimation of the PWV variation associated with the parent storm of an F3 Fujita scale tornado that occurred in Ibaraki prefecture on May 6, 2012. Differential reflectivity observed by a dual-polarimetric radar showed the existence of a developed parent cloud approximately 1 h before the tornado occurred. A high-resolution numerical weather model simulation showed the existence of a strong PWV gradient around the parent cloud, made evident by the co-existence of a strong updraft and downdraft within an approximately 5-km radius. The PWV gradient calculated using the GNSS observation network with an average spacing of approximately 17 km could not detect such a small-scale, strong PWV gradient. The PWV gradient estimated using the proposed procedure revealed a strong PWV gradient and its enhancement. In this case, higher order inhomogeneity component of each SPD played a critical role.

However, the gradient was weaker than the NWP simulation. This might be partly because of the insufficient observation density. Horizontal scale of the higher order inhomogeneity component of each SPD is about several kilometers and we adopt distance cutoff of 5 km. In order to analyze several kilometer scale PWV distribution, we need denser GNSS network with at least 10 km horizontal spacing. Another possible reason for the weaker gradient may be insufficient and inhomogeneous coverage of GPS satellites. As of 2012, carrier waves transmitted from six to twelve GPS satellites could be observed simultaneously at each GNSS site in Japan. This might be insufficient for estimating the water vapor gradient in all directions. Also, we need to carefully check the quality of each SPD. In this study, following Shoji (2013), the effects of the satellite clock error and multipath (reflected wave) are tried to eliminate. However it is difficult to distinguish atmospheric signal with those noises, especially under local severe weather.

The number of GNSSs has been increasing. As of December 2013, 24 satellites of the Russian GLONASS are in operation. The European Union's GNSS (Galileo) is in the experimental phase and China is also developing an independent GNSS system named COMPASS. Furthermore, a number of space-based augmentation systems (e.g., Japan's QZSS) and regional navigation satellite systems (e.g. the Indian Regional Navigation Satellite System, or IRNSS) will contribute further satellites and signals to the multi-constellation GNSS. In the next step of this study, we will assess the impact of the increased number of SPDs on multi-GNSS.

Numerical Simulation on Retrieval of Meso-gamma Scale PWV Distribution with the Quasi-Zenith Satellite System (QZSS)

OIGAWA, Masanori[1*] ; REALINI, Eugenio[1] ; SEKO, Hiromu[2] ; TSUDA, Toshitaka[1]

[1]Research Institute for Sustainable Humanosphere (RISH), Kyoto University, [2]Meteorological Research Institute (MRI), Japan Meteorological Agency (JMA)

A simulation study was conducted to investigate the retrieval of meso-gamma scale Precipitable Water Vapor (PWV) distribution with QZSS, using the output of a non-hydrostatic numerical weather prediction model. The evaluation was performed on PWV values obtained by simulating three different methods: using all GPS satellites above an elevation angle higher than 10 degree (PWVG) (conventional GPS meteorology method), using only the QZSS satellite at highest elevation (PWVQ) and using only the GPS satellite at highest elevation (PWVHG).

The RMSEs of PWVG, PWVQ and PWVHG were compared, assuming the vertically integrated water vapor amount of the model as true PWV. As a result, the RMSEs of PWVG, PWVQ and PWVHG were 2.78, 0.13 and 0.59 mm, respectively, 5 minutes before the rainfall. The PWVHG time series had a large discontinuity (~2 mm) when the GPS satellite at the highest elevation changed, whereas that of the PWVQ time series was small, because the elevation angle at which the replacement of the highest elevation QZSS satellite occurs is much higher. The standard deviation of PWVQ was smaller than those of PWVG and PWVHG, which vary largely depending on the GPS satellites geometry.

When the spatial distributions of PWVG and PWVQ were compared to the meso-gamma scale distribution of the reference PWV, PWVG smoothed out the PWV fluctuations whereas PWVQ captured them well, due to the higher spatial resolution achievable by using only high-elevation slant paths. These results suggest that meso-gamma scale water vapor fluctuations associated with a thunderstorm can be retrieved by using a dense GNSS receiver network and analyzing PWV derived from a single high elevation GNSS satellite. In this paper we focus on QZSS, as this constellation is especially promising in this context since it is going to provide nearly continuous PWV observations also as its highest satellite changes, contrary to using highest satellites from multiple GNSS constellations.

Data assimilation experiments of refractivity distribution observed by an operational Doppler Radar of JMA

SEKO, Hiromu[1*] ; SATO, Eiichi[2] ; SAKANASHI, Takanori[3]

[1]Meteorological Research Institute, JAMSTEC, [2]Meteorological Research Institute, [3]Japan Meteorological Agency

Because low-level convergence of water vapor generates the convections, accuracy of local heavy rainfall forecasts is expected to be improved when horizontal distribution of low-level water vapor is observed. We focused on radio waves of Doppler Radars that are returned from fixed structures. Because the radio waves are delayed by water vapor while passing atmosphere, we can estimate refractivity, which is a function of temperature and water vapor, from the delay of radio waves. If radio waves of many Doppler Radars that have been deployed in Japan are used in producing initial conditions of numerical forecasts, the forecast accuracy of thunderstorms is expected to be improved through improvement of water vapor fields by using this technique.

In this presentation, temporal variations of refractivity observed by Tokyo Radar and the impacts of refractivity on the rainfall forecasts will be presented.

Overview and future strategy of docomo Environmental Sensor Network(ESN)

TSUBOYA, Hisakazu[1*] ; HIGASHI, Kuniaki[2] ; FURUMOTO, Jun-ichi[2]

[1]Division of life support business promossion,NTT DOCOMO Corporation, [2]Research Institute for Sustainable Humanosphere, Kyoto University

NTT docomo had launched a nation-wide and hyper-dense network for the measurement of both weather and environmental element since 2008 and provide them as new information contents to the markets. Its realtime data could be applied to various industrial issues, namely hazard prediction, agriculture, and medical&healthcare. docomo make the new network infrastructure more sophisticated and is planning to expand its sensor stations, which has been set only to its radio base stations up to now, to any customers who need to measure their own environment.

Meisei developed compact weather sensor (POTEKA Sta.) and cloud data-transfer system (POTEKA Lab.) to achieve high dense observation network. ”POTEKA” stands for ”Point Tenki Kansoku”. POTEKA project has been demonstrated the validity for the use of disaster prevention, health and medical care, teaching material, agriculture and energy management, and comfortable living environment in cooperation with local companies and education board since August 2013.

POTEKA Sta. measures wide range of meteorological and environmental variables such as temperature, relative humidity, pressure, sunlight, and rain detection with a one minute resolution. This low-cost weather sensor enables us to achieve finer-meshed or higher density weather observation system economically. Finer-meshed and more extensive data collected are easily accessible through ordinal Web sites (PC, Tablets, etc.) without any special software.

Spatio-temporal high dense observation network (total 55 stations, 1.5˜4km-mesh) was installed in Isesaki city, Gunma, Japan. Observation with elementary/junior high school and convenience store (SAVE ON) are performed at 14 stations and 41 stations, respectively, which spatially captured local surface weather phenomenon (fig. 1).

This paper presents some examples including 1. local distribution of surface temperature around Isesaki, 2. preventing heat stroke at school, and 3. school education for class and research.

Acknowledgments: The authors would like to thank SANDEN Corporation, SAVE ON, and Board of Education of Isesaki city for support POTEKA project.

[1]National Defense Academy, [2]Meisei Electric

On the evening of 11 August 2013, a severe thunderstorm passed over the Takasaki and Maebashi city, Gunma prefecture, and produced gusty wind damages. The change of surface weather elements was recorded by dense observation network POTEKA when gust occurred. In this study, we follow the development and propagation of gust-front and downburst through the analysis of features of the pressure field observed by POTEKA. The result of this analysis reveals that the reason of gust caused damages in Maebashi city is downburst.

Helicopter-borne thermocamera measurements of surface temperatures in downtown Tokyo -Comparison of 2013 with 2007-

TSUNEMATSU, Nobumitsu[1*] ; YOKOYAMA, Hitoshi[1] ; HONJO, Tsuyoshi[3] ; ICHIHASHI, Arata[1] ; ANDO, Haruo[1] ; MATSUMOTO, Futoshi[1] ; SETO, Yoshihito[2]

[1]Tokyo Metropolitan Research Institute for Environmental Protection, [2]Chiba University, [3]Tokyo Metropolitan Research Institute for Environmental Protection/Tokyo Metropolitan University

Annual mean air temperatures in downtown Tokyo have increased about 3 degrees Celsius in the past 100 years due to global warming and urban heat island. The frequency of heat stroke outbreaks in Tokyo tends to increase in recent years. The Tokyo metropolitan research institute for Environmental Protection has therefore investigated the current situation of the temperature rises in Tokyo through the monitoring of urban heat island. This can contribute to verification of measure effects on urban heat island.

As part of the investigations, we performed helicopter-borne infrared thermocamera measurements of surface temperatures in downtown Tokyo (mainly an Otemachi-Marunouchi-Yurakucho area) on two different extremely hot days, Aug. 19, 2013 (hereafter, HTM13) and Aug. 7, 2007 (HTM07). The measurements were carried out in the daytime (12-13 local time) and the nighttime (20-22 local time), using a Robinson R22 helicopter with a longwave (8-14um) infrared thermocamera (TS7302) developed at NEC Avio Infrared Technologies Co., Ltd. An altitude of the helicopter flight was 610 m. The daytime air temperatures on those days reached 32-33 degrees Celsius although southerly sea breezes prevailed in the area. Compared with the HTM07 case, a higher air temperature condition was predominant prior to HTM13.

Results of analyses of data from the thermocamera-derived images (a 2 m ground resolution) show that surface temperatures obtained from HTM13 are relatively large in the greater part of the area, compared with HTM07 (refer to a figure shown below), whereas, smaller surface temperatures can be recognized in redevelopment areas where new buildings have been constructed after 2007. (Note that the emissivity of each surface material can influence it.) Also, the thermocamera-derived images projected on Google Earth show higher surface temperatures on intersections.

In addition, we would like to show geographical distributions of the observed surface temperatures in the nighttime, differences between the daytime and nighttime surface temperatures, and a relationship between surface temperatures and sky view factors.

How Does A Typhoon Affect The Local Downslope Wind Hirodo-Kaze In Japan?

FUDEYASU, Hironori[1*] ; KIYOHARA, Yasutomo[2] ; OHASHI, Yukitaka[3] ; KUWAGATA, Tsuneo[4] ; MORIYAMA, Fumiaki[1]

[1]Yokohama National University, [2]The Certified and Accredited Meteorologists of Japan, Japan, [3]Okayama University of Science, Japan, [4]National Institute for Agro-Environmental Sciences, Japan

The Hirodo-kaze is one of the well-known strong local winds in Japan. Hirodo-kaze occurs at the southern base of Mt. Nagi (1240 m) in the northeastern Okayama Prefecture, when the lower-troposphere synoptic wind is strong northerly in association with a typhoon. Previous studies have described the mechanisms that force downslope winds and large-amplitude mountain waves. However, descriptions of the effect of temporal changes in the large-scale environment on the severe downslope wind are not enough. The purpose of present study is to examine the forcing mechanisms during a Hirodo-kaze and the effects of typhoons on the occurrence of a Hirodo-kaze.

The Hirodo-kaze that occurred in association with Typhoon Pabuk was investigated as a case study. At 06 UTC on 21 August 2001, when Pabuk was located over the sea about 80 km southwest of the Kii peninsula, strong surface winds related to the cyclonic circulation of Pabuk were observed in Shikoku and Kinki districts. Relatively weak northerlies prevailed in Chugoku district far from Pabuk, but a strong northerly was observed at the station located in the lee of Mt. Nagi, about 5 km south of the crest of Mt. Nagi, namely Hirodo-kaze.

The mesoscale model, MM5, successfully reproduces the major features of the observed Hirodo-kaze and Typhoon Pabuk. During the Hirodo-kaze, the severe downslope winds in the transitional flow develop in the lower troposphere below the mean-state critical layer. The Hirodo-kaze is closely linked to the strong wind region accompanying the severe downslope winds. After the cessation of the Hirodo-kaze, distinct mountain waves dominate in the lower troposphere where the Scorer parameter decreases with height. The region of strong wind retreat windward as the Hirodo-kaze ceases. Temporal changes in the characteristics of mountain waves in the lee of Mt. Nagi are primarily attributed to the changes in the large-scale environmental winds due to the movement of Typhoon Pabuk.

The effects of intense typhoons on the occurrence of the Hirodo-kaze were also investigated statistically using data using European Center for Medium Range Weather Forecast 40?year re?analysis data (ERA-40). According to the several reports of Okayama meteorological station, twelve Hirodo-kaze events occurred between 1989 and 2001. During these events, strong lower-tropospheric northerlies were overlain by middle-tropospheric southerlies. These favorable conditions occur only as an intense typhoon moves over the sea southwest of Kii peninsula. Thus, the intense typhoon that moves over the sea southwest of the Kii peninsula creates favorable environmental conditions that support the occurrence of the Hirodo-kaze.

The phased array radar system which was installed in 2012 in Osaka University has the unique capability of scanning the whole sky with 100m and 10 to 30 second resolution up to 60 km. The system adopts the digital beam forming technique for elevation scanning and mechanically rotates the array antenna in azimuth direction within 10 to 30 seconds. The radar transmits a broad beam of several degrees with 24 antenna elements and receives the back scattered signal with 128 elements digitizing at each elements. Then by digitally forming the beam in the signal processor, the fast scanning is realized. After the installation of the PAR system in Osaka University, the continuous operation has been done and succeeded in getting several hazardous rain fall events with lightning locations. The data for these events captured by the Phased Array Radar shows the unique capability of the high resolution weather radar. In this presentation, over view of the Phased Array Radar is firstly given, and after that observation results and future direction of the Phased Array Radar Network with polarimetric capability is shown.

Statistical analyses on the characteristics of heavy rainfall events

TSUGUTI, Hiroshige[1*] ; KATO, Teruyuki[1]

[1]Meteorological Research Institute

In this study, to clarify general characteristics of heavy rainfall events in Japan, we have conducted various statistical analyses on them.

For the warm seasons (April - November) from 1995 to 2009, we objectively extracted heavy rainfall events occurring in Japan by using Radar-Raingauge analyzed rainfall dataset produced by the Japan Meteorological Agency. As a result, 386 events were extracted. Over 75 % of all events occurred during three months of July, August, and September, and many events were distributed around the coastal areas of the Pacific Ocean in Kyushu, Shikoku, Kinki, and Tokai regions. Synoptic weather conditions causing the heavy rainfall events were clarified, and consequently the pattern associated with typhoons or tropical cyclones was the most predominant, which accounted for 32.4 % of all events. Then, stationary fronts, remote precipitation of typhoons or tropical cyclones, and low depressions accounted for 21.2 %, 17.9 %, and 14.2 %, respectively. The classification for the shape of the precipitation systems causing the heavy rainfall events showed that the most predominant system was ”band-shaped”, which accounted for 43.5 % of all events.

The environmental fields of heavy rainfall events ($>$130 mm/3hr) were statistically analyzed using the Japanese 55-year reanalysis data (JRA-55). Characteristics of them were elucidated by comparing the environmental fields of moderate rainfall events (10-30 mm/3hr). In July (the late Baiu season) in Kyushu region, the low-level equivalent potential temperature and water vapor flux in the vicinity of Kyushu Island were significantly larger in heavy rainfall events than in moderate ones, and the atmospheric stability became more unstable in heavy rainfall events. Furthermore, to distinguish heavy rainfall events from moderate ones, the combination of two elements of low-level water vapor flux and atmospheric stability was more effective than the unique usage of each element.

MRI Rapid-Scan and Super-Resolution Observations in severe storms: Recent Progress and Future Plans

KENICHI, Kusunoki[1*] ; INOUE, Hanako[1] ; YOSHIDA, Satoru[1] ; KATO, Rhohei[2] ; FUJIWARA, Chusei[3]

[1]Meteorological Research Institute, [2]Alpha-denshi Co., Ltd., [3]East Japan Railway Company

In this presentation, we will introduce the recent progress, present examples, and future plans of rapid-scan and super-resolution observations in severe storms of the Meteorological Research Institute (MRI).

1. A linear array of pressure and wind sensors for high resolution in situ measurements in winter tornadoes

In order to improve our understanding of near-surface tornadic features, we developed a linear array of wind and pressure sensors (LAWPS) for high resolution in situ measurements in winter tornado cores. The pressure and wind sensors were deployed along a 1.2km-long linear array that is located parallel to and about 100m from the shoreline. Wind data are obtained using 12 two- dimensional fast-response ultrasonic anemometers placed at a height of 5 m at intervals of 100 m. Pressure data are obtained using 25 barometers placed at a height of 50cm at intervals of 50m. The pressure ports are designed and loaded to the barometers to reduce the dynamic pressure associated with wind and turbulence. In this presentation, the system overview and the measurement technique will be described, as well as some examples of actual winter tornado observations of the system and X-band Doppler radar simultaneously.

2. An X-band phased array Doppler radar for the research of severe storms

Many severe storms evolve on time scales shorter than that resolved by conventional mechanically scanning radar systems. MRI has a new project of development of severe storm observations and detections from a phased array radar. The azimuth scan is similar to the conventional scan with a mechanically rotating antenna and at a variable rate between 1- 6 rpm. 128 slotted waveguide array elements fixed above the antenna panel produce transmit beam and an electronic elevation scanning will be performed. With the electronic elevation and mechanical azimuth scanning, the radar can observe the entire sky in less than a minute. Such high temporal resolution sampling will be expected to provide a realistic structure of rapidly evolving storm. In this presentation, some basic characteristics of the radar and a brief description of future tasks for detection and prediction of severe storms will be presented.

Fine radar echo structure revealed by a high scanning and high-range-resolution X-band marine radar

FUJIYOSHI, Yasushi[1*]

[1]Inst. Low Temp. Sci., Hokkaido Univ.

We used an X-band (9410 MHz) marine radar (KODEN Co., Ltd.), which is not powerful and not very sensitive (its peak transmitted power is 25 kW and minimum detection power is -90 dbm); however, the radar has a high range resolution (15 m). Although its antenna usually rotates horizontally to detect ships, we changed the rotation direction of the slot antenna (2 m in length) from horizontal to vertical (Range Elevation Indicator-scan), and recorded every 2 s. We deployed this radar at various places. We will report very interesting phenomena that are firstly detected by this high-scanning and high-resolution radar.

Applications of weather radar network in private companies

TESHIBA, Michihiro[1*]

[1]Weathernews Inc.

Recently, various weather radars have been developed not only with novel functions of observation, but with low cost. As a result, each private companies can deploy their own weather radars and make a radar network. In the US, for example, local TV stations have their weather radars and the current situation is analyzed through their radars' data. However, in Japan weather radars have not been deployed yet. In this paper I would like to introduce the Weathernews (WNI)'s weather radar network in Japan and we would discuss future work in order to expand this type of network in Japan.

Temporal Variation of Close-Proximity Soundings within a Significant Tornadic Supercell Environment

ARAKI, Kentaro[1*] ; ISHIMOTO, Hiroshi[1] ; MURAKAMI, Masataka[1] ; TAJIRI, Takuya[1]

[1]Meteorological Research Institute

We examined proximity soundings at intervals of a few minutes and at distances of less than 20 km from a significant tornadic (SIGTOR) supercell that occurred on 6 May 2012 in Japan. We used a 1-dimensional variational (1DVAR) technique that combined the observations of a ground-based microwave radiometer with outputs from a numerical model. Based on the results of the 1DVAR, several supercell and tornado forecast parameters were calculated and compared with values typical of SIGTOR supercell environments in the United States. One and a half hours before the occurrence of the tornado, the value of convective available potential energy increased significantly to about 1000 J kg^{-1}, a value that is smaller than the typical value in the United States. Low-level vertical wind shear and some composite parameters attained maximum values at the time when the distance to the supercell was the smallest. The vertical wind shear parameters and some composite parameters indicated that the environment fell into the SIGTOR supercell category. This result shows that the thermodynamic environments became unstable before the approach of the supercell, and the low-level vertical wind shear changed locally near the supercell.

Data Assimilation experiment of Tsukuba tornado on May 6, 2012 using MRI Doppler Radar data

YOKOTA, Sho[1*] ; KUNII, Masaru[1] ; SEKO, Hiromu[2]

[1]Meteorological Research Institute, [2]Meteorological Research Institute/JAMSTEC

A strong tornado with F3 scale caused serious damage in Tsukuba city on May 6, 2012. This tornado was generated at the southern tip of a precipitation area, which was moving northeastward over the Kanto Plain. Besides the Tsukuba tornado, two tornadoes were observed a few ten kilometers north of the Tsukuba tornado. The lower vortex associated with the Tsukuba tornado, as well as its precipitation area, was well captured by the Doppler Radar of the Meteorological Research Institute (MRI), because the Tsukuba tornado passed 15 km north of the MRI. However, data assimilation experiments using the high-resolution data, such as Radar data, have not been performed yet. In this study, Doppler wind data observed by the MRI-Radar were assimilated with an ensemble Kalman filter so as to evaluate the impact of the assimilation of Doppler wind.

In this experiment, a Nested Local Ensemble Transform Kalman Filter (Nested- LETKF) system, with 12 ensemble members, was used. In Outer-LETKF (horizontal grid interval: 15 km), hourly operational observation data used in the Japan Meteorological Agency (JMA) operational model were assimilated with 6 hour intervals. In Inner-LETKF (horizontal grid interval: 1.875 km), data obtained every 10 minutes was assimilated with 1 hour intervals. To assess the impact of the Doppler wind observations, we basically performed two experiments. The ”CTL” experiment used conventional observations, that is, the original settings of the Nested-LETKF. The other ”VR” experiment assimilated the Doppler wind data observed by MRI-Radar additionally in Inner-LETKF, while all other settings were the same as CTL. After the data assimilation experiments, downscaling ensemble experiments (horizontal grid interval: 350m) were carried out by using the analyses and 12 perturbations of each CTL and VR at 10:00 JST on May 6, 2012 as initial conditions.

In the downscaling ensemble experiments, two vortices were formed although three vortices were actually observed. The southern vortex in VR was stronger and passed about 2 km closer to the observed tornado than that in CTL. To clarify those differences, we focused on Storm Relative Helicity (SReH) and low level humidity (Low-Qv) at 10:00 JST. The SReH and Low-Qv were compared to the maximum velocity of the Tsukuba tornado vortex (Vmax) and to the latitude where the vortex existed when it passed 140E (L140), using the analyses and 12 perturbations of VR. As a result, Vmax had a positive correlation to SReH in and south of the precipitation area. It also had a positive correlation to the Low-Qv in the south of the precipitation area, and in the south of the genesis point of the vortices. In fact, Low-Qv in the south of the genesis point of vortices in VR was increased by the assimilation of Doppler wind. On the other hand, L140 had a negative correlation with Low-Qv in the south of the precipitation area. It shows that the precipitation area was elongated in the meridian directions and that the vortex was generated further to the south if humidity was higher in the south of the precipitation area.

The wind speed and location of the vortex had correlations with SReH in and south of the precipitation area. They also had correlations with Low-Qv in the south of the precipitation area and in the south of the genesis point of vortices. Therefore, proper correction of these values by data assimilation is important to better reproduce the vortex.

Development of Phased Array Weather Radar and Doppler Lidar Network Fusion Data System

SATOH, Shinsuke[1*] ; YASUI, Motoaki[1] ; MAENO, Hideo[1] ; HANADO, Hiroshi[1] ; TAKAHASHI, Nobuhiro[1] ; IWAI, Hironori[1] ; KAWAMURA, Seiji[1] ; KOJIMA, Shoichiro[1] ; AMAGAI, Jun[1] ; TANAKA, Kenji[1] ; OCHIAI, Satoshi[1] ; KUBOTA, Minoru[1] ; IGUCHI, Toshio[1]

[1]National Institute of Information and Communications Technology

At National Institute of Information and Communications Technology (NICT), we promote advanced research and development of remote sensing technology, to reduce the damage of severe weather disasters caused by localized heavy rainfalls or tornadoes. An industry-academia-government team consisting of Toshiba, Osaka University, and NICT developed one-dimensional phased array weather radar (PAWR) that it is possible to seamless 3D observation in 10 ? 30 seconds. In May 2012, we installed PAWR at Osaka University Suita Campus, and started test observation. From the observation, a first echo appeared in an isolated cumulonimbus cloud was falling to the ground for about 10 minutes. In order to predict the generation point of the cumulonimbus cloud, we need other data which includes wind fields before cloud generation, distributions of water vapor and aerosol, and so on. For that reason, we develop a sensor fusion system with PAWR, Doppler lidar, and others. We install the systems to both NICT Advanced ICT Research Institute (Iwaoka, Nishi-ku, Kobe, Hyogo) and NICT Okinawa Electromagnetic Technology Center (Onna, Kunigami, Okinawa), and install the network data system to NICT headquarters (Koganei, Tokyo).

The sensor fusion system consists of the PAWR antenna in a radome installed on the roof of a 20 m tower, Doppler lidar (Leosphere 400s) on the deck at the height of 15 m of the tower, microwave radiometer to measure water vapor, and sky-radiometer to measure aerosol. Also, temperature, humidity, wind speed components (u, v, w), pressure, rainfall amount, radiation budget, and cloud images (4 directions and whole sky) are measured. All sensors are connected by network for remote operation and automatic data acquisition. The observation data are transferred in real-time through the fast network lines (JGN-X) from Kobe and Okinawa to Koganei for data processing to make a composite map, and so on. The processing data are displayed on a big 4K display TV, and are published using a web server.

We will start test observation after the system completion in March, 2014. At NICT, we also promote research and development of network data system using advanced ICT for big-data processing, transfer, visualization. We give this system a nickname of PANDA: **P**hased **A**rray weather radar and Doppler lidar **N**etwork fusion **DA**ta system, and will publish the data from http://panda.nict.go.jp/.

Campaign Observation at Keihanshin Area for Detecting Convection Genesis

YAMAGUCHI, Kosei[1*] ; NAKAKITA, Eiichi[1]

[1]Disaster Prevention Research Institute

In 2008, around 50 people who enjoyed sunny days along the riverside were flushed away by a sudden flash flood in a small river channel (Toga River) in Kobe urban area of Japan. This extreme event was a combinational result of steep basin slope, paved urban area, and severely localized heavy rainfall, which is more frequent happening in the recent summer of Japan. There are many short and steep rivers passing through urban areas in Japan, and the most of riverside along these rivers are used as a public open place. Because of the steep basin slope and the paved urban area, only short time of the localized heavy rainfall, such as 30 minutes of rainfall with 50mm/hr of intensity, can cause very dangerous situation in urban areas as in the Toga River case.

In order to prevent such flash flood damages, it is very necessary to detect the rain-cells, which may develop to sever storm, as soon as possible and to alert people to evacuate from riverfront before the severe events occur. In this study, we develop a detection technique for the early stage of rain-cell as the first cell aloft (hereafter, baby-cell) in the middle atmospheric layers before it generates heavy rainfall on the ground. The early detection technique is utilizing the 3-D volume scanning data from X-band Multi Parameter radars (X-MP radars), which are equipped near to the most urban area in Japan recently. In our recent study using the 3-D volume scanning information from the X-MP radars, we have successfully developed an algorithm (1) to detect newly generated baby-cells, (2) to identify dangerous level of the baby-cells, and (3) to trace the movement of the baby-cells.

In the developed algorithm, firstly, the detection of newly generated baby-cells is based on the information of 3-D volume scanning data with very fine resolution of the X-MP radars. Secondly, the identification of the dangerous level, whether the detected baby-cells will grow up to heavy rainfall on the ground, is evaluated with the information of vorticity of the baby-cells based on the Doppler velocity information from the radars. Finally, the tracking of the baby-cells is based on the conventional cell tracking scheme. The preliminary test of the algorithm shows that especially, the identification of the developing baby-cells with the vorticity information is very powerful, and most of baby-cells in the early stage of heavy rainfall events were successfully identified. In detail, all the 19 developing baby-cells under our surveillance were successfully detected, and there was only one false alarm (forecasted as a heavy rainfall event, but it was not).

In our presentation, upgraded performance index of our proposed algorithm will be introduced based on various rainfall events happened in Kyoto and Osaka area, Japan. In addition to improving this practical early detection algorithm for localized heavy rainfall events in urban area, we are conducting newly designed observation combination in Kansai area with numerous sensors and equipments as shown in figure to identify the mechanism of the localized heavy rainfall events in urban area, such as Osaka, Kobe and Kyoto. It is definitely our mission to realize a next-generation operational observation network with different types of sensors for earlier detection and/or prediction of generating storm from the stage of air plume and/or cloud. Presentation partly includes current situation and future plan of a plot type field experiment with X-band- polarimetric radar, Ku-band cloud radar, Lider, and X-band phased array radar.

Analysis of fine-scale airflows over complex topography by super-high-resolution numerical model

TAKEMI, Tetsuya[1*]

[1]Disaster Prevention Research Institute, Kyoto University

With the increase in computational resources, mesoscale meteorological simulations with the grid spacing on the order of 100 m have been conducted not only in idealized studies but also in studies that deal with real cases. In real cases, the benefits from such high-resolution simulations are considered to be better representations of surface topography such as complex terrains and complex distribution of man-made structures. In this presentation, we will demonstrate how fine-scale airflows over complex topography such as terrains and urban districts are represented in numerical simulations of local-scale wind fields under real meteorological settings. Some of the case studies of high wind events are described. For the numerical simulations of specific weather events, we use the Weather Research and Forecasting (WRF) model by downscaling from kilometer-scales to 100-meter-scales with the use of nesting capability. Further downscaling from 100-meter-scales down to 10-meters or higher requires the explicit representation of not only complex terrains but also buildings and structures. For this purpose, we developed an approach to couple a mesoscale meteorological model (i.e., the WRF model) and a computational fluid dynamics (CFD) model (Nakayama et al. 2012). A large-eddy simulation model for airflows over urban geometries (Nakayama et al. 2011) is employed as a CFD model. A unique feature of the present coupling approach, an improved version of the perturbation recycling method of Mayor et al. (2002), is to generate turbulence due to urban-like roughness obstacles with the meteorological effects produced by the mesoscale model being retained. The basic idea of this coupling approach and a case study for a high wind event in the downtown district of Tokyo are demonstrated. Furthermore, some other applications of the present approach for airflow simulations over complex topography including airflows over complex terrain of Fukushima during March 2011 will be briefly introduced.

A study on an atmospheric propagation delay estimation method using a fixed radio source

INAKA, Shigeru[1*] ; FURUMOTO, Jun-ichi[1] ; SEKO, Hiromu[2] ; TSUDA, Toshitaka[1] ; HASHIGUCHI, Hiroyuki[1] ; ISHIHARA, Masahito[3]

[1]Research Institute of Sustainable Humanosphere, Kyoto University, [2]Meteorological Research Institute, [3]Education unit for Adaptation to Extreme Weather Conditons and Resilient Society, Kyoto University

This study aims to develop a new method to observe water vapor horizontal distribution using a side-lobe emission of the 1.3 GHz-band wind profiling radar (WPR). The phase delay of the received side-lobe emission is mainly due to the refractive index fluctuation along the propagation path. In the atmospheric boundary layer, the temporal and spatial non-uniformity of water vapor determines the refractive index fluctuation. Main scope of the study is to extract humidity information from the atmospheric phase delay of side-lobe emission from a WPR. Horizontal humidity distribution can be derived by the data assimilation into numerical prediction model.

The receiver system and data analysis algorithm were developed. A software radio, USRP N200 with an RX daughter board was employed to detect side-lobe emission received by an antenna. A Rubidium frequency standard and a 1 pps signal source of GPS receiver were used for accurate estimation of phase delay variation. The frequency stability of a crystal oscillator, which is generally employed for a reference frequency source of WPR, is insufficient for the accurate estimation. We proposed a new method to compensate the frequency uncertainty of WPR by using data of the additional receiver nearby the WPR site.

IQ data detected by USRP B210 which is controled by GNURadio, an open source software. By using GNURadio the system will be low cost.The program written in IDL language extracts the temporal variation of the phase delay from the received IQ signal. In order to achieve good performance even in low SNR conditions, we developed an algorithm using STFT (Short-term Fourier transformation) aiming to remove noise in undesired frequency range.

The developed system is promising to derive humidity information from side-lobe emission from various WPRs such as the operational WPR network in Japan (WINDAS (WInd profiler Network and Data Acquisition System)).

Development of a 266 nm Raman lidar for profiling atmospheric water vapor

UESUGI, Takuma[1*] ; YABUKI, Masanori[1] ; LIU, Yutong[1] ; TSUDA, Toshitaka[1]

[1]Research Institute for Sustainable Humanosphere

It is projected that localized extreme weather events could increase due to the effects of global warming, resulting in severe weather disasters, such as a torrential rain, floods, and so on. Understanding water vapor's behavior in the atmosphere is essential to understand a fundamental mechanism of these weather events. Therefore, continuous monitoring system to measure the atmospheric water vapor with good spatio-temporal resolution is required. We have developed several water vapor Raman lidar systems employing the laser wavelengths of 355 and 532 nm. However, the signal-to-noise ratio of the Raman lidar strongly depends on the sky background because of the detection of the weak inelastic scattering of light by molecules. Therefore, these systems were mainly used during nighttime.

Hence, we have newly developed a water vapor Raman lidar using a quadrupled Nd:YAG laser at a wavelength of 266 nm. This wavelength is in the ultraviolet (UV) range below 300 nm known as the "solar-blind" region, because practically all radiation at these wavelengths is absorbed by the ozone layer in the stratosphere. It has the advantage of having no daytime solar background radiation in the system. The lidar is equipped with a 25 cm receiving telescope and is used for measuring the light separated into an elastic backscatter signal and vibrational Raman signals of nitrogen and water vapor at wavelengths of 266.1, 283.6, and 294.6 nm, respectively. This system can be used for continuous water vapor measurements in the lower troposphere. This study introduces the design of the UV lidar system and shows the preliminary results of water vapor profiles.

Since 2008, the automated meteorological observation network has been developed by NTT DOCOMO corporation and a total of 4,000 stations are operating now.

The hyper-dense wind measurement network was constructed through the industrial-academical corporation between NTT DOCOMO and Kyoto University, which enables us to elucidate the detailed characteristics of strong downslope windstorm, Hira Oroshi, blowing down in the West coast of the Lake Biwa.

This paper discussed the outline of our activities and fruitful results will be discussed in detail.

Surface Pressure Distributions of Downburst and Tornado captured by High Dense Ground Observation Network ”POTEKA”

SATO, Kae[1*] ; KURE, Hirotaka[1] ; YADA, Takuya[1] ; MAEDA, Ryota[1] ; KOJIMA, Shinya[1] ; MORITA, Toshiaki[1] ; IWASAKI, Hiroyuki[2]

[1]Meisei Electric Co. Ltd., [2]Faculty of Education, Gunma University

Meisei developed low-cost compact weather sensor (POTEKA Sta., hereinafter referred to as the POTEKA), which can measure temperature, relative humidity, pressure, sunlight, and rain detection per one minute and achieve higher density weather observation system economically. We installed economical and high dense ground observation network (total 55 stations, 1.5˜4 km-mesh) in Gunma, Japan. This paper presents observation of wind gust phenomena around Takasaki city and Maebashi city on 11 August 2013 and tornado in Midori city on 16 September 2013.

Pressure jumps of 1-2 hPa were recorded at POTEKA with one minute resolution, indicating that the temporal high pressure was caused by downburst downflow. Beside, two pressure jump can be found at some stations. The first and second jumps are coincided with gust fronts and down flow of downburst, respectively (Discrimination between downburst and gust-front by the surface dense observation network POTEKA).

In the September 16, tornado occurred in Typhoon passes, and blackout occurred at 2:20(JST). At the point from 1.2km away, surface pressure was decreasing 3hPa in 3 minutes at 1.6km blackout area away (Fig.)

Local weather observation network consisting of POTEKA succeeded in capturing the change of surface pressure caused by gust wind phenomena with unprecedented spatio-temporal resolution, which enables us not only to distinguish between gust fronts and downbursts but also to detect such wind phenomena earlier. The observation network is going to continue in the future to data accumulation.

Acknowledgments: The authors would like to thank SANDEN Corporation, SAVE ON, and Board of Education of Isesaki city for support POTEKA project.

A sensibity study on the role of the urban land surface scheme for a regional climate model, NHRCM

SHIDO, Fumitake[1*] ; AOYAGI, Toshinori[1] ; SEINO, Naoko[1] ; SASAKI, Hidetaka[1]

[1]Meteorological Research Institute, Japan Meteorological Agency

The conditions of land surfaces give large impacts on surface air temperature, via the dynamical and thermal energy exchanging. In order to forecast the physical quantities, such as momentum, heat, and vapor fluxes from the land surface, we have selected a sophisticated vegetation scheme of the SiB (Simple Biosphere) as the land surface scheme of the MRI's NHRCM (Non-Hydrostatic Regional Climate Model). Recently, as model-resolution became higher up to several kilo-meter, non-vegetation but urbanized grids had appeared, and these grids were treated as dried bare ground on the SiB to express the so-called urban deserts. But, in these grids, reproducibility of the climatology seemed to be insufficient. Therefore, we need to apply the new scheme to improve the representation of radiation and heat budgets in such urban area. For that purpose, we developed a new scheme for urban land surface to applied to a regional climate model. This new scheme is called SPUC (Square Prism Urban Canopy, Aoyagi and Seino 2011).

In this study, we applied SiB and SPUC scheme to the 4km-resolution NHRCM, executed present climate simulations, and compared outputs with observational data of JMA(Japan Meteorological Agency). The target area was Kanto-Koshin region including Tokyo metropolitan area. As initial and boundary condition, we used the JMA's RANAL (Regional analysis) dataset (20km resolution), which was downscaled once by NHRCM10km with SiB scheme for all grid. The 10km resolution dataset was also downscaled by NHRCM4km. We executed the 4km experiments, using SiB scheme for all land grids (NHRCM-SiB), and using both SiB for natural surface grids and SPUC for urban surface grids (NHRCM-SPUC).Time integration was continuously executed for about 5 years from August 1st, 2001 to September 1st, 2006.

The result of the experiment using SiB scheme had negative bias(about -1.3 ^{o}C) in the surface temperature in the Tokyo metropolitan area. By using SPUC scheme, this negative bias changed to positive(+1.55 ^{o}C). Although the bias remains, the correlation factor between the simulation and observation was improved from 0.73 (NHRCM-SiB) to 0.86 (NHRCM-SPUC). This improvement implies that NHRCM-SPUC had the better reproducibility on horizontal distribution of air temperature. On the other hand, the difference was hardly seen in total amount of precipitation in five years.

This research is supported by SOUSEI program of MEXT, Japan.

Localized downslope wind often causes severe disasters, although the dynamics of these severe phenomena has not fully elucidated due to their small temporal and spatial scale. The damage by downslope wind is strongly determined by the instantaneous maximum wind speed. Since the numerical model can derive averaged wind speed along time and space determined by the model resolution. The classical analogous theory points out that the gust ratio, which is defined as the ratio of maximum wind velocity to the averaged wind velocity, becomes a constant value (1.5-2.0), depends only on the roughness length of surface condition.

In the actual atmosphere with the horizontal inhomogeneity, the gust ratio may varies with time even at the same location. The sophisticated modeling of gust ratio beyond the simple constant model is very important for the forecasting of gust damage. The detailed characteristics of gust ratio was investigated by the data of hyper-dense surface observation network in the Hira Oroshi region. The temporal and spatial characteristics of gust ratio and future prospective to install our algorithm into the numerical prediction models are discussed in the presentation.

[1]Research Institute for Sustainable Humanosphere, [2]Meisei Electric Corporation

The fine tungsten wire (10 um diameter) temperature sensor, whose response time is 5/1000sec on surface and 40/1000sec at around 30km altitude, were employed to detect turbulence intensities. For the temperture data at the sampling frequency of 16Hz were used for the tuebulence detection. The comtamination of the wake of the ballon should be carefully removed from the original data before the analysis of turbulence.

We are developing the new method to extract temperature purtarvation by turbulence at the vertical wavelength shorter than the effects of pendular movement of radiosondes.

The preliminary results show very promissing to detect turbulence intensities to compare with echo intensity of atmosphere radar.

The detailed scheme and first results are discussed in the presentation.

High resolution numerical study of migrating strong downslope wind ”Hira-Oroshi” in Japan

HIGASHI, Kuniaki[1*] ; FURUMOTO, Jun-ichi[1] ; HASHIGUCHI, Hiroyuki[1]

[1]Research Institute for Sustainable Humanosphere Kyoto University

This paper studied the generation mechanism of a unique downslope wind in the west coast of Lake Biwa, Shiga, Japan. This strong downslope wind, feared as ”Hira-Oroshi” for millennial years shows the narrow gust of a few kilometers in the various location within 10 km width area. This feature cannot be explained by the conventional mechanism of previous studies: the location of downslope wind is strongly restricted by the location of valley in mountain range. Due to such distinct characteristic, the numerical prediction of this gust wind is too inaccurate to use operationally.

Considering strong demands to the prediction of this gust wind, this study aims to elucidate the mechanism via very fine numerical forecast model with the horizontal resolution of 50 m. The results successfully represented the narrow gust wind structure in the edge of the mountain range. The spots of gust wind due to complicated topographical structure is also seen in the simulation results, although the gust wind speed changes with the larger scale wind direction and speed. Because the stagnant region due to the breaking of the mountain wave is widely extended in the leeward of the mountain range in the free atmosphere (˜1 km), the location of the gust wind looks to be determined by the detailed topographic structure of the mountain range and the a kilometer-scale eddies over the Lake Biwa.

The simulation results suggested these synergy effects determined the gust generation and its location. The unveiled behavior of the gust wind is also beneficial to the improvement of the gust prediction.

Modeling of marine biogeochemical and ecosystem in Japan: future perspective and review during the last 20 years

YAMANAKA, Yasuhiro[1*]

[1]Faculty of Earth Environmental Science, Hokkaido University

The first global 3-D marine biogeochemical modeling was developed by Bacastow and Maier-Reimer(1990), and marine ecosystem model was developed by Fasham(1993) as pioneer works, such as Yamanaka and Tajika (1996) and Kawamiya et al.(2000) in Japan. Around 2000, most of marine biogeochemical models have the explicit ecosystem components as well as ecosystem model with focusing short-termed changes in nutrient concentration and pCO2 associated with spring bloom in sub-arctic regions. And representation of iron cycle was an important issue for both modeling, and trial of coupling between climate and carbon cycles was also started.

Everybody wish to develop the ultimate model explicitly and detailed representing hundreds, thousands, millions of plankton and nekton groups. As the first step, Plankton Functional Types (PFTs) models dealing with relatively small number of plankton and nutrient were introduced (e.g., Le Quere, 2005; Kishi et al., 2007). We have two directions as future model developments for marine biological cycles and marine ecosystem. Former focuses on grouping of phytoplankton having large energy (material) flow, and latter focuses on grouping of zooplankton having the linkage to higher trophic levels such as fish as wood web. If both two directions were covered by the almighty model, we would need unlimited number of prognostic values as plankton number multiplied by elemental components (and grazing-grazed relations proportional to square of plankton numbers). Therefore, model developing along two directions are separated necessarily. We are easily focusing on number of prognostic values as a discussion of model complexity (e.g., Friedrichs et al., 2007). But, we do not forget important improvements leaded by studying individual process and trade-off problem between parameters. For example, recent studies discussed formulation using affinity instead of half saturation constant as classical Michaelis-Menten fomula, unrestricted nutrient uptake optimized by the parameter of restricted nutrient, and different impacts by the global warming between these formulations (Smith and Yamanaka, 2007; Smith et al., 2009). Many people are interesting in another type of models relevant to biodiversity are recently developed (Follows, 2007)

I would like to mention another view such as developing researcher community developing biogeochemical cycles and ecosystem model. Pioneers for marine biogeochemical modeling launched Ocean Carbon cycle Model Intercomparison Project (OCMIP). Studies are leaded by the pioneers at earlier periods but by young researchers relevant to OCMIP around the end of Phase 2. It goes without say that they are the present world-leading scientists in this academic field (such as Le Quere, Follows, Gruber etc.). MARine Ecosystem Model Intercomparison Project (MAREMIP) as going project is designed based on OCMIP experiences, and next generations figure just in this field. I should mention other groups. I think developing NEMURO, a marine ecosystem model, in North Pacific marine Science Organization (PICES) as another good international collaboration. As for formulating specific processes such as trade-off problem, North Germany group are leading. Finally, I would like to express my wish that next generation in Japan friendly and positively get chance to lead international research projects one of world-leading scientists with their beautiful lives. This is based on my cancelled invited talk in the last year.

Modeling fish production in the ocean: impacts on biogeochemical cycles and ecosystem service evaluation

ITOH, Sachihiko[1*] ; ITO, Shin-ichi[2]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, [2]Tohoku Nationarl Fisheries Research Institute, Fisheries Research Agency

Marine organisms play fundamental roles in biogeochemical cycles in the ocean. Ecosystem models formulating chemical and biological processes relevant to these organisms and materials have been developed in the past few decades, enabling quantitative evaluation of biological production, carbon and nutrient cycles, and their impact on the climate system. However, many of these models consider trophic levels up to zooplankton. Although much of storage and flux of carbon and nutrients are observed in the lower trophic levels, which is a good reason to focus on this level, importance of higher trophic levels has been increasingly recognized. Here, we review modeling studies incorporating higher trophic levels than zooplankton, especially focusing on fish production models. There are two major motivations developing the fish production model. The first one is that lower trophic level models with zooplankton as the highest trophic level are sometimes controlled too strongly by parameterized zooplankton mortality terms. Although parameterization of mortality terms is needed unless the model contains the apex predator (trophic closure), inclusion of planktivorous fish components does decrease the arbitrariness of the biogeochemical cycle in the model. The second reason to develop fish production models, the more classical reason than the first one, is based on the fact that fish stocks themselves have been major food resources for human societies. In this context, some recent models do not only include commercially important large piscivorous fishes but also consider fishing fleets. Increasing concern for the conservations of marine mammals and sea birds also enhances the model development. There are two different streams of the fish modeling at present: size-based and species-based approaches. We review their advantages and limitations and discuss future improvements of preferable frameworks of the higher trophic models.

The iron budget in ocean surface waters in the 20th and 21st centuries: projections by the Community Earth System Model

MISUMI, Kazuhiro[1*] ; LINDSAY, Keith[2] ; MOORE, Keith[3] ; DONEY, Scott[4] ; BRYAN, Frank[2] ; TSUMUNE, Daisuke[1] ; YOSHIDA, Yoshikatsu[1]

[1]Central Research Institute of Electric Power Industry, [2]National Center for Atmospheric Research, [3]University of California at Irvine, [4]Woods Hole Oceanographic Institution

We investigated the simulated iron budget in ocean surface waters in the 1990s and 2090s using the Community Earth System Model version 1 and the Representative Concentration Pathway 8.5 future CO_2 emission scenario. We assumed that exogenous iron inputs did not change during the whole simulation period; thus, iron budget changes were attributed solely to changes in ocean circulation and mixing in response to projected global warming, and the resulting impacts on marine biogeochemistry. The model simulated the major features of ocean circulation and dissolved iron distribution for the present climate. Detailed iron budget analysis revealed that roughly 70 % of the iron supplied to surface waters in high-nutrient, low-chlorophyll (HNLC) regions is contributed by ocean circulation and mixing processes, but the dominant supply mechanism differed by region: upwelling in the eastern equatorial Pacific and vertical mixing in the Southern Ocean. For the 2090s, our model projected an increased iron supply to HNLC waters, even though enhanced stratification was predicted to reduce iron entrainment from deeper waters. This unexpected result is attributed largely to changes in gyre-scale circulations that intensified the advective supply of iron to HNLC waters. The simulated primary and export production in the 2090s decreased globally by 6 and 13 %, respectively, whereas in the HNLC regions, they increased by 11 and 6 %, respectively. Roughly half of the elevated production could be attributed to the intensified iron supply. The projected ocean circulation and mixing changes are consistent with recent observations of responses to the warming climate and with other Coupled Model Intercomparison Project model projections. We conclude that future ocean circulation has the potential to increase iron supply to HNLC waters and will potentially buffer future reductions in ocean productivity.

Response of phytoplankton community structure to global warming

HASHIOKA, Taketo[1*] ; HIRATA, Takafumi[2] ; CHIBA, Sanae[1] ; YAMANAKA, Yasuhiro[2]

[1]JAMSTEC, [2]Hokkaido Univ.

In recent studies using high-performance liquid chromatography (HPLC) pigment data, empirical relationships between total chl-a concentration and a phytoplankton size/PFT fraction on a global scale are shown. For example, a fraction of diatoms increases with total chl-a concentration. The same tendencies can be seen in the most of the hindcast experiments by current PFT models of MARine Ecosystem Model Intercomparison Project (MAREMIP) and Coupled Model Intercomparison Project Phase5 (CMIP5) although the reproduced absolute values of a phytoplankton fraction still has large uncertainties. Then, two different mechanisms can be expected as potential responses of phytoplankton community to global warming. One is a possibility that the phytoplankton community structure (i.e., relationships between a phytoplankton fraction and total chl-a concentration) can be significantly changed by changes in ecosystem dynamics under global warming condition (e.g., changes in grazing pass/strength, decomposition/mortality/respiration rate and phytoplankton stoichiometry). Another possibility is that the plankton community shifts to the other stable states associated with changes in total chl-a concentration (e.g., by decrease/increase in nutrient supply to the surface ocean by changes in stratification) while maintaining the current relationship between a phytoplankton fraction and total chl-a concentration. To clarify impacts of both effects, we analyzed model results of future simulation, which was conducted by CMIP5 and MAREMIP under the RCP8.5 emission scenario. PFT model more than half showed that relationships between phytoplankton composition and total chl-a concentration are stable against environmental changes associated with global warming. In these model results, changes in phytoplankton composition are mainly caused by plankton community shifts associated with changes in total chl-a concentration. This result suggests the possibility that current empirical relationships obtained by HPLC would be maintained in a future environment. Based on this hypothesis, we project a potential future community structure of phytoplankton using a multi-model ensemble mean of future changes in total chl-a concentration with the empirical relationship of HPLC. Some other models projected large changes in the community structure in specific regions and seasons. These results also suggest potentially important mechanisms, regions and seasons.

Introduction to our on-going development of an adaptive model for plankton communities in the North Pacific

SMITH, S. Ian[1*] ; YOSHIKAWA, Chisato[1] ; SASAI, Yoshikazu[1]

[1]RIGC, JAMSTEC, [2]CREST, JST

This presentation will introduce our on-going efforts, as part of a CREST project funded by JST, to develop a new prototype model to represent the biodiversity and adaptive capacity of lower-trophic ecosystems in the North Pacific. The ultimate goal is to develop a computationally efficient representation of the community-level interactions of the producers (phytoplankton) and consumers (zooplankton) with each other and with the marine environment. This of course includes the adaptive response of plankton communities to changing environmental conditions, and later potential feedbacks, including for example the impact of plankton communities on controlling nutrient concentrations. We will present the size-based model of phytoplankton communities that is already under development and one scientific result already obtained, regarding the size-scaling of growth parameters, as commonly applied in large-scale models, in terms of the more commonly measured parameters for nutrient uptake kinetics. This scaling relationship provides a basis for consistently incorporating observed allometries into models based on Monod growth kinetics. This new simplified model of phytoplankton communities accounts for biodiversity via size-scaling of phytoplankton traits and for flexibility of the C:N ratio of biomass.

Fig. 1. Traits, which define how organisms respond to environmental conditions, have evolved subject to inescapable biophysical constraints. Thus have arisen trade-offs in competitive ability under different conditions, here illustrated for typical small phytoplankton adapted to low-nutrient, high-light conditions, which have high affinity (α), low maximum uptake rates (V_{max}) and relatively less allocation to chlorophyll/light harvesting ability, vs. large phytoplankton adapted to high-nutrient, low-light conditions, which have low α, high V_{max}, and relatively more allocation to chlorophyll/light harvesting ability. Maximum growth rate (μ_{max}) is constrained by the opportunity cost of allocating resources to the various processes necessary to support growth.

Exploring mechanisms of phytoplankton coexistence using a marine ecosystem model with eddy-resolving resolution

MASUDA, Yoshio[1*] ; YAMANAKA, Yasuhiro[1] ; NAKANO, Hideyuki[2]

[1]Hokkaido University, [2]Meteorological Research Institute, Japan

Observational studies estimate that there are over 70,000 phytoplankton species. Various mechanisms which enable phytoplankton coexistence are proposed. Niche segregation are inspected under pelagic environment, using a numerical model. Since we considered that variation of pelagic environment resulted in mesoscale eddies plays an important role on phytoplankton diversity, an eddy-resolving model is employed. Based on NEMUEO and MEM, we developed a marine ecosystem model which can express a few hundred phytoplankton species and combined it to a physical oceanic model, MRI.com. The physical field represents idealized subpolar and subtropical gyres in a rectangular model domain of 30 by 30 degrees. To explore niche segregation, we seeded 240 phytoplankton species which have different trait for temperature, light and nutrient. After 10 years integration, 31 species are survived. In the subpolar (subtropical) region, species favorable high (low) nutrient condition are survived. Segregation with temperature is also confirmed.

Numerical analysis of the influences of the meso-zooplankton mortality

YOSHIE, Naoki[1*] ; TOMITA, Kazuyuki[1] ; OKUNISHI, Takeshi[2] ; ITO, Shin-ichi[2]

[1]Center for Marine Environmental Studies, Ehime University, [2]Tohoku National Fisheries Research Institute, Fisheries Research Agency

In recent years, marine lower-trophic level ecosystem consisting of phytoplankton and zooplankton has been seriously affected by the various environmental changes due to the climate changes and the human activities. The quantitative assessment of the lower-trophic level ecosystem changes with the environmental changes is important for the human beings in the world. This is because the lower-trophic level ecosystem changes closely links to the fisheries resources and the global carbon cycles. For example, copepod which is one of the meso-zooplankton in the lower-trophic level ecosystem is main food for the fishes of good-catch such as Japanese saury and anchovy. Copepod also exports a huge amount of organic carbon from the surface water to the deep water in the ocean by the seasonal vertical migration to around 1000m depth and the rapid sinking fecal pellet. We have been developing a plankton functional types (PFTs) model which explicitly calculates each functional group of organisms such as copepod above. In particular, we developed a PFTs model eNEMURO (4-Nutrient, 4-Phytoplankton, 4-Zooplankton, 4-Detritous), which was an extend version of NEMURO [a standard lower-trophic-level marine ecosystem model of PICES (The North Pacific Science Organization)] by introducing the microbial food web and the phosphorous cycles and dividing diatoms to two compartments according to temperature dependency. eNEMURO successfully reproduced the spatio-temporal variations in the lower-trophic level ecosystem around Japan. In this study, we investigated the influences of the meso-zooplankton mortality which was little known from the filed observations and the laboratory experiments on the lower-trophic level ecosystem. We conducted the sensitivity analysis of two parameters of the meso-zooplankton mortality in eNEMURO in five regions with different types of the lower-trophic level ecosystem around Japan. Model result shows that the increase of the meso-zooplankton mortality associated with water temperature rising has large impacts on the nutrients concentrations, the biomasses of phytoplankton and zooplankton, especially in the regions with the high temperature. We also introduce results from the biological parameters optimization of eNEMURO using the genetic algorithm method.

A benthic-pelagic coupled ecosystem model to clarify nutrient cycles in coastal areas

TATENO, Satoshi[1*] ; HATA, Kyoko[1] ; NAGAO, Kentaro[1]

[1]IDEA Consultans, Inc.

In many enclosed coastal seas in japan, coastal environment have changed due to increase of nutrient loading and land development after 1960s. This caused loss of material cycles balance, generation of red tides, anoxic conditions and hydrogen sulfide.Water quality has been gradually improved because of some policies such as water quality standard and water pollution control law, but the loss of balance remains in many areas. It is because various factor such as benthic system, fishery industry and the open sea of the areas affect it.

We developed a benthic-pelagic coupled ecosystem model to clarify the role and the contribution of them. The model also included important factors for the coastal environment as dissolved oxygen, oyster and eelgrass.

It was developed for Mitsu Bay area in the western part of Seto Inland Sea. In this area, oyster culture distribute widely. Model results indicated the most important factor for the material cycles was advection from out of the area. Nutrient load had lower impact than advection and oyster. Anoxic water did not appear but the oyster culture caused accumulation of organic matter on the sediment under oyster rafts and hydrogen sulfide production. It was suggested that control of it is important for improve the material circulation and keep it in balance.

A challenge to investigate environmental factors which determine spawning migration variability of small pelagic.

ITO, Shin-ichi[1*] ; OHNO, Sohsuke[1] ; OKUNISHI, Takeshi[1] ; SUYAMA, Satoshi[1] ; NAKAGAMI, Masayasu[1] ; AMBE, Daisuke[1] ; KAMEDA, Takahiko[1] ; KAKEHI, Shigeho[1]

[1]Fisheries Research Agency

In recent years, lower trophic ecosystem models, which represent phyto and zoo-plankton, have been coupled to fish growth-migration models. These coupled models enable to elucidate fish response to climate variability. However, mechanisms of fish migration has not been well clarified. Especially the mechanisms of spawning migration, by which spawner fish can home on to their spawning grounds, are one of the most difficult behavior to represent by a numerical model. Using realistic initial and boundary condition, an Euler-type model of Pacific saury was applied to investigate environmental factors which determine spawning migration variability. The initial distribution of Pacific saury was defined by synoptic surface trawl surveys and satellite derived environmental conditions were used as forcing; sea surface temperature (SST), prey density estimated from surface chl-a concentration and surface current speed. Growth of Pacific saury was calculated by a fish bioenergetics model (NEMURO.FISH). A fitness algorithm was applied for feeding migration in which the fish are assumed to be moving towards a place with optimal growth condition. A larvae fitness algorithm was applied for spawning migration in which the spawning fish moves to a place of the optimal growth of larvae. For spawning migration, westward migration was added to reproduce realistic spawning grounds around Japan Islands. Strength of the westward migration was adjusted to realize observed variability of saury migration to fishing grounds. The adjusted westward migration variability showed high correlation with basin wide SST in the North Pacific. This result suggested a strong influence of climate to fish spawning migration.

Impacts of global warming on fisheries estimated from climate models: An application to Japanese scallops in Hokkaido

SHIBANO, Ryota[1*] ; FUJII, Masahiko[1] ; YAMANAKA, Yasuhiro[1] ; YAMANO, Hiroya[2] ; TAKAO, Shintaro[1]

[1]Faculty of Env. Earth Sci., Hokkaido Univ., [2]NIES

Climate change such as global warming is considered to affect marine ecosystem. For example, rise in seawater temperature in future may change distributions of marine species. We estimated the impacts of global warming on Japanese scallop, *Mizuhopecten yessoensis*, in Hokkaido. Japanese scallops are important target species for Japanese fisheries resources. Combining sea surface temperature output obtained from climate models and simplified indices that express distribution of Japanese scallops, we estimated suitable domains for Japanese scallop fisheries. We found rise in water temperature from 1990 to 2100 has an impact to aquaculture industries of Japanese scallops across Hokkaido. This study suggests a simplified method to estimate distributions of coastal marine species and the importance of observed data in the future projection.

Interannual variations and its control factors of evapotranspiration in a temperate Japanese cypress forest

TSURUTA, Kenji[1*] ; KOSUGI, Yoshiko[1] ; TAKANASHI, Satoru[2] ; TANI, Makoto[1]

[1]Graduate School of Agriculture, Kyoto University, [2]Forestry and Forest Products Research Institute

1.Introduction

Evapotranspiration from forests is a major factor affecting water yield and therefore water resources. Understanding the long-term impacts of variations of meteorological factors on variability of evapotranspiration is important, especially in the context of current and future climate change. Long-term continuous measurements of evapotranspiration using the eddy covariance method provide an opportunity to examine the response of forest ecosystem processes to climate change. We quantified the interannual variations of evapotranspiration, and examined its control factors using the multi layer model.

2.Material and methods

Observations were made in the Kiryu Experimental Watershed in the south of Shiga Prefecture, central Japan. The forest around the watershed comprises mainly 50-year-old Japanese cypress forest. A meteorological observation tower is located in the watershed. The fluxes of momentum, sensible heat, latent heat, and CO2 were measured using eddy covariance methods at a tower height of 28.5 m. Precipitation was observed at the open site.

We used the multi layer model to clarify the control factors of interannual variations of evapotranspiration. The model contained sub-models that calculated the gas exchange processes, including H2O and CO2 exchanges of leaves and the ground surface. This multi layer model simulates the above-canopy fluxes based on vertical profiles of meteorological factors. This model requires the above-canopy environmental variables as the input data. The parameters representing leaf gas exchange characteristics are determined by leaf gas exchange measurements. We used 7 years of eddy covariance data (from January 2001 to December 2007) in this study.

3.Results and discussion

Annual evapotranspiration for the seven years ranged between 715 (2001) and 780 mm (2004) with the average of 743 mm. Maximum interannual fluctuation in evapotranspiration was 75 mm.

Diurnal, seasonal, and interannual variations of evapotranspiration for the seven years were reproduced by a model simulation. This indicates that the model structure and parameterization are validated.

We calculated the components of evapotranspiration such as transpiration, evaporation, and soil evaporation. Each component shows interannual variations relating to meteorological factors. Wet years such as 2001 and 2002 had small annual evaporation and large annual transpiration. Dry years such as 2003 and 2006 had large annual evaporation and small annual transpiration. Both annual evaporation and transpiration were relatively large in 2004. Annual soil evaporation was slightly smaller than evaporation and transpiration. Interannual fluctuations in soil evaporation were also small compared with evaporation and transpiration.

We examined seasonal variations of evapotranspiration for the contrasting two years; 2004 and 2003 with maximum and minimum annual evapotranspiration simulated, respectively. The deviations of evapotranspiration for the two years were large in summer from June to August. Transpiration increased with vapor pressure deficit and solar radiation. Transpiration was relatively small in 2003, which had low vapor pressure deficit and solar radiation in the summer. Transpiration was relatively large in 2004, which had high vapor pressure deficit and solar radiation in the summer. Soil evaporation for the two years showed the similar seasonal variations with transpiration. Seasonal variations of evaporation were the similar to those of precipitation.

Each component of evapotranspiration showed different responses to the meteorological factors seasonally and annually. Interannual variations of evapotranspiration were almost explained by those of meteorological factors.

Evapotranspiration and water use efficiency on a coniferous planted forest watershed in south western Japan

SHIMIZU, Takanori[1*] ; TAMAI, Koji[1] ; KUMAGAI, Tomo'omi[2] ; ISHIZUKA, Shigehiro[3] ; OHTANI, Yoshikazu[1] ; SHIMIZU, Akira[3]

Japanese cedar (*Cryptmeria japonica* D. Don) and Japanese cypress (*Chamaecyparis obtusa* Endl.) are the most popular planted species in Japan. These species cover about 20% of the land surface of the country. On a mountainous topography which is common in Japan, Japanese cedar was usually planted from valleys to lower hillsides with relatively wet and fertile soils, while Japanese cypress was planted on the drier and more nutrient poor ridge areas. Accordingly, evapotranspiration (ET) and carbon assimilation may be variable in the two species.

We applied multiple methods to estimate ET from a planted forest watershed located in Kyushu Island, south western part of Japan. The watershed existed on mountainous terrain, and the right bank was mainly covered with well-grown Japanese cedar while the larger part of the left bank was covered with relatively less-grown Japanese cypress. We applied the eddy covariance method, using an observation tower built in the center of the watershed. The eddy covariance data were experimentally divided to two sectors by wind direction, right bank side and left bank side of the watershed, and the lack of data for each wind sector were interpolated by the mutual imputation method. The analysis period in this study is 2007-2008. Within the period, the rainfall interception loss (I_c) and sap-flux density were also measured in Japanese cedar plots, and the lower canopy ET was estimated by a model. From the eddy covariance result, ET from the left bank side was estimated as 85% of that from the right bank side in the period. Compared the right bank side ET with the combination of I_c, upper- and lower-canopy ET, the difference in annual total ET was about 1% when global solar radiation (S_d) was greater than 0, which assured the accuracy of the eddy covariance method even over the complex terrain.

As for carbon assimilation, we simultaneously measured CO_2 flux and CO_2 concentration profile by using the observation tower. Based on the measurements, we can estimate the CO_2 exchange between the forest and atmosphere through the similar procedure to ET. Thus in this study, we will estimate the carbon budged and calculate the water use efficiency of the whole ecosystem of the watershed and of the both bank sides. From the tentative result obtained at present, the average NEE of the left bank side was 87% to that of the right bank side, in the daytime ($S_d > 0$) in 2007-2008. From the value and the aforementioned ET ratio (0.85), the water use efficiency of the both bank sides were might be almost the same as each other. In the presentation, we will discuss about the detail, considering the respired CO_2 in the nighttime and the rainfall interception in the Japanese cypress plot.

Water budget and the consequent canopy duration period in a teak plantation in a dry tropical region

TANAKA, Katsunori[1*]

[1]Japan Agency for Marine-Earth Science and Technology

A soil-plant-air continuum multilayer model was used to numerically simulate canopy net assimilation (A_n), evapotranspiration (ET), and soil moisture in a deciduous teak plantation in a dry tropical climate of northern Thailand to examine the influence of soil drought on A_n. The timings of leaf flush and the end of the canopy duration period (CDP) were also investigated from the perspective of the temporal positive carbon gain. Two numerical experiments with different seasonal patterns of leaf area index (LAI) were carried out using above-canopy hydrometeorological data as input data. The first experiment involved seasonally varying LAI estimated based on time-series of radiative transmittance through the canopy, and the second experiment applied an annually constant LAI. The first simulation captured the measured seasonal changes in soil surface moisture; the simulated transpiration agreed with seasonal changes in heat pulse velocity, corresponding to the water use of individual trees, and the simulated An became slightly negative. However, in the second simulation, A_n became negative in the dry season because the decline in stomatal conductance due to severe soil drought limited the assimilation, and the simultaneous increase in leaf temperature increased dark respiration. Thus, these experiments revealed that the leaflessness in the dry season is reasonable for carbon gain and emphasized the unfavorable soil water status for carbon gain in the dry season. Examining the duration of positive A_n (DPA) in the second simulation showed that the start of the longest DPA (LDPA) in a year approached the timing of leaf flush in the teak plantation after the spring equinox. On the other hand, the end appeared earlier than that of all CDPs. This result is consistent with the sap flow stopping earlier than the complete leaf fall, implying that the carbon assimilation period ends before the completion of defoliation. The model sensitivity analysis in the second simulation suggests that a smaller LAI and slower maximum rate of carboxylation likely extend the LDPA because soil water from the surface to rooting depth is maintained longer at levels adequate for carbon gain by decreased canopy transpiration. The experiments also suggest that lower soil hydraulic conductivity and deeper rooting depth can postpone the end of the LDPA by increasing soil water retention and the soil water capacity, respectively. These hypotheses will be verified based on observations.

Influence of canopy interception on the recovery in water balance after clear-cutting at a small headwater catchment

ODA, Tomoki[1*] ; EGUSA, Tomohiro[1] ; OHTE, Nobuhito[1] ; HOTTA, Norifumi[2] ; TANAKA, Nobuaki[3] ; GREEN, Mark[4] ; SUZUKI, Masakazu[1]

[1]Graduate School of Agricultural and Life Sciences, The University of Tokyo, [2]Faculty of Life and Environmental Sciences, University of Tsukuba, [3]Ecohydrology Research Institute, The University of Tokyo Forests, Graduate School of Agricultural an, [4]Center for the Environment, Plymouth State University

The impact of forest disturbance on stream runoff has been well studied using the paired catchment approach, usually finding increased stream runoff following forest disturbance due to the decline of transpiration and canopy interception. However the recovery processes of transpiration and interception have rarely been directly observed under a recovering forest, therefore mechanisms behind recovery time of stream runoff following forest cutting is still not well understood. The objective of this study is to evaluate the contribution of interception to the change of stream runoff after forest cutting. This study was conducted in a pair of small headwater catchments, where one catchment was clear-cut in 1999 and planted with the same species in 2000. Annual runoff increased 200 to 300 mm/yr after forest cutting and the higher runoff remains 12 years after cutting. Interception ratio in the clear-cut catchment were lower than 10 % of precipitation in 2007, 2011 and 2012, and those in the control catchment were 20 to 24 % of precipitation. The mean annual interception was still around 300 mm/yr smaller in the young forest compared to the mature forest, although canopy cover and LAI were similar. These results suggested that the recovery of interception rate is an important controlling factor for the recovery of stream runoff after forest cutting, and not only canopy structure, but also the microclimate condition above the canopy of young forest could be also important factors affecting interception.

Changes in interannual variability of runoff in a conifer and deciduous hardwood mixed forested watershed

NOGUCHI, Shoji[1*] ; MURAKAMI, Wataru[1] ; TANI, Makoto[2]

[1]Forestry and Forest Product Research Institute, [2]Graduate School of Agriculture, Kyoto University

The National Forest Management conducts forest management in National Forests for the fulfillment of multi functional roles of forest including long-term wood production management. On the other hand, there are few studies that evaluated the runoff characteristics including a state of the forest for a long term. This study was conducted within the Kamabuchi No1 experimental watershed (3.06ha) in North part of Japan. Hydrological observation has been continued in cold snowy region since 1939. It is the longest record in this region in Japan. The site is covered with Natural hardwood forest (ex. Fagus crenata, Quercus mongolica var. grosseserrata and Quercus serrata) and coniferous plantation forest (Cryptomeria japonica and Chamaecyparis obtuse) which planted around 1912 to 1916. Surficial geology is tuff and shaletic tuff of the Tertiary period and soils are clay loam. Meteorological observation was conducted Yamagata experimental forests located to 800m from the watershed to the northeast. A 71-year record (1939-2010) of the precipitation and runoff was used for an analysis of the flow-duration curve. Tree (DBH ≥ 6cm) census in the watershed was also conducted at 5 times (1942, 1950, 1957, 1979, 2008). The tree volume of Chamaecyparis obtuse is a regular tendency and the tree volume of Cryptomeria japonica linearly increased. Stem volume of oak trees has increased remarkably from 1942 to 1979 but there was a close tendency of an increase in 2008 because mortality of oak trees occurred in the watershed. Based on 5 times tree census, positive linear relationship was found between tree volume and age of stand. While the proportion of plentiful runoff has shown a tendency to decrease over long term, those of ordinary, low and scanty runoffs have tended to increase with increasing the tree volume.

Is there any general rainfall-runoff response function in mountainous catchments?

UCHIDA, Taro[1*] ; ASANO, Yuko[2] ; KANBARA, Jun'ichi[1] ; TOMOMURA, Mitsuhidde[3]

[1]National Institute for Land and Infrastructure Management, [2]University of Tokyo, [3]Meteorological Engnieering Center

Clarifying rainfall-runoff response function in mountainous catchments is one of key issues for flood and sediment disaster prediction, management of aquatic environment, water supply and so on. So, rainfall-runoff response function in mountainous catchments has been debated in more than several decades. A variety of studies, observation, modeling, theoretical studies etc., has been conducted. Many noble efforts have been conducted for clarifying complex systems in catchment hydrology through intensive observations. These observations were effective for documentation of the idiosyncrasies of each catchment environments. However, it has been difficult to derive general rainfall-runoff response function from these basin-centric approaches. So, several researchers emphasized the importance of intercomparison so as to better see first order controls of hydrologic responses. Except for several exceptions, intercomparisons for rainfall-runoff responses in many catchments are still limited. Thus, still it is very hard to predict rainfall-runoff response function at ungauged basin.

Thus, we compiled rainfall and stream flow data for around 150 catchments in Japan. We focused relatively small catchment (<100 km2) and a variety of geological, topographical and climatic conditions. We removed catchments where strongly affected human activities, such as urbanized catchment etc., from our intercomparison.

In this study, we randomly sampled 10 storms, i.e., total rainfall amounts were large than 50 mm, for each catchment and calculated three indices, peak specific discharge, peak lag time and direct runoff ratio, to characterize rainfall-runoff response. Also, we defined rainfall-runoff responses using three reservoirs model. We parameterized all of catchments using four storms data using SCE-UA method and validated these parameters using other four storms data. Then, we tested the roles of rainfall condition, climate, geology and topography on rainfall-runoff responses. We used multiple regression analysis to define first order controls of rainfall-runoff responses.

We found large variability in rainfall-runoff responses and it is hard to define general response patterns. While, through multiple regression analysis, we found several interesting results, as follow;

-Climatic conditions affected peak specific discharge and direct runoff ratio, suggesting that climate might give impacts on hydrological characteristics soil and bedrock.

-Geology, such as type of rocks and geological age, gave impacts on rainfall-runoff responses, but effects of geology were not so large, although many study focused on rock-controls on hydrology.

-Flowpath length, calculated by DEM, was one of important topographic parameters for describing rainfall-runoff responses.

A method of generating virtual drainage-basin by introducing models of slope/stream evolution

NAKAKITA, Eiichi[1*]

[1]Eiichi Nakakita

A method of generating virtual drainage basin to understand relationship among characteristics of geomorphic distribution, rainfall distribution, and runoff distribution was developed. Here the concept of generating virtual drainage-basin is that the drainage-basins are generated at random under some physically based conditions on the basin form. The method is an improvement of Nakakita and Matsuda (2007). They proposed the method of generating virtual drainage-basin based on erosional developing model of channel network by Horton (1945). For the improvement, mathematical models of evolution of slopes and streams were introduced into the methodology. As a result, we achieved to introduce the concept of time into the generating virtual drainage-basin model.

Rock control, denuded hillslope and discharge system in warm humid regions

IIDA, Tomoyuki[1*]

[1]Center for Research in Isotopes and Environmental Dynamics, University of Tsukuba

Under humid and warm regions as Japan, a stable discharge system of seepage water in hillslope is maintained by not only geophysical structures(soil and weathered layer) but also biological system such as forest. From long term point of view, topography, soil, ecosystem and water discharge system play hydro-geomorphological interactions directly or indirectly to one another. In the discharge system, both macro and micro pores of soil layer or weathered bedrock play especially important roll, which controls the permeability and storage capacity under the ground. Among them, natural pipes consisting of continuous macro pores play a roll in the water discharge during a heavy rainfall event. The capillary water stored in micro pore can be used by trees in dry season. These macro pores and micro pores are made by physical and chemical weathering processes. However, biological weathering is the most important for the development of these pores in soil. Forest ecosystems can evolve a matured soil system from soil particles in order to adjust a suitable environment for their own lives. Because the tree root system needs not only water but also enough air, an efficient discharge system may be created as one of the most important environment. This discharge system changes as follows according to the rainfall conditions.

1) In the case of usual storms: The discharge system is stable and it can discharge successfully the seepage water.

2) In the case of unusual heavy storms: The slope failure may occurs due to increasing of water pressure when the water table of throughflow, rises or the pipe-discharge system becomes plugged and partially destroyed. However, this system is recovered with the recovery of forest and soil. This can be called a healty feedback. The humid and warm climate suitable for forest contributes much to these recovery. Therefore, this feedback can contol the expansion of a denuded area made by a slope failure and a wide denuded area may not been naturally developed.

3) In the case of unusual heavy storms in bare lands created by severe human activities: In this case, especially in granite area or the Tertiary area, an unhealty feedback acts because the critical threshold of healty feedback is exceeded. Then, the bare land expands rapidly throughout a mountain area. It is almost impossible for forest and soil to be recovered naturally. Human afforestation work is necessary. Such hillslopes were founded in the wide area of Japan till the second half of 20th century. There is no stable discharge system in such bare hillslopes. Consequently, frequent occurrence of overland flow surface flows caused severe floods and soil hazard.

The discharge system seems to be made as a part of hillslope development. The geological character of the bedrock and the climate (rainfall and temperature) play an important roll in making of the discharge system. This system can be considered as one of the effects of rock control.

The making method of two dimensional distribution map of the collapse prevention force with tree survey

ATSUJI, Makoto[1*] ; KITAHARA, Hikaru[2] ; ONO, Hiroshi[2]

[1]Graduate School of Agriculture, Shinshu University, [2]Faculty of Agriculture, Shinshu University

The collapse prevention force of the forest root system is a grand total of the pulling out resistance of each root per vertical cross section ($1m^2$) of soil layer. The pulling out resistance of root (T,N) shows a following equation using root diameter (D,mm) , $T=aD^{1.6}$, varies in the coefficient by a tree class. The quantity of root system is distributed concentrically from the tree center and decreases for distance from tree exponentially.

Here I propose the two dimensional distribution map of the collapse prevention force with only the ground information of tree survey, breast height diameters and distribution of trees.

I performed an investigation that each in 3 Hinoki artificial plantation stand and 1 natural broadleaf forest, and made a two dimensional distribution map of the collapse prevention based on the tree positioning and the diameter of trees at breast-height. And I compared which I got by investigating every tree and compared the outcome of maps and the actual measurement that I dug a trench. As a result, the estimated values and the actual values did not exactly match, however a very meaningful relation was seen in both value within 1% of the risk ratio.

Furthermore, I applied this method and estimated a chronological order change of the collapse prevention force. Because the data required for estimating the ability of collapse prevention are only positioning of the trees and diameter measurement at trees breast-height, I can even estimate a change in the result after thinning, by using it in conjunction with the growth prediction by the density management curve.

The growth-collapse simulation method of soil depth in which the effect of vegetation was taken into consideration

KUROKAWA, Ushio[1*]

[1]Kyushu Research Center, FFPRI

The impact accompanying the transition of the watershed conditions in a forest appears under the structurally development process of a triplex in which time scales differ; geographical feature is formed by a tubercle and erosion of a mountain, the soil which supports and grows up in the root system of a vegetation repeats a collapse and a renature, the forest grows and withers. Without understanding this process, the runoff impact evaluation of watershed conditions cannot occur. We paid our attention to the collapse process in which a soil grows up again, after the soil was supported by the root of the forest, grew up and collapsed with progress of a temporal. And the development method of the longterm soil growth simulation was considered.

This method is computed for every mesh. The following routines perform the compute process of geomorphic development. First, the amount of growths of the soil stratum in the fixed period in each mesh is computed. The amount of developments of the soil depth used the equation of the following which Heimsath et al. (1999) proposed.

Soil Production(m/million year)=77×exp(-0.024×Soil Depth)

The soil depth after a fixed period is computed by applying to the initial soil depth of each mesh the value calculated by the equation. Slope stability is computed using the soil depth set up newly. It is considered by the equation that the mesh by which the safety factor was computed or less with one is that to which the collapse occurred. After setting the value of the soil depth in the mesh to 0, the altitude data after a collapse and a soil depth are re-calculated. A prolonged soil development simulation is computed by repeating the predetermined number of these processes. The simulation was computed at the place which many shallow landslides caused by heavy rainfall. The initial soil depth in the mesh which the collapse caused by the heavy rain was set to 0, and the mesh which has not collapsed was set to 1 m. And, the soil layer assumed the condition of being completely saturated by the heavy rain. In addition, the effective soil internal angle was 32 degrees, effective soil cohesion was 0.01 kPa, unit weight of the moist soil was 17.64 kN/m^3, and unit weight of water was 9.8 kN/m^3. The effect of the vegetation was included in the simulation as the cohesion.

As results of the simulation, It was confirmed that the soil layer which collapsed with progress of the temporal is recovered. Moreover, when a vegetation does not exist, the probability that a soil layer will repeat a collapse becomes high, but when a vegetation exists, a soil layer does not collapse but is recovered early.

Limits of Soil Production and the Couplings with Hillslope Hydrology

HEIMSATH, Arjun[1*]

[1]School of Earth and Space Exploration, Arizona State University

Rocky mountain ranges are broken down to sediment that is ultimately removed to the sea. Tectonic forces continually push mountains up, while physical and chemical processes continually transform bedrock to sediment and move it down. This simple sounding cycle is thought to regulate global climate over long timescales, while also responding to climate forcing itself, although the causal direction remain a mystery despite decades of sleuthing. Similarly mysterious are the connections between mechanisms of sediment production and the responses of watersheds to changes driven by humans, climate, or tectonics.

To address some of the potential connections between sediment production and hillslope hydrology, I focus here on soil mantled and steeply sloped landscapes from around the world, some thought to be at a critical threshold of soil cover. Observations reveal that even in the most rapidly eroding landscape there are significant areas mantled with soil that fit the conceptual framework of a physically mobile layer derived from the underlying parent material with some locally-derived organic content. The extent and persistence of such soils depends on the long-term balance between soil production and erosion despite the perceived discrepancy between high erosion and low soil production rates. I present cosmogenic Be-10-derived soil production and erosion rates that show that soil production increases with catchment-averaged erosion, suggesting a feedback that enhances soil-cover persistence, even in threshold landscapes. I also show that a process transistion to landslide-dominated erosion results in thinner, patchier soils and rockier topography, but find that there is no sudden transition to bedrock landscapes. The landslide modeling is combined with a detailed quantification of bedrock exposure for these steep, mountainous landscapes.

To conclude, I draw an important conclusion connecting the physical processes producing and transporting soil and the chemical processes weathering the parent material by measuring parent material strength across three different field settings. Parent material strength is observed to increase with overlying soil thickness and, therefore, the weathered extent of the saprolite. Soil production rates, thus, decrease with increasing parent material competence. These observation highlight the importance of quantifying hillslope hydrologic processes where such multi-facted measurements are made.

Soil production functions and soil layer mobility in Japanese mountainous catchments underlain by granitoid rocks

MATSUSHI, Yuki[1*] ; MATSUZAKI, Hiroyuki[2]

[1]DPRI, Kyoto University, [2]MALT, The University of Tokyo

Soil-mantled hillslopes cover a major area of mountainous catchments in humid temperate regions. The soil layer on hillslopes is maintained by a balance between soil production and transport especially at hill noses, while the soil accumulated in hollows is eventually removed by a rainfall-induced shallow landslide. The rates of soil production and soil creep pace the growth of soil thickness at a hollow and thus determine the return period of landsliding. The soil layer buffers rainfall infiltration into hillslopes and hence controls subsurface runoff system in a catchment. Hydro-geomorphological evolution of a catchment results from the interaction between long-term soil layer development and short-term rainfall runoff processes. The quantification of soil dynamics on hillslopes is thus critical in understanding present-day hydrological condition of a catchment and for geomorphological landslide hazard mitigation.

The uppermost part of decomposed bedrock (saprolite) gradually disintegrates to form the mobile soil layer, which achieves to a steady-state thickness reflecting sediment budget at a soil column. The saprolite-to-soil conversion rate beneath a soil column decreases with increasing thickness of the soil layer, which is called as soil production function (SPF). Soil particles apart from the saprolite move downslope by soil creep at a rate controlled by slope gradient, biological activity and soil thickness. Evaluation of SPF as well as the soil layer mobility is essential when we simulate soil dynamics on a hillslope. SPF can be determined from concentration of terrestrial cosmogenic nuclides at uppermost part of saprolite, while soil layer mobility can be estimated by soil thickness survey by digging pits on a nose-hollow pair of hillslopes. We present examples of SPFs in Japanese mountainous catchment underlain by granitic rocks, and demonstrate results of simulation of soil development to map potential sites of shallow landslide and to assess volume of sediment that may yield at a catastrophic landslide event by heavy rainfall.

Interrelation between hillslope soil moisture and stream flow in a Paleozoic sedimentary rock watershed

HOSODA, Ikuhiro[1*]

[1]Kansai Research Center, FFPRI

It is well known that geology is one of influential factors on river regime. In the Paleozoic sedimentary rocks area in Japan, hydrographs are characterized by low base flow and spiky peak flow. To clarify the reasons of such characteristics occur, observation focused on hillslope soil moisture condition was conducted in the gauged Tatsunokuchi-yama Minami-tani watershed (34 ^{o} 42 ' N, 133 ^{o} 58 ' E, 50-257 m, 23 ha) underlain by Paleozoic sedimentary rocks. The watershed is covered with primarily *Quercus serrata* dominant mixed forest, and partly *Chamaecyparis obtusa* stands planted in 1970s. Annual precipitation is about 1200 mm with little snowfall.

Ground water levels (GWL) and soil moisture were continuously measured in and around boreholes in a concave slope in the middle reach. Deeper than 0.3 m from ground surface, a thick fractured and weathered bed rock layer extends down to about 10 m at upper slope, and about 16 m at mid-slope. Below the weathered bed rock layer, boring core was relatively unweathered. But conspicuous cracks were obviously seemed to perform as water flow pathway because the surface of crack was dyed. Low coefficients of permeability which ranged from 2^{-8} to 1^{-6} m/s were measured by in situ test in the boreholes.

In the mid-slope, GWL appeared about 15 to 17.5 m in depth from ground surface when surface soil layer was more than field moisture capacity. Although GWL greatly respond to about over 40 mm rainfall events, direct flow rate did not simply increased. In a little antecedent rainfall condition, GWL rising was detected only at the lower slope. Depending on increase of antecedent rainfall, fluctuations of GWL at the mid-slope and the upper slope became obvious, and also direct flow rate went up. The greater amount of rainfall including antecedent rainfall was brought, the more GWL rising belated to stream flow peak observed. The greater intensity of rainfall leads quick rising of stream flow, but it was not effective for GWL rising. According to the stream water quality, rain water component increased when intense rain was brought, subsequently ground water component increased for the duration of rainfall event.

It is realized that water movement is having macroscopic interrelation in the space from upper slope to stream channel. Its complexity would be derived from large soil moisture change by rainfall amount and vegetation activity in the thick weathered bed rock layer in the hillslope as water flow pathways. And it is considered that since the permeability of subsoil is low, stream flow respond by spiky peak against intense rainfall.

Introduction

Previous studies have noted that bedrock groundwater is one of the important factors influencing stream discharge and streamwater chemistry. However, most previous studies were conducted not by direct measurement of bedrock groundwater but by using indirect methods, such as solute tracers and water budget analysis. Thus, the movement and chemical characteristics of bedrock groundwater remain incompletely understood based on direct measurements of bedrock groundwater. To better understand the dynamics of bedrock groundwater, we investigated groundwater table movement and water chemistry of bedrock groundwater using dense borehole wells at a small catchment in a mountainous area.

Methods

The study was performed at the Fudoji Experimental Watershed located in the Tanakami Mountains in the southeastern part of Shiga Prefecture, central Japan. Precipitation was monitored using tipping-bucket rain gauges, and discharges were observed at eight small catchments, ranging in area from 0.1 to 2.3 ha. Seven small catchments (subcatchments) were included in the largest catchment (2.3 ha), within which we installed 61 borehole wells. The water table of bedrock groundwater was then observed at these borehole wells. Rainwater, streamwater from the small catchments and bedrock groundwater from the borehole wells were sampled, and the concentrations of major ions and SiO_2 as well as the water stable-isotope ratios $d^{18}O$ and dD were measured in the Graduate School of Agriculture, Kyoto University.

Results and Discussion

The results of the analysis of the groundwater table of bedrock groundwater indicated that there were several fluctuating characteristics and that these characteristics of groundwater table change had locality. At the area having higher altitude in the ridge, the bedrock groundwater-table changes were gradual but the ranges of fluctuation were larger than those of the lower wells. At the lower-altitude points, although the bedrock groundwater table responded rapidly, the ranges of fluctuation of the groundwater table were small relative to those of the higher points. Some areas responded only to peak rainfall over a short time. Based on the groundwater flux analysis, bedrock groundwater moves across the surface divide. A catchment inflowed by a neighboring catchment showed a high specific discharge. Additionally, the direction of groundwater movement changed during rainfall events, and such changes were similar for rainfall events of the same size.

The relationships among chemistries derived from the chemical weathering of bedrock indicated that although the weathering processes were similar in the catchment, the weathering level varied among the borehole wells. The chemistries of bedrock groundwater at each catchment and of streamwater at each catchment showed large variability. The concentrations of Na^{+} and Ca^{2+} had local characteristics, but no clear characteristics were observed among other bedrock groundwater components. The chemical concentrations of bedrock groundwater were higher than those of streamwater. We chose borehole wells that may contribute directly to the stream based on the direction of groundwater movement by an analysis of groundwater flux and distance from the borehole wells, and noticed that there were also large gaps between the chemistries of streamwater and bedrock groundwater. These results indicate that complex processes of chemical dynamics occur in the weathered bedrock and from the weathered bedrock to the stream.

Mean residence time and hydrochemistry of bedrock groundwater aquifer in a Granite mountain

KATSUYAMA, Masanori[1*] ; KOSUGI, Ken'ichiro[2] ; TANI, Makoto[2]

[1]Center for the Promotion of Interdisciplinary Education and Research, Kyoto University, [2]Graduate School of Agriculture, Kyoto University

Bedrock groundwater dynamics is one of the latest frontier of hillslope- and catchment hydrology. Although it relate to water resources as well as sediment disasters, only few studies have accessed directly with boreholes to bedrock groundwater aquifer because of, for example, high costs. In this context, tracer approach is effective to clarify the bedrock groundwater dynamics and water pathways within deeper layers of mountains. We have been keeping on monitoring of the chemical and isotopic compositions of bedrock groundwater and streamwater in Kiryu Experimental Watershed (KEW), Japan since 2003. We set up a nested observation system; a hillslope plot (AP, 0.024ha), a subcatchment (A catchment, 0.086ha), and whole of KEW (K catchment, 5.99ha), and monthly sampled the streamwater of K and A, the outflow from AP, which occurs as saturated throughflow on the soil-bedrock interface during rainstorms, and groundwater in the soil sediment. Moreover, we excavated the bedrock and installed some tension lysimeters at 0.1, 0.2, 0.4, and 0.8 m deep and boreholes at 12, 15, and 20 m deep below bedrock surface, and sampled them. The stream flow from K and A were perennial. The SiO2 and Na+ concentrations increased along with the infiltration process. On the other hand, the NO3- concentration was highest at the surface soil water, and removed along with the infiltration process. The concentrations of both solutes in the streamwater from A and K were intermediate between the concentrations in the surface soil water and bedrock groundwater. These facts mean that the streamwater is the mixture of shallow soil water and deep groundwater. The mean residence times calculated by delta 18O variations were about 4 or 5 months in the groundwater in the soil sediment and in the shallow (<0.8m) bedrock groundwaters, about 50 months in 12- and 15 m deep, and about 120 months in 20 m deep, respectively. That in the streamwater in A was estimated as about 30 months. Thus, the MRT in 20 m deep groundwater is quite different from the others. The relationship between the MRTs and the solute concentrations were different in each solute; for SiO2, the concentration increased as a saturation curve, and it increased as linearly for Na+. It exponentially decreased for NO3-. The streamwater chemistries in A were on these curves. Therefore, the solute concentrations can be described as functions of MRTs. These results suggest that a part of the bedrock groundwater can contribute to the stream from the shallower layers. The fact that the stream flow is perennial in this subcatchment A means that plentiful supply of groundwater from the relatively shallow bedrock layers exist. On the other hand, other part of the bedrock groundwater infiltrate deeply and less contribute to the stream in this small subcatchment; we have to consider whether the deeply infiltrated groundwater may contribute at the outlet of K catchment. Moreover, as the deeper bedrock groundwater have especially long residence time, we have to keep long-term monitoring to understand the dynamics and roles of this groundwater to hydrological and hydrochemical processes, because it will be a key of spatio-temporal scaling of these processes, as well as the water yield function of forests.

Hydrological change at the catchment scale: The need to address both velocity and celerity

MCDONNELL, Jeffrey[1*]

[1]Global Institute for Water Security, University of Saskatchewan CANADA

Water quantity and quality response to climate- and land use change are difficult to predict. Much of this relates to the complexities of water flow paths and our inability to relate measureable catchment properties to measureable hydrologic response metrics. To date, most work has focused on rainfall-runoff response — that is, the celerity component of change. Here I present new work from 15 headwater catchments, (0.1 to 100 km^2) in the Oregon Cascades and Oregon Coast Range in the USA, aimed at quantifying both celerity and flow velocities (i.e. particle transport through the system). I illustrate this velocity component through stable isotope analysis of runoff components and the mean transit time and residence time analysis of surface water and groundwater, respectively. Results show that despite very similar rainfall-runoff determined celerities, these systems have distinctly different tracer velocities, where transit time of headwater streamflow is 1-3 years in the catchments draining the Western Cascade mountains and 3-11 years in the streams draining the Coast Range mountains. More importantly, the scaling of surface water mean residence time in the Cascades is linked to internal topographic structure of individual sub-catchments whereas Coast Range sites show no evidence of this; and streamwater residence times scale linearly with catchment area. I discuss the implications of these celerity-velocity differences for catchment-scale climate- and landuse change effects in the USA Pacific Northwest and for more general efforts like the IAHS Panta Rhei initiative.

Toward understanding causal interrelationships between stormflow and erosion processes in a steep zero-order basin

TANI, Makoto[1*]

[1]Graduate School of Agriculture, Kyoto University

Stormflow generation and soil-erosion process on a steep zero-order basin have close interdependencies though their timescales are far different. This study pays attention to a difference in interdependences of stormflow and erosion processes between a near-ridge nose and a concave hollow within a zero-order basin.

Due to strong erosional forces in an active tectonic region, soil moves down by the gravity force throughout the basin. In a convex nose near the ridgeline, soil moves gradually by diffusive processes, and the curvature of bedrock surface controls the soil depth (Heimsath, Geomorphology 27, 1999). On the other hand, in a concave hollow, soil layer suddenly collapses as a landslide and a long-term soil-layer evolution at a timescale of 10^2 - 10^4 years continues unless a landslide occurs (Tsukamoto et al., IAHS Publ. 137, 1982). In the nose, the soil layer may move downslope with vegetation on it without disturbances. The recovery of soil layer after a landslide occurrence in a hollow is supported by the soil supply from the nose by the diffusive movement. The diffusive process near nose and the recovery process near hollow are closely related each other.

In order to ensure these processes, saturation excess overland flow should be suppressed both in a nose and a hollow because it is a trigger of landslide initiation. We can assume that the drainage capacity through pipe-like preferential paths (McDonnell, Water Resour. Res. 26, 1990) plays an important role in the suppression.

One hydrological analysis for addressing the assumption is attempted from estimating the expansion of stormflow contribution areas from rainfall-runoff responses in a small catchment. In the wet conditions when most of all the rainfall contributes to the stormflow, a hydraulic continuum under a quasi steady state is created and a single tank model can well simulate rainfall-runoff responses (Tani: Hydrol. Earth Syst. Sci., 17, 2013). This simple characteristic was utilized to estimate the contribution-area expansion with rainfall increases inversely from the runoff responses.

Results show that except a short dry period at the beginning of a storm, the waveform transmission of rainfall to runoff was simulated well by the same model parameters of our tank model though the contribution area only increased. This result suggests the waveform transmission was originated mainly from the vertical water movement instead of the downslope subsurface flow or the overland flow. As suggested from a conceptualized model (Montgomery and Dietrich, Water Resour. Res. 38, 2002), rainwater may be confined within the soil layer due to a large drainage capacity of the pipe-like preferential paths. This strongly encourages the soil-layer evolution process against strong erosional forces not only in a nose but also in a hollow.

Runoff and erosional processes are certainly linked, and collecting field evidences is expected. In addition, however, reanalyzing the existing hydrological data may also provide a new interesting finding from the linking point of view.

Interaction between bedrock groundwater and surface-hydrological and geomorphological processes in mountainous headwater

KOSUGI, Ken'ichirou[1*] ; FUJIMOTO, Masamitsu[2] ; YAMAKAWA, Yosuke[3] ; MASAOKA, Naoya[1] ; ITOKAZU, Tetsushi[1]

[1]Kyoto Univ., [2]Ritsumeikan Univ., [3]Tsukuba Univ.

Enormous landslides with deep slipping surfaces, which are likely to be triggered by the huge storms expected with climate change, can be one of the major geomorphological processes in the temperate climate zone. This study focuses on groundwater in mountainous headwater regions as a potential cause of such landslides. Recent hydrological studies have revealed that large amounts of rainwater infiltrate into bedrock, suggesting the possibility that steep mountains could contain greater amounts of groundwater than previously thought. The decline in groundwater levels due to water harvesting should be effective for the prevention of landslides. At the same time, the exploitation of groundwater resources in mountainous regions may contribute to establish a sustainable supply of safe water; that is, groundwater in mountainous regions is of better quality and less vulnerable to pollution because human activities are limited in the source areas. Thus, the exploitation of groundwater resources in mountainous regions should produce a win?win situation that achieves both disaster mitigation and a sustainable water supply. This study investigates hydrological methods for observing and analyzing quantitative and qualitative signals in mountain streams that can be used for detecting groundwater dynamics in steep mountains. Such hydrological methods are effectively combined with geophysical surveys.

In the steep Rokko mountain range of central Japan, which consists of granite and has been greatly affected by diastrophic activities, discharge hydrographs are characterized by significant amount of baseflow. In order to elucidate contributions of bedrock groundwater to the hydrograph formation, long-term hydrological observations were conducted by using bedrock wells with depths of 7-78 m drilled at 31 points within a 2.1-ha headwater catchment in the Rokko mountain range. Results indicated a fairly regionalized distribution of bedrock groundwater; that is, upper, middle, and lower aquifers were present. We observed large differences in water level among the aquifers, instead of a gradual and continuous decline in water level. Discharge hydrograph from the catchment was notably characterized by gentle and significant variations in base flow and exhibited triple-peak responses. Flashy first peaks occurred just after rainfall peaks, while the second peaks lagged behind the rainfall peaks by a few days. Broad peaks in the base-flow discharge corresponded to the third peaks, which occurred once or twice in each hydrological year. The triple-peak discharge responses were explained by three types of water pathways: the first peak was caused by the peak in soil mantle groundwater around the outlet of the watershed; the second peak was caused by the first peak in the lower aquifer, which was fed by vertical rainwater infiltration; and the third peak was caused by the second peak in the lower aquifer, resulting from an increased lateral water supply from the middle aquifer. The middle aquifer was recharged by vertical infiltration through weathered bedrock and lateral flow from the upper aquifer. Because of its broad regional expanse and large capacity, the middle aquifer had a dominant effect on formation of the discharge hydrograph. Thus, this study has demonstrated how discharge from the steep headwater catchment is dominated by complex flow systems within bedrock groundwater; the spatial expanse of bedrock aquifers and interaction among aquifers are key factors.

Evaluation of transpiration in a mature stand of Japanese cedar in Kanto region, Japan

IIDA, Shin'ichi[1*] ; SHIMIZU, Takanori[1] ; TAMAI, Koji[1]

[1]Department of Soil and Water Conservation, Forestry and Forest Products Research Institute

Forests cover about 70% of land area of Japan, and Japanese cedar (*Cryptomeria japonica*) occupies about 20% of total forested area. To understand the hydrologic cycle in Japan, we need measurements conducted in forested area, especially for the most representative species of Japanese cedar. Recently, the water balance of a stand of Japanese cedar has been made clear quantitatively by using eddy-covariance method and sap flow technique in Kyushu Island, south-western part of Japan (Kumagai et al., 2014; Shimizu et al., submitted). However, although Japanese cedar is most representative species in Japan, very few studies have been carried out in other part of the country. Based on the sap flow technique, we started to evaluate the amount of transpiration of a stand of Japanese cedar located in Kanto region, in the central part of Japan. In this paper, we show the relationship between outermost sap flow (Q_{0-20}) and single-tree transpiration (Q), tree-size parameter affecting Q, and correlation between stand transpiration (TR) and meteorological factors.

We conducted measurements in a mature stand of Japanese cedar, whose age is 61, within Tsukuba Experimental Watershed located in southern part of Mt. Tsukuba, Japan. Tree density is 1115 trees/ha, and annual mean leaf area index measured with LAI-2000 (LI-COR, USA) is 3.6. We set an observation plot in a Japanese cedar stand, and measured sap flux densities for all trees of the plot, 13 trees, with Granier method (Granier, 1985). Based on the wood core sampling with an increment borer, we determined the width of sapwood for 13 trees. Japanese cedar has white zone, in which water movement stops, in the sapwood area. We injected acid fuchsin into stem, and distinguished colored area as sapwood. The length of Granier sensor was 20 mm: in case that the width of sapwood was more than 20 mm, additional sensors were inserted into the sapwood at the depths from 20 to 40 mm and 40 to 60 mm. The sap flow at each depth is calculated as the product between the sapwood area corresponding to the depth and measured sap flux density. Q is finally obtained as total sum of sap flow of all depths. We calculated TR as the sum of Q of 13 trees divided by the area of the plot. On the meteorological tower, air temperature, humidity and net radiation were measured. Analyses are performed in the period from August to November, 2013.

The value of $Q/(Q_{0-20})$ had positive linear relationship with canopy projection area unshaded by other trees (CPA_{TH}). This trend implied that the contribution of Q_{0-20} to Q is small for trees having good light condition. Q had positive linear correlation with diameter at breast height (R^2=0.62), however, the higher correlation (R^2=0.70) was found between Q and CPA_{TH}. In this stand, CPA_{TH} is probably important factor affecting distribution of sap flow within the stem and tree-to-tree difference in Q. On the other hand, through the analysis period, TR had high positive correlation with equilibrium evaporation (R^2=0.83), but had lower correlation (R^2=0.39) with vapor pressure deficit (D). Focused on the summer period from August to September, we found higher correlation between TR and D (R^2=0.74). Thus, in summer, the driving energy of transpiration is mainly D due to the large aerodynamic conductance at the stand. However, the correlation between TR and D became small in the autumn. This stand is located in the north-facing slope, and has very high contrast in meteorological condition between summer and autumn. The different relationship between TR and D probably implies that plant physiological response of Japanese cedar in summer is different from that in autumn.

SURFACE RUNOFF ESTIMATION BASED ON TOTAL RAINFALL-TOTAL LOSS RAINFALL RELATIONSHIP FOR CATCHMENTS IN ISHIKARI RIVER

SUPRABA, Intan[1*] ; YAMADA, Tomohito J.[2]

[1]Member of JSCE, M.Sc., Doctoral Student, Graduate School of Engineering, Hokkaido University, [2]2Member of JSCE, PhD., Associate Professor, Faculty of Engineering, Hokkaido University

One of the main objectives of research in hydrology is to improve the accuracy of surface runoff estimation for enhancing flood prediction. Rain water falling to the ground surface will infiltrate into the soil and the excess rainfall will be surface runoff. The infiltrated water is defined as loss rainfall and loss rainfall is subtracted from total rainfall (actual rainfall intensity) to obtain the surface runoff (excess rainfall intensity). The non-linearity of surface runoff phenomena in the mountainous basins based on universal lumped kinematic wave model has been studied. Current study about total rainfall-total loss rainfall relationship by using tanh fitting curve has been conducted for 65 catchments located in 27 prefectures in Japan. Hourly rainfall and hourly runoff observation data for 10 years during summer time is used as required input data. Runoff parameters in the tanh function represented by *a* and *b* parameters are utilized to estimate effective rainfall based on water holding capacity theory. The purpose of this study is to estimate surface runoff by using effective rainfall for semi-ungauged river basins at the upper catchments area in Ishikari River Basin, Hokkaido Island, Japan. The obtained results are compared to the observation data for validation purpose.

Integrate simulated annealing algorithm and WASH123D to develop an automatic identification system for Chuoshui River in

CHANG, Ya-chi[1*] ; WANG, Yu-chi[1] ; CHEN, Cheng-hsin[2]

[1]Associate Researcher, Taiwan Typhoon and Flood Research Institute, NARL, Taiwan, [2]Assistant Researcher, Taiwan Typhoon and Flood Research Institute, NARL, Taiwan

Taiwan is located in the subtropical areas and often suffers from typhoons and heavy rains. In order to reduce the threat caused by typhoon, it is necessary to accurately estimate the water level of a river for flood disaster prevention and mitigation. Hydraulic analysis of a river is important in river management planning and engineering design. The identification of hydraulic parameter has huge impact on the water level estimation of a river during the hydraulic analysis. Manning ′ s roughness coefficient is usually used to describe a river ′ s surface roughness and sinuosity in hydraulic modeling. This coefficient is usually determined empirically in the past, which is tedious and time-consuming. Therefore, the optimization algorithms become an effective tool for engineers to select the Manning ′ s roughness coefficient.

The concept of simulated annealing algorithm (SA) is based on an analogy to crystallization process of the physical annealing from a high temperature state. Since SA has the Metropolis mechanism to escape local optimum trap, it has been applied to various types of optimization problems. In addition, the hydraulic model plays a crucial role for flood simulation and the WASH123D, an integrated multi-media, multi-processes and physics-based computational model suitable for various spatial-temporal scale, is selected in this study to simulate the water level. The purpose of this study is to integrate SA and WASH123D to develop a system for automatically identifying the optimal Manning ′ s roughness coefficients of the reach according to the given upstream and downstream boundary conditions of the river. Firstly, the cross sections and related hydrological data of the river are collected for flood hydrograph simulation in WASH123D and make sure the model can be executed for the reasonable range of the Manning ′ s roughness coefficient. Then, the system incorporates SA with WASH123D to identify the optimal Manning ′ s roughness coefficient according to the objective function for minimizing the difference between observed and simulated water level. The system is applied to the Chuoshui River in Taiwan. Flood in two typhoon events is simulated and the flood hydrograph is analyzed in this study to find the optimal Manning ′ s roughness coefficient. Results demonstrate that the system proposed in this study has feasibility to automatically identify the Manning ′ s coefficient.

Groundwater levels and qualities in megacities of Korea

YUN, Sang woong[1*] ; JEON, Woo-hyun[1] ; LEE, Jin-yong[1]

[1]Department of Geology, Kangwon National University, Republic of Korea

This study was conducted to evaluate the groundwater levels and groundwater qualities in six metropolitan cities (Seoul, Busan, Daegu, Incheon, Daejeon and Ulsan) of Korea. For this purpose, we collected the groundwater level data of 2001-2011 from the Korean National Groundwater Monitoring Stations in the cities and semi-annual groundwater quality data analyzed by the Korean Ministry of Environment for the same period. Using these collected data, we analyzed the change in the water levels in and outskirt of the cities and in groundwater qualities in the cities. The groundwater levels in the outskirt were generally higher (0.84-15.66 m bgs), compared with those in the central part of the city (3.89-75.16 m bgs), and well responded with the seasonal rainfall (higher in the summer but lower in the winter). However, the groundwater levels in the central part of the city were largely affected by pavement, deep underground building such as subway, and artificial pumping, not by the seasonal effect. The six metropolitan cities showed ranges of 0-507 mg/L and 0-22,000 mg/L for NO_3-N and coliform, respectively. In addition, groundwater contamination with TCE (0.00-4.50 mg/L), PCE (0.00-0.48 mg/L) and 1.1.1 TCA (0.00-0.11 mg/L) was also found. The groundwater contamination with these contaminants was relatively severe especially in Seoul and Busan, which may be attributed to their high densities of populations and industrial facilities. This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (NRF-2011-0007232).

Variation in groundwater-stream water interaction with season: focus on water level, temperature and chemistry

JEON, Woo-hyun[1*] ; YUN, Sang woong[1] ; LEE, Jin-yong[1]

[1]Department of Geology, Kangwon National University, Republic of Korea

This study was conducted to reveal seasonal variations of the groundwater and stream water interaction in Gangwon province of Korea using analyses of measured water levels, water temperature and water chemistry from August to November of 2013. For measuring the water levels in the hyporheic zone, four piezometers (IYGW-1˜4) were installed at depths of 0.830˜1.565 m below stream bed, perpendicular to stream flow direction and the stream level was also measured at IYSW-1. The water level and water temperature were measured every hour using an automatic logger (DIVER). In addition, nearby groundwater, hyporheic water and stream water were collected for ion and stable isotope analyses in the wet (September) and dry seasons (November) along with field measurements of pH, EC, DO and ORP. The water levels of the piezometers generally increased with rainfall, and they were lower than the stream water level in September, indicating a losing stream, but the former was higher than the latter in November, indicating a gaining stream. The reversal of the heads occurred at October 10. The stream water temperature (IYSW-1), directly affected by the surrounding air, was between 0.9˜22.9 ℃ with a large fluctuation. However, the hyporheic water (IYGW-4; 1.565 m depth) showed a small range of 13.2˜17.8 ℃. The water temperature at IYGW-4 was lower than those of the other piezometers but the reversal of the water temperatures also occurred at October, like the water levels. The groundwater, hyporheic water and stream waters were all classified as Ca-HCO_3 type by Piper diagram, which is indicative of effect of ambient air. The EC of IYGW-4 was the highest (136.7 μS/cm), indicating relatively higher influence of the groundwater. This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (NRF-2011-0007232).

Change of groundwater condition by operation of geothermal heat pump

PARK, Youngyun[1] ; MOK, Jong-koo[2] ; PARK, Yu-chul[2] ; LEE, Jin-yong[1*]

[1]Department of Geology, Kangwon National University, Republic of Korea, [2]Department of Geophysics, Kangwon National University, Republic of Korea

This study was conducted to evaluate the influence of open loop geothermal cooling and heating system (OLGCHS) and closed loop geothermal cooling and heating system (CLGCHS) on temperature and water level of local groundwater. For this study, groundwater temperature and level were measured daily using level logger at two sites where OLGCHS and CLGCHS are installed for approximately 30 months. In OLGCHS, fluctuation of groundwater temperature was similar to seasonal variation of ambient air temperature. However, this is not attributed to influence of air temperature. The groundwater temperature was fluctuated according the load of OLGCHS. The groundwater temperature was largely changed by operation of OLGCHS in summer compared to those in winter. These results represent that load of OLGCHS in summer is larger than that in winter. The groundwater levels were mainly controlled by precipitation and were slightly influenced by operation of OLGCHS. In CLGCHS, the groundwater temperature and level did not affected by operation of CLGCHS. The groundwater temperature was changed with 3^{o}C. The groundwater level was mainly influenced by precipitation because groundwater is not used directly in CLGCHS. In addition, response of groundwater level for precipitation was slower than those at OLGCHS because of difference of hydraulic conductivity. These results show that groundwater temperature and level did not significantly changed by OLGCHS and CLGCHS. However, it is necessary that long-term monitoring of groundwater temperature and level at sites, where OLGCHS and CLGCHS are installed, because OLGCHS and CLGCHS can affect the hydrological properties of aquifer with scale and type of use of geothermal energy. This work is supported by the Energy Efficiency and Resources of the Korea Institute of Energy Technology Evaluation and Planning (KETEP) grant funded by the Korea government Ministry of Knowledge Economy (No.20123040110010) and by the Korean Ministry of Environment under ”The GAIA project (No. 171-101-011)”.

Impact of ground source heat pumps operation on groundwater condition

KIM, Namju[1*] ; PARK, Youngyun[1] ; JEON, Woo-hyun[1] ; YUN, Sang woong[1] ; LEE, Jin-yong[1]

[1]1Department of Geology, Kangwon National University, Republic of Korea, [2]Geo Engineering Co. Ltd

This study was conducted to summarize status of installation of open loop geothermal cooling and heating system (OLGCHS) and to evaluate impact caused by its operation on groundwater condition. In this study, six facilities where OLGCHS is installed were considered. Groundwater is directly used in OLGCHS. The facilities considered in this study have been operated over two years. Groundwater temperature ranged from 6.0 to 24.2oC. Water temperature of natural groundwater and groundwater used to operating of OLGCHS showed difference of 5 to 9oC. pH and EC ranged from 7.5 to 9.1 and from 138 to 465 uS/cm, respectively. pH and EC of natural groundwater and groundwater used to operating of OLGCHS did not show significant difference. All groundwater meet Korean standard of water quality for domestic purpose In addition, saturation indexes of most major dissolved components except H4SiO4 showed lower than 1. These results represent undersaturated condition and that there are no minerals which can be precipitated from groundwater used in OLGCHS. Consequently, impact of ground source heat pumps operation on groundwater condition do not observed. However, these monitoring have been conducted continuously because contamination by ground source heat pumps operation can occur in any time. This work is supported by the Energy Efficiency and Resources of the Korea Institute of Energy Technology Evaluation and Planning (KETEP) grant funded by the Korea government Ministry of Knowledge Economy (No.20123040110010).

Change of the stream discharge process affected by the rainstorm magnitude in the small headwater catchment

KUDO, Keishi[1*] ; SHIMADA, Jun[1] ; TANAKA, Nobuhiro[2]

[1]Kumamoto University, [2]Kumamoto prefecture office

Recently, because rainstorm characteristics such as total and peak rainfall is increasing along with global warming, a lot of disaster as flood and landslide has been occurring in many areas worldwide. This change might engender changes in the water resource of a particular area. Therefore, this study was conducted for the two component hydrograph separation using EC value during rainstorm event between July 2012 and November 2013 in two small adjacent forest and grassland catchments at the headwaters of the western foot of Mt. Aso, Kumamoto prefecture, southwestern Japan, aims to understand the relationship between the groundwater discharge ratio and rainstorm magnitude. EC values of the stream water were recorded at 10-min interval at each Parshall flume using EC logger. We compared our results and data which we summarized, with published literature (Onda et al.,2006; Ichiyanagi and Kato, 1998; Ichiyanagi et al.,1994; Iwagami et al.,2010; Ohrui et al.,1992; Katsuyama et al.,2000; Katsuyama et al.,2001).

We observed 18 rainstorm events of varied magnitude in which total rainfall range from 9 mm to 727 mm and peak rainfall range from 5 mm/h to 94 mm/h. As a result, we reaffirmed that the groundwater discharge ratio decreased due to increase total rainfall and peak rainfall for small rainstorm event where total and peak rainfall were less than 200 mm and 20 mm/h respectively, and agreed with previous studies. The total discharge also increased in conjunction with an increase of ”new water” component. However; increasing of groundwater discharge ratio was observed for large rainstorm event where total and peak rainfall were larger than 200 mm and 20 mm/h, respectively. In this case, the total discharge increased in conjunction with an increase of ”old water” component. Therefore, we found that the rainstorm magnitude has an impact on the formation of the peak stream discharge during rainstorm. The peak stream discharge phenomena from catchment can be classified into two stages based on previous literature and our present studies. In the first stage, stream discharge is dominated by the old water before rainstorm, but the old water component of stream discharge decrease gradually with an increase of rainstorm magnitude. As the total rainfall reach 200 mm, most of stream discharge is dominated by the new water. Under larger rainstorm events, additional stream discharge increased in conjunction with an increase of ”old water” component (the second stage).

General discussion on insight into change and evolution in hydrology

TANI, Makoto[1*]

[1]Graduate School of Agriculture, Kyoto University

Fluctuations in the water and chemical cycles icluding floods, droughts, and water-quality impacts are influeced by long-term changes and/or evolutions in catchment properties and climate conditions. For example, to predict stormflow responses only from the cachment topography is difficult because the runoff mechanism is strongly controlled by bedrock-weathering and soil-evolution processes.

Such a concept of change and evolution is raised by IAHS, called 'Panta Rhei,' as its decadal intiaitive from 2013 following PUB (Predictions in ungauges basins), and the international disscussions have started.

In paralle with this activity, we are now conducting a project on dependences of rainfall-runoff responses on a temporally-nested structure of topographic, soil, and vegetation developments under the JSPS budget from 2011 to 2015.

In this session, presentaions addressing effects of natural changes and their interactions on the water and chemical cycles are encouraged, and chaneges originated from human influences including the disturbances and managements are also welcomed.

Radon Concentration around Tachikawa Active Fault

TSUNOMORI, Fumiaki[1*]

[1]Graduate School of Science, University of Tokyo

Characteristics of a radon concentration distribution around the Tachikawa active fault will be focused in this report.

According to the Headquarters for Earthquake Research Promotion, occurrence potentials of earthquake in active faults in Japan were updated after the Tohoku Earthquake (March 11, 2011). The report denotes the potential of the Tachikawa active fault while next 30 years was increased from 0.5-2% to 0.9-2%. In order to monitor a state change of the fault system by groundwater analysis, we have been surveying water qualities of spring water and hot-spring water.

Our survey of shallow spring waters around the fault in 2012 revealed that the radon concentration of shallow groundwater was affected by a cultivation process of groundwater on the ground surface around the northwest area of the Tama district. Therefore the shallow groundwater around the fault is not appropriate to get information on the state change of the fault. Our survey of deep hot-spring water around the fault in 2013 indicated the good relation between the radon concentration distribution and the location of the fault. The nearer the location of the hot-springs to the fault is, the higher the radon concentration becomes. Therefore the deep groundwater around the fault is useful to monitor the state change of the fault.

Reconstruction of summer precipitation during last two millennia in central Japan by tree-ring oxygen isotope ratios

NAKATSUKA, Takeshi[1*] ; SANO, Masaki[1] ; XU, Chenxi[1] ; OHISHI, Kyohei[2] ; SAKAMOTO, Minoru[3] ; NAKAO, Nanae[4] ; YOKOYAMA, Misao[5] ; HIGAMI, Noboru[6] ; MITSUTANI, Takumi[7]

Introduction

To establish long-term plans of flood control by river management and/or water supply by dam construction, it is necessary to predict future change in precipitation due to global warming. Because precipitation can change at various time scales, it is important to understand the statistical probability of giant flood occurring once a century or millennium. However, due to the shortage of hydrological and meteorological records, it has been difficult to understand statistical characteristics of precipitation in very long time scales. Recently, we have found that tree-ring cellulose oxygen isotope ratios (d18O) record summer precipitation in the corresponding years very precisely and started reconstructions of long term summer precipitation changes in annual time resolution all over Asia monsoon area. Here, we present the two millennial data of summer precipitation in central Japan based on the tree-ring d18O of Hinoki cypress samples obtained from various periods and discuss its meanings in historical hydrology.

Fundamental of precipitation reconstruction

Because cellulose is produced from carbohydrate originally photosynthesized in leaf, its d18O records changes in leaf water d18O. Leaf water d18O is controlled by two meteorological factors, precipitation d18O and relative humidity. It is positively correlated with precipitation d18O and negatively correlated with relative humidity due to the transpiration process. Because there are negative correlation between rain amount and precipitation d18O (amount effect) and positive correlation between rain amount and relative humidity, we can finally realize that there is distinct negative correlation between rain amount in growing season and tree-ring cellulose d18O.

Tree ring samples for long d18O time series

Because trees can seldom live more than several hundred years, we must collect many tree-ring samples during various periods to establish reliable time series of tree-ring d18O beyond last two millennia, not only from living trees, but also from old architectures, archaeological remains, tree logs buried by landslides and so on. Tree-ring samples of Japanese cypress were collected from a certain wide area in central Japan, where we can find consistent tree-ring d18O variations among different trees at different sites and combine many d18O time series, according to the consistent d18O patterns, to establish statistically reliable two millennia length of tree-ring d18O time series.

Application to historical hydrology

The time series of tree-ring d18O was first compared with various meteorological, historical and archaeological evidences on summer precipitation in Japanese history, including modern instrumental meteorological records, summer rainfall amounts quantitatively reconstructed from early modern diary weather notes, medieval documentary records on notorious flood and drought, and pit-house number in lowland plains of ancient Japan, and it was demonstrated that the tree-ring d18O coincides those records very well and successfully reconstruct past change in summer precipitation irrespective of reconstructed periods. However, the tree-ring d18O of Japanese cypress has a distinct age effect where it decreases gradually during its all life time, so that we cannot extract real precipitation trends more than 200 years periodicity from the cypress data. By comparing the tree-ring d18O time series with historical flood records in various rivers in central Japan, we found that there are very good coincidences in decadal time scale before 11th century, but the relation becomes diverse in 18th century, so that good coincidence disappeared in highly developed area where artificial flood control and/or excess logging might have influenced river hydrology. The summer precipitation records based on tree-ring d18O are useful to elucidate both of natural variability and human responses on the historical precipitation changes.

Water vapor origins in all over Japan in winter simulated by the regional isotope circulation model

TANOUE, Masahiro[1*] ; ICHIYANAGI, Kimpei[1] ; YOSHIMURA, Kei[2] ; SHIMADA, Jun[1]

[1]Graduate School of Science and Technology, Kumamoto University, [2]Atmosphere and Sea Research Institute and Institute of Industrial Science, University of Tokyo

In this paper, water vapor origins in all over Japan in winter were simulated by using a regional isotope circulation model with stable isotopes in water (δ^{18}O and δD). Precipitation and stable isotopes were simulated for the period between December to February in 2001 — 2010, spatial distributions of them were reproduced observations well. Simulated daily sea-level pressure patterns were divided into two types: winter monsoon (WM) type and extratropical cyclone (EC) type. In the WM type, precipitation rate was high and low along the Japan Sea side and the Pacific Ocean side, respectively. Spatial distribution of δ^{18}O in precipitation was recognized the latitude effect (values decrease with increasing latitude) on the Pacific Ocean and the Japan Sea. Spatial distributions of d-excess (=δD-8$\times\delta^{18}$O) in precipitation and evaporation were above 16 ‰ around Japan, those were extreme high (above 22 ‰) especially on the Pacific Ocean and the Japan Sea. Simulated water vapor evaporated from the Japan Sea was predominant in all over Japan in the WM type without southwestern islands of Japan. Interestingly, a portion of this moisture moved eastward to the Pacific Ocean, however, the moisture was not contributed to total amount of precipitation along the Pacific Ocean side because it was little precipitation. In contrast, precipitation rate was high in all over Japan in the EC type. Spatial distribution of δ^{18}O in precipitation was recognized the latitude effect on the Pacific Ocean and the Japan Sea and the amount effect (values decrease with increasing precipitation amount) across Japan. Spatial distributions of d-excess in precipitation and evaporation were below 14 ‰ around Japan without the western part of the East China Sea. Simulated water vapor evaporated from the Pacific Ocean was predominant in all over Japan. Comparing δ^{18}O and d-excess in precipitation between the WM type and the EC type, those were 2 ‰ and 8 ‰ higher along the Japan Sea side in the WM type than in the EC type, respectively.

Preliminary results of the stable isotopes in precipitation throughout Japan observed in 2013

ICHIYANAGI, Kimpei[1*] ; TANOUE, Masahiro[2]

[1]Isotope Mapping Working Group, JAHS, [2]Kumamoto University

Stable isotopes in precipitation are used for a proxy of climate change, which is related with temperature or precipitation amount. By using the atmospheric general circulation model with stable isotopes in water, water vapor origins (where the water vapor evaporated from?) can be estimated to determine the air mass transportation process. There are a lot of studies to observe stable isotopes in precipitation at only one or a few places in Japan. Tanoue et al. (2013) revealed seasonal variation and spatial distribution of stable isotopes in precipitation over Japan from the previous observational data at about 50 stations. However, spatial and temporal variations of stable isotopes in precipitation across Japan are still unknown, because a specific site and an observation period are different among the previous studies. Intensive observation of stable isotopes in precipitation over the whole Japan is required during the same period.

The Isotope Mapping Working Group of Japanese Society of Hydrological Sciences was conducted intensive observation of stable isotopes in precipitation throughout the year in 2013 (IOP2013). More than 2,000 precipitation samples are already collected at about 50 stations, and are analyzing its stable isotopic ratios by the Isotope Ratio Mass Spectrometer (Delta-V, Thermo Scientific) in Kumamoto University. Stable isotopic ratios in precipitation across Japan will be considered the relationships with locations (i.e. latitude, altitude, and distance from the coastline) and meteorological elements (i.e. temperature, precipitation amount, winds, specific humidity). Also, water vapor origins are estimated by using atmospheric general circulation model with stable water isotopes. Finally, the equations to reproduce stable isotopic ratios in precipitation at a specific place in Japan will be determined by its location and/or meteorological elements. It's a useful for the paleo-climate change as a proxy data of temperature and/or precipitation amount in the past.

In this study, we present the preliminary result of the IOP2013.

Stable isotope technique is increasingly used to provide ecological information to understand biological cycling and tracking environmental pollutants. The technique used for tracing phosphorus (P) in water is primarily based on the possibility of distinguishing the different P inorganic sources by phosphate oxygen isotopic signatures ($\delta^{18}O_p$) [1]. To date, there are only few studies to examine P cycling on watershed scales using the phosphate oxygen isotope analysis.

Here we aim to characterize individual $\delta^{18}O_p$ signatures of water, natural sources and potential anthropogenic sources in the Yasu River, the largest tributary river in the Lake Biwa Watershed. Special attention was paid to identify primary sources of P loadings in the Yasu River, associating with the land use pattern in its each catchment.

Materials & Methods

We collected river waters from 19 sites across the mainstream of Yasu River and its branches, whose catchment areas greatly vary in land use pattern. We also gathered water samples from 8 sewage treatment plants, 2 agricultural waste water plants and one livestock farm as point sources of anthropogenic P. We regarded phosphate fertilizers and sewage treatment plant waste waters as indicators for agricultural and domestic non-point P sources, respectively. We also collected sand from the riverbed of 5 headwaters as natural P sources. The sand samples were acid extracted to desorb dissolved inorganic phosphates [2]. These samples were treated with magnesium-induced coprecipitation (MagIC) method for phosphate extraction and then converted to silver phosphate after purification through the sequence of resin separation and precipitation [1,3]. We determined $\delta^{18}O_p$ for each of these silver phosphate samples using a thermal conversion elemental analyzer coupled to a continuous flow isotope ratio mass spectrometer via a helium stream.

We constructed an isotopic mixing model to estimate the relative contribution of individual P sources in each catchment.

Results & Discussion

A wide range of $\delta^{18}O_p$ in river water was detected. This indicates that this technique is a promising tool to trace P sources in the watershed ecosystems.

The isotopic mixing model showed that urban land use accounted for spatial variation in the relative contribution of domestic P loadings though there were some uncertainty in the model simulation.

Stable isotopic map of spring water and surface water in the Shirakami Mountains, Japan

AMITA, Kazuhiro[1*] ; MIURA, Takuya[1] ; HAYASHI, Takeshi[2]

[1]Department of Earth Science & Technology Faculty of Engineering and Resource Science Akita Universit, [2]Faculty of Education and Human Studies, Akita University

The Shirakami Mountains is the general name given to an extensive mountainous region of 130,000 hectares ranging from the southwest of Aomori to the northwest of Akita prefecture. Within this area are 16,971 hectares of land, enclosing virgin forests of Japanese beech, which were registered as a world heritage region in December 1993. However, environmental impact by acid rain at the Shirakami Mountains is becoming an issue these days. Acid rain deposits nitrates that can lead to increases in nitrogen in forests. So we have studied about the chemical and isotopic compositions of river and spring waters in the Shirakami Mountains area, to clarify origin and geochemical characteristics since 2011.

The result of the investigation was that delta-18O and delta-D of water samples showed -8.8 to -11.5 permil and -48.8 to -64.8 permil, respectively. Stable isotope composition of the samples roughly resemble those of meteoric water (delta-D = 8delta-18O+20), thereby indicating that these are local meteoric water. The least-squares regression line for all data is: delta-D = 5.7delta-18O + 1.7 (R2 = 0.88). On the other hand, the regression line calculated with data from NW-part is: delta-D = 6.0delta-18O + 0.5(R2 = 0.98). Characteristics of two regression line suggest that these water origin were brought by rain from different air mass, respectively.

Source of spring water and nitrate in northern foot of Mt.Fuji

NAKAMURA, Takashi[1*] ; HASEGAWA, Tatsuya[2] ; YAMAMOTO, Shinya[2] ; UCHIYAMA, Takashi[2]

[1]ICRE, University of Yamanashi, [2]Yamanashi institute of environmental Sciences

Water chemistry of spring water in Northern foot of Mt. Fuji is discussed with special reference to its source of water and nitrate. Monthly spring water and river water samples were collected from 8 springs and 7 locations of the 3 rivers, from June 2013 to January 2014. Land use of the study area are urban located about <1000m, forest distributed >1000m and forest limit is about 2500m. The oxygen isotope range of all spring water samples shows temporal variation (>1.0 permil), which suggests the possibility of the water changes of groundwater water recharge elevation. The nitrate-nitrogen concentration ranges from 0.2 to 1.8 mg/L and from 0.1 to 2.2 mg/L in river water and spring water samples respectively. Similarly, nitrate-nitrogen isotope values ranges from 2.7 to 9.9 permil and 1.4 to 10.4 permil in river water samples and spring water samples respectively. Although nitrate concentration was low, nitrogen isotope values overlaps with forest soil nitrogen and sewage or manure nitrogen. This trend suggests that the recharge elevation of the spring water might spread across a wide area. This presentation will discuss about recharge processes of the spring water including temporal variation of the isotopic values and water quality.

Spatial distribution of vanadium concentrations and water isotopes in lake bottom water from Lake Kawaguchi

YAMAMOTO, Shinya[1*] ; HASEGAWA, Tatsuya[1] ; YOSHIZAWA, Kazuya[2] ; NAKAMURA, Takashi[3] ; UCHIYAMA, Takashi[1]

[1]Yamanashi Institute of Environmental Sciences, [2]Yamanashi Institute for Public Health, [3]International Research Center for River Basin Environment, University of Yamanashi

Spatial distribution of vanadium concentrations was examined in bottom water from Lake Kawaguchi, on the northern foot of Mt. Fuji, in order to test the hypothesis that the water outflow from underwater springs in Lake Kawaguchi could affect the vanadium concentrations of lake water. The samples were collected from the east lake basin and the Funatsu lake basin on July 14-August 2, 2005, and from the west lake basin on November 1 and October 31, 2013. Vanadium concentrations in the bottom water from Lake Kawaguchi range from 0.66 μg/L to 3.18 μg/L. Because vanadium concentration in precipitation is generally $<$0.1 μg/L, the variations are most likely attributed to the dilution of the lake water due to precipitation, and/or the input of water masses with high vanadium content. Although the concentrations of vanadium are significantly lower than those in the groundwater of the Mount Fuji, we found a relatively vanadium-enriched water mass along the southern coast of the west lake basin, off coast of Higashiken lava flow from Mount Fuji. The area matches well with the potential location of underwater springs in Lake Kawaguchi, and the lack of any riverine input around the area suggests that a water mass with relatively high vanadium concentration is likely provided from underwater springs that are located in off coast of the basaltic lava flow of Mount Fuji. We also plan to discuss the source of underwater springs based on stable water isotope ratios in the presentation.

Contribution of volcanic gas to spring waters in the Mt. Yotei.

KUSANO, Yukiko[1*] ; YASUHARA, Masaya[2] ; ASAI, Kazuyoshi[3] ; INAMURA, Akihiko[2] ; TAKAHASHI, A., hiroshi[2] ; MORIKAWA, Noritoshi[2]

[1]The University of Tokyo, [2]Geological Survey of Japan, AIST, [3]Geo science Laboratory Co. Ltd.

The Mt. Yotei is a stratovolcano in southwest Hokkaido with an altitude of 1893 m. There are a lot of springs in the foot of the mountain and most of these are found from the altitude of 200 to 260 m. This elevation is consistent with that of boundary between volcanic rocks of the volcano and basement consists of tuff and pumice. Northern, eastern, and southern slopes of the mountain are covered by pyroclastic fall and reworked deposits of that, while the western slope is covered by lava erupted from summit and parasitic volcanos in western slope (Katsui, 1956).

It is revealed that springs in eastern and southern slopes tend to show lager discharge and lower dissolved components, while those in the western slope tend to show smaller discharge and higher dissolved components (Yamaguchi and Sato, 1971; Yamaguchi, 1972; Tsurumaki, 1989). Because of higher HCO_3^- and free CO_2 gas concentrations and higher temperature of springs in the western slope, addition of volcanic gas to those is estimated (Yamaguchi and Sato, 1971; Tsurumaki, 1989). However, contribution of volcanic gas to groundwater has not been evident. In this study, contribution of volcanic gas to spring waters will be discussed based on dissolved components and isotopic compositions.

Spring water samples were collected on August 2013, and were analyzed for major dissolved components, isotopic compositions (δD, δ^{18}O, δ^{13}C, ^{3}He/^{4}He), and groundwater-age indices (CFCs and SF_6). Dissolved components of spring waters are Ca-HCO_3 type or Na-HCO_3 type. Spring waters in the western slope tend to show higher HCO_3^- and free CO_2 gas concentrations. These results are consistent with those of previous studies. δ^{13}C of dissolved inorganic carbon (DIC) in spring waters in eastern and southern slopes are -21.7 to -17.7 ‰, while those of the western slope are -18.1 to -3.0 ‰. This result suggests that spring waters in western slope contain DIC of which origin is different from that contained in springs in eastern and southern slopes. Dissolution of marine carbonates is unlikely because groundwater flow in volcanic rocks. Relationship between δ^{13}C and inverses of concentrations of total carbon are plotted in mixing zone of volcanic CO_2 and soil CO_2, and spring water showing higher δ^{13}C and total carbon concentration were correspond to higher contribution of volcanic CO_2. These results suggest that spring waters in western slope showed higher δ^{13}C and total carbon concentrations because of addition of volcanic CO_2. δD and δ^{18}O of spring waters are plotted along the meteoric water line (GSJ, undisclosed data), suggesting contribution of magmatic water is quite small. Effect of parasitic volcanos in the wastern slopes is suggested by Yamaguchi and Sato (1971) as a possible factor for higher contribution of volcanic gas to springs in the western slope. Further discussions based on dissolved components, isotopic compositions, and groundwater-age indices will be performed to reveal relationship between contribution of volcanic gas and groundwater flow system.

Mt Yotei is a stratovolcano located on southwestern part of the Hokkaido. 17 springs with flow rate over 20 L/s distribute on the foot of the volcano body. We used the multi tracer method to estimate the recharge elevation and the residence time for the springs. Water samples were collected from 14 springs at August 2013, and were measured in stable isotope, Tritium, CFCs and SF6. In this presentation, we discuss the relationships between the scale of groundwater flow system and the hydrogeology of volcano body, based on the recharge elevation and the residence time for springs.

A study using a coupled hydrological and geochemical (water chemistry, δD·δ^{18}O, δ^{13}C, and helium isotope) approach is in progress to elucidate the groundwater system in and around Mt. Sambe, a 1126-m high active volcano located in western Japan. Groundwater in its south to east flanks proved to be characterized by high δ^{13}C values (in the range between -9 - -5 ‰ δ^{13}C) as well as an elevated concentration of total carbon compared to those in other flanks. These observations clearly indicate an admixture of magmatic fluid into shallow groundwater of the south to east flanks, being also in accordance with its water chemistry with an increased chloride ion concentration.

Origin of the high-chloride groundwater in the central part of the Kanto Plain from the viewpoint of noble gas hydrology

MORIKAWA, Noritoshi[1*] ; YASUHARA, Masaya[1] ; HAYASHI, Takeshi[2] ; MIYAKOSHI, Akinobu[1] ; INAMURA, Akihiko[1] ; TAKAKASHI, Masaaki[1] ; NAKAMA, Atsuko[1]

[1]Gelological Survey of Japan, AIST, [2]Akita University

There exist three regions in the Kanto plain, central Japan, whose artesian groundwater is characterized by a high Cl^- concentration: 1) central parts of the Kanto plain (Saitama Prefecture), 2) south-east parts of Gunma Prefecture), 3) floodplains and deluvial uplands along the lower reaches of Kokai and Tone rivers (Ibaraki and Chiba Prefectures).

As for that in the central parts of the Kanto plain, confined groundwater with a high Cl^- concentration of up to 216 mg/l is obtained from the productive boreholes of 200-430 m depth. The area of Cl^--rich groundwater, spreading from the northwest to southeast, corresponds with the so-called Motoarakawa tectonic zone (ca. 10 km wide by 35 km long) bounded by the fault on its longer sides. The $^{36}Cl/Cl$ results of these high chloride groundwaters imply that admixture of meteoric water and sea water in the period of the Shimosueyoshi transgression (peak period at around 125,000 yrs. BP) is likely to account for its elevated Cl^- concentration (Yasuhara et al., 2011). Morikawa et al (2006) conducted dissolved noble gas analyses for the groundwaters in the Motoarakawa tectonic zone. The results of helium isotopes are as follows; (1) there is a tendency of high ^4He concentration in the groundwaters inside the tectonic zone, (2) helium isotopic ratios ($^3He/^4He$) are relatively homogeneous with an end member of 0.8-1.1 x 10^{-6}. Helium-4 concentration show clear positive correlation with chloride concentration. Combined with this correlation and characteristics of helium isotopic ratio, it is inferred that the groundwater from the tectonic zone is a mixture of meteoric water and high chloride saline water bearing with high 4He or is stagnant old groundwater and that the groundwater flow system is distinct from those from outside of the tectonic zone.

In this study, we investigated the noble gas in the deeper groundwaters (hot springs) around the Motoarakawa tectonic belt and the high-chloride groundwaters from south-east parts of Gunma Prefecture to elucidate the origin of water and chrolide component in the central parts of the Kanto plain. Low $^3He/^4He$ ratios in the hot springs indicate that there is no interconnectivity between the high chloride groundwater and hotspring water around the Motoawakawa tectonic zone. In contrast, both $^3He/^4He$ ratio and correlative ^4He and Cl concentration in the high-chrolide groundwaters from south-east parts of Gunma Prefecture are similar to those in the groundwaters in the Motoarakawa tectonic zone.

Geochemical study of hot spring waters and gases in Jozankei area, Hokkaido, northern Japan

TAKAHASHI, Masaaki[1*] ; KAZAHAYA, Kohei[1] ; SASAKI, Munetake[1] ; MORIKAWA, Noritoshi[1] ; TAKAHASHI, Hiroshi[1]

[1]Geological Survey of Japan, AIST

Jozankei hot spring area is located in the western part of Sapporo city, Hokkaido, northern Japan. In this area, hot spring waters >85 degree C. are springing out from the entire Toyohira river volley. Total discharge rate of hot spring waters is about 10 tons/min and the ”heat energy index” is rank V (Fukutomi, 1965). Hydrogen and oxygen isotopic study clarified that the major origin of hot spring water is local meteoric water (Matsubaya et al., 1978)

To understand the other origin of Jozankei hot spring, analyses of chemical compositions, hydrogen and oxygen isotope ratios were carried out for hot spring waters from Jozankei area and its adjacent area. From the good correlation among chloride ion content, oxygen and hydrogen isotope ratio of hot spring waters in Jozankei area, it is clarified that one of the end member of hot spring waters of Jozankei area is originated from magmatic fluid and chemical composition of magmatic fluid is 3-5 NaCl wt%.

Genesis of Kashio brine: slab-derived fluid

KAZAHAYA, Kohei[1*] ; TAKAHASHI, Hiroshi[1] ; MORIKAWA, Noritoshi[1] ; OHWADA, Michiko[1] ; INAMURA, Akihiko[1] ; YASUHARA, Masaya[1] ; TAKAHASHI, Masaaki[1]

[1]Geological survey of Japan, AIST

In this study, we show the results obtained be investigation of a very saline spring named Kashio brine, central Japan and discuss its genesis and cause of chemical and isotopic features. The brine water is spouting out through the cracks of metamorphic rocks close to Median Tectonic Line (MTL) at 700m asl. The Cl concentration of water is greater than that of the seawater with ^{18}O-shifted isotopic composition. The brine is thought to originate from slab-derived fluid with the chemical and isotopic composition of water like the Arima hot spring, in spite of its low temperature and CO_2-less features. The cause of this chemical character might be explained by a reaction with ultramafic rocks existed close to Kashio area which causes high pH condition to deposit all the CO_2 as $CaCO_3$. The low temperature may be interpreted by the low upwelling rate because of the low $^3He/^4He$ ratio (lower than 2Ra) due to the addition of crustal 4He. The amount of NaCl is finally supplied to the river and is estimated to be 2000kg/day.

GC/C/IRMS as a tool to evaluate the degradation of chlorinated organic compounds in groundwater

YONEYAMA, Yuki[1*] ; ARAI, Yohei[2] ; NAKAMURA, Takashi[1] ; KAZAMA, Futaba[1]

[1]ICRE, UNIVERSITY OF YAMANASHI, [2]Hitachi Plant Services Co.,Ltd

The in-situ remediation techniques by microbial activity are used for reduction of chlorinated organic compounds in polluted groundwater. However, the evaluation of microbial activity for decomposition of chlorinated organic compounds is not clear by only the concentration analysis. So, we focus on the usage of the stable carbon isotope analysis of chlorinated organic compounds such as trichloroethylene (TCE), and its daughter products; cis-dichloroethylene (cis-DCE) and vinyl chloride (VC).

The stable carbon isotope ratio (δ^{13}C) of these organic compounds were analyzed by a GC (Agilent : 7890A) coupled to an isotope ratio mass spectrometer(SerCon : 20-22) with combustion interface (SerCon : GC-CP) (GC/C/IRMS). The system was equipped with a purge-and-trap concentrator (GL science : AQUA PT 5000J PLUS) connected to the GC. In the δ^{13}C value measurement, the measurement limit was usually 200ng-C, and standard deviation in TCE, cis-DCE and VC were $\pm$0.08, $\pm$0.37, $\pm$0.11 permil, respectively.

Groundwater samples were collected at polluted site with and without bioremediation treatment.

In samples from without treatment site, even the concentration decreasing were detected, the δ^{13}C values of TCE are almost same as original one. On the other hands, δ^{13}C values of not only TCE but also the daughter products increase with a decrease in concentration of TCE. These results show the usefulness of GC/C/IRMS for distinguishing the reason of concentration reduction by in-situ microbial activity of decomposition of these organic pollutants from physical factors such as dilution, diffusion, and adsorption.

Isotope characteristic of rain water and atmospheric vapor in Hiratsuka, Japan

TAKAGI, Kenta[1*] ; OOKI, Seigo[2] ; OHBA, Takeshi[2]

[1]Course of Chemistry, Graduate School of Science, Tokai University, [2]Course of Chemistry, School of Science, Tokai University

Introduction

The stable isotope ratios of hydrogen and oxygen in meteoric water (δD and δ^{18}O) are affected by geological and climatic conditions. Global meteoric water line (GMWL) describes the average isotopic compositions in the world. According to Craig (1961), the relationship between δD and δ^{18}O was expressed as

$\delta D=8\delta^{18}O+10$ (1)

However those intercept are not always 10 in each area. In Japan, the meteoric water originates in both Pacific Ocean and Japan Sea. The effects of two seas vary due seasonally. The isotope ratio of atmospheric vapor is important for study of atmospheric circulation, however, the number of published paper is not so much. In this study, we investigate the d-excess (d=δD -8δ^{18}O) of rain water and atmospheric vapor in Hiratsuka, Japan.

Sampling methods

Samples were collected on the roof of a No.17 building at Shonan campus, Tokai University from May to December 2013. Rain water samples were collected based on a method described by Negrel et al. (2011) and Yoshimura (2002). The collection duration was days or hours in scale. Rain water samples were percolated through 0.2 μm filter, and kept into a 100 ml low-density polyethylene bottle. Atmospheric vapor samples were collected through a trap cooled with ethanol and dry ice mixture. Samples were 42 of rain water and 11 of atmospheric vapor. δD and δ^{18}O of samples were measured by a Cavity Ring-Down Spectrometer analyzer (model L2120-I from PICARRO). Some data of rain water, which were sampled several times in a day, were processed to be the average value.

Results and discussion

Rain water shows a wide variation in δD and δ^{18}O from -86.4 to +6.2 ‰ and -12.6 to -2.6 ‰, respectively. Atmospheric vapor shows a variation from -223.5 to -98.6 ‰ and -31.2 to -14.7 ‰, respectively. The δD-δ^{18}O relationship of rain water gives a regression line: $\delta D=9.2\delta^{18}O+24.0$ (R^2=0.95) and that of atmospheric vapor gives a regression line: $\delta D=7.3\delta^{18}O+7.9$ (R^2=0.96). The d-excess values show a variation from 4.4 ‰ to 33.2 ‰. In Japan, origin of meteoric water affects to d-excess (Waseda and Nakai, 1983). In case of Pacific Ocean, d-excess is low (10$\geq$d). In case of Japan Sea, d-excess is high (20$\leq$d). In this study, the d-excess was low in summer when southern winds were blown from Pacific Ocean as the seasonal wind, and that value was high in winter when northern winds were blown from Japan Sea. Samples of atmospheric vapor show also this trend. Suggesting that atmospheric vapor is influenced by the same effect of meteoric water. The meteoric water line of rain samples was affected by d-excess which reflects variations of moisture sources, which is the reason why the slope of this line would be bigger than GMWL.

Exploring the sources of sulfur ion deposition and runoff in forest watersheds on the northern side of Lake Biwa

NAKAZAWA, Koyomi[1*] ; HORIE, Seigo[1] ; NAGAFUCHI, Osamu[1] ; OSAKA, Ken'ichi[1] ; NISHIMURA, Takuro[1]

[1]The University of Shiga Pref.

To clarify the sources of sulfur ions in precipitation and runoff from forest watersheds, bulk deposition and stream water samples were collected within the small Kutsuki and Surumi forest watersheds on the northern side of the Lake Biwa basin, central Japan. Samples were analyzed for major ions and δ34S. Continuous monitoring from 1990 to 2010 showed that the average SO_4^{2-}concentration in stream water samples was 1.62 $\pm$0.31 (0.76, 3.58) mg l^{-1}at Kutsuki and 6.59 $\pm$1.54 (3.68, 16.1) mg l^{-1}at Surumi (t-test, $p<0.01$). However, the average SO_4^{2-}concentration in bulk deposition samples was similar in both watersheds: 2.15 $\pm$ 1.31 (SD) mg l^{-1}(range, 0.202-10.2 mg l^{-1}) at Kutsuki and 2.24 $\pm$ 1.29 mg l^{-1}(0.350?6.07 mg l^{-1}at Surumi (t-test, $p>0.05$). The δ34S values in bulk deposition samples fluctuated from +8.86 to +9.14 ‰ at Kutsuki and from +9.87 to +11.1 ‰ at Surumi, whereas non-sea salt (nss-) δ34S in stream water samples varied from +6.89 to +12.0 ‰ and from ?4.64 to +5.11 ‰ , respectively (t-test, $p<0.01$). It is said that the δ34S values in coal products from northern China varied from -3 to -1 ‰ and Japanese oil varied from +5 to + 18 ‰ .

Our findings suggest that the difference in the ability of canopies in the watersheds to catch SO_4^{2-}dry deposition is the reason for the significant difference in nss- δ34S values in stream water samples. The more open canopy in the Kutsuki watershed consists of young conifers and deciduous broadleaf trees, whereas the canopy in the Surumi watershed consists of mature conifer trees at a high density. Therefore, it appears that the Kutsuki watershed was only affected by SO_4^{2-}deposition from the Asian continent.There were not any domestic air pollution sources on the north side of Kutsuki. In contrast, the dense canopy of the Surumi watershed was affected by local SO_4^{2-}pollution sources of national roads which were located 1 km northwest from Kutsuki, rather than continental sources. Overall, this investigation suggests that the difference in stream water SO_4^{2-}concentrations in both watersheds is caused by the canopy differences.

Geochemical and isotope systematics of Asahi and Yoshii rivers

KAMEI, Takahiro[1] ; YAMASHITA, Katsuyuki[1*] ; OONISHI, Ayaka[2] ; KURIHARA, Yoko[2] ; CHIBA, Hitoshi[1] ; NAKANO, Takanori[3]

[1]Graduate School of Natural Science and Technology, Okayama University, [2]Faculty of Science, Okayama University, [3]Research Institute for Humanity and Nature

We have undertaken a detailed geochemical and isotopic analysis of water samples collected from the Asahi and Yoshii rivers of the Okayama Prefecture, Japan. More than 300 samples were collected from the rivers and their tributaries during March 2011 to January 2014. In several locations, samples were collected periodically in order to monitor the long-term fluctuation of the geochemical properties. All samples were filtered with 0.2 μm filter prior to the analyses for major dissolved constituents (F, Cl, NO_3, SO_4, Br, PO_4, Ca, Mg, Na, K), trace elements and O-H-Sr-S isotopes.

Based on the results obtained so far, we have constructed a high-resolution geochemical map of the rivers covering central to eastern Okayama Prefecture. The map shows that the concentrations of most major dissolved constituents, as well as the O-H-Sr isotope ratios changes systematically from the upstream towards the downstream. For example, the deuterium excess (DE) is generally high in the upstream ($>$20) and gradually decreases towards the downstream ($<$12). This difference in the DE exceeds the seasonal variation observed in locations where the long-term monitoring was conducted. Thus, the regional change in the DE is interpreted to be the result of different air mass contributing to the meteoric water of different locations.

The Ca, Sr, and Ba concentrations are generally low in the upstream and gradually increase towards the downstream. The $^{87}Sr/^{86}Sr$ also changes from approximately ˜0.705 and ˜0.706 in the headwaters of the Asahi and Yoshii rivers, respectively, to ˜0.708 in the areas close to the Seto inland sea. The shift in the Sr isotope ratio seems to correlate well with the change in the ages of the rocks exposed in the river basin. This implies that these variations are likely related to the water-rock interactions.

The concentrations of other important dissolved constituents such as the NO_3 and SO_4 tend to increase abruptly in the densely populated regions. This is also accompanied by a shift in the S isotopic composition. These variations may reflect a change in the degree of human influence such as breakdown of fertilizers used for agricultural activities.

To clarify the total discharge rate of the submarine spring from Mt. Chokai, base-flow observation was conducted on 15 streams around western foot of Mt. Chokai at the end of January 2014. In this presentation, based on the distribution of specific discharge rate, we discuss the characteristics of the groundwater discharge and the hydrological balance in this area.

Estimation of groundwater recharge area at the south foot of Mt. Bandai using the observation data in 2013

YABUSAKI, Shiho[1*]

[1]Faculty of Symbiotic Systems Science, Fukushima University

The Mt. Bandai (1,816 m a.s.l.) which is an active volcano of the Quaternary period is located at Fukushima prefecture. Because of the geological characteristics in the volcanic area, it is estimated the groundwater recharge is large around Mt. Bandai. The groundwater and spring water around Mt. Bandai is used as the source of the public tap water, so it is important to comprehend the groundwater flow and groundwater recharge ratio at Mt. Bandai. To make clear the groundwater flow systems at Mt. Bandai, the investigation was carried out.

The EC value is under 10 mS/m and water quality indicates the Ca-HCO_3 type at most points in the south slope of Mt. Bandai. The oxygen isotopic ratios ($\delta^{18}O$) are -11.1 to -10.8 ‰ (Site 1) and -11.2 to -11.1 ‰ (Site 2), and hydrogen isotopic ratios (δD) are -67 to -65 ‰ (Site 1) and -68 to -67 ‰ (Site 2). The altitude effect is recognized in these areas. The average recharge area (altitude) in the south slope at Mt. Bandai is estimated from 1,150 to 1,270 m (Site 1) and from 1,360 to 1,420 m (Site 2). These recharge area (altitude) in the south slope is lower rather than the north and west slopes. In future, the investigation at more low altitude area (about 520 to 550 m) will be carried out, and estimate the groundwater flow in the south slope at Mt. Bandai.

Future Projection of flow regime and water quality in Arakawa river basin

ISHIDAIRA, Hiroshi[1*]

[1]Interdisciplinary Graduate School of Medicine and Engineering

The research project of Core Research for Evolutional Science and Technology (CREST): ”Development of well-balanced urban water use systems adapted for climate change” (PI: Hiroaki FURUMAI, Univ. of Tokyo, Research area: Innovative Technology and System for Sustainable Water Use) have been conducted from 2009.

The objectives of this project are 1) to reexamine the current urban water use system, and 2) to propose a new urban water use system adaptive to the future climate change. In the new system, each water resource is properly allocated to each water use by considering the balance between supply potential of various water resources and demand. The information on available amount and detailed quality of water resources should be evaluated.

For the implementation of the project, 5 sub-groups were organized:
(1) Watershed Water Resources group
(2) Urban Rainwater Management and Use group
(3) Urban Groundwater Management and Use group
(4) Water Quality Assessment group
(5) Urban Water Use Design group

In this presentation, activities of Watershed Water Resources group (and collaborative work with Urban Groundwater Management and Use group) will be presented.

An isotopic study on the origins of sulfate ion in shallow urban groundwater of the Musashino Plateau, Tokyo, Japan

YASUHARA, Masaya[1*] ; HAYASHI, Takeshi[2] ; NAKAMURA, Takashi[3] ; INAMURA, Akihiko[1] ; ASAI, Kazuyoshi[4]

[1]Geological Survey of Japan, AIST, [2]Akita University, [3]University of Yamanashi, [4]Geo Science Laboratory

Shallow groundwater in the highly-urbanized Shakujii-gawa River basin on the Musashino Plateau, Tokyo, Japan shows a remarkable spatial variability of its sulfate ion concentration in the range between 7-135 mg/L. The average sulfate ion concentration is 35mg/L, 36mg/L, 33mg/L, 21mg/L, 19mg/L, and 28mg/L in Kita Ward, Itabashi Ward, Toshima Ward, Nerima Ward, Nishi-Tokyo City, and Kodaira City, respectively, indicating higher concentration in the lower reaches of the river where urbanization has started earlier and progressed more rapidly than its upper reaches. To discuss possible origins of sulfate ion in groundwater, a hydrologic study using stable isotope of sulfur was carried out in 2012 to 2013. Although a limited number of samples, higher sulfur isotope measurements (+10.5 and +10.6 per mil delta-34S for Toshima and Kita Wards, respectively) suggest contribution of leaking sewage from aging, deteriorated sewer pipes, accounting for an elevated sulfate ion concentration in the lower reaches of the river.

PPCPs polution in an urban watershed in Musashino upland, Tokyo

HAYASHI, Takeshi[1*] ; YASUHARA, Masaya[2] ; NAKAMURA, Takashi[3]

[1]Faculty of Education and Human Studies, Akita university, [2]Geological Survey of Japan, AIST, [3]ICRE, University of Yamanashi

Human activities discharge various chemical substances to water environment in urban area around the world. Some substances are concerned to affect health of human and aquatic organism because these substances are hardly decomposed not only in natural environment but also water treatment plant. We study on shallow groundwater environment in Musashino upland, Tokyo to evaluate sources and recharge processes of groundwater and present state of groundwater pollution by domestic wastewater (e.g. Hayashi et al., 2012; Nakamura et al., 2013; Yasuhara et al., 2013). Based on the result of our previous research, we newly collected water samples of river water and shallow unconfined groundwater in the watershed and measured PPCPs components. Three samples of river water were taken from two rivers: a natural river mainly recharged by groundwater and an artificial river recharged by treated waste water. 15 groundwater samples were collected from private wells that were distributed in the water shed of the natural river. A for PPCPs, 78 substances were measured by semi-quantitative analysis and another six substances (amantadine, caffeine, carbamazepine, crotamiton, ibuprofen, N,N-diethyl-m-toluamide) were measured quantitatively.

As for river water samples, 19 substances from semi-quantitative analysis and six substances from quantitative analysis were detected in the artificial river, and three substances from semi-quantitative analysis and five substances from quantitative analysis were detected in the natural river. On the other hand, only one substance from semi-quantitative analysis and four substances (amantadine, carbamazepine, crotamiton, N,N-diethyl-m-toluamide) from quantitative analysis were detected in groundwater samples in both peri-urban upstream area and urbanized downstream area.

We present present characteristics of PPCPs components and spatial distribution in the study area.

Title: Household water treatment for the removal of contaminants in groundwaters in Hanoi, Vietnam

DO, Thuan an[1] ; TAKIZAWA, Satoshi[1*] ; KURODA, Keisuke[1] ; HAYASHI, Takeshi[2] ; TRAN, Viet nga[3]

[1]The University of Tokyo, [2]Akita University, [3]University of Civil Engineering, Hanoi

Between 2000 and 2025, the urban population in Vietnam is expected to double from 19 million to 40 million. Therefore, urbanization and increasing water demand is one of the most important challenges in Vietnam, especially in Hanoi. At present, Hanoi city relies on groundwater as a main source of water supply, but it is going to shift to the surface water as the demand increases in the near future. However, variation of rainfall, dam construction in the upstream of the Red River and climate change in the near future make the surface water unreliable water source for water supply in Hanoi City. As the extension of water supply coverage is slow, many households still rely on groundwater as their drinking water sources. However, groundwater is contaminated by ammonia, arsenic, iron, bacteria and others. In order to obtain clean drinking and cooking water many households use point-of-use (POU) treatment devices including sand filters, ceramic filters, reverse-osmosis filters, and UV irradiation.

To identify the impact of POU usage to water consumption and water quality, a survey of POU usage in 170 households in six communes in Hanoi was carried out in 2012 and 2013 Water samples were also taken to investigate the treatment efficiency of those POUs. As a result of the household survey, it was found that many households in rural and suburban areas have multiple water sources and use them for different purposes, while the urban households use only piped water supply. The result indicated that between 18% and 76% of the households in these communes used POU water treatment devices, of which RO devices accounted for 58%. Groundwater was contaminated by arsenic (max 0.3 mg/L), ammonia (max. 26 mg/L), and manganese (max. 3 mg/L). Although most of the arsenic was As(III) form in groundwater, it was oxidized to As(V) in the sand filters. Thus, RO filtration was found quite effective in removal of arsenic from groundwaters.

Recent surface displacement in Bangkok associated with groundwater recovery

ISHITSUKA, Kazuya[1*] ; FUKUSHIMA, Yo[2] ; TSUJI, Takeshi[3] ; YAMADA, Yasuhiro[1] ; MATSUOKA, Toshifumi[1]

[1]Graduate School of Engineering, Kyoto University, [2]Office of Research Promotion, Tohoku University, [3]International Institute for Carbon-Neutral Energy Research (I2CNER), Kyushu University

In many cities in the world, groundwater level decrease and subsequent land subsidence has been observed associated with groundwater pumping. Bangkok, the capital city of Thailand, is also one of the cities that had been suffered from land subsidence due to groundwater extraction. Since 1960s, groundwater has been extracted for commercial and personal use. Subsequently, the cumulative subsidence of about 1 m has been reported. Recently, Thailand government has implemented several measures to regulate groundwater use, and groundwater level recovery has been reported.

In this study, we used persistent scatterer SAR interferometry (PS-InSAR) analysis, which is the method to process a series of SAR data equipped on repeat-pass satellite, to estimate ground displacement in Bangkok from November 2007 to December 2010. Since SAR data is acquired by satellite, PS-InSAR analysis has an advantage for mapping displacement pattern in wide area with high spatial density.

As a result, we estimated ground uplift with the rate of about 1 cm/year. The secular uplift has decayed over time, and can be modeled by exponential function of time. Since the groundwater recovery has been observed in areas where uplift was estimated, this uplift is likely associated with groundwater recovery. Moreover, we also estimated seasonal displacement correlated with the cycle of precipitation in eastside of Bangkok.

The Use of Isotopic Technique to the Assessment of River Recharge to the Depleted Ground Water Systems in Dhaka, Banglad

NAHAR, Mst. shamsun[1*] ; ZHANG, Jing[1]

[1]University of Toyama, Department of Environmental Biology and Chemistry

Surveys of groundwater quality across Dhaka demonstrate the impact of intensive groundwater abstraction, which has led to invasion of the Dupi Tila aquifer by lower quality water in parts of the city. Groundwater chemical/isotopic monitoring is capable of discriminating between the effects of induced recharge from the polluted River Buriganga and of enhanced vertical leakage through the Madhupur Clay in contaminated urban areas. Over-exploitation of the aquifer has led to a progressive decline in water levels. The resulting cone of depression is thought likely to be causing the infiltration of polluted surface water. Stable isotopic techniques were used to characterize the hydrogeology and water sources the Dupi Tila aquifer beneath Dhaka. An interpretation of the linear δ^{18}O versus δ^{2}H relationship as a simple two-member mixing series between river water and recent meteoric recharge suggests that all groundwater in the lower Dupi Tila aquifer of Dhaka contains at least 30% river water.

Environmental isotope distributions approaches identify the polluted River Buriganga as the main threat to groundwater quality, indicating priorities for monitoring and aquifer protection.

Groundwater Level and Flow Rate Model and Barometric Response of Water Level of Well at Otomeyama Park in Shinjuku Ward

TAKANO, Yuki[1*] ; YOSHIMURA, Kei[2] ; MURAKAMI, Michio[3] ; UEMURA, Takeshi[4]

[1]Dept. of Earth and Planetary Phys., Univ. Tokyo, [2]Atmosphere and Ocean Research Institute, Univ. Tokyo, [3]Institute of Industrial Science, Univ. Tokyo, [4]Kaijo Junior and Senior High school

Spring at Otomeyama Park in Shinjuku Ward is one of the 57 Great Springs of Tokyo, Japan. Recently, decreasing of the spring water quantity at Otomeyama Park has been at issue. In order to figure out long-term variations of the spring water quantity, the flow rate and the groundwater level have been continuously observed by Kaijo Earth Science Club since 2011. In this paper, we report the results of the examination concerning the groundwater level variation and the model, which can express the groundwater level and the flow rate simultaneously.

Otomeyama Park is located at Ochiai escarpment on the eastern part of Musashino plateau. The stratum near Otomeyama park are Kanto loam layer, Shimosueyoshi loam layer (tuffaceous clay layer), Musashino gravel layer, Tokyo layer (sand layer or clay layer) and Tokyo gravel layer from the top. Sato et al. (2013) estimated that the aquifer of the spring water is Musashino gravel layer and the catchment area is about 10-100 ha. The spring water finally joins Kanda River through the water way in the park.

Based on the flow rate observation at Otomeyama Park for more than one year, the arithmetic mean flow rate was about 20 L/min. The flow rate intensely responded to precipitation. The flow rate increased from 4 L/min to 50 L/min in 35 hours at the rainfall event in April 2-3, 2012, whose total amount of rainfall was 118 mm.

The water level of wells were observed at three stations: well No.1 (at Otomeyama park), well No.2 (at Otomeyama park) and Mejiro well (at Shinjuku Ward, 0.5 km to the north from Otomeyama park). The water level of the wells was calculated by subtracting atmospheric pressure from the water pressure in aquifer. The aquifer of well No.1 is Musashino gravel layer and is confined, while the aquifer of well No.2 is Tokyo gravel layer and is confined. The aquifer of Mejiro well is Kanto loam layer and is unconfined.

Semidiurnal fluctuation of water level was observed at well No.1 and No.2. The daily composites of water level of well No.1 in dry periods showed that the atmospheric pressure was at its top at about 9 a.m. and 9 p.m. (JST) in Tokyo by atmospheric tide, while the water level of well fluctuated anti-phase to atmospheric pressure. This barometric response caused by balancing the water level variation of well with atmospheric loading when pore pressure of aquifer is not affected by atmospheric loading (Rojstaczer, 1988). This is attributed to three reasons for the barometric response of water level of well No.1. The mouse of the well is open, so that barometric fluctuation is directly transferred to the water surface in the well. Since the well diameter is 51mm, small water exchange between the well and the aquifer can change the water level in the well. Simosueyoshi loam layer above the aquifer is difficult to infiltrate atmospheric pressure. In contrast, the water level of Mejiro well was not responded to atmospheric load, since there is no air-barrier layer above Kanto loam layer.

Better performance model is needed to figure out long-term variations of the spring water quantity. Sato et al. (2013) predicted flow rate from precipitation using two-tank model, but the model did not utilize groundwater level. We developed a model, which express both flow rate and groundwater level. Our model was based on three-tank model. The first tank of the model represents intermediate flow. The second tank infiltrates water into the third tank but does not have side outlet. The third tank corresponds to the groundwater level. The model parameters were estimated for the flow rate and the water level of Mejiro well by means of SCE-UA method (Duan et al., 1993). In the simulation, the model accurately reproduced the observed value.

The Seasonal variation of the amount of flowing artesian well springwater in the Ashigara Plain, Kanagawa Prefecture.

MIYASHITA, Yuji[1*]

[1]Hot Springs Res. Insti. of Kanagawa Pref.

Introduction

Many of cities are located in the alluvial plain of an area along the shore for our country which is an island country. In the alluvial plain, the confined groundwater cultivated in an upside fan or mountain area is used as the source of industrial water, or a source of tap water with river water. Overuse of groundwater in the city region in period of high economic growth caused groundwater obstacles, such as ground subsidence as one of the seven typical pollution and depleted of springwater.

Also in the flowing artesian well area from which is distributed in the Ashigara plain in the western area of Kanagawa prefecture decline has been reported after the 1960s. Moreover, the investigation in 2011 showed that there were 1,000 or more flowing artesian wells in the whole Ashigara plain. Furthermore, it turned out that about 50,000 tons per day of from the whole artesian wells . However, although relation with the irrigation to a paddy field is pointed out about the seasonal variation of the amount of the springwater from flowing artesian wells, there are many questions about details.

So, in this study, investigation over one year was conducted about the flowing artesian well springwater distributed in the Ashigara plain, and seasonal variation of the amount of springwater which gushes from a flowing artesian well was clarified.

Results of an investigation and consideration

Investigation conducted one investigation per month for 205 flowing artesian wells for June, 2013 to one year, and performed measurement of the amount of natural flows, water temperature, electrical conductivity, pH, and dissolved ion concentration. Since the amount of natural flows measured at 205 points had the large variation in the amount of natural flows for every point, it standard scoreized the amount of natural flows of every month, and grouped by cluster analysis for every point where the change pattern of the amount of natural flows was alike.

As a result, the change pattern of the amount of natural flows was able to be classified into ”the type corresponding to an irrigation term” which increases to the irrigation term to a paddy field, and ”the type corresponding to un- irrigation term ” with which a remarkable changing trend is not seen through every year. Moreover, many flowing artesian wells on the west side of the Sakawa river of ”the type corresponding to an irrigation term” classified according to the above-mentioned method were distributed, and ”the type corresponding to un-irrigation term” was mostly distributed on the east side of the Sakawa river.

Three-dimensional mapping of geochemical and isotopic characteristics of groundwater beneath the Osaka Plain

SHINTANI, Tsuyoshi[1*] ; MASUDA, Harue[1] ; FUCHIDA, Shigeshi[1] ; EVEN, Emilie[1] ; MORIKAWA, Noritoshi[2] ; YASUHARA, Masaya[2] ; NAKANO, Takanori[3]

[1]Graduate school of science,Osaka city University, [2]National Institute of Advanced Industrial Science and Technology, [3]Research Institute for Humanity and Nature

Osaka Basin, which is a large Quaternary sedimentary basin beneath the Osaka Plain, is a large reservoir of groundwater resources. The uptake of groundwater has been strictly regulated since 1960 to avoid land subsidence, which actively occurred in the period of rapid economic growth. Although the land subsidence has stopped since 1970s because of the regulation, it became a threat again due to start of uptake of groundwater for private water supplies after 2000 ' s. Excess groundwater uptake from 100 to 300 m depths for those purposes would squeeze porewater from impermeable marine clay layers causing subsidence again.

In this study, groundwaters were mainly sampled from the wells >100 m depths, and stable hydrogen and oxygen isotope ratios and major chemical components were determined to estimate origins of water. Combining the results of our and previous studies, overall picture of three-dimensional mapping of groundwater geochemistry was drawn to discuss the groundwater flow system and the relationship to the land subsidence.

In the coastal region below sea level, seawater invaded into the groundwater aquifers <100 m depth. Stable isotope ratios of the groundwater at >100m of this area(δ^2H:-50 ‰~ -60 ‰,δ^{18}O:-8 ‰~ -9 ‰) is smaller than those of groundwater at <100m(δ^2H:-40 ‰~ -50 ‰,δ^{18}O:-6 ‰~ -7 ‰). Especially low isotope ratios of the groundwaters, of which chemistry was diluted Na-HCO3 type, from the lowland west of Uemachi plateau suggest squeezing the pore water from clay layers.

In the same area, high electric conductivity and Na-Cl type chemistry indicates seawater invasion into the groundwater aquifers <100 m depth. Uemachi Fault works as recharging path for the groundwater aquifers <100 m along the western edge of Uemachi plateau. However, the recharge is not enough to fill the aquifer >200 m apart from the fault. These observations indicate that the aquifers in the aquifers beneath western lowland of Osaka Plain have not been recovered by newly recharged groundwater.

Source of nitrate in shallow groundwater in the Shakujii river catchment, central Tokyo, Japan

NAKAMURA, Takashi[1*] ; HAYASHI, Takeshi[2] ; YASUHARA, Masaya[3]

[1]ICRE, University of Yamanashi, [2]Akita University, [3]Geological survey of Japan, AIST

Water chemistry of shallow groundwater in the Shakujii river catchment in the downtown Tokyo is discussed with special reference to its nitrate and chloride concentrations. The catchment is divided into the highly urbanized lower reaches (Toshima, Kita and Itabashi Wards) and the upper reaches which have been urbanized to a lesser extent (Nerima Ward, and Nishi-Tokyo and Kodaira Cities). Shallow groundwater samples were collected from 28 wells of less than 10m deep at October 2012 and October 2013. Groundwater aquifer is in the Kanto loam layer and/or underlying stream terrace gravels. The nitrate-nitrogen concentration had wide ranges (from 0.1 to 13.6mg/l). The total coliform was detected from all shallow groundwater samples. The nitrate nitrogen isotope ranges from 5.6 to 12.3 permil, which overlaps fertilized soil and wastewater nitrogen. Moreover, End-member mixing analysis using hydrogen and oxygen isotope values revealed spatial distribution in the contribution ratios of the local precipitation and domestic water (sewage and tap). The concentration of nitrate nitrogen and total coliform was increasing along with contribution ratios of precipitation in shallow groundwater, except some samples that has high nitrogen isotope and chloride concentration. This trend suggests that the nitrate source in this area is not only from sewage leakage. It also needs to consider the loading of the nitrogen fertilizer to shallow groundwater by the precipitation infiltration.

Underground structure and groundwater flow in Saijo plain

RYOTA, Ochi[1*] ; TANAKA, Kazuhiro[2] ; SUZUKI, Koichi[3] ; TOKUMASU, Minoru[4]

[1]Yamaguchi University, [2]Yamaguchi University, [3]Central Research Institute of Electric Power Industry, [4]Saijyo City Hall

Many flowing wells are excavated in the Saijo plain,Saijo-shi,Ehime Prefecture, which have been made use for supplying an industrial and agricultural water.

Objectives of the study is to investigate the underground structure and groundwater flow in the Saijo plain and to discuss about the relationship between geological structure and groundwater flow by CSA-MT geophysical exploration and groundwater geochemistry.The study area is composed of the late Cretaceous Izumi Group and Holocene sediments.CSA-MT method was applied to obtain the two dimensional resistivity distribution about 2 km long and 500 m deep along 3 lines with north-south direction in the Saijo Plain.As a result,the Okamura fault that displaces the Holocene and the Izumi Group with east-west strike was detected in the southern part of the area.The newly named Kita-Saijo fault that displaces the Holocene sediments with west-east strike was detected in north of the area,displacing the Kikai-Akahoya tephra (K-Ah) bed erupted at 6 Ka.River waters are penetrated from the Kamo river to the Holocene sediments in the Saijo Plain and flow on the paleo-seawater with low resistivity.Some of them were penetrated under the impermeable layer composed of silt and clay and interrupted by impermeable layer 2 m thick disturbed by the Saijo-Kita fault.Consequently,penetrated groundwater is pressurized by impermeable layer and fault.Then,pressurized groundwater erupts at the flowing wells named Uchinuki.

Keywords: flowing wells, CSA-MT method, groundwater flow, underground structure

The subsurface distribution of saltwater and freshwater in the Nakano-shima island, by electromagnetic exploration

KUSANO, Yukiko[1*] ; SUZUKI, Koichi[2] ; TOKUNAGA, Tomochika[1]

[1]The University of Tokyo, [2]CRIEPI

Groundwater recharged during the last glacial period is revealed to remain in coastal aquifers and sub-seafloor formations, and it has been interpreted that the low-permeability formations have delayed the intrusion of saltwater into sub-seafloor formations (e.g. Groen et al., 2000). Thus, the effects of long-term sea-level change should be taken into account to better understand the groundwater flow system in coastal areas.

The Nakano-shima island, Oki-Dozen, is a volcanic island on a continental shelf. Because the island is situated on the continental shelf, the seafloor around the islands was most likely widely exposed during the last glacial period, and hence the distribution of salt/fresh water in subsurface is estimated to have been affected by the sea-level change after the Last Glacial Maximum. According to a well-drilling report of a hot spring well in the island, groundwater of which Cl concentration corresponds to 20% of sea water was obtained when the well reached to 320 m deep, and groundwater of which Cl concentration corresponds to 5% of sea water was obtained when the construction was completed (screen depth: 560 - 866 m). In addition, the hot spring water taken from the screen depth is suggested to be recharged in colder climate than present based on the stable isotopic ratios of water, dissolved components, and groundwater-age indices (Kusano et al., in press). These results suggest that the groundwater containing higher salinity exists in shallower than 320 m deep, and that the groundwater containing lower salinity and recharged in colder climate exists in deeper formations. In this study, electromagnetic exploration using CSAMT method was conducted to reveal the distribution of salt/fresh water beneath the island.

A 2.5 km-long measurement section for the electromagnetic exploration was set, along which the hot spring well exists, in east-west direction. Measurement points were placed at about 100 m intervals. Measured apparent resistivity data were used to obtain a two dimensional resistivity structure along the measurement line by two-dimensional inversion scheme developed by Uchida and Ogawa (1993). For better interpreting the resistivity structure in the island, volcanic and sedimentary rock samples obtained from the island were used to measure the bulk resistivity as a function of salinity of the pore water.

The result of two-dimensional inversion showed the higher resistivity zone from the surface to about 100 m depth, a continuous lower resistivity zone throughout the section in between 100 and 200 m depth, higher resistivity zone below, and lower resistivity zone further below, i.e., existence of four distinct resistivity zones. Resistivity values in between 100 and 200 m depth and those in the deepest zone were consistent with bulk rock resistivities saturated with higher salinity water. The results are consistent with the fact that groundwater with higher salinity was obtained when the well reached to 320 m depth and that groundwater with lower salinity was obtained after the well reached to 866 m depth. The obtained resistivity structure might suggest that fresh groundwater recharged in the last glacial period remains in the subsurface of the island, and salt water was intruded into the 100-200 m deep zone after transgression.

The method of an estimation of underground parameters of a geyser induced by boiling using the dynamical model

KAGAMI, Hiroyuki[1*]

[1]Nagoya College

We have proposed a static model, a dynamical model and a modified dynamical model of a geyser induced by gas inflow based on observation and model experiments of it and have also proposed a combined model combining above two models. And numerical simulations of the modified dynamical model or the combined model reappear spouting dynamics of a geyser induced by gas inflow and it becomes possible that parameters (volume of the underground space, depth of spouting hole and so on) under a geyser are estimated through comparison between results of numerical simulation and those of observation. Moreover we proposed a dynamical model which assumed more than two underground gas supply sources by extension of above-mentioned usual dynamical model. As a result, irregular spouting dynamics of a geyser induced by gas inflow could also be reappeared by the modified model. As a result, spouting mechanism of all kinds of geysers induced by gas inflow has been clarified.

However, in general, geysers are classified into two types dependent on inducer. That is, one is a geyser induced by inflow of gas and the other is a geyser induced by boiling. The latter is more popular and many ones exist all over the world. Though qualitative spouting models of a geyser induced by boiling have been proposed, its dynamics has not been discussed sufficiently. Therefore, then we derived a dynamical model of a geyser induced by boiling applying the above-mentioned dynamical model of a geyser induced by inflow of gas. Then we tried to estimate time derivation of spouting rate of a geyser induced by boiling through numerical simulations. Using the model we can estimate underground parameters of a geyser induced by boiling by comparison of results of numerical simulation of the model and those of observation of a geyser induced by boiling.

In this presentation, after we review above-mentioned models of a geyser induced by gas inflow and one induced by boiling in outline, we explain the method of an estimation of underground parameters of a geyser induced by boiling using the dynamical model.

Rapid alkalization in Lake Inawashiro: implications for future changes in the carbonate system of terrestrial waters

MANAKA, Takuya[1*] ; USHIE, Hiroyuki[1] ; ARAOKA, Daisuke[1] ; INAMURA, Akihiko[2] ; SUZUKI, Atsushi[2] ; KAWAHATA, Hodaka[1]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, [2]National Institute of Advanced Industrial Science and Technology

The global carbon cycle, one of the important biogeochemical cycles controlling the surface environment of the Earth, has been greatly affected by human activity. Anthropogenic nutrient loading from urban sewage and agricultural runoff has caused eutrophication of aquatic systems. The impact of this eutrophication and consequent photosynthetic activity on CO_2 exchange between freshwater systems and the atmosphere is unclear. In this study, we focused on how nutrient loading to lakes affects their carbonate system. Here, we report results of surveys of lakes in Japan at different stages of eutrophication. Alkalization due to photosynthetic activity and decreases in PCO_2 had occurred in eutrophic lakes (e.g., Lake Kasumigaura), whereas in an acidotrophic lake (Lake Inawashiro) that was impacted by volcanic hot springs, nutrient loading was changing the pH and carbon cycling. When the influence of volcanic activity was stronger in the past in Lake Inawashiro, precipitation of volcanic-derived iron and aluminum had removed nutrients by co-precipitation. During the last three decades, volcanic activity has weakened and the lake water has become alkalized. We inferred that this rapid alkalization did not result just from the reduction in acid inputs but was also strongly affected by increased photosynthetic activity during this period. Human activities affect many lakes in the world. These lakes may play an important part in the global carbon cycle through their influence on CO_2 exchange between freshwater and the atmosphere. Biogeochemical changes and processes in these systems have important implications for future changes in aquatic carbonate systems on land.

Variation of ?carbon isotope signatures of particulate organic matter in the Kuzuryu River system in Japan

NAGAO, Seiya[1*] ; KANAMORI, Masaki[2] ; ARAMAKI, Takahumi[3] ; OCHIAI, Shinya[1] ; YAMAMOTO, Masayoshi[1]

[1]LLRL, INET, Kanazawa University, [2]Grad. School of NST, Kanazawa University, [3]National Institute for Environmental Studies

Radioactive and stable isotopes of carbon (^{14}C and ^{13}C) can serve as powerful tools for identifying sources and estimating turnover times of organic matter in aquatic systems. This study discussed with the transport of particulate organic matter in the rivers from a river system with different watershed condition using carbon isotopic signatures.

The Kuzuryu River system is located in Fukui Prefecture in the central part of Japan and consists of a main river, Kuzuryu River and a main tributary of the Hino River. River research was conducted at a fixed station in the Hino River (Fukatani site) and the Kuzuryu River (Nakatsuno site) during June-October in 2010. Suspended solid samples were collected from 130-140 L of river waters using continuous centrifugation. Prior to analysis, inorganic carbonates were removed by adding 0.1 M HCl solution, rinsing with Milli-Qwater, and drying again. Stable carbon isotopic ratio of a sample and the VPDB standard used for normalization were made by analyzing sub-samples of CO_2 gas generated during graphite production using a triple collector mass spectrometer with precision of $\pm$ 0.2 ‰ as the $\delta^{13}C$ value. Radiocarbons were determined using accelerator mass spectrometry at the Japan Atomic Energy Agency. Radiocarbon values were reported as $\triangle^{14}C$ corrected for sample $\delta^{13}C$ with absolute error of less than 10 ‰.

$\delta^{13}C$ of organic matter in riverine suspended solids has -26.3 to -24.0 ‰ for the Kuzuryu River and -27.0 to -26.1 ‰ for the Hino River. The $\triangle^{14}C$ vales of the Kuzuryu and Hino samples are -168 to -87 ‰ and -209 to -143 ‰, respectively. The $\triangle^{14}C$ values of Hino River depleted in $\triangle^{14}C$ rather than the Kuzuryu River. The averaged TOC/TN ratio is 9.1 $\pm$ 1.1 for the Kuzuryu and 8.2 $\pm$ 1.1 for the Hino. There is a positive correlation with the $\triangle^{14}C$ vales and water discharge. These results indicate that the differences in POM character may be explained by the differences in watershed conditions and controlled by water discharge.

Age dating of spring water, groundwater and stream water in mountainous watersheds using multi-tracer approach

IKEDA, Hayato[1*] ; TSUJIMURA, Maki[2] ; KATSUYAMA, Masanori[3] ; NAGANO, Ryuhei[4]

[1]College of Geoscience, School of Life and Environmental Sciences, University of Tsukuba, [2]Faculty of Life and Environmental Sciencies, University of Tsukuba, [3]Inter-Graduate School Unit for Sustainable Development and Survivable, Kyoto University, [4]Graduate School of Agriculture, Kyoto University

This study aims at estimation of mean residence time (MRT), to reveal the spatial distribution using multi-tracer approach in mountainous catchment, and to make clear relationship between hydrological characteristics and the variation of the residence time. First, we conducted field survey and sampling in Kiryu Experimental Watershed, in southern Shiga, in June, August and October, 2013 and analyze major dissolved inorganic ions, SiO_2, chlorofluorocarbons (CFCs) and stable isotopes (SI). Second, we estimated MRT using CFCs. We also evaluate MRT using seasonal variation of SI of rainfall, groundwater and stream water that collected monthly from 2008 to 2012.

The MRT of stream water and groundwater were estimated to be ranging from approximately 2.8 to 4.4 years by using SI as tracers. The MRT of spring water and groundwater were estimated to be ranging from 1.5 to 8.5 years and 15 to 23 years, given a water temperature as recharge temperature using CFCs. The relationship between Na^+ concentration and MRT based on CFCs suggested that short MRT that provided from decrease trend in atmospheric CFCs concentration is appropriate.

The MRT of water by CFCs ranged from 1.5 to 8.5 years, whereas that by SI ranged from 2.8 to 4.4 years in this catchment. This result conforms that of previous studies using SI, however the MRT by CFCs shows larger value range because CFCs represent time resolution information. In addition, the MRT varies in time and space due to mixing of different subsurface flow with different MRT and flow path.

Water demand in Hanoi city, the capital of Viet Nam, has been increased with recent rapid urbanization. Although high concentration of Arsenic is contained, groundwater is one of important water resources in this city. Groundwater abstraction has induced depletion of groundwater levels in major aquifers (Holocene shallower aquifer and Pleistocene deeper aquifer) not only in the central area but also sub-urban areas. On the other hand, urbanization reduces the surface water areas such as ponds, rivers and canals, and paddy fields. We focus on the interaction between surface water and groundwater to clarify water cycle and solute transport process in Hanoi area for sustainable water resource management. We are carrying out regular measurement of geochemical properties of surface water and groundwater, monitoring of groundwater levels in the major aquifers, and evaluation of groundwater age in some sub-urban villages.

The result of our previous study shows the surface water with evaporation process is a major source of groundwater in the study area. From the result of the regular measurement of surface and ground water and monitoring of groundwater levels in the shallower aquifer (unconfined condition), we found seasonal change of groundwater levels and geochemical properties of groundwater related with fluctuation of rainfall between rainy season and dry season. Also, seasonal change of geochemical properties was delayed several months to that of groundwater levels. This difference suggested the relatively slow infiltration of surface water with evaporation process into the shallower aquifer. On the other hand, result of CFCs and SF6 measurement showed apparent groundwater age in the shallower aquifer of the study area is several decades. These results may suggest groundwater abstractions enhance water cycle in the study area.

Long-term trends of climate variability in upper Dong Nai river basin in Vietnam

TRUONG, Nguyen cung que[1*] ; KONDOH, Akihiko[2]

[1]Department of Earth Sciences, Graduate School of Science, Chiba University, [2]Center for Environmental Remote Sensing, Chiba University

According to a report of the Intergovernmental Panel on Climate Change (IPCC) and last studies, Vietnam is considered as one of the most countries affected by climate change. That are in the sea level rises (SLR) 1 m scenarios, about 10-12% of Vietnam's population are directly impacted and the country will lose up to 10% of GDP. With the combination of SLR and an increase in precipitation in the rainy season, there is a possibility of a serious impact on low-lying coastal area and leads to flooding of up to 40,000 km2 of the coastal delta and 90% of the Mekong River delta. It is also expected that temperatures will rise more significantly in the plateau region. Dong Nai river basin is located in the Southern Vietnam along with the Mekong River, that have supplied the major water resources of southern. Dong Nai river originates from the plateau of the Southeastern, through the Tri An reservoir, a major power generating dam of southern Vietnam, in the lower area it mixed with the tributaries of the Mekong Delta downstream and after that flows to East sea.

In the state which continues of changes on water resources Mekong river due to climate change, controversy about the potential impact of sediment transport and river flows downstream due to the cascade hydroelectric power plant system or dam construction on the upper Mekong basin, because of Dong Nai river basin is a water resources that can controlled by Vietnam, it is considered that is necessary to analyses change in hydrological regime due to climate variability and adaptation to that changes. The purpose of this study is detecting long-term changes in the climate data and runoff due to climate change in the Dong Nai river basin.

As hydrological information of the target basin, the Dong Nai river basin, last 20 years (form 1992 to 2011) data which observed by National Center for Hydro-Meteorological Forecasting (NCHMF), Department of Natural Resources and Environment (DONRE) of each region, Tri An hydroelectric power plant management office were analyzed by Empirical Mode Decomposition (EMD) to detected a long-term change in rainfall, temperature, potential evapotranspiration and runoff at the basin outlet (inflow of Tri An reservoir). EMD has recently been pioneered by Huang et al. for adaptively representing nonstationary time-series data as sums of zero-mean amplitude modulation frequency modulation components. The components, called intrinsic mode functions (IMFs), allow the calculation of a meaningful multicomponent instantaneous frequency.

The results show that trend of rainfall and temperature slightly increase, but the trend of potential evapotranspiration and runoff decrease in the last two decades within the basin. In the comparison with the results of Mekong River Commission or World Bank research on Climate change in Vietnam, we similarly conclude that rainfall and temperature tend to increase. It is considered change in land cover and land use within the basin is one of the causes of the downward trend of runoff. This is planning on the next study.

A consideration of sustainable grazing over Mongolia, as point of view of recent climate change and vegetation responses

KAWAKAMI, Satoshi[1] ; HIGUCHI, Atsushi[2*]

[1]HP Japan, [2]CEReS Chiba University

We will present two topics. One is winter extreme-cold-events (ECE) detected by JRA-25/JCDAS reanalysis object dataset over Mongolia. Since 2000's ECE frequently occurred rather than 1990's, closely linking with synoptic scale circulation change in mid-high latitude. Such synoptic scale circulation change triggered by changing area of sea-ice over Barents Sea. Second topic is vegetation reaction process revealed by satellites observation. We used MODIS spectral reflectance dataset boarded on Terra/Aqua platform. Also we used two vegetation indices: One is major vegetation index, NDVI, the other is Green-Red ratio Vegetation Index (GRVI). NDVI is applied as proxy index of biomass, GRVI is regarded as proxy of biodiversity index. Based on matrix field of NDVI and GRVI, we define the recover status (2012) from herbaceous degradation in 2009. We found that faster recovered areas were located in the foot-fill. More detailed (e.g. degradation process period) analysis will be show in presentation.

Effect of snow depth on hydrology of highland marshes - Analysis of PALSAR/ALOS data at Kiritappu, Sarobetsu and Oze -

IGARASHI, Masatoshi[1] ; HISADA, Yasuhiro[1] ; DEMURA, Hirohide[1] ; OGAWA, Yoshiko[1*] ; SOBUE, Shinichi[1]

[1]Univ. of Aizu, [2]RESTEC

It is basically very difficult to monitor the hydrological environment of highland marsh with snow in winter. We lastly reported that the most famous highland marshes Oze keeps a largest amount of liquid water body under the thick snow layer (more than 2 m) in midwinter based on our analysis of PALSAR/ALOS data, a kind of L-band radar. We concluded that such liquid water would be squeezed out from peat layers by the load of heavy snow and not the meltwater. In this presentation, we show our new analysis results at Kiritappu and Sarobetsu, both of which are highland marshes locating in Hokkaido, where it snows a lot but not as much as Oze in winter. The PALSAR/ALOS data is used again. This time we find almost no liquid water body in midwinter and recognize the singularity of Oze. We try to evaluate the effect of snow depth, peat depth on hydrology of highland marshes in winter.

Modeling of hydrological temporal-spatial data by a universal model

KUZUHA, Yasuhisa[1*] ; ARAKI, Daisuke[1] ; SAITOH, Hanako[2] ; GOMI, Chieko[3] ; SENDA, Makiko[4]

[1]Graduate School of Bioresources, Mie University, [2]Faculty of Bioresources, Mie University, [3]Aichi Prefectural Government, [4]Kyoto Koka Women's University / Osaka Seikei University / Osaka Seikei College

We propose "the universal model" which generates hydrological temporal or spatial data. First a white noise is generetaed ,then the white noise is filterd by a specific filter and data are generated. If a field is fractal, log-log-linear-filter(ω vs.P(ω)) is used (Lavall*é*e, 2008). If a field is modeled by e-model (Gomi and Kuzuha, 2013), an exponential filter is used. We examined rainfall time series, spatial rainfall filelds, time series of ion concentration in river water, and ion concentration in tap water. As a result, those data were modeled by the universal model.

Characteristics on groundwater salinization in a downstream area of dam reservoir, a coastal region of NorthEast Tunisia

UCHIDA, Chisato[1*] ; KAWACHI, Atsushi[2] ; TSUJIMURA, Maki[2] ; SHIBAYAMA, Naoyuki[1] ; ZIADI, Amira[3] ; TARHOUNI, Jamira[3]

[1]Graduate School of Life and Environmental Sciences, University of Tsukuba, [2]Faculty of Life and Environmental Sciences, University of Tsukuba, [3]National Institute of Agronomy in Tunisia

This study tried to characterize salinization processes of coastal shallow groundwater in a downstream are of dam reservoir, based on field investigation and chemical water analyses in order to indicate positive effects of dam reservoir on prevention of the groundwater salinization or seawater intrusion. Thus, focusing on two neighboring watersheds: Lebna and Chiba watersheds located in Korba aquifer (North-East Tunisia), the field investigation was carried out at 72 locations in June 2013, then water samples were collected at the 63 locations.

At first groundwater table contour map was drawn using investigated groundwater level data, and the groundwater flow was estimated. From the chemical analyses, spatial distributions of dissolved inorganic ions' concentrations, and stable hydrogen and oxygen isotopic compositions were obtained. Then, the seawater ratio in the groundwater samples were calculated using mass balance equation of chloride concentration under assumption chloride was derived from seawater. Using the seawater ratio, a theoretical concentration of each parameter were estimated, and differences between the analytical and theoretical concentrations were obtained. Additionally saturation indices were calculated based on chemical equilibration theory. Moreover, multivariable analyses: Cluster Analysis (CA) and Principal Component Analysis (PCA), were conducted to classify the groundwater salinization process and to determine the important parameters associated with the process.

As a result, the groundwater level (GWL) in the downstream of Lebna dam reservoir was higher than the sea level, while the GWL in Chiba watershed was lower than the sea level. The lowest point is about -10 m above sea level. According to seawater ratios and stable isotopic compositions, the study area were categorized into the following three types: (i) high seawater ratio, (ii) low seawater ratio and low isotopic compositions, and (iii) low seawater ratio and high isotopic compositions. On the other hand, CA results showed the study area were categorized into 5 clusters, and the PCA showed the following three phenomena were main reasons for the 5 clusters: (a) seawater ratio in groundwater, (b) inverse cation exchange by reaction between seawater and clay minerals, and (c) directly or indirectly groundwater recharge from Lebna dam reservoir. Moreover, considering totally the three types (i), (ii), (iii), three phenomena (a), (b), (c), and groundwater level, the study area could finally be divided into 3 areas A, B, C which have different characteristics on groundwater salinization

Area A is located around Lebna dam reservoir, in which groundwater level is higher than sea level and the stable isotopic compositions are relatively higher. High groundwater level is probably sustained by the direct recharge from the reservoir, or by infiltration of the irrigation water from the reservoir in the farm land. Area B is located near shoreline, in which groundwater level ranges 0 to -4 m above sea level, and high seawater ratio and high concentration of each dissolved ion are observed. The groundwater in this area has high concentrations of sodium and chloride (derived from seawater) and calcium (derived from inverse cation exchange) due to seawater intrusion. Area C is located in inland area of Chiba watershed, in which groundwater level is lower than -4 m above sea level. There should be three groundwater flows: from Area A, and the upstream of Chiba watershed with fresh groundwater derived from precipitation, and from Area B with saline water, especially high concentration of calcium. Therefore, the groundwater in this area probably consists of the three different origin waters.

Geochemical features of groundwaters around the southern Itoigawa-Shizuoka tectonic line, western Kofu Basin

YAGUCHI, Muga[1*] ; MURAMATSU, Yoich[2] ; CHIBA, Hitoshi[3] ; OKUMURA, Fumiaki[4] ; YAMAMURO, Masumi[1]

[1]Gra.Shc.,The Univ.Tokyo, [2]Fac.Sci. and Tech.,Tokyo Univ.Sci., [3]Fac.Sci.,Okayama Univ., [4]Japex R.C.

Over the last few decades, drilling of thermal wells for hot spring bathing purposes were performed extensively on a deep aquifer at the depths more than 1000m in the non-volcanic area of Japan. Around the southern part of Itoigawa-Shizuoka Tectonic Line (ISTL), western Kofu Basin of central Honshu, many numbers of ground waters from drilled wells have been used for hot spring bathing. Some of these waters have high salinity, up to more than sea water salinity level, but their genesis and the formation mechanism of water quality have not been clarified previously. In this study, chemical and isotopic compositions of hydrogen (D/H), oxygen ($^{18}O/^{16}O$) and sulfur ($^{34}S/^{32}S$) of several ground water samples from, such as, natural spring and drilled wells around the southern part of ISTL, western Kofu Basin were analyzed in order to discuss the origin of waters and the formation mechanisms of water quality.

Temperature of the samples was up to 48.8 ℃, and the pH is between 6.4 and 9.7. The waters were subdivided into a Ca-HCO_3 type, Ca·Mg-HCO_3 type, Na·Ca-HCO_3 type, Na-HCO_3 type, Ca-SO_4 type, Na-Cl·HCO_3 type, and Na-Cl type. Among these, Na-Cl type was the most dominant water quality and maximum Cl concentration of the samples was up to about 23000 mg/L.

Due to plot of Na and Cl concentration of groundwaters were distributed along with mixing line between rain water and sea water, Na-Cl type water, which is dominant water quality type in the study area were appears to be derived from mixing of rain water and sea water end-members. δD and δ^{18}O plot of the low salinity waters were distributed along with the Global Meteoric Water Line, supporting that the low salinity end-member is originated from rain water. However, δD and δ^{18}O values of the waters which have high salinity (more than sea water salinity) were low compared with modern seawater values. The Mg/Cl and SO_4/Cl ratio of these high salinity waters were very low compared with modern sea water, whereas the Ca/Cl ratio is higher than modern sea water. These chemical and isotopic characteristics of the sample waters indicate that the high salinity end-member of the study area is altered sea water.

A Study on the Origin of a Spring in Tottori Sand Dunes using various geophysical and hydrological methods

SHIOZAKI, Ichiro[1*] ; KAWAI, Takayuki[2] ; NOGUCHI, Tatsuya[1] ; SAITO, Tadaomi[3]

[1]Graduate School of Engineering, Tottori University, [2]Research Institute for Natural Hazards and Disaster Recovery, Niigata University, [3]Faculty of Agriculture, Tottori University

There is an oasis that changes its appearance depending on the season in the depression south of Umanose (horseback), which is a symbol of the undulations of Tottori Sand Dunes. This oasis is not always visible. It disappears during the summer. The influent that constantly flows over the ground surface into the oasis depression forms Shirinashigawa River when oasis is gone, as the inflow water permeates into the sand or evaporates. By what mechanism does this oasis appear and disappear? That is, where does this influent come from and where does it go? This question about the oasis spring has been a scientific interest for a long time. For example, there have been a proposal that the rainwater from rain in the sand dunes became groundwater, some of which formed a spring and appeared on ground surface again(Akagi, 1991), a proposal that the rainwater permeating into the sand dunes with low water-holding property accumulated as groundwater near the impermeable stratum of the bedrock or volcanic ash layer with low water permeability and formed spring (Natural Parks Beautification and Management Foundation, 1995), and a recent study that investigated the relevance of oasis formation and the changes in water level in Tanegaike which is located south of the sand dunes (Hoshimi, 2009).

To answer this question, that is, to search for the origin of the spring in sand dunes (oasis), this study was conducted on the subsurface structure and circulation of groundwater in Tottori Sand Dunes. We estimated the subsurface structure of Sand Dunes and obtained basic data on groundwater existence, mode of its flow, the base structure of sand dunes using various nondestructive geophysical exploration methods, and tried to elucidate the origin of the oasis spring and the quantitative rise and fall mechanism also incorporating hydrological methods. While the specific methodologies used here will be described in a later section, we applied electrical resistivity imaging method, 1 m-depth geothermal prospecting, self-potential method, tremor probing and gravity probing to estimate the former subsurface structure and introduced continuous water level observation on oasis and analysis of evaporation quantity, groundwater level survey in oasis and its proximity, and analysis on stable isotope ratio of oasis spring water and water sampled from Tanegaike for the latter. For the former application, we conducted a GPS survey using a differential method so that we could understand the positions of observation points and grasp the overall topography of the sand dune area. For the latter application, we conducted a survey using total station to grasp the microtopography of the oasis area and its proximity.

As a result, we reached a conclusion as described below regarding the subsurface structure of Tottori Sand Dunes and the origin of the spring in sand dunes (oasis). “ Rainwater permeates into the sand dunes and form groundwater. A part of it is lead to the aquifer mainly formed on the volcanic ash layer (as perched water) and flows into the oasis spring. Then, the oasis spring flows into the sea through underground of Umanose. There is no simultaneous or direct relevance between oasis spring and the water in Tanegaike. We found association between the overall groundwater distribution in Tottori Sand Dunes area (sand dunes for sightseeing) and the undulations of the bedrock structure estimated by the subsurface structure analysis. ” It is surmised that this study verified these things from quantitative observation values including subsurface structure, changes in water level, changes in isotopes and so forth of sand dunes had significance of its own. This article will report on the basic scientific background, an outline of the study, the results of multiple surveys and their interpretation, and an overall summary of them.

Keywords: Tottori sand dunes, underground water, geophysical exploration methods

Spatial distribution and transport of phosphorus in a hillslop profile in Ichikawa City, Chiba Prefecture, Japan

PIAO, Jingqiu[1*] ; TANG, Changyuan[1] ; ZHANG, Han[1] ; SAKO, Yoko[1]

[1]Graduate School of Horticulture, Chiba University

Transport of phosphorus (P) in subsoil is presumed to be minor in comparison to transport in topsoil. Three Soil columns that located at upland (agriculture land), hillslope and forest (background) were sampled in Ichikawa City (35.76^{o}N, 139.97^{o}E), Chiba Prefecture, Japan. Contents of the total P (STP), organic P (OP) and inorganic P (IP) were determined to assess the spatial distribution, origin and transport pathways of P in the soil of unsaturated zone. In unsaturated zone soil texture is in a sequence surface layer (SF), Kanto loam layer (LO), Joso clay layer (CY) and Narita sand layer (SA) of the upper part of slope profile and SF, the secondary deposited loam layer (SE), clayey sand layer (MI) and SA of the down part of slope profile. Soil samples were obtained from the slope profile at four sites (A, B, C, D). LO, CY and SA is covered the forest soil profile.

In forest soil, the contents of STP, OP and IP were 30-163 mg/kg, 5-63 mg/kg and 19-103 mg/kg, respectively. There averages in different layers were in the order: LO >CY >SA, respectively. In hillslop, the contents of STP, OP and IP were 42-1723 mg/kg, 20-1229 mg/kg and 18-839 mg/kg, respectively. The average in different layers were in the order: SF (1564 mg/kg) >SE (1349 mg/kg) >LO (494 mg/kg) >MI (492 mg/kg) >SA (91 mg/kg) >CY (69 mg/kg). There were similar changing trends between OP, IP and STP with the average in different layers. And the contents of OP were not higher than IP content in most layers, however, more than twice in SF and SE. Ratios of OP/STP in SF and SE were 63% and 64% which were similar with the ratios in topsoil of upland profile. Therefore, it is supposed that P in topsoil of hillslope was transported from upland by runoff and soil erosion. In addition, the average ratios of OP in LO, CY, MI and SA were 30-52%, lower than the average in SF and SEin hillslope profile.

STP contents of subsoil in hillslope were much higher than forest. It is assumed that there was external phosphorus loading on the subsoil in slop profile. The results indicated that P transported form the surface soil to subsoil. Moreover, there was an accumulation on the soil above CY which the depth is 2.8-3.4m than upper LO of A site. The CY is supposed to block the P transport along the profile. In SE, there was no obvious change of site B and C, showing that the soil of SE may be in saturation status of the P adsorption. And STP contents of MI and SA were lower than SE. It means there was no a great phosphorus accumulation on MI and SA. So P could transport toward to deeper stratum with soil water flow. Finally, P would be likely to enter the groundwater.

The results indicated that the contents of STP, OP and IP varied greatly in different stratum. And this study inferred that two P transport pathways. One was P transports as particulate form by surface runoff, soil erosion in the topsoil. The other one was P transports with the infiltration of soil water as soluble phosphate in the unsaturated zone. And P is likely to enter the groundwater, and would be moved towards wetland with groundwater flow, affect the ecological environment finally.

Nitrogen budget of a headwater wetland

LI, Xing[1*] ; TANG, Changyuan[1] ; HAN, Zhiwei[1] ; CAO, Yingjie[1] ; PIAO, Jingqiu[1]

[1]Graduate School of Horticulture, Chiba University

As human activities continue to alter the global nitrogen cycle, understanding of the impact of increased nitrogen loading to freshwater systems is becoming more and more important. The study area is a typical headwater wetland, located at Ichikawa City (35.76oN, 139.97oE), Chiba Prefecture, Japan. The wetland valley is U-shaped with an elevation of about 16 m above sea level. The wetland receives discharge (both groundwater and overland flow) from an adjacent upland (elevation 26-31m) area with vegetation consisting of mostly pear orchard. A stream flowing through the wetland valley is recharged by spring water and groundwater in the wetland. Average flow rate of the stream all around a year is 21.7 L S-1 at the export of the wetland. The wetland is with surface area of 48000 m2, corresponding to 4.7% of the watershed. The uplands are covered by pear orchard, whereas the lowland is wetland. The average nitrate load is 501.9 mg S-1 at export of stream and average dissolved N2O load is 151.9 ug S-1 at export around a year. Ammonia and nitrite were nearly undeletable in the upland groundwater stream water in this study.

For the upland, annual nitrogen inputs refer to the sum of fertilizer application and atmospheric deposition, whereas the outputs refer to root absorption, N2O emission from soil surface and leaching of nitrogen. Nitrogen fertilizer is 346 kg ha-1yr-1 which is relative high to other studies. Annual average N deposition by precipitation over Japan was from 7 to 10 kg ha-1yr-1(with a mean value of 8.5 kg ha-1yr-1) during the past few decades (Hara, 1995). The composition in leaching nitrogen is only nitrate and the leached nitrate is 202 kg ha-1 yr-1in upland. The annual N2O emission was 5.77 kg ha-1 from the upland area.

For the wetland, annual nitrogen inputs refer to the sum of nitrate leaching from upland and atmospheric deposition of wetland. Annual nitrogen outputs refer to the sum of export by stream, and gas emission. The wetland receives 20652 kg-N yr-1 from atmospheric deposition and groundwater which recharge from agricultural upland. The nitrogen exports by stream were 15359.8 kg yr-1. The measured emission of N2O was 61.6 kg yr-1 and the calculated emission of N2 was 5218.6 kg yr-1. As a result, our estimate of N retention for the wetland watershed was 26.5%. Valigura (1996) and Whitall and Paerl (2001) estimated that N retention in urban watersheds ranges from 25% to 95%, with a best estimate of 40%. From the view of literature, the nitrate-nitrogen retention by mass was extremely low in this study. It is assumed that the high loading of nitrogen is a limit factor of nitrogen retention in wetland. The reason that the low percentage of nitrate-nitrogen retention may due to the extremely high load of nitrate input of groundwater (430 g-N m-2yr-1 or 4300 kg ha-1 yr-1). However, the nitrate-nitrogen retention was 110 g-N m-2yr-1 which is much higher than that (39 g-N m-2yr-1 and 46 g-N m-2yr-1) in study of William J. Mitsch (2005) and reach the retention level of constructed wetland.

Direct emission factor EF1 was 0.017 which is higher both than the default values of IPCC 1996 and 2006, but was still in agreement with the range of uncertainty. Indirect emission factor EF5-g was 0.003 which is much lower than the default value of IPCC 1996, whereas it was agreement with the default value of IPCC 2006. EF5-g value in this study was also consistent with the result of (0.0025) another study in Japan (Sawamoto, 2005). Ratio of dissolved N2O and NO3- in groundwater ranged from 0.00026 to 0.0157, with an average value of 0.0025. Using 0.0025 as the EF5-g value would revise the estimation of the indirect emission from this wetland, resulting of 51.5 kg yr-1. The measured emission of wetland was 61.5 kg yr -1 which is the same order of magnitude with calculated value, indicating that the method advised by IPCC could reasonable predict the indirect emission of wetland.

Influence of the Noboribetsu hydrothermal systems on surrounding water regions

OCHIAI, Yasuhiro[1*] ; CHIKITA, Kazuhisa[1]

[1]Division of Earth and Planetary Dynamics, Department of Natural History Sciences, Faculty of Science

A variety of hydrothermal systems exist in the Noboribetsu area, Hokkaido, which produces neutral to acidic hot springs. The high δD and δO^{18} values for the hot springs suggest that they originate from magmatic water (Matsubadani et al., 1977). Also, this area, including Lake Kuttara next to Noboribetsu, exhibits high geothermal gradient of 90 ℃/km (Matsubadani et al. 2011). However, a short knowledge of the geological structure makes us difficult to discuss the whole hydrothermal systems. In this research, water and heat budgets of a boiling pond, downstream of the Ohyunuma Pond, were estimated by monitoring water temperature. As a result, the heat fluxes from the bottom of the pond were estimated at 2,482 W/m^2 and 3,360 W/m^2 for two periods. Meanwhile, water temperature of Lake Kuttara was measured vertically and continuously at the deepest point. Using the data of a TCTD profiler, the heat flux at the bottom was estimated at 1.01 W/m^2, suggesting hot water input to the bottom. Henceforth, we will explore the relations between the bottom thermal variations and Noboribetsu geothermal activity.

Nitrogen and phosphorus export to watershed from Water-Conservation Forest

KAWABE, Ryosuke[1*] ; TANJI, Kazunori[2] ; OKAMURA, Masato[3]

[1]Faculty of Policy Management Keio University, [2]Faculty of Environment and Information Studies Keio University, [3]Graduate school of Media and Governance Keio University

The purposes of this study are to estimate and validate water contamination of Total nitrogen(T-N) and Total phosphorus(T-P) from forest as runoff, in order to discuss policy measures for controlling non-point source loads. The study area is Doshi village in Yamanashi Pref . Total population of the are is 1,884, forest area is 7,468ha, 4,594ha of whole region is designated as Water-Conservation Forest for Yokohama City. Rest 2,823ha is private forest area for forestry.

The Water-Conservation Forest has been done thining by Yokohama Waterworks Bureau, but private forest, especially coniferous plantation area has been hardly done thining because of the decline of forestry. Therefore it is great concern that decreasing of water supply, declining quality of drinking water by increasing of sediment discharge and non-point source loads from the forest. A mean inflow at Doshi reservoir is 6.7(?/sec), Water transfer to other reservoirs from Doshi reservoir reached 3.0(?/sec), as a result of them water discharge to downstream is 3.7(?/sec). Consequently, increase of non-point source loads of nitrogen and phosphorus influence on water quality of reservoir such as Sagami reservoir and Miyagase reservoir.

Non-point source load of forest depends on surface run-off volume. To take account of this difference InVEST model (P.Kareiva et,al., 2011) is adopted for estimation of non-point source loads. Equations are shown (1)-(3):

$EXPx = EAFx * polx \prod(1-Ey)$ (1)
$EAFx = \log \Sigma Yu / \log \sum Yw$ (2)
$Yx = \sum(1-AETx/Px)Ax$ (3)

Where EXPx is non-point source loading value at pixelx, polx is the export coefficient at pixel x, y is a pixel of the upper reaches of pixel x. u means all grids located upstream of x, w means a basin including x and y. We used the export coefficients at the Fuji river basin(S.Shrestha et. al.,2007) as polx value. E_y is nutrient retention coefficient. Because of calculating E_y by comparing with result of L-Q equation, E_y is set to be equal zero. EAFx is the hydrologic sensitivity score at the pixel x which is calculated as (2). Y_x is the water yield at pixel x. P_x is the annual precipitation. AETx is the annual actual evapotranspiration on pixel x. A_x is the area on pixel x.

In addition, we made two L-Q equations to explain relation of Total Nitrogen and water discharge., Total phosphorus and water discharge based on the observed water discharge from 1956 to 2012, and water quality from 1991 to 2012.

As a result, when nutrient retention coefficient is zero, non-point source loads of nitrogen is 251.5(t/yr) and that of phosphorus is 5.9(t/yr). In these result, artificial load s of nitrogen such as household is 1.8(t/yr) and that of phosphorus is 0.1(t/yr). These results show that non-point source loads come from forest area. Results of L-Q equation are $TN=0.791*Q^{0.0616}$,(R2:0.8374), $TP=0.00762*Q^{0.0238}+0.004$. Using these L-Q equations non-point loads are 192.3(t/yr) in T-N, 2.4(t/yr) in T-P.

In conclusion, the difference of nitrogen between result of InVEST model and L-Q equation is 59.0(t/yr) 23.5%, that of phosphorus is 3.5(t/yr) 59.3%. These difference due to amount of nutrient retention functions of forest area. It is also cleared that discharge of run-off are concentrated in valleys. Therefore, we conclude that it is important and necessary that forests in valleys are managed by appropriate thining.

Estimation of hourly nitrogen flux in a suburban watershed using SWAT model

SHIMIZU, Yuta[1*] ; ONODERA, Shin-ichi[2] ; MATSUMORI, Kenji[3]

[1]NARO/WARC JSPS-PD, [2]Graduate School of Integrated Arts and Sciences, Hiroshima University, [3]NARO/WARC

The objective of this study is to estimate hourly nitrogen flux from a suburban watershed, using Soil Water Assessment Tool (SWAT). SWAT, which is a model developed by USDA-ARS and Texas A&M University, is a river basin-scale model to simulate the quality and quantity of surface and ground water. The model is widely used in assessing soil erosion prevention and control, non-point source pollution control and regional management in watersheds because one of the reason is that it can estimate reasonable result even if data is limited. However it is not suit for estimation of nitrogen flux in flood condition because the time step of the model is basically calculated in daily. On the other hands, the model has an option for hourly estimation of runoff if sub-daily precipitation data are inputted. So we tried to estimate hourly nitrogen flux in Takaya watershed located on Hiroshima prefecture using the option. Monthly water quality data in ordinary condition and hourly data in flood condition which are observed by authors ' group were used for validation. A result show that although the reproductively of hourly runoff was slightly decreased than daily estimation in validation period, estimated runoff peaks were fitted to observed. It was found that improvement of the model for hourly estimation of nitrogen flux, however, the result of the estimation was almost acceptable.

Trace elements fluxes and budgets in two forest watersheds

ITOH, Yuko[1*] ; KOBAYASHI, Masahiro[1] ; SHINOMIYA, Yoshiki[2]

[1]FFPRI, [2]FFPRI, Tohoku

Atmospheric deposition supplies some nutrients to forest ecosystem, serving as a source of reactive nitrogen, sulfur and the trace elements.

The objective of this study was to compare the behavior of four trace elements (Rb, Cs, Sr, Ba) in forest soil profiles in two forest sites: the Tsukuba experimental forest watershed and the Katsura experimental forest watershed.

The percolation mechanism in a forested drainage basin: The Oikamanai River basin

MIYAMOTO, Takuto[1*] ; CHIKITA, Kazuhisa[2] ; IWASAKA, Wataru[1] ; HOSSAIN, Md motaleb[1]

[1]Graduate School of Science, Hokkaido University, [2]Faculty of Science, Hokkaido University

The rainwater movement in soils of high permeability is important to know how river runoffs are produced, and how sediment and nutrient are additionally loaded. In this study, we focus on runoff processes in the forested Oikamanai river basin, Tokachi Hokkaido. The catchment area is 62.6km2, consisting of 88.3% forest and 10.6% farmland (mostly, grassland). Surface geology of the basin is mostly Miocene conglomerate, sandstone and mudstone. These are distributed on the hillslope or in mountainous regions. Farmlands are developed on the Holocene flood plane deposits. The Miocene sedimentary rocks are supposed to be highly permeable. We set a soil moisture profiler (4 channels) at each of forested area and grassland, and calculated the amount (mm) of percolation in the rainfall events (total rainfall of more than 50mm). As a result, the amount of percolation is near to total rainfall amount, and the ratio of the percolation amount to runoff height at a gauging station was low at ca. 12% in the forested area and ca. 19% at grassland. These low values suggest that the groundwater recharge to the deep zone is great because of the high permeability of the bedrock with many faults. Meanwhile, there is a soil layer of low permeability at depths of more than 20cm at grassland. Hence, it is suggested that saturated throughflow is more active than in forested area during the rainfall events. We set one more observation point near the upstream end of farmland. We will quantitatively estimate the farmland's contribution to water discharge and nutrient load by their comparison between the upper and lower observation points.

The radioactivity of cesium in stream water during base flow from a small watershed in forested headwaters

SHINOMIYA, Yoshiki[1*] ; KOBAYASHI, Masahiro[2] ; TAMAI, Koji[2] ; OHNUKI, Yasuhiro[2] ; ITOH, Yuko[2] ; SHIMIZU, Takanori[2] ; IIDA, Shin'ichi[2] ; NOBUHIRO, Tatsuhiko[3] ; SAWANO, Shinji[2] ; TSUBOYAMA, Yoshio[2] ; HIRUTA, Toshihide[4]

[1]Tohoku Res. Ctr, For. and For. Prod. Res. Inst., [2]For. and For. Prod. Res. Inst., [3]Hokkaido Res. Ctr., For. and For. Prod. Res. Inst., [4]Fukushima Pref. For. Res. Ctr.

The radiocaesium was released by the accident in Fukushima Dai-ichi nuclear power plant. Although the woodland is thought to have strong tendency to maintain radiocaesium within a forest ecosystem, the very small amount of radiocaesium flows downwards through stream water. As stream water was used for agriculture and transported nutrient materials to river and lake. Therefore, radiocaesium discharged from headwaters may influence the ecosystem in river and lake or agriculture, like rice crop. In this time, we report the radioactivity of cesium in stream water during base flow from a small catchment in forested headwaters, Fukushima Prefecture.

The investigation was carried out in a small catchment (drainage area 1.2 ha) in the Tadano experimental forest of the Fukushima Prefecture forestry research center in Koriyama city, Fukushima Prefecture (Annual rainfall 1163 mm and mean air temperature 12.1 ℃; the elevation 358 to 409 m, and the relief 0.42). The geology is a sedimentary rock (sandstone and tuff). As for the vegetation, the deciduous broad-leaved species such as Quercus serratas exists together with the Japanese red pine woods in the Cryptomeria japonica and the Chamaecyparis obtusa plantation (about the 48 years old). The runoff was observed by setting up the v-notched weir and the water level gauge in the catchment end. Stream water was collected twice a month (volume; about 10L) near the weir. The radiocaesium was divided to particulate and dissolved fractions by filtration (Glass fiber filter, 0.7um). Dissolved cesium-137 was measured after concentration by extraction disk(Sumitomo 3M, Empore Raddisk Cesium)

Based on results obtained from June 2012 to March 2013, the radioactivity of cesium-137 tended to be higher in summer and lower in winter. In January and February, the radioactivity of cesium-137 was not detected, but it began increasing in March. There is a possibility that variation in the radioactivity of dissolved cesium-137 has a relation with the decomposition of organic matter according to the temperature elevation. The change in radioactivity of particulate cesium-137 was almost same way as dissolved cesium-137. This is because the discharge of suspended solid was increasing during high flow and because suspended solid concentration kept low while a catchment was covered by snow.

Contribution of suspended solids to the migration of radiocaesium in forests

KOBAYASHI, Masahiro[1*] ; SHINOMIYA, Yoshiki[2] ; OHNUKI, Yasuhiro[2] ; HIRUTA, Toshihide[3]

[1]Forestry and Forest Products Research Institute, [2]Tohoku Reseach Center, Forestry and Forest Products Research Institute, [3]Fukushima Prefectural Forestry Research Centre

A wide area of forested land in eastern Japan was seriously contaminated by radiocaesium after the accident of the Fukushima Daiichi Nuclear Power Plant. In the contaminated forests, radiocaesium first trapped at the canopy and the litter layer has migrated to the mineral soil as throughfall (TF) and litter leachate (LL). TF and LL often contain suspended solids (SS) which are thought to transport the radiocaesium. The objective of this study is to clarify the contribution of the SS to the migration of radiocaesium in forests.

Throughfall (TF) and litter leachate (LL) were collected in forested slopes in Ibaraki and Fukushima prefectures. The concentration of Cs-137 of the water samples were measured by germanium detectors before and after filtration using membrane filters with pore size of 0.45 micrometer.

The concentrations of Cs-137 of the TF collected in the Ibaraki site (evergreen coniferous forest) in March and April 2011 were 14 - 60 Bq/L. In this period, the most of Cs-137 was detected as dissolved. Then the total concentration (dissolved + SS) of Cs-137 decreased and the proportion of Cs-137 in SS increased. The total concentration temporarily exceeded 20 Bq/L in the following summer season and the most of Cs-137 was detected from SS. The temporal increase in the radiocaesium in SS also observed in LL. The similar patterns of the concentration change of Cs-137 in summer observed in TF and LL at the evergreen coniferous forest and the deciduous forest in Fukushima. In winter, the total concentration of Cs-137 decreased and the migration rate also decreased. From these results, it was confirmed that the contribution of SS to the migration of radiocaesium as TF and LL in forests increased during summer.

Water and radiocesium balance in several paddy fields in Fukushima

YOSHIKAWA, Seiko[1*] ; EGUCHI, Sadao[1] ; ITAHASHI, Sunao[1] ; IGURA, Masato[1] ; KIHOU, Nobuharu[1] ; FUJIMURA, Shigeto[2] ; SAITO, Takashi[3] ; FUJIHARA, Hideshi[1] ; KOHYAMA, Kazunori[1] ; YAMAGUCHI, Noriko[1] ; OHKOSHI, Satoru[3]

[1]National Institute for Agro-environmental Sciences, [2]National Agriculture and Food Research Organization, [3]Fukushima Agricultural Technology Centre

1. Introduction

By the released radionuclides from the Fukushima nuclear disaster in March, 2011, brown rice harvested at a 0.2% of paddy fields exceeded the provisional regulation value in 2011 in Fukushima. Water and radiocesium balance was studied in 3 paddy fields at different geographical sites in Fukushima to estimate radionuclides contamination in brown rice and to develope models for predicting radionuclides dynamics at watershed scale.

2. Monitoring and measurements

Field monitoring has been conducted in the following three paddy fields in Fukushima since spring in 2012. ; (1) a reorganized paddy field facing to forest in one side (clayey soil), (2) mountainous terraced paddy field surrounded by forest in three sides (sandy soil), (3) mountainous terraced paddy field surrounded by forest in three sides (organic soil). Water levels and turbidity of irrigation and drainage water in paddy fields and precipitation have been measured continuously. Water infiltration rates were measured several times during rice cultivation period in (2) and (3) fields. Water samples have been collected once a month for atmospheric precipitation, irrigation, surface drainage, subsurface pipe drainage, and seepage water on a ridge between terraced paddy fields. A membrane filter (0.025μm) was used to suspended solid (SS) and filtrate samples. The radiocesium concentrations were determined by Ge semiconductor detector after drying the SS and filtrate samples, respectively. Rice which was grown experimentally was harvested and measured its radiocesium concentrations by each part. Based on the relationship between turbidity and radiocesium concentrations, and flow rates of irrigation and drainage water, radiocesium concentration in rice plant, in/out flows of radiocesium in paddy fields were estimated for the monitoring period of one year (23rd May, 2012 ˜27th May, 2013). Radiocesium in/out flows induced by heavy rainfalls of 50˜150 mm by in July and October in 2013 were also estimated.

3. Results and Discussions

Monitored precipitation was about 800,900 and 1000mm,the estimated flow-in water (irrigation(+flow-in from spring which could be measured)) was about 300, 1300 and 3300 mm, the estimated flow-out water (surface drainage) was about 600mm, 1000mm and 7700mm for the one year in the (1), (2) and (3) field, respectively. Continuous spring-out of water was observed from side slope of the upper field in (2) and (3) fields. Infiltration and spring-out were almost same level in the surface in (2) field, however, averagely about 4 mm/day of spring-out was measured from the surface of (3) field during rice cultivation period. Furthermore, water flow-in and flow-out on the soil surface under snow and/or ice was observed in winter even in the latter part of January. Therefore, larger amount of water in/out flows were gained in the mountainous paddy fields (2) and (3) in comparison with common paddy fields located in flat areas like (1) field. Radiocesium concentrations of water samples, mainly taken at usual meteorological conditions, were 0.1-0.31 Bq/L for irrigation water, 0.02-1.4 Bq/L for surface drainage, 0.2-0.9 Bq/L for atmospheric precipitation, and 0.01-0.03 Bq/L for pype drainage. Most of the radiocesium was existent in the SS. Radiocesium inflow by irrigation, inflow by atmospheric precipitation, outflow by surface drainage, and carryout by rice harvest were 10^2, 10^2, and 10^3, and 10^2 Bq/m^2 orders in the 3 fields for the one year, respectively. Radiocesium net flow in the 3 fields for the one year was estimated to be outflow of 0.2%, 0.2%, and 0.7% to the amount of radiocesium in soil, respectively. Most of outflows of SS and radiosecium occurred at events such as puddling, transplanting, midsummer drainage, drainage, and heavy rain etc.. The heavy rainfalls in July and October in 2013 induced large amount of SS and radiocesium outflows.

Some of the five coastal lagoons in the Tokachi region of southeastern Hokkaido, open a few times per year to the Pacific Ocean. The openings affects water quality and deposits in the marine coastal region by discharging the lagoon water offshore. The Oikamanai River is a main river flowing into the Oikamanai Lagoon. The river basin is almost forested (ca. 88 % in area), from which the discharge and sediment load build up the ecosystem of the lagoon and its back marsh. In order to explore how the suspended sediment discharges into the Oikamanai Lagoon, we obtained hourly time series of discharge, Q (m3/s), and suspended sediment concentration, C (mg/L), in the upper Oikamanai River. As a result, it was found that, following the sediment availability (sediment amount to be eroded), the precedent type (peak C temporally precedes peak Q), synchronous type (two peaks synchronously appear) and antecedent type (peak Q precedes peak C) appear on the Q vs. C diagrams for sequential rainfall runoffs. The river-suspended sediment often originates from the river channels and/or basin slope. Hence, In order to judge the criterion for sediment erosion in the river channel and basin slope, the extended Shields diagram was applied to lognormal subpopulations separated for cumulative grain size distributions of river-bed sediment and basin soils.

Supply of detrital material from river can affect the continuity, sedimentation rate, and composition of marine sediments deposited in front of the river system, which is controlled by the relief, weathering rate, and precipitation of the hinterland. In spite of the small drainage area, the small rapid rivers in the island arc located under warm humid climatic condition supply a huge amount of detrital materials to the surrounding seas. In addition, sediment transports tend to be concentrated during flooding events. In order to understand the depositional history and utilized it for paleo-climate reconstruction, it is necessary to study a mechanism of suspension generation and controlling factor of its composition.

We conducted a field survey during 2005-2011 in the Hidaka area in Hokkaido, Japan, to evaluate the influence of the flooding mud to marine sediments, promoted by the typhoon precipitation in August, 2003. We selected the Saru River as our target, and conducted the river water sampling and turbidity measurements along the main stream and a major branch called Nukabira River. Water samples were taken from the surface of flow center of each stream and stored in plastic bottles. The collected water was filtered through Millipore filter with 0.4 um opening and the suspended particles were collected and weighed in the laboratory. Mineral composition of the collected suspended materials on the filter was measured using an X-ray diffraction analysis (XRD).

Distribution of the turbidity in the Saru River drainage shows that high turbid water is localized only to the Nukabira River and others are relatively clear. The turbidity seems to be supplied only from one local source. Mineral composition of the suspended material in the Nukabira River does not contain serpentine, while the upper main stream before the junction with the Nukabira River contain serpentine. The suspended material in the lower main stream is also characterized by the lack of serpentine because of higher contribution from the Nukabira River. The surface sediment at the mouth of the Saru River also shows the same character. We also examined the mineral composition of marine surface sediments supplied as flood mud during the typhoon event in August, 2003. The flood mud contains the major amount of serpentine, which was not expected from the mass budget of suspended materials from the upper main stream and the Nukabira River under usual condition.

In order to estimate the suspension loads from the upper main stream and the Nukabira River, we compared the water discharge and suspension loads and established the rating curve for each tributary. Water discharge data for the main stream was available from the Water Information System of the Ministry of Land, Infrastructure and Transport, Japan. However, since the database contains too many missing data for the Nukabira River after 2008, we calculated the water discharge for this branch using the Hydrometeorological and multi-Runoff Utility Model (Nakada et al., 2012). As a result, the rating curve of the upper main stream is steeper than that of the Nukabira River, and the suspension load of the upper main stream could be larger than the Nukabira River at the water discharge of $>$300 m3/s. Therefore, the Nukabira River transports 5-10 times more suspended materials than the main stream during the usual discharge, which is reversed during the flooding situation.

Estimation of Sediment discharge with distributed USLE and L-Q Equation in Water-Conservation Forest

NAKASHIMA, Ryoichiro[2*] ; TANJI, Kazunori[2] ; OKAMURA, Masato[3]

[1]Faculty of Policy Management Keio University, [2]Faculty of Environment and Information Studies Keio University, [3]Graduate school of Media and Governance Keio University

The purpose of this study is to estimate and validate sediment discharge from forest area for providing water resources in order to discuss policy measures for controlling sediment discharge. The study area is Doshi village in Yamanashi Pref. Its population is 1,884, forest area is 7,468ha, 4,594ha of whole region is designated as forest area preserved for provision of water resource for Yokohama City. Rest 2,824ha is private forest area for forestry. The forest area preserved for provision of water resource has been done thining by Yokohama Water Bureau, nowadays the private forests are seldom do because of a decline of forestry. Therefore, it is concerned that the degradation of provision of water resources, the increase of sediment discharges volume.

To estimate the sediment discharge, we adopted USLE (Universal Soil Loss Equation) model. It considers 5 factors, R (the rainfall erosivity index), K (the soil erodibility factor), LS (the slope length-gradient factor), C (the cover-management factor) and P (The support practice factor).

We converted and integrated sets of data such as forest management plan in Doshi village, soil texture map, precipitation data analyzed by radar-AMeDAS and others to the proper dataset for utilizing GIS. The output data shows sediment discharge in 60 sub-watershed (Max:1,000ha) and in distributed 25m^2 grid. In addition, we tried to estimate more detailed information which is related to the land information, such as slope degree, land use and land cover.

Next, to validate the estimated result, we calculated the annual SS flux derived from L-Q equation, which makes correlation between the water discharge and SS density data. They were observed from 1955 to 2012 at the Doshi reservoir located down-stream of Doshi River. Based on the LQ equation, we estimated the annual sediment discharge.

As a result of evaluation with USLE, sediment discharge per year is valued 97,820 (t/yr). On the other hand, SS flux estimated 400(t/yr) [SS=1.732Q0.0238(R2=0.3223)] and sediment deposition in the reservoir is 62,500(t/yr) with LQ equation. It is known that SS load from households are valued 1.8(t /yr). Therefore the anthropogenic loads is not dominant factor in this area.

The result of USLE does not mean exported sedimentation to observation station. This indicates potential of sediment loss in each grid and their summation in total grid. The reason why sediment loss value decay in runoff process is considered to be the function of sediment retention of each grid. On the other hand, there are three dominant factors of sediment runoff from forest area.

First, more sediment runoff come from natural forest area than coniferous area. Second, more sediment runoff come from abandoned coniferous plantation area. Third, Slope factor is main reason of sediment export.

The results suggests that 1st sediment retention of in this area is able to retain 27% of total sediment discharge in this region, 2nd dominant sediment supply come from natural forest and abandoned coniferous plantation area, preservation measures to control sediment discharge are prioritize forest management in steep area.

Exploring fluvial sedimentary processes on catchment scale is useful for studies on the forest management, material cycle and ecosystem of short time scale and topographic evolution of long scale. The fluvial transportation of sediment is also related to sedimentation, material cycle and ecosystem in coastal regions. A considerable portion of suspended sediment discharging into a costal lagoon, the Oikamani Lagoon, Tokachi, Hokkaido annually is contributed by the forested Oikamanai River catchment with many tectonic faults. It is important to find out the sediment source in such forested catchments. Here, we have tried to find how sediment load occurs by rainfall and snowmelt runoffs in the forested (ca. 90% area) catchment. Grain size and mineralogy of catchment soil and stream sediment, survey techniques, and turbidimeters provide the information that allows us to understand fluvial sedimentary processes and the sediment source and its availability. Here, a semi-distributed model, ArcSWAT2012, was applied to time series of discharge and sediment load, which were obtained in 2011 to 2013. In ArcSWAT2012, the total basin area (62.48 km^2) was divided into 3 sub-basins, as subbasin into hydrological response unit (HRU) based on soil type, land use and slope classes that allow a high level of spatial detail simulation. In this study we have used the data of discharge, Q (m^3/s), suspended sediment concentration (SSC; C, mg/L) and sediment load, L (kg/s) of April 2011 to October 2013, weather data of 2008 to 2013, and soil data. Discharge and sediment load simulations by SWAT2012 offer reasonable results. The simulations of sediment load time series and hysteresis analysis indicate that most of the sediment input is coming from sub-basin 2, especially, from its basin slope.

In the alluvial fan, there are many palaeo-channels which are composed of more permeable media like gravel and sand, and many springs and wells on those have been useful for human life as well as ecosystem. These type of the springs have the different waveforms of the seasonal thermal variation from those of the river or air which is the thermal source. In detail, the phase shifting and amplitude declining are confirmed in springs. In this research, we examine to confirm the thermal waveforms in the river and springs and to estimate the horizontal bypass flow velocities in palaeo-channels around the river in the alluvial fan. The study areas are Asahi river springs in Okayama prefecture of western Japan. At the springs of Asahi River, the temperature data was collected 1 week interval. The temperature data of Asahi River springs was analyzed, assuming the subsurface water flow only through the bypath as the one-dimensional advection-diffusion equation and heat flux from the ground surface depends on the temperature gradient between the aquifer and the upper layer. The analytical solution of this equation was verified by parameter fittings with the data.

The Darcy velocity of subsurface flow was estimated about 1.3 m/day. The distribution of one-dimensional subsurface temperature in the alluvial fan was simulated that thermal conductive flux from the river exponentially decreased. The flux was mainly controlled by the advection process. In addition, the heat flux from the ground surface varied spatially from the rivers depends on the variation of the heat gradient. Especially, the flux was about 0 at several sites where heat gradient decreased.

We examined to confirm the surface water-groundwater interaction in Hachiro-gata of Akita prefecture and nutrient transport with the water flow. Hachiro-gata have decreased since 1960s. The reclamation land touches mainly at the east and south side to Hachiro-gata. The height of the reclamation land is lower than the lake water level. Water flow in the underground between the lake and land would have the stable direction from the lake to the land. Because the eutrophication often occurs in Hachiro-gata lake, the nutrient would accumulate in sediment. We installed three piezometers at the bankside of the lake and reclamation land, respectively. The water levels were monitored from September to December in 2013 and water samples were collected in September and December in 2013. We confirmed water flow from the lake to the land with the gradient of from 0.05 to 0.1. In addition, DOC and nutrient concentrations of groundwater were higher in the land than in the lake and lake water. The lake water has recently eutrophic condition, and so many organic matter originated from phytoplankton are deposited. The porewater in the lake bottom near the bank had the high nutrient and DOC concentrations. Based on this research, we can make a hypothesis of nutrient conversion from the lake to the land with groundwater flow.

1 Introduction

In the hydrological system, headwater catchments are source areas for water, nutrients, sediment, and biota for larger steams (Sidle et al., 2000). Unsaturated zone is an important pathway for nutrition leaching in headwater where baseflow dominates (Costa et al., 2002), and the leach pattern is mainly controlled by soil texture and corresponding hydraulic properties. In this study, an intensive study including soil physics investigation, long-term monitoring about the soil water and groundwater hydrochemistry and sources identification of nitrogen by nitrogen isotope are conducted to describe the conceptual soil water-groundwater flow system and discuss the factors controlling the local groundwater hydrochemistry.

2 Study area

The study area is a typical headwater catchment in Ichikawa City (35.76oN, 139.97oE), Chiba Prefecture, Japan (reference). The annual average precipitation is 1,316mm, with the maximum monthly precipitation of 226.5mm/month in study area. The annual average temperature is 15.6 oC while the highest temperature of 31.2 oC occurring in August.

3 Result

From the surface, there are sandy loam (0-1 m), loam (1-2.5 m), clay loam (2.5-3.2 m) and sandy clay (3.2-4.5 m). The porosity shows slight increases from 0.68 at the surface to 0.78 at depth of 4.3m. Due to the occurrence of the Joso clay underlying the loam, the Ks of layer below 3.2 m in depth about two orders lower than the loam and sandy loam. The vertical profile of θr changes little with an average of 0.30.

The average background values for Cl-, NO3- and SO42- were 17.64 mg/L, 0.33 mg/L and 1.52 mg/L, respectively. At the pear orchard, Cl-, NO3- and SO42- concentrations increased dramatically due to anthropogenic inputs of fertilizers. The average concentrations of Cl-, NO3- and SO42- were 32mg/L, 233 mg/L and 85 mg/L, respectively. The concentrations of Cl-, NO3- and SO42- in groundwater of the valley in average are 35.17 mg/L, 129.67 mg/L and 2.39 mg/L, respectively.

4 Discussion

Base on the soil texture of the cross section A-A, there are three flows, interflow along the slope (I), local groundwater flow (LG) and regional groundwater flow (RG), and all of them finally dischage to the valley wetland. In average, the groundwater discharging to the valley at S4 is consisted of waters from LG (43%), RG (56%) and I (less than 1%). Mixing ratios also show seasonal variations. In winter, the ratio of RG with an average of 68% is larger than LG (32% in average), which implies that lateral discharge of groundwater is the dominant factor controlling the groundwater flow in the wetland. While in summer, the contribution of LG becomes higher, and the ratio of LG has exceeded that of RG in May and July, showing the strength of recharge from the upland to LG.

5 Conclusion

An intensive study including both hydrochemical monitoring and numerical simulation are applied to discriminate pollutants sources, evaluate pollutants behaviors and predict long-term effect of soil pollution to local groundwater.

Base on the soil texture and physics investigation, three runoff components interflow (I), local groundwater flow (LG) and regional groundwater flow (RG), are discriminated in the hillslope soil water-groundwater flow system. Two anthropogenic pollutants NO3- and SO42-, which have been approved keep conservation in both soil groundwater according to isotope and redox analysis, are treated as traces to separate these components. And it is found that in average, about 43% of groundwater comes from local groundwater recharge (LG) and 56% comes from regional groundwater recharge (RG). The ratio of interflow (I) only takes up smaller than 1%.

Coastal shallow lake sediment play an important role in the lake eutrophication process, it should be considered important sinks and sources of phosphorus. The accumulation and regeneration of sediment nutrients would be affected by some hydrological process. Lake Hachirogata is a shallow eutrophic lake located in north of Akita City. It used to be the second largest brackish water lake in Japan before the land reclamation project finished in 1977. A salt water barrier has been constructed at the outlet of the regulating reservoir through which water is discharged intermittently out to the Japan Sea. There probably exists the water flow from lake water into sediment due to the lower altitude of the farmland than lake water level after the land reclamation project. We would like to research on the sediment phosphorus accumulation and its activities base on the sediment phosphorus profiles, in consideration of the water flow effects. In order to better understand the possible change on lake phosphorus cycle by land reclamation.

Two core sediment samples were collected by piston core sampler (7-8 cm diameter), in east and west part of the lake (core HL-1 represents the core samples near river mouth area, core HL-2 represents the core samples which was collected near land reclamation area) during the investigations in September 2013. Samples were sliced at 1cm interval then centrifuged for extracting pore water soon after sampling, pore water nutrient and chlorine ion were determined in the laboratory with a spectrophotometer. The advanced SEDEX methods was used in sediment phosphorus fractionation.

Our results shows different pore water Cl^- and nutrient patterns between two locations. In HL-1 core, it shows an increasing trend of Cl^- from around 50mg/L at surface to around 500mg/L at bottom, however in HL-2 this profile shows relatively a constant range around 40mg/L. Both the DTP and DTN concentrations from the HL-1 core showed an increasing trend towards bottom, and they shows relatively constant and low in the HL-2 core, respectively. In sediment P fractionations, Iron bounded P comprise the main phosphorus species in HL-2 core, which comprises 42-72% of total phosphorus. this value is 15-28% in HL-1. Based on the dating information calculated by ^{210}Pb, it shows a larger sediment accumulation rate in HL-2 than HL-1 but with higher phosphorus burial trend in HL-1.

The sediment pore water profile shows significant change after the land reclamation project. Due to the enclosing of the sluice gate decades before, the changing from saline environment to freshwater could reflected by gradually decreasing trend of Cl^- profile towards current in HL-1. The pore water DTN DTP molar ratio shows large variations in HL-1 core. In HL-2, the low Cl^- and DTP in HL-2 provides an evidence that the diluting and transporting pore water phosphorus by water flow from lake into the sediment. On the other hand, it shows high sedimentation accumulation rate and sediment P accumulation rate in HL-2 core site, both at about 3.5 times of the HL-1 core. The supplying of relatively oxic lake water in into pore water may inhibit the iron bounded phosphorus releasing from sediment, decrease and average the mineralization process in sediment, this change in sediment could also be reflected by high phosphorus content, high phosphorus activities in HL-2 core. The increasing in sediment nutrient may be resulted from filtration by water flow into sediment, enhancing the sediment accumulation. Large mobile phosphorus trapped in sediment may increase the phosphorus releasing risk and intensify the algal bloom in Lake Hachirogata. Due to the high sediment phosphorus content and high activities in core HL-2, it would also be a considerable pollutant resources brought by water flow into coastal groundwater. The detailed results on sediment phosphorus property would be described in the presentation.

Effect of DO fluctuation on the manganese cycle around the sediment water interface in bottom of the Lake Biwa

ITAI, Takaako[1*] ; HYOBU, Yuika[1] ; CHIKAOKA, Kosuke[1] ; MORISHITA, Yohei[1] ; SHIN, Yoshiki[1] ; KUMAGAI, Michio[3] ; NAKANO, Shin-ichi[2] ; TANABE, Shinsuke[1]

[1]Center for Marine Environmental Studies (CMES), Ehime University, [2]Center for Ecological Research (CER), Kyoto University, [3]Ritsumeikan University Research Center for Biwako Sigma

Enrichment of Mn and As in the surface of sediment has been reported from various lakes in the world. This enrichment is generally caused by the precipitation/adsorption of MnO_2 and arsenate after upward diffusion of Mn^{2+} and arsenite. Lake Biwa is a typical example, in which clear enrichments of Mn and As within thin surface enriched layer (<2 cm) of sediment were observed. However, progressive hypoxia recently reported from the lake can induce release of these elements into water column (Yoshimizu et al. 2010, Itai et al. 2012). In order to reveal the dynamics of Mn and As in the lake bottom, we made geochemical survey through determination and speciation of Mn and As in sediment, porewater and lake bottom water. According to our estimation, total Mn and As in the enriched layer of Lake Biwa was roughly 10000 and 240 tons, respectively (Itai et al., 2012). These amounts are ca. 1800 and 12 times respectively higher than the inventory of these elements in Lake water, suggesting that releasing a portion of Mn and As from enriched layer can be a cause of large increase of these in lake water. The speciation of Mn and As in sediment determined by X-ray absorption fine structure (XAFS) indicated that predominant species of Mn from surface to 2 cm depth was MnO_2 while divalent Mn, likely ionic form, was predominant below enriched layer. Similar to Mn, oxidation state of As was gradually changed with depth, i.e., arsenate was predominant in surface, then arsenite and As in sulfide becomes predominant toward deep. These results suggested that Mn and As in enriched layer should be reduced when DO level in lake bottom becomes lower. The flux of Mn and As from the lake sediment to water column estimated by porewater profile were 3400 - 16000 and 400 - 1800 mg m^{-2} $year^{-1}$, respectively. The fluxes were higher in deeper part of the lake in which sediment character was more reducing than shallower part. With progressive hypoxia, this flux should increase. The monthly monitoring of DO and Mn level in lake water suggested that Mn level in water above 1 m of the lake floor increased from August to December with the highest level was ca. 100 times higher than the baseline level. This trend is consistent with the gradual decrease of DO during thermal stratification period. In the bottom water, the threshold DO level where apparent Mn release started was estimated to be 5-6 mgO_2/L. This value is higher compare to the inter-annual DO minimum ever reported (<4 mgO_2/L). If 40% of Mn released from enriched layer then completely mixed in whole lake, the Mn level becomes 0.6 mg/L which corresponds to lethal levels of some crustaceans and insects. Although such an extreme situation is unlikely, continuous monitoring Mn and As levels is important to safeguard the lake ecosystem and food supply.

Current status of the research on the phosphorus dynamics in the coastal groundwater discharge area

SAITO, Mitsuyo[1*] ; ONODERA, Shin-ichi[2]

[1]Okayama Univ., [2]Hiroshima Univ.

A large fraction of phosphorus (P) in groundwater generally exists as the dissolved form which is more efficiently used in nutrient cycle and ecosystem than the suspended form. It suggests phosphorus transport by groundwater discharge (e.g. SGD: Submarine Groundwater Discharge) significantly effects on the coastal ecosystem. In the paper, we aimed to review the previous researches related on phosphorus dynamics in the coastal groundwater discharge area and discuss on the future prospects on it.

Distribution and sources of uranium in Okinawan rivers, Japan

MOCHIZUKI, Akihito[1*] ; HOSODA, Ko[1] ; SUGIYAMA, Masahito[1]

[1]Graduate School of Human and Environmental Studies, Kyoto University

We measured natural background concentrations of dissolved U in 194 Japanese rivers and the highest concentrations were observed in two Okinawan rivers in the limestone region, the Hija and Kokuba Rivers (Mochizuki and Sugiyama, 2012). However, the U concentrations in the earth's surface of their drainage areas are relatively low and therefore the mechanisms of U supply to these rivers are of interest. In this study, we determined U concentrations as well as major chemical compositions in 17 Okinawan rivers and estimated the sources of U supplied to these rivers.

The major chemical compositions of the rivers in the northeastern region of the island were the Na-Cl or Na-HCO_3 types, while those in the southwestern region were the Ca-HCO_3 type. The Ca-HCO_3-type composition is derived from the dissolution of limestone, which is widely distributed in the southwestern region. The U concentrations in rivers were much higher in the southwestern region (32 - 3500 ng/L) than in the northeastern region (5.6 - 18 ng/L).

In the 11 rivers with Ca-HCO_3-type compositions, the limestone-derived fraction of U was estimated using the concentration ratio of U/Ca in the limestone and the Ca concentration derived from limestone. The U concentrations were almost explained by the simple dissolution of limestone in 6 rivers, but this mechanism could not account for the concentrations in 5 rivers with higher U levels (710 - 3500 ng/L). These results suggest that the U in these 5 rivers is supplied by other mechanisms, such as selective dissolution of U from rocks in the drainage areas by carbonate ions.

Longtime behavior (<50 yr) of Groundwater Quality with Dissolution of a Ryukyu-limestone Aquifer in Okinawa Island

NAKAYA, Shinji[1*] ; YASUMOTO, Jun[2] ; PHAN MIN, Ha[1] ; AOKI, Hideto[1] ; NAKANO, Takuji[2]

[1]Shinshu University, [2]The University of Ryukyu

Dissolution of a terrestrial limestone layer by chemical weathering is one of the most important factors affecting the carbon cycle and the transport of calcium from the land to the ocean. Residence times of sulfur hexafluoride (SF_6) and chlorofluorocarbons (CFCs), as well as their chemical composition in the groundwater, were investigated to estimate the longtime behavior of field dissolution of the Ryukyu-limestone aquifer on Okinawa Island, Japan. The Ca, (HCO_3+SO_4) and Pco_2 increase with groundwater residence time. The field dissolution of Ca was estimated to be 0.090 mM(Ca)/L/yr, with groundwater Ca ranging from 1.75 to 4.0 mM/L. The increase observed in groundwater alkalinity and SO_4 over time (0.170 meq(HCO_3+SO_4)/L/yr; 16 to 34 yr) implies that the groundwater acts as a CO_2 sink through chemical weathering of the Ryukyu-limestone aquifer when groundwater CO_2 (gas) concentrations range from 1.0% to 4.5%(logPco_2=-2 ˜-1.35 atom). The (Ca + Mg) content of groundwater was also affected by groundwater alkalinity (HCO_3), SO_4 and NO_3 derived from fertilizers used on Okinawa Island. These findings imply that the influence of fertilizer and the high partial pressure of groundwater CO_2 on the dissolution of Ryukyu-limestone aquifer may not be negligible. pH decreases with dissolution of the Ryukyu-limestone aquifer.

Rapid procedure for d15N and d18O determination and identifying nitrate sources in agricultural watershed

YADA, Saeko[1*] ; NAKAJIMA, Yasuhiro[1] ; UNO, Hikaru[1] ; ITAHASHI, Sunao[1] ; ASADA, Kei[1] ; YOSHIKAWA, Seiko[1] ; EGUCHI, Sadao[1]

[1]National Institute for Agro-Environmental Sciences

The natural abundance of nitrogen (δ^{15}N) and oxygen isotopes (δ^{18}O) of nitrate (NO_3^-) can be a powerful tool to discriminate the source of NO_3^- in agricultural watersheds. This dual isotopic approach has been used successfully to evaluate the denitrification process in an upland vegetable-field dominant watershed. Recently, determination of δ^{15}N and δ^{18}O of NO_3^- has been updated using a autosampler for automatic analysis. In this study, we developed a further time-saving procedure, which advanced the time-event efficiency by controlling sample traps and 6-port valves. Moreover, the procedure was used to identify sources of riverwater NO_3^- in a rice paddy watershed in Tsukuba, Japan, where the irrigationwater was supplied from out of the watershed.

The δ^{15}N and δ^{18}O values were determined by isotope-ratio mass spectrometry (IRMS) after converting NO_3^- to N_2O gas using the denitrifier method. We conducted sample purge and determination at the same time. Our developed procedure doubled the sample throughput, saving the amount of He carrier gas and liquid N_2. It also engaged the versatile utility of IRMS, since changeover of equipment was not required. This rapid procedure can be applied to other trace gas analysis, which require cryofocus e.g. CO_2, and will contribute for GWG dynamics studies.

Using the developed procedure, we identified principal sources of NO_3^- in mainstream riverwater of the watershed. The δ^{15}N — δ^{18}O relationship during irrigation period indicated that NO_3^- in mainstream riverwater were mainly provided from mountainstream and irrigationwater, and that significant effects of denitrification on the decrease in NO_3^- concentration were locally limited at some irrigationwaters and drainagewaters in the watershed.

Keywords: agriculture, irrigation, IRMS, nitrate, stable isotope, watershed

Study on Effect of Rainfall Distribution and Rainfall Intensity on Discharge at The Concentration Point of The Basin

YOSHIMI, Kazuhiro[1*] ; WANG, Chao-wen[1] ; YAMADA, Tadashi[2]

[1]Graduate School of Science and Engineering, Chuo University, [2]Department of Civil and Environmental Engineering, Chuo University

In resent years, the damage caused by flood comes obvious because of unprecedented record-breaking rainfall event or largest recorded rainfall. Because of this situation, river planning starts to be looked at again in Japan. For example, it has been reported by MLIT (Ministry of Land, Infrastructure, Transport and Tourism) that even if total rainfall is the same when the rainfall distribution differs in a basin, the discharge at a reference point may differ (refer to MLIT). In other words, it is necessary to innovate a new intellection considering the difference of rainfall distribution when creating river planning.

This study aims to clarify the relation between rainfall distribution in a target basin and peak discharge at a reference point. The authors therefore verified how the peak discharge at a basing point responds to rainfall distribution at an intended basin. Moreover, the authors examine the impact on discharge at a reference point if rainfall intensity increases or decreases in a basin.

A target basin of this study is *Tone* upper river basin. In addition, largest recorded flood of this basin is Kathleen typhoon which 3-days accumulated rainfall is about 320mm(refer to document of Japan Society of Civil Engineers) in the basin. First, the authors separated the target basin into 4 parts (refer to document of Science Council of Japan). Then, we did runoff analysis for a number of rainfall distributions using this typhoon event as basic rainfall pattern. The conditions of this calculation are, first, average rainfall of *Tone* upper river basin is the same in every rainfall distribution. Secondly, soil condition and geotechnical condition do not change in every case. After that, we compared every peak discharge at the reference point. Moreover, the authors also did runoff analysis using a number of average-rainfall over watershed 0.8, 0.9, 1.1, 1.2 times as much as basic rainfall event. And then, we compared the peak discharge in the same way.

In consequence, the authors indicated that peak discharge at the point of reference was about from 20800m^3/s to 23800m^3/s in which case rainfall distribution differs. These range of values is $\pm$7% in contrast with basic design flood of *Tone* river. In particular, the peak discharge of the reference point becomes 22000m^3/s or more in which case heavy rainfall intensity occurred in a watershed nearby the point. Furthermore, it was found that the range of values of peak discharge grows wider as average-rainfall over watershed builds in intensity. Therefore, flood exceeding the designed level is necessary to be defined newly and exactly in *Tone* upper river basin.

Increasing Water Level in the Vietnamese Mekong Delta

FUJIHARA, Yoichi[1*] ; HOSHIKAWA, Keisuke[2] ; FUJII, Hideto[3] ; YOKOYAMA, Shigeki[3] ; NAGANO, Takanori[4] ; KOTERA, Akihiko[4]

[1]Ishikawa Prefectural University, [2]Kyoto University, [3]Japan International Research Center for Agricultural Sciences, [4]Kobe University

The Mekong Delta is highly susceptible to the impacts of flood, sea level rise, and land subsidence. We considered three factors that could have increased the water level: (1) decrease in flood mitigation functions due to dyke constructions, (2) sea level rise, and (3) land subsidence. We used daily maximum water level, daily minimum water level, and daily water level data. We analyzed data of 21 stations from 1987 to 2006. First, we classified the Delta into two groups; one area is dominated by flows from the upstream, while the other is dominated by the tide. Moreover, we obtained the trend of annual maximum and minimum water levels. Regarding land use, we used the NDVI to estimate the area of dyke construction and the area of the flood plain. It is found that (1) the constructed area of the dyke does not coincide with the area of water level increase, (2) the area with the water level increase correlates with the area with the minimum water level increase. The area with the minimum water level increase is located in the tide dominated zone, indicating that the increase in the maximum water level is caused by the relative increase of sea level.

Furthermore, we examined the trend of sea level rise, and detected a 2.4 mm/year sea level rise. The average of the minimum water level increase was 7.3 mm/year, and therefore, 4.9 mm/year must be the subsidence. In addition, we eliminated the trend of the increasing water level and reconstructed the data without sea level rise and subsidence. We estimated the probabilistic value of water level using the reconstructed data set, and estimated the probability of 100-year water level using the current data set. As a result, the 100-year probabilistic water level in the reconstructed data becomes 21.2-year water level in the current.

Applicability of EUROSEM for surface runoff in forested slope plain

IKEDA, Hideshi[1*] ; WAKAMATSU, Takashi[1] ; NAKAYA, Ko[1] ; ABE, Seiya[1]

[1]Central Research Institute of Electric Power Industry

Sediment yield in agricultural area has been environmental and economic problems in many countries. In order to restrain sediment yield and to conserve water resource, scientific watershed managements are required in many watersheds. In USDA (United State Department of Agriculture), USLE model (Universal Soil Loss Equation) was developed and applied to many sites. USLE model is empirical model, and requires long term observation data. Then, physical based models, such as WEPP (Water Erosion Prediction Project) and EUROSEM (EUROpean Soil Erosion Model), were developed and applied to watersheds where long-term observation had not been conducted.

In some Japanese forest, forest management, such as thinning, has not been conducted fitly in these years. In poorly managed forest area, sediment yield with surface runoff has occurred and supplied suspended solids into stream, reservoir and coastal area. However, in forested watersheds, application of these models has not been conducted frequently, and it is required to validate and apply these models based on observation of meteorology, forestry, pedology and hydrology.

EUROSEM model is one of the useful tools for evaluation of sediment yield in forested area. In this study, hydrological applicability of EUROSEM is discussed. EUROSEM is a prediction model for sediment yield, which was developed by European Union in 1990s. It consists of hydrological and sediment sub-models, those are physical-based process models in non-steady state. EUROSEM has been applied to agricultural areas in Europe and China, for example in watershed of Three Gorge dam, Yangtze River. On the other hand, it is not applied to Japanese forest area frequently, where sediment yield is reported recently.

In Central Research Institute of Electric Power Industry (CRIEPI), we have been conducting observation for sediment yield since June 2010 in Akagi testing center, located in north Kanto plain. The observation system consists of 3 sites, one open field and two forest stands. For open field, precipitation was observed using Laser Precipitation Monitor (LPM,THEIS, FRG) consequently. For in two forest stands, vegetation, meteorology and hydrology survey were conducted. In vegetation survey, canopy analyzing and forest floor survey were conducted in every months. In meteorology survey, precipitation was observed using LPM consequently. In hydrology survey, surface runoff was observed in experimental area with 2m length and 0.5m width using tipping gauge continuously. Soil moisture and temperature were observed in every 10 minutes in experimental area.

In these two forest stands, EUROSEM hydrological sub - model was applied in 35 storm events, and siumlated surface runoff was validated based on observed data. EUROSEM hydrological sub model was applied to 10 storm events in previous study and appeared to simulate surface runoff for storm events with rainfall intensity between 2.0 - 5.0mm / 10mim. In this study, surface runoff was simulated well in storm events with rainfall intensity larger than 5.0mm/10min using infiltration rates lower than those in laboratory experiments.

Distribution of trace elements in 3 small rivers and the surrounding geology in the North Osaka prefecture, Japan

EVEN, Emilie[1*] ; NOJIMA, Aki[1] ; MASUDA, Harue[1]

[1]Department of Geosciences, Osaka City University, Japan

The Rivers Yono, Ibaraki and Minoh, that are tributaries of the River Yodo in the northern part of the Osaka prefecture, Japan, flow across the Paleozoic-Mesozoic sedimentary formations and the Ibaraki granitic complex. Waters from these rivers have been used for domestic purposes and some trace metals have been reported in concentrations above the environmental standard limits. Previous studies have shown that the sedimentary rocks were the sources of trace metals, especially arsenic, whereas the granitic sequence of quartz diorite, granodiorite and adamellite is believed to be the source of rare earth elements (REEs). In addition to track back of the origin of these trace elements, the transportation phases and the geochemical budget of trace metals along the river flow are examined as a first step to set up a simple transportation model. Here are presented first results.

Results showed that the geochemical patterns of riverbed sediments matched the distribution of the source rocks. The geochemistry of trace elements in river water is likely controlled by the weathering of riverbed sediments. River sediments from sandstone and quartz diorite contained high amount of trace elements and yielded high concentrations of trace metals in river water but low concentrations of REEs. Comparatively, river sediments originated from adamellite contain lower amounts of trace elements but river waters flowing across this formation showed to have the highest concentrations of REEs. O/H isotopic ratio in river water pointed at the meteoritic origin of the water in the upper reaches of rivers and the contribution of groundwater in the lower reaches. The fractionation of trace elements regarding the different size pools of total concentration, 0.45μm and 0.22μm filtration showed that most of the trace elements were transported within the $<$0.22μm phase. Temperature of river water seems to influence the concentrations of elements, as concentrations increased with increasing temperature throughout the year. The role of organic matter (likely as colloidal carriers) is limited since an inverse relationship was observed. Water mixing calculation with major and trace elements yielded accurate geochemical budget model ($<$5% error), where as redox sensitive species induce large errors of $>$15%, even on few meters distance along the flow path.

An Overview of Recent Hydrological Models for Estimating Phosphorus flux

SHIMIZU, Yuta[1*] ; ONODERA, Shin-ichi[2] ; SAITO, Mitsuyo[3]

[1]NARO/WARC JSPS-PD, [2]Graduate School of Integrated Arts and Sciences, Hiroshima University, [3]Graduate School of Environmental and Life Science, Okayama University

Phosphorus which derived from forest, agricultural area and urban is discharged to river stream via surface runoff and drainages. There is a time lag from ”inflowing to river channel” to ”outflowing to coastal area” because most of transported phosphorus is retained in river channel due to physical, chemical and biological processes. Previous studies about material balance in watersheds show that total amount of phosphorus emission is not correspond to total amount of discharged phosphorus. This is because of phosphorus retention in watersheds. So it is necessary to understand about phosphorus retention processes for estimation of phosphorus transportation. In recent years, distributed hydrological models are used to estimate phosphorus transportation. Most of these models are developed in western countries, and have been improved its accuracy of estimation of sediment and water quality. The objective of this study is to review phosphorus retention process in watersheds and model description for understanding model limitation for phosphorus transportation.

Water pollution and arsenic behavior in the Red River, North of Vietnam

INOUE, Ryo[1*]

[1]graduate school of science,Osaka City

Water pollution and arsenic behavior in the Red River, northern Vietnam.

Inoue,R1.Shinntani,T1.Masuda,H1.Yonezawa,G1.Truong Xuanluang2.Hang Do Thi2.
(1 Osaka City University, 2 Hanoi University of Mining Geology)

The Red River, flowing through the northern part of Vietnam, is originated in Yunnan, China and running parallel to the Hoang Lien Son mountain range. Arsenic pollution of groundwater has been a serious problem in rural area located on the Red River delta. The sources of arsenic must be carried to the aquifer through the river, although transportation processes are not well understood. In this study, arsenic transportation process through Red River was studied from the analytical results of river water, suspended particles, river-bed sediments which were collected in the Vietnam territory. In addition, general situation and the cause of the river water pollution was considered.

Total dissolved ions of river water sample is 5.0meq/L in Lao Cai located at the upper most stream in Vietnam, 2.4meq/L in Bao Ha and 2.1meq/L in Yen Bai at middle-stream, and 3.4meq/L in Hanoi at downstream. Low concentration of dissolved solids between Lao Cai and Hanoi is due to the inflow of the surface water from Hoang Lien Son mountain range. Such an inflow is clear from the lower oxygen and hydrogen isotope ratio of river water than those of main channel waters. δ18O: -9.9∼-10.0 ‰ and δ2H: -69 ‰ in Lao Cai. δ18O: -12.9∼-13.0 ‰ and δ2H: -91∼-92 ‰ in the branch channel in Hoang Lien Son mountain range, and δ18O:-11.6∼-11.9 ‰ and δ2H:-82∼-84 ‰ in Bao Ha and Yen Bai at middle-stream. Branch channel water in Hoang Lien Son mountain range diluted the dissolved salts and pollutants such as As and Pb. Arsenic is transported as dissolved components (∼60%) and adsorbed components (∼40%) in the river.

Arsenic concentration has clearly positive correlation to the XRD intensity of smectite. Weak positive correlation between arsenic and kaolinite was also found. However, there is no relationships between arsenic and iron, indicating that the arsenic doesn ' t behave with iron oxyhydroxides in the river. And, smectite found only in suspended particles sample of Red River main channel water, thus, the arsenic is transported with clay minerals in the Red River.

Estimation of water balance in a coastal agricultural catchment using SWAT and HYDRUS Model.

JIN, Guangzhe[1*] ; SHIMIZU, Yuta[2] ; ONODERA, Shin-ichi[1] ; SAITO, Mitsuyo[3] ; MATSUMORI, Kenji[2]

[1]Hiroshima University Graduate School of Integrated Arts and Sciences, [2]National Agriculture and Food Research Organization, Western Region Agricultural Research Center, [3]Graduate School of Environmental and Life Science, Okayama University

Quantify the rate of ground water recharge and clarify the water balance in watersheds is basic and important for efficient ground water resource management. It is particularly important in regions with little rain which face with the risk of water shortage. However, the rate of aquifer recharge is one of the most difficult factors to evaluate. Especially, the former method of groundwater recharge estimation, are normally subject to large uncertainties and easily to cause errors. Recently, there are several attempting for estimation of groundwater recharge using distributed hydrological models in the world.

The Soil and Water Assessment Tool (SWAT) Model is one of a physically based and quasi-distributed continuous time hydrological model used to estimate water budget in previous researches around the world. SWAT Model has been implemented for watershed hydrology related issues such as estimation of surface water flow and groundwater recharge rate. We could more specific testify the groundwater flux combined SWAT Model with HYDRUS Model which is a software package for simulating water, heat, and solute movement in two- and three-dimensional variably saturated media. The objective of this research is to estimate water balance and to clarify the groundwater recharge parameter in an agricultural catchment in the Seto Inland Sea, using the SWAT Model, and to estimate the groundwater flow using the HYDRUS Model.

The study site is located on the southern part of Ikuchi Island, which is one of the islands in central Seto Inland Sea. The orange groves cover approximately 50% of the total catchment area. Due to the small annual precipitation (approx.1000mm/y) with large inter-annual variation, Ikuchi Island is facing a risk of water shortage in the serious dry year.

As input to SWAT Model, topographic data (10 m grid), soil map (1/25000), land use map (1/25000) and weather information were used to build and calculate the SWAT Model. Evaporation was estimated by the Penman-Monteith method. Simulation time periods is 2000-2013, including warm up period of 2000-2003 and calibration period of 2003-2004. The calibration was conducted using the Sequential Uncertainty Fitting (SUFI2). The reproducibility of daily discharge in calibration period by the model was found to be acceptable (NSE=0.69, RSR=0.56, PBIAS%=18, R^2=0.75). Amount of groundwater recharge is accounted as the water discharge into aquifer except the flows which are eventually discharged from aquifer, such as return flows into river and amount of water moving into the vadose zone.

The result shows spatial difference in groundwater recharge rate. About 10 times higher groundwater recharge rate was found in middle and downstream areas. While middle and downstream area are indicated the main groundwater recharge area, upstream is small recharge rate due to steep slope. Groundwater recharge shows smaller volume than river discharge, it comprise about 17% of total precipitation in annual average consideration. From the comparison of water balance calculation, it is found that both of river discharge and groundwater recharge fluctuated in high precipitation year of 2011 (1,527mm), low precipitation year of 2005 (781mm) compared to average balance. In high precipitation year, groundwater recharge rate increased about 6 times than in low precipitation year, the increasing of river discharge is at about 2.5 times.

Consequently, it was confirmed that spatial and temporal variation of groundwater recharge rate in long term. And we could estimate the long term water balance base on these information. However, it is noted that this result may include some uncertainty and chance to improve. Seat model could not reflect the groundwater flow, simulated with HYDRUS Model on the groundwater flow could provide us with the groundwater data. In the presentation, more detailed data cover long time periods and results testifying groundwater level variation with HYDRUS Model will be displayed.

Seasonal variation in nutrient dynamics in the tidal zone of Yamato river

ONODERA, Shin-ichi[1*] ; SAITO, Mitsuyo[2] ; SHIMIZU, Yuta[3] ; MARUYAMA, Yutaka[1] ; MIYAOKA, Kunihide[4] ; JIN, Guangzhe[1] ; ARITOMI, Daiki[1]

[1]Hiroshima University, [2]Okayama University, [3]NORO, [4]Mie University

In coastal megacities, sever groundwater depression and water pollution occurred. These impacts affected to river environment change. Especially, the river mouth area has been deposited the polluted matters. These areas have characteristics of water level fluctuation which causes river water-groundwater interaction and the associated change in dynamics of nutrients. However, these effects on the nutrient transport in tidal reaches and nutrient load to the sea have not been fully evaluated in previous studies. Therefore, we aimed to clarify the nutrient dynamics with the river water-groundwater interaction in the tidal river of Osaka metropolitan city. We conducted the field survey from the river mouth to the 7km upstream area of Yamato River, which has a length of 68km and a watershed area of 1070 km2. In addition, model simulations were also conducted. Spatial variations in radon (222Rn) concentrations and the difference of hydraulic potential between river waters and the pore waters suggest that the groundwater discharges to the river channel in the upstream area. In contrast, river water seeped into the groundwater in the river mouth area. It may be caused by the lowering of groundwater level associated with the excess abstraction of groundwater in the urban area. The spatial and temporal variations in nutrient concentrations indicate that nitrate-nitrogen (NO3-N) concentrations changed temporally and it negative correlated with dissolved organic nitrogen (DON) concentrations. Inorganic phosphorous (PO4-P) concentrations showed the increasing trend with the increase of the river water level. Based on the mass balance, nutrient reproduction from the river bed was suggested in tidal reach during a summer, especially phosphorus was large.

We aimed to examine on the classification and ecological index of the small ponds based on the stability of stratification. The seasonal variation of the stratification was examined using the monitoring data of water temperature in multiple depths in the 4 different ponds located on an island which is highly influenced by agricultural activity. DO, fluorescence, nutrients data were used for the evaluation of ecosystem condition.

We examined the influence of land reclamation on rock magnetic profiles in Lake Hachirogata. In this lake, all flowing rivers exist on an east side and a large reclamation land touch at west and north sides. Two sediment core samples were collected at the eastern central (HL-1) and northwestern bankside (HL-2) sites in this lake in September 2013, using the 1m piston core sampler (7-8 cm diameter). HL-1 was 77cm and HL-2 was 78cm.

Previous studies have revealed that submarine groundwater discharge (SGD) is one of the important pathways for nutrients and the other dissolved materials from terrestrial area to the marine environment. For the evaluation of the effect of SGD, the timescale of nutrient transport in the coastal area derived by SGD such as residence time is important as well as nutrient flux by SGD. Radioactive isotopes of radon (222-Rn) and radium (226-Rn, 228-Ra) are one of the useful tracers for the evaluation of SGD and residence time of water mass in the coastal area. The objective of the study is to examine the spatial variation of 222-Rn and 226-Rn, 228-Ra in the coastal seawater of the central part of Seto Inland Sea and its controlling factors. The study area is southwestern part of the Hiuchi-Nada with the area of approximately 30 km $\times$ 13 km. Relatively high concentrations of 222-Rn, 226-Rn and 228-Ra were detected in the southern part of the study area. These results suggest the effect of SGD from seafloor.

Arsenic distribution in porewater and coexisting sediments of Kumano Basin, Nankai Trough

YOSHINISHI, Haruka[1*]

[1]Osaka City University

Arsenic contamination of groundwater is a serious problem in the world, especially in the deltas along large rivers originated from Himalayas such as Bangladesh and West Bengal, India. Sulfide minerals including pyrite in shales is one of the candidates of source minerals causing arsenic contamination. However, the mechanism of arsenic concentration in sedimentary rocks has not been well understood. In this study, arsenic behavior in the porewater and host sediments was determined to understand the fixing process of arsenic during early stage of diagenesis in modern marine sediments.

Porewaters and squeezed cakes were sampled at three sites (C0002, C0021, C0022) in the Nankai trough by IODP, Expedition 338. The sediments from Site C0002 is composed hemipelagic mud of distal turbidites, those from Site C0021 of mass transport deposits (MTDs), Site C0022 is dilled at right above the megasplay fault, and highly fractured zone, likely related to the megasplay faulting was found at 100 mbsf (meters below seafloor).

Arsenic concentration of the porewaters at Site C0002 was constant 0-1.1μM at 200-300 mbsf, and it increased with depth to 3μM in 300-400mbsf. The highest concentration (3μM) was recorded at 400 mbsf, and the concentration decreased below that depth. In C0021, arsenic concentration of the porewaters is 0.2μM on an average at 0-160 mbsf and give no relationship to the depths. It increased quickly to 1.2μM down to 200 mbsf. In C0022, arsenic concentration is 0.3μM on average at 0-100mbsf. The highest concentration (1.5μM) was observed at 130-160mbsf, and then drastically decreased to 200 mbsf. Arsenic concentration became constant below that depth.

Arsenic concentration of sediments is 40-120μM at 300-500 mbsf in Site C0002, 40-90μM at 100-150mbsf in Site C0022. The arsenic concentration is varied without relationship to the depth.

Mineral composition determined by XRD showed that the all sediments analyzed were dominated by quartz, feldspars, micas, calcites, smectite, and chlorite/ kaolinite. Hornblende and pyrite were occasionally observed.

Compared to the major chemical composition determined onboard, arsenic concentration of porewater correlated to pH, Fe, Pb, and Mn. It is suggested that the arsenic was accumulated in the sediments via coprecipitation with iron hydroxides/oxides at the sea floor, similar to many trace heavy metals, and was released intio the porewater by desorption under reducing environment, or by decomposition of iron hydroxides/oxides. After that, arsenic may be fixed into pyrite with depth, however, the fixing mechanism of arsenic in the deep is not clear at present.

Research on dissolved inorganic phosphorus concentrations forming process in a forested mountainous stream

TAKEDA, Manami[1*] ; OHTE, Nobuhito[1] ; EGUSA, Tomohiro[1] ; SUZUKI, Masakazu[1]

[1]Department of Forest Science Graduate School of Agricultural and Life Sciences

Since the ecosystems of river, lake, and ocean are supported by P supply from terrestrial area, it is important to understand the mechanisms behind the P discharge from the catchments through the aquatic system. It has generally been considered that loss of P from a forested area through a headwater stream is small, because it is preserved tightly within forested ecosystem. It has previously been reported that heavy rainfalls lead to a large P loss from forested catchments, and major fractions of exported P is particulate form absorbed onto soil particles. Therefore, many studies have focused on particulate P load during high flow condition. However, it has been still poorly understood about the controlling mechanisms of sources and transport of dissolved inorganic phosphorus (DIP), which is directly available for organisms. In order to explain the controlling mechanisms of DIP discharge, we conducted field investigations on the DIP dynamics through the elemental hydrological processes in the hill slopes of a headwater catchment, and illustrated the spatial distribution of DIP concentrations of the stream network in meso-scale catchment.

The study site was Fukuroyamasawa experimental watershed located in The University of Tokyo Chiba Forest and Inokawa watershed including Fukuroyamasawa. The size of Fukuroyamasawa is 1 ha, and that of the Inokawa watershed is 503 ha. Through fall water, stem flow water, litter layer infiltration water, soil water, groundwater and stream water were sampled once every two weeks from August 2013 to November 2013. Rainwater was collected at the meteorological station located near by Fukuroyamasawa. In Inokawa watershed, flow observation and stream water sampling at the point with various watershed area on low-flow period in September 2013 and December 2013. The samples were filtered by 0.45 micrometer membrane filters immediately after the sampling. Then DIP was analyzed using molybdenum blue (ascorbic acid) absorptiometry.

The average DIP concentration of rainwater was 0.2 micromol / L during the observation period. That of through fall, stem flow and litter layer infiltration water were 0.9, 1.7 and 10.9 micromol / L respectively. DIP concentration felt remarkably with soil layer passage, and the average DIP concentration of soil water, groundwater and steram water was 0.6 micromol /L. DIP concentration in Inokawa stream water ranged from minimum limit of determination, 0.1 micromol /L, or less to 9.2 micromol / L. When we investigated the relation between DIP concentration and a contributory area, DIP concentration differed in about 2 km2 or less, and it increased at the larger than 2 km2 as the contributory area became large. There was a strong positive correlation between DIP concentration and EC.

In Fukuroyamasawa, it was shown that DIP added during canopy passage was almost absorbed in the soil layer at particles, and was removed from the water, and hardly contributing to the outflow to a mountain stream. EC is an index for underwater dissolved matter concentration, and it turns out that the amount of the dissolved matter concentration of mineral origin is shown at Inokawa watershed. Therefore, the relationship of DIP concentration and EC has suggested that mountain stream underwater DIP mainly originates in bedrock weathering, and that the spatial distribution of DIP concentration is determined with the contribution of a groundwater course which passes bedrock.

Mixing of river water as deduced from major component concentration, Sr and S isotopic ratios in Tama River, Akita.

WAKASA, Sachi[1*] ; ISHIYAMA, Daizo[2] ; MATSUBAYA, Osamu[3] ; SATO, Hinako[2] ; SHIN, Kicheol[4] ; NAKANO, Takanori[4]

[1]Center for Geo-Environmental Science, Akita Unisity, [2]Faculty of International Resource Sciences, Akita University, [3]Emeritus professor, Akita University, [4]Research Institute for Humanity and Nature

The acidic high temperature hot spring discharged from the Tamagawa hot spring (Ohbuki) into the Tama River system through the Shibukuro creek is still acidic downstream. The acidity of the Ohbuki hot spring water is neutralized using limestone before it discharges into the Shibukuro creek. In this study, geochemical signatures of mixing between Tama River and its tributaries were deduced from concentration of major chemical components, Sr and S isotopic ratios. The Ohbuki hot spring water has high concentration of chloride and sulfate. The δ^{34}S of sulfate is the highest (δ^{34}S = 31.8 ‰) in the watershed. Due to the neutralization, the concentration of calcium, strontium and strontium isotopic ratio increases (^{87}Sr/^{86}Sr = 0.7068). The mixing rate of water flowing out from the neutralization facility is about 20% and 8% before and after the confluence of Shibukuro and Tama Rivers, respectively. The concentration of the major chemical components decreases gradually downstream and is almost similar to other tributaries in the Tama and Omono Rivers system. The pH of the water also decreases from 3 to neutral (about 7). The strontium isotopic ratios of 0.7040, 0.7068 and 0.7049-0.7062 for the Ohbuki, the neutralization facility and tributaries of the Tama River respectively, reflect the geology of the catchment area. A two component mixing phenomena is observed in the Tama River and its tributaries based on the major chemical components. However, the two component mixing relationship is not clearly distinct with the Sr isotope ratios. The δ^{34}S of sulfate in the Ohbuki thermal water (+31.8 ‰) and Tawa River (+6.6 – +8.8 ‰) near the confluence of the Tama and Omono Rivers supported the two component mixing relationship observed from the major chemical component. The results observed in this study are used to interpret the mixing mechanisms operating between the Tama River and its tributaries.

Feature of distribution of radioactive cesium in irrigation canal

KUBOTA, Tomijiro[1*] ; TARUYA, Hiroyuki[1] ; TANAKA, Yoshikazu[1] ; HAMADA, Koji[1]

[1]National Institute for Rural Engineering, NARO

The purpose of this study is to clarify distributive characteristics of a radioactive cesium in the irrigation canal by examining the radioactive cesium contained in the bottom sediment along the canal from its intake to the downstream. One of the millrace located in Fukushima Prefecture was selected as a case for investigation, and the distribution of the amount of the sedimentation, the concentration of radioactive cesium in the bottom sediment, and the air dose rate were examined. The sandy deposit was seen in the upstream of the canal, and those concentration of radioactivities Cs were comparatively low with 1-5kBq kg^{-1}. On the other hand, relatively high concentration of radioactivity Cs was seen in the downstream of canal, and was within 3-28kBqkg^{-1}. The air dose rate in the waterway were relatively low because of the influence of ponding, relatively high air dose rate were seen in the place where the depositional surface had been exposed.

The study is aimed to examine the current status of the groundwater use in an island of the Seto Inland Sea, southern Japan. This area is characterized by high risk of drought with low annual rainfall and limited water resource. We conducted face-to-face surveys in the form of a multiple-choice questionnaire in two areas (districts of Miyabara and Hayashi) with different main resource of agricultural water in Ikuchijima-island, Onomichi-City. Citrus farms such as orange, lemon etc. are widely cultivated in both areas.

The rate of households having domestic well is about 74% in Miyabara district, and is about 62% in Hayashi district. The main purposes of groundwater use are watering in garden and car wash in both areas. About 20% of respondents answered that groundwater resource is not enough for the agricultural use in the dry season. It indicates the groundwater is regarded as one of the important water resource in the island. Averaged daily domestic use of groundwater per household are estimated to be 361L/day and 271L/day in Miyabara and Hayashi, respectively.

Evaluating the impact of disturbances on the carbon balance of forest ecosystems in Hokkaido by using data and model: fr

HIRATA, Ryuichi[1*] ; ITO, Akihiko[1] ; TAKAGI, Kentaro[2] ; HIRANO, Takashi[3] ; SAIGUSA, Nobuko[1]

Changes in carbon flux and storage in forest ecosystems are influenced by climate at various temporal and spatial scales, whereas carbon flux and storage are affected instantaneously and heterogeneously by artificial and natural disturbances at the local scale. Disturbance events such as forest fire, damage by insects, and forest harvest drastically change NEP and carbon storage. In this study, we address the effect of disturbance on carbon balance based on two scale; one is site scale and another is local scale.

First, we performed a baseline simulation of carbon dynamics and compared these values with those observed across a wide range of stand ages (old mixed forest and young and middle-aged larch forests). By taking into account seasonal variation in the understory leaf area index, simulated net ecosystem production (NEP), gross primary production, ecosystem respiration, and biomass for the three types of forests were consistent with observed values.

We compared two cases of simulations concerning the carbon balance: one taking account of spatial distribution of disturbance-induced forest age derived from forest inventory data (disturbance case) and another ignoring the disturbance impact (non-disturbance case). NEP was gradually and spatially changed ranging from 0 to 1 t C/ha/y depending on meteorological conditions such as temperature or solar radiation. On the other hand, in the case of disturbance, large NEP ranging from 3 to 5 t C/ha/y were distributed patchwise like hotspots, because forest age of these spots ranging from 20 to 100 years old and then younger than those of the non-disturbance case. In the 1970s, wood harvest and tree planting were intensively conducted in Hokkaido. In the disturbance case during this period, there were many hotspots which show negative NEP.

Examining initialization procedures of terrestrial carbon cycle models

ITO, Akihiko[1*]

[1]National Institute for Environmental Studies

It has been realized that long-term trends in model simulation is affected by initialization procedure. In terrestrial carbon cycle models, insufficient stabilization can result in artificial trends (lingering sink or source in CO2 flux) in the simulated carbon budget, making it difficult to interpret simulation results and make comparison with observational data. Conventionally, an equilibrium state of terrestrial carbon budget has been obtained through iterative calculations using an appropriate forcing data. This spinning-up method requires high computational cost, typically, at over 90% of total computational cost. On the other hand, terrestrial modeling has another problem related to initialization; actual ecosystems are not always at steady state due to disturbance and environmental change. As a result, different model groups adopt different initialization procedures, raising some problems in inter-model comparison. In this study, I examined how an alternative initialization method (semi-analytical solution) works in a terrestrial carbon cycle model and is effective to reduce computational cost in comparison with the conventional spinning-up. I discuss possibility of better initialization procedures, in terms of idealism, realism, and generality, not only with model researchers but also with filed researchers.

Interannual variation of carbon allocation in a cool-temperate deciduous forest from 1999 to 2006

KONDO, Masayuki[1*] ; ICHII, Kazuhito[2] ; UEYAMA, Masahito[3]

[1]Faculty of Symbiotic Systems Science, Fukushima University, [2]Japan Agency for Marine-Earth Science and Technology, [3]Graduate School of Life and Environmental Sciences, Osaka Prefecture University

Carbon allocation is the key factor controlling the dynamics of carbon cycle. It determines partitioning of assimilated carbohydrate to components of vegetation, leaves, woody organs, and fine roots. To analyze seasonal and annual scale carbon allocation of forest ecosystems, it is conventional to use the mass-balance approach, which combine individual estimations of flux and biometric observations such as gross primary production, ecosystem respiration, soil respiration, net ecosystem production, leaf and tree biomass, litterfall, and soil organic carbon considering appropriate balances with each components. However, it is often the case that an attribution of fine roots was not fully assessed because it is required significant effort to monitor its dynamics in a long term. Pulse labelling technique allows directly measure allocation of assimilated carbon from foliage to belowground in various tree species. This approach provides detailed aspects of allocation dynamics, but assessing labelled carbohydrate allocated to fine roots is still challenging. Absence of allocation to fine roots limits our knowledge about mechanism of carbon allocation because net primary productivity of fine root (frNPP) potentially account for one-third of the annual total NPP. To compensate limited observation, a model-data integration technique would be a useful tool, in which a process-based biosphere model combined with multi-year biometric observations to inversely estimate plausible allocation to fine roots.

This study investigated the interannual variability of carbon allocation of a cool-temperate forest in the Takayama Forest Research Site, Japan. The multi-year biometric observations are available for most of carbon cycle components at the Takayama site (e.g., woody tissue net primary productivity (wNPP), foliage NPP (fNPP), aboveground and belowground woody biomasses, litterfall, recruitment, and mortality) except fine root NPP (frNPP); only one year data of frNPP is available for 2000?2001. To compensate the limited frNPP measurement, we calculated frNPP from 1999-2006 by a model-data integration technique. In the process of calculation, unnecessary freedom in the simulation of a process-based ecosystem model, Biome-BGC, was constrained as much as possible with multiple biometric observations at the Takayama site. With the observed components of allocation (fNPP and wNPP) in conjunction with the modeled frNPP, we characterized the internnual variability of carbon allocation at the Takayama site by focusing two aspects: (1) allocation priority among leaves, woody components, and fine roots, and (2) controlling climate factors for these allocation components.

Net nitrogen input through the atmospheric deposition and irrigation water at a paddy field in central Japan

HAYASHI, Kentaro[1*] ; ONO, Keisuke[1] ; TOKIDA, Takeshi[1] ; NAKAMURA, Hirofumi[2] ; HASEGAWA, Toshihiro[1]

[1]Natl. Inst. Agro-Environ. Sci., [2]Taiyo Keiki

The aim of the present study was to evaluate the net nitrogen input through the atmospheric deposition and irrigation water at a paddy field for single cropping of paddy rice in central Japan, where the wet deposition and exchanges of gases and particles (as the difference between the dry deposition and emissions) were measured for the atmospheric deposition. Target species of reactive nitrogen (Nr) were ammonium (NH_4^+) and nitrate (NO_3^-) for the wet deposition, ammonia (NH_3), nitric acid (HNO_3), and nitrous acid (HNO_2) as gases and particulate ammonium (pNH_4) and nitrate (pNO_3) as particles for the atmosphere-rice paddy exchange, and NH_4^+, NO_3^-, and organic nitrogen (OrgN) for the irrigation water.

Monitoring of those processes were conducted for three years from September 2010 to September 2013 at a paddy field in central Japan which was devoted for an experimental site of free-air CO_2 enrichment (FACE). Rainwater samples were collected weekly and the wet deposition was calculated using the Nr concentration and the collected volume of water. The air concentrations of Nr were measured using a filter-pack method at two heights of 6 m and 2 m above the ground surface on a weekly mean basis with day/night separation. A filter-pack consisted of five filter holders to collect the target Nr. The diffusion velocity was calculated using the micrometeorological and eddy covariance data in half-hourly basis and then the weekly-mean values in the daytime and nighttime were calculated. The exchange fluxes were expressed as the product of the difference in air concentration between the two heights multiplied by the diffusion velocity. Cumulative exchange fluxes were also calculated based on the weekly mean exchange fluxes. The flow rate and quality of irrigation water was monitored in the cropping seasons in 2011, 2012, and 2013 at a bay in the paddy field. Each of two inlets and one outlet at the bay was equipped with a flow gaging weir and the water flow was measured continuously. Water was sampled at the weirs every week in principle and the concentrations of Nr were measured, where OrgN was calculated as the difference between the total nitrogen and the sum of NH_4^+ and NO_3^-. The inflow and outflow of Nr by irrigation were then calculated using the flow rate and concentration data.

Annual wet deposition of Nr was 9.5, 8.6, and 5.9 kg N ha^{-1} yr^{-1} for the first, second, and third years, respectively, where NH_4^+ and NO_3^- showed similar contributions quantitatively. In addition, the contribution of OrgN was negligible in the wet deposition. Annual exchanges of Nr between the paddy field and the atmosphere were estimated to around 2-3 kg N ha^{-1} yr^{-1}, where a certain extent of the dry deposition was counterbalanced by the emissions. Ammonia was the most dominant Nr among the target species in the atmosphere. Ammonia also showed the largest dry deposition among Nr; however, a large part of which was canceled by the emissions of NH_3 from the paddy field. The differences between the inflow and outflow for the irrigation water were 10.7, 8.8, and 6.7 kg N ha^{-1} yr^{-1} for the first, second, and third years, respectively, where OrgN accounted for 30-40% of Nr. In total, the net input of Nr to the paddy field through the atmospheric deposition and irrigation water was estimated to approximately 20 kg N ha^{-1} yr^{-1} which corresponds to approximately 30% of a standard application rate of nitrogen fertilizers in this area. However, it is desired that the following processes are also incorporated to complete the evaluation of the nitrogen balance: the biological nitrogen fixation and the dry deposition of nitrogen oxides (nitrogen monoxide and nitrogen dioxide) as inputs; and the denitrification (nitrogen monoxide, nitrous oxide, and dinitrogen) and the leaching of Nr to the groundwater as outputs.

The variations of ORP in the paddy soil and effects on the methane emission from a periodically irrigated paddy field.

YAGI, Kenta[1] ; WAKIKUROMARU, Naoki[1] ; IWATA, Toru[1*]

[1]Graduate school of Environmental and Life Sciense, Okayama University

Oxidation-Reduction Potential (ORP) in the paddy soil was measured during rice cultivaled season at a periadically irrigated paddy field, and some effects on the methane flux from the paddy soil was investigated. ORP showed rapid decrease when irrigation water was introduced in the paddy field, and lower ORP was shown under the longer flooded condition. From the seasonal-term point of view, lower ORP was shown in later rice season. ORP was suitably modeled as a function of irrigation time. During an irrigation period for four days, higher methane emissions were shown under lower OPR conditions. From the seasonal-term point of view, however, no significant relationship between ORP and methane fluxes. It is suggested that seasonal change of methane flux is affected by seasonal changes of soil temperature and the growth level of rice plants.

Carbon emission by open burning from a paddy field and decomposition of the residual biomass in the paddy soil

OKADA, Kazuya[1] ; ONO, Keisuke[2] ; IWATA, Toru[1*]

[1]Graduate school of Environmental and Life Sciense, Okayama University, [2]National Institute for Agro-Environmental Sciences

Twice sampling surveys of residual biomass above ground surface were conducted before and after the open burning, and carbon contents compared for the estimation of carbon emission by the burning. It is suggested that about 43% of carbon contents of above-ground rice plant was yield out as grain by the harvest, and about 30% of carbon emitted as CO2 by burning. Coarse Organice Matter (COM) in the paddy soil of a single-crop rice field was sampled on a regular schedule for three years. The carbon emission from the COM decomposition of residual biomass was estimated by analyzing of the variations in carbon content of COM. Decrease in COM was accelerated at the warming season between April and June, but it was resisted during rice cultivated season. It is estimated that 70% of COM was decomposed after a year.

Continuous measurement of forest floor CO2 fluxes in a larch forest on the base of Mount Fuji

TERAMOTO, Munemasa[1*] ; LIANG, Naishen[1] ; ZENG, Jiye[1] ; IDE, Reiko[1] ; SAIGUSA, Nobuko[1] ; TAKAHASHI, Yoshiyuki[1]

[1]Center for Global Environmental Research, National Institute for Environmental Studies

Carbon fluxes of forest floor are thought to be important part of forest carbon dynamics. Multi-channel automated chamber system was installed to a larch forest site on the base of Mount Fuji in 2006 for continuous measurement of forest floor CO_2 fluxes. We prepared soil chambers for measuring soil respiration (Rs) and heterotrophic respiration (Rh). Root trenching was applied to separate Rs and Rh. Net ecosystem exchange (NEE) on the forest floor was measured with plant chambers. In 2013, the average efflux of CO_2 was 2.24, 1.81 and 2.11 μmol CO_2 m^{-2} s^{-1} in Rs, Rh and NEE, respectively. Root respiration was estimated to occupy 80.7% of Rs. Plants of forest floor was suggested to absorb about 5.9% of CO_2 in Rs, and it meant that the amount of carbon fixed by those plants was relatively low. There was little rain in summer time (July-August), and forest floor CO_2 fluxes were decreased due to decreased soil moisture. Q_{10} was 2.49 and 2.87 in Rs and Rh, respectively. Soil respiration was estimated to be 8.48 tC ha^{-1} yr^{-1}, and the forest floor was seen as 7.98 tC ha^{-1} yr^{-1} carbon source.

Change in carbon dioxide absorption by a deciduous broadleaf forest due to the 2004 typhoon disturbance

MIZOGUCHI, Yasuko[1*] ; YAMANOI, Katsumi[1] ; UTSUGI, Hajime[1] ; TOBITA, Hiroyuki[1]

[1]Forestry and Forest Products Research Institute

Natural disturbances occur in forests at various scales and frequencies. It has an impact on the amount of carbon dioxide (CO_2) absorption by a forest. In Japan, large-scale disturbance often occurs in forests due to damage caused by strong winds of a typhoon. The 18th typhoon passing in 2004 brought about large-scale damage to forests, mainly in Iburi and Ishikari districts of Hokkaido. The Hitsujigaoka experimental forest (Sapporo forest meteorology research site, SAP) located in the southeastern area of Sapporo also suffered large-scale damage. An investigation related to CO_2 absorption, including flux observation, was conducted before the typhoon disturbance. After a 1-year interruption of the investigation due to facility damage by the typhoon, flux observation was reinitiated. To study the process of regeneration in the forest, the fallen trees were left into site. We report the results of a long-term observation of flux and biomass.

According to flux observation data, the annual carbon budget changed to negative after the disturbance. At present, carbon release is continuing. The supply of a lot of dead trees has caused a large amount of decomposition, which has lead to 1.5-fold heavy increases in ecosystem respiration. Meanwhile, average annual GPP from 2007 to 2012 decreased 5% compared with that before the typhoon.

Yearly maximum LAI including both trees and dwarf bamboo estimated by the attenuation rate of photosynthetically active radiation and the biomass survey was approximately 7 before the disturbance. It decreased to 4 in the following year and increased thereafter. It has been approximately 5.5 since 2007. The main source of total LAI recovery is the LAI of dwarf bamboo, which increased 2-fold. The amount of biomass of trees decreased to 70% after the typhoon, while that of dwarf bamboo increased 1.5-fold. However, biomass of bamboo was approximately 10% of that of trees. Therefore, dwarf bamboo did not fill in gaps due to a decrease in biomass of trees.

Photosynthetic increase due to dwarf bamboo partially compensated for photosynthetic decrease due to trees, and ecosystem respiration increased due to the increase in dead trees. As a result, the forest became the carbon source. To change the status of the forest from the carbon source to a carbon sink, it is necessary for carbon release to decrease with the advancing decomposition of dead trees.

Keywords: deciduous broadleaf forest, dwarf bamboo, CO_2 flux, disturbance

Evapotranspiration of tropical peat ecosystems

HIRANO, Takashi[1*] ; KUSIN, Kitso[2] ; LIMIN, Suwido[2] ; OSAKI, Mitsuru[1]

[1]Research Faculty of Agriculture, Hokkaido University, [2]University of Palangkaraya

In Southeast Asia, mainly in Indonesia and Malaysia, peatland is widely distributed, coexisting with swamp forest, over an area of 2.48×10^5 km^2 and accumulates 11-14% of global peat carbon (Page *et al*., 2011). The peatland, however, has been rapidly degraded by deforestation and drainage. As a result, the proportion of forest cover in the peatlands of Peninsular Malaysia, Sumatra and Borneo fell from 77% to 36% from 1990 to 2010 (Miettinen *et al*., 2012). Such human pressures made the huge peat carbon pool vulnerable and raised the risk for the pool to be a large carbon source to the atmosphere chiefly because of peat fires and lowered groundwater level (GWL). The carbon balance of peatland is chiefly controlled by local hydrology, which determines saturation or unsaturation of surface peat. Under unsaturation conditions, peat is aerated, and its soil organic compounds are easily oxidized into carbon dioxide (CO_2). Therefore, drainage to lower GWL necessarily enhances oxidative peat decomposition and its resultant CO_2 emissions. Because tropical peatland is typically ombrotrophic, GWL varies according to residuals (storage change) between precipitation as input and evapotranspiration (ET) and runoff as output. Although precipitation can be also affected by large-scale deforestation, ET and runoff are directly affected by deforestation and drainage, respectively. To predict GWL under human pressures and assess the carbon balance of tropical peatland, therefore, it is crucial to quantify ET and elucidate the effects of disturbances on ET.

We have measured fluxes of sensible heat and latent heat using the eddy covariance technique and determined ET and energy balance at three sites within 15 km on tropical peatlands near Palangkaraya, Central Kalimantan, Indonesia (Hirano *et al*., 2012). The sites are different in disturbance degree: a relatively intact peat swamp forest with little drainage (UF), a heavily drained swamp forest (DF) and a drained burnt swamp forest (DB). Here we show the results of field measurement for four to six years between 2002 and 2009, including El Nino and La Nina events and discuss the effects of disturbances on the energy balance and ET of tropical peat swamp forest.

Because of energy imbalance (84 to 91% on an annual basis), ET was adjusted to close energy balance on a daily basis. Mean annual ET (±1 standard deviation) for the four years from 2004 to 2008 was 1636 ± 53, 1553 ± 117 and 1374 ± 75 mm y^{-1}, respectively, for the UF, DF and DB sites, which account for 67, 64 and 56% of mean annual precipitation of 2435 mm y^{-1}, respectively. Annual ET of the DB site was significantly smaller than those of the other sites, mainly owing to less transpiration due to few trees. This fact indicates that more water is lost by surface and groundwater runoff in the DB site. In addition, annual ET showed a positive linear relationship with annually mean GWL at each site. This significant linearity suggests that annually mean GWL is a robust indicator to assess the annual balances of carbon and water in tropical peat ecosystems (Hirano *et al*., 2012).

Withering of Japanese oak by sulfuric acid of an air pollutant. and prevention from withering by charcoal

OMORI, Teiko[1*] ; YOSHIIKE, Yuzo[2] ; OKAMURA, Shinobu[3] ; IWASAKI, Masato[4]

[1]Teiko Omori, [2]Yuzo Yoshiike, [3]Shinobu Okamura, [4]Masato iwasaki

The sulfuric acid which generates by the combustion of a fossil fuel is carried by wind and adheres to trees and only water evaporates and the sulfuric acid concentrates and accumulates.Sulfuric acid is dropped on the root of a tree by rain and it acidi?es the soil.The metal ingredient in the soil becomes a soluble compound.The eluted metal ion is absorbed by trees and it combines with phosphoric acid.The trees become shortage of phosphoric acid and decay.If the tannin contained in Japanese oak combines with metal ion it becomes harmless to insect.Withering of trees originates in acidi?cations of soil.Charcoal can neutralize the acidi?ed soil.The results of an investigation are explained on the basis of consideration from chemical standpoint.

Chemical dynamics of snow in the Japanese Alps region

KURAMOTO, Takayuki[1*] ; SASAKI, Akihiko[1] ; SUZUKI, Keisuke[1]

[1]IMS, Shinshu University

The Japanese Alps region is one of the heaviest snowy regions in Japan. In this area, winter precipitation is observed mainly two patterns such as winter monsoon pattern and low pressure pattern. Therefore, the chemical characteristics of the snowpack are different by snowfall types. In this study we aimed to clarify chemical dynamics of snowpack in the Japanese Alps region. We conducted a snow pit studies in the Japanese Alps region. We collected snow samples at the large flat place without obstruct by trees and the impact of human activities. The samples were melted, then pH, electric conductivity and major ions (Na^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, $NO_3{}^-$ and $SO_4{}^{2-}$) were analyzed in clean room. The Na^+ concentration correlates well with Cl^- concentration. These ions are considered to be sea-salt components. On the other hand, $SO_4{}^{2-}$ concentrations included non-sea-salt components.

Change for chemical compornent of rime ice in two decades

NAGAFUCHI, Osamu[1*] ; YOKOTA, Kuriko[2] ; NAKAZAWA, Koyomi[1] ; HISHIDA, Naoko[1] ; IKEDA, Keisuke[1]

[1]the University of Shiga Prefecture, [2]Toyohashi University of Technology

Rime-ice and snow samples were collected at mountainous sites in Kyushu Island, Japan during from 1991 to 2014, and both soluble and insoluble substances in the melted rime-ice were analyzed by ion chromatography, inductively coupled plasma-mass spectrometry (ICP/MS) and analytical electron microscopy, in order to find the change of composition ratio of atmospheric pollutants cause by East Asian region. Although N/S ratio in rime-ice ranged from 0.1 to 0.3 in 1990's, recent year this ratio increased about 1.0. This phenomenon indicates that the composition of atmospheric pollutants changed during two decades in Eat Asian Continent.

Variations in chemical composition of suface ice and meltwater on Svalbard glaciers

KONNO, Yudai[1*] ; TAKEUCHI, Nozomu[1]

[1]Graduate School of Science, Chiba University

Snow and ice on glaciers usually contain small amounts of various soluble substances. These chemical substances were supplied through the atmosphere, rain, and snow. Chemical substances in glacier surface ice and melting water are important to understand atmospheric circulation, material cycle and the ecology of glacial microbes. We analyzed the major soluble ions of surface ice, melt water, and fresh snow for three glaciers (Austre Broggerbreen, Midtre Lovenbreen, and Pedersenbreen) in the northwestern part of Svalbard in the melting season of 2013.

The concentrations of all of the solutes were low generally, but the compositions varied among the samples. Based on the significant correlation on the concentration of each samples, the solutes could be classified into 3 groups: Group A (Cl^-, SO_4^{2-}, Na^+),B (Mg^{2+}, Ca^{2+}), and C (NO_3^-, NH_4^+, K^+). They are likely to be derived from different sources. Group A solutes are probably sea salt origin, and Group B solutes are terrestrial dust origin, and Group C are anthropogenic or other unknown origin.

The altitudinal distribition of the concentration on Austre Broggerbreen showed that Groupe A (sea salt) solutes varied significantly although Group B (dust) solutes did not. Group A solutes were particularly higher in the higher area of the glacier. This variation can not be explained by distance from sea. It is probably due to supply from snow area remaining upper part of the glacier.

The chemical composition of the melting water was generally similar to those of the ice at the same site. However, some of the solutes (K^+ and SO_4^{2-}) were more abundant in meltwater than glacier ice at specific locations. This is probably due to supply from upper part of the glacier.

[1]University of Toyama/JAMSTEC, [2]JAMSTEC, [3]Institute of Tibetan Plateau Research, Chinese Academy of Science, [4]Hokkaido University, [5]Tohoku University, [6]Institute of Meteorology, Hydrology, and Environment, Mongolia

It is necessary for the southern limit of snow cover and the semi-arid region to be supplied with sustainable water. Mongolia is located in the southern limit and the semi-arid region. The capital, Ulaanbaatar, lies in a valley on the Tuul River. In order to investigate the actual conditions of snow water equivalent (SWE) in the upper Tuul River as water resources, the snow survey in the upper Tuul River has been carried out from 2002 to 2013. We have observed in each February when it will be the maximum amount of SWE. The snow water equivalent was estimated using a cylindrical snow sampler with 0.005-m^2 area. The total amount of SWE in the upper Tuul River basin was estimated using a global digital elevation model (DEM) with a horizontal grid spacing of 30 arc seconds (GTOP30) and a relationship between altitude and SWE. The main results obtained are shown below. The amount change of SWE in the upper Tuul River basin fluctuates over multiple years. The range of fluctuation was $0.25 \pm 0.07 km^3$. It was not necessarily fluctuating in monotone. The steep rise of the amount of SWE in the upper Tuul River basin coincides with increasing air temperature and snowfall roughly.

Identifyig the ice thickness of five perennial snow patches in the Tateyama Mountains based on GPR soundings

FUKUI, Kotaro[1*] ; IIDA, Hajime[1]

[1]Tateyama Caldera Sabo Museum

We carried out ground penetrating radar (GPR) soundings in the Kuranosuke, the Hamaguri-yuki, the Tsurugisawa, the Chojiro and the Ikenotan-migimata perennial snow patches in the Tateyama Mountains, the northern Japanese Alps since 2012. The Kuranosuke and the Ikenotan-migimata perennial snow patches had large ice masses (>30 m in thickness). We had measured the surface flows of both ice masses since 2011. The maximum surface flows of the Ikenotan-migimata and the Kuranosuke perennial snow patches were about 2 m a^{-1} and 0.14 m a^{-1}, respectively. Thus, we regard the both snow patches as active glaciers.

The Hamaguri-yuki, the Tsurugisawa and the Chojiro perennial snow patch had thin ice masses (<20 m in thickness). It is possible that these ice masses are not flowing at the present time. Thus, we guess that these snow patches are glacierets rather than active glaciers.

Studies on internal structure of active glacier in the Tateyama Mountains

IIDA, Hajime[1*] ; FUKUI, Kotaro[1]

[1]Tateyama Caldera Sabo Museum

In 2013, we carried out 20 m depth boring in the Sannomado Glacier (2000 m above sea level), in the Tateyama Mountains, the northern Japanese Alps. The 20 m core was analyzed paying attention to the structure of firn and ice.The following observations were carried out;

(i) stratigraphic observation of snow layer and glacier ice.
(ii) measurement of density profi1e.
(iii) measurement of grain shape and profile of grain size.
(iv) observation of elongation of air bubbles.

The internal structure of the Sannomado Glacier was characterized by obvious boundary between firn and ice. At the depth of 5m, there was a distinct dirt layer formed in the last autumn. Above this dirt layer, firn transformed into ice abruptly and the density curve showed a discontinuity to 850kg/m^3. The temperature of the snow and ice measured in the borehole was 0 ℃ throughout the layer. Spouting water was found in the borehole, indicating an aquifer in the glacier. From these results, such a rapid transformation process from snow to ice in this glacier will be discussed.

The grain size gradually increased with depth and elongation of air bubbles was shown below 15m which suggests internal flow of the glacier.

Contribution ratio of glacier discharge to the river water in Mongolian Altai

KONYA, Keiko[1*] ; KADOTA, Tsutomu[1] ; DAVAA, Gombo[2] ; PURVDAGVA, Kalzan[2]

[1]JAMSTEC, [2]IMHE, Mongolia

The discharge from glaciers is an important theme for arid regions like Mongolia. The water from glaciers are accounted for the important water resources in Mongolia where little water is supplied from precipitation. It is to be revealed that how much water is available from the glaciers. In this study, we estimate how much water is available in the present states and in the future by analyzing water chemistry and water quantity.

We have measured the discharge, water temperature, electric conductivity (EC), pH, dD, d18O of the river at the beginning, middle and end of the melt season of the glacier. The contribution rate of the melt water to the river water were estimated by the two methods; A) discharge and EC, B) glacier melt rate.

The contribution rate was estimated to be 20-50 % of the flow. The future change of the contribution rate was estimated by method B with the temperature warming rate in the future estimated by the climate models in Mongolia. The results show that the river water is supposed to be increasing in next some decades and decreasing in next century. The snow melt water to the river is also need to be taken into account.

Comparison of surrounding land features on the glacier terminal areas in the Himalayas derived from DEM

SUZUKI, Ryohei[1*]

[1]none

Radiation field on the surface of mountain glaciers is reported to be controlled by the surrounding land features and does not distribute uniformly. Net radiation, which is obtained as a result of radiation budget, has been reported as an important factor to melt the ice surface of glaciers in the Himalayas by the previous studies. On the other hand, the lower areas of many glaciers in the south area of Himalayas are covered with debris that has variety of thermal properties, which corresponds to the one of the factor to cause the spatial variety of ice melt rates fields. Considering the surrounding land form features in the radiation field is probably required for estimating thermal properties on the debris-covered glaciers accurately. However, in-situ observation of those phenomena cannot be conducted mainly due to the difficulties of accessibility to the Himalayas. Thus, application of satellite remote sensing techniques is a powerful tool as an alternate method.

This study focuses on the Lunana region, Bhutan, which corresponds to the target area where in-situ observation has been carried out since 2002, as a case study to estimate the influence of surrounding land features around the lower glacier areas on their radiation field. I calculated a distribution of azimuth and zenith angles from each target point (pixel) on the lower glacier areas to each direction to the skylines with an approximate method to derive surrounding land feature; the value 1 corresponds to the full sky view and it decreases to 0 with the decrease of openness. My first result, which was derived from 8 directions for each pixel with the limit of about 4.5 km far from the point as a line of sight, shows it ranges from 0.7 to 0.9 regarding the three glaciers; Thorthormi, Lugge and Lugge Ⅱ.

Because these values depend on the method to move the line of sight on the DEM, in other words, the method for processing the raster image as well as the accuracy of both elevations and horizontal positions, I would also like to present the other experimental results that were calculated with some different conditions to discuss the influence of the surrounding land form on the radiation field in the Himalayas.

Glacier lake and glacier lake outburst floods in Tien Shan and Ladakh Range

NARAMA, Chiyuki[1*] ; KAZEHARE, Saiga[1] ; YAMAMOTO, Minako[1] ; UKITA, Jinro[1] ; IKEDA, Naho[2] ; TADONO, Takeo[3]

[1]Niigata University, Department of Environmental Science, [2]Tohoku University, Institute for Disaster Reconstruction and Regeneration Research, [3]JAXA

As a result of recent glacier melting, present glacier lakes develop rapidly at glacier fronts in Tien Shan Mountains, Central Asia and Ladakh Range, Indian Himalayas. Although glacier lakes in the Tien Shan and Ladakh Range are small, compared to those in the eastern Himalayas (Bhutan and eastern Nepal), several GLOFs in the past have caused fatalities and serious damage to infrastructure and crops. With recent changes in the development of glacier lakes in these mountain regions, floods are becoming an increasing threat to local residents. However, the current status of glacier lakes is poorly characterized in this region. In this study, we researched glacier lakes in the Tien Shan Mountains and Ladakh Range using high-resolution ALOS/PRISM-AVNIR-2 images taken in 2007-2010. In addition, we report the characteristic of glacier lake and glacier lake outburst floods (GLOFs) in Tien Shan, using investigation of the appearance of glacier lake and GLOFs in the past.

We examined about 1600 glacier lakes ($>$0.001 km^2) in the Tien Shan. Although glacier lakes are distributed throughout the Tien Shan Mountains, regional differences in their number and size are large. Larger glacier lakes are found in the Teskey and Ili-Kungoy regions, whereas most small glacier lakes occupy other mountain ranges (4000-5000 m asl), such as the Pskem, Talas, and Kyrgyz Ala-Too ranges. In seven mountainous regions, many present-day glacier lakes have appeared since the 1980s. Glaciers in these mountain regions are most glacier shrinkage area in Tien Shan over the 30 years, and these glacier lakes appeared after glacier shrinkage area. We report our results in detail in JpGU meeting.

Chemical Composition on the surface in the Urumqi No.1 glacier, Tien Shan, China

WAKABAYASHI, Kozue[1] ; TAKEUCHI, Nozomu[1*] ; TANAKA, Sota[1] ; AMEMIYA, Shun[1]

[1]Graduate School of Science, Chiba University

Various chemical solutes are deposited in snow and ice on glaciers. Such solutes are usually washed out of glaciers during melting season. However, concentration and composition on snow and ice during melting season are little known. The solutes are important to understand microbes living on the glacier surface since chemical conditions affect their growth. In this study, we analyzed chemical compositions of ice surface in the melting season on Urumqi glacier No.1, Tien Shan Mountains in central Asia. Results showed that calcium ion was dominanted more than 60% in all of the area on the glacier. This indicates that the chemical composition on the melting glacial surface is greatly affected by dust from desert in this region. Total concentration of nigrogen solutes (ammonium) was highest in the middle part of the glacier. Measurements of chlorophyll a concentration revealed that it was also maximal in the middle of the glacier. The altitudinal variation of solutes may affect the algal community and biomass on the glacier.

Digital-image processing to analyze grain size variation in ice core from Gregoriev Ice Cap, Kyrgyz Tien Shan

MATSUHASHI, Yuta[1*] ; FUJITA, Koji[1] ; TAKEUCHI, Nozomu[2] ; VLADIMIR B, Aizen[3]

[1]Nagoya University, [2]Chiba University, [3]University of Idaho

It is known that impurities in ice core (etc. dust from continental) prevent grain growth rate at high-latitude regions. On the other hand, the effect of impurities for grain growth is not understood for ice cores retrieved from mid-low latitude glaciers, despite of higher dust concentration. This study aims to reveal relation between dust and grain size in an ice core drilled at Gregoriev Ice Cap, Kyrgyz Tien Siam in 2007.

We made thin sections which are reduced to thickness of 0.4mm. Three different images were taken by changing angle of crossed polarizers (0 deg, 30 deg, 60 deg). Changing controlled contrast and RGB, we converted the images into binary. Grain boundaries are then able to be picked by digital image-processing. This process made efficient extracting boundary and obtain area of grain using binary images.

We will present detailed procedures and preliminary results of comparison with dust concentration along the ice core.

Post-depositional alteration of major ions under different accumulation environment in Antarctica

HOSHINA, Yu[1*] ; FUJITA, Koji[1] ; IIZUKA, Yoshinori[2] ; MOTOYAMA, Hideaki[3]

[1]Nagoya University, [2]Institute of Low Temperature Science, Hokkaido University, [3]National Institute of Polar Research

Major soluble ions and water stable isotopes are important for reconstructing paleo-environment and atmosphere circulation. It is also known that ion and isotope signals are modified after deposition if firn or ice core samples are analyzed at high temporal resolution such as seasonal scale. In inland Antarctica, we revealed that low accumulation rates have resulted in significant post-depositional modification of ions and isotopes due to long time exposure of snow near the surface.

We further investigated relation between major ion concentration and accumulation rate using a several snow pits and firn cores taken from east and west Antarctica. To exclude the geographical factor (east or west), we analyzed correlations with ions against oxygen stable isotope. Correlations of sea salt against oxygen stable isotope are gradually changed from no correlations under higher accumulation sites near coast to more negative correlations under dry environment in inland. On the other hand, correlations of MSA (methanesulfonic acid) against oxygen stable isotope rapidly are changed from positive to negative correlations at 100 kg m^{-2} a^{-1} of accumulation sites. Those different trends suggest different mechanisms of post-depositional modification for these ion species.

Greenland temperature variations in the last millennium climate simulation

YOSHIMORI, Masakazu[1*] ; ABE-OUCHI, Ayako[1]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo

A series of climate simulations of the last millennium are conducted using the MIROC climate model. These include a simulation under volcanic-only, solar-only, or total forcings. Sensitivity experiments using different strength of volcanic and solar forcings are also conducted. With these dataset, we analyze the factors that influence Greenland temperature variations during the last millennium. Attention is paid to the effect of different external forcings and changes in the atmosphere and ocean circulations such as the North Atlantic Oscillation and the Atlantic meridional overturning circulation.

In this study, we analyze the result of Last Millennium (LM) Experiment using GCM and ESM, to verify the response of the cryosphere to the hundereds-year-scale climate change. In addition to the sensitivity analysis between the forcing conditions, comparison with existing climate/paleoclimate data. The period of the LM experiment covers the Little Ice Age and Medieval Climate Anomaly, and responses of the cryosphere during those periods are of interest.

The models used in this study are the Atmosphere-Land-Ocean General Circulation Model MIROC and the Earth System Model MIROC-ESM. Resolution of atmosphere/land components are T42 (ca 2.8o) in horizontal, 80 layers in vertical. Ocean component has a resolution of 1.4o (longitude) by variable 0.56?1.4o (latitude) in the horizontal and 44 levels in the vertical. As an ESM, MIROC-ESM has a carbon-cycle components for the land and ocean ecosystems. Setup of the experiments follow the protocol of model inter-comparison CMIP5/PMIP3.

As preliminary results, temporal variations in surface air temperature, snow amount, and snow/rain ratio for Siberia region was analyzed. Winter warming during 20th century is clear. Signatures are shown in rise of February Temperarure, decrease in snow amount, increase in runoff during spring. Ratio of Snow fall / Precipitation is sensitive to the temperature, which may caused the above-mentioned trends in snow.

Cosmogenic nuclides (^{10}Be, ^{14}C, ^{26}Al, ^{36}Cl) in paleoenvironmental archives serve as a proxy indicator of the paleointensity of cosmic ray, controlled largely by the strength of the solar/geomagnetic fields. Here, we present a millennial record of cosmogenic ^{10}Be covering the past 300 kyr and obtained from ice cores drilled at the Dome Fuji station (77^{o}19'S, 39^{o}42'E), inland East Antarctica. A number of specific increases in ^{10}Be were observed in this record and were connected semi-quantitatively to those in the cosmic-ray intensity caused by geomagnetic excursions during the last 300 kyr. These features can be used as stratigraphic time-markers for synchronization of not only Antarctic ice cores but also various paleoenvironmental archives such as deep-sea sediments

Investigation of the roles of different forcings (e.g. orbital variations and greenhouse gases) on climate and sea level requires a paleoclimate chronology with high accuracy. Such a chronology for the past 360 ky was constructed through orbital tuning of O2/N2 ratio of trapped air in the Dome Fuji and Vostok ice cores with local summer insolation (Kawamura et al., 2007). We extend the O2/N2 chronology back to ˜500 kyr by analyzing the second Dome Fuji ice core, and find the duration of 11 ka, 5 ka, 9 ka, and 20 ka for MIS 5e, 7e, 9e and 11c interglacial periods in Antarctica, with similar variations in atmospheric CO2. The termination timings are consistent with the rising phase of Northern Hemisphere summer insolation.

Marine sediment cores from northern North Atlantic contain millennial-scale signatures in various proxy records (e.g. SST, IRD), including abrupt climatic shifts and bipolar seesaw. Based on the bipolar correlation of millennial-scale events, it is possible to transfer our accurate chronology to marine cores from the North Atlantic. As a first attempt, we correlate the planktonic d18O and IRD records from the marine core ODP 980 with the ice-core d18O and CH4 around MIS 11. We find that the durations of interglacial plateaus of planktonic d18O (proxy for sea surface environments) and benthic d18O (proxy for ice volume and deep-sea temperature) for MIS 11c are 20 and 15 ka, respectively, which are significantly shorter than originally suggested. These durations are similar to that of Antarctic climate and atmospheric CO2. However, the onsets of interglacial levels in ODP980 for MIS 11 are significantly later than those in Antarctic d18O and atmospheric CO2 (by as much as ˜10 ka), suggesting very long duration (more than one precession cycle) for the complete deglaciation and northern high-latitude warming for Termination V. Atmospheric CO2 may have been the critical forcing for this termination. The long duration of Termination V is consistent with our new ice sheet simulations (extended from the work of Abe-Ouchi et al., 2013) in which an ice-sheet/climate model is forced by insolation and CO2 variations. In the presentation, comparisons for other interglacial periods will also be reported.

What is the major factor which control global climate in the ice age?

KUMON, Fujio[1*]

[1]Faculty of Science, Shinshu University

The author and his co-workers have been analyzed total organic carbon (TOC) and total nitrogen (TN) contents of the various lake and marine sediment cores. The temporal changes of TOC show quasi-periodic fluctuation patterns similar to LR04 marine oxygen isotope curve and delta 18O profile of NGRIP ice core. Among the several long records of TOC in and around the Japanese islands, the TOC record from the Japan Sea is the most excellent one, and can be correlated precisely with the NGRIP record both on the orbital- and millennial time-scale in the ice ages.

This intimate relationship of climate is confirmed between Greenland and the Japanese islands. The good concordance of climate change can be explained by a hypothesis that extension of ice sheets in the Arctic region is major factor to control global climate not only in orbital-time scale but also in millennium-time scale.

The influence of glacial ice sheet on Atlantic Meridional Overturning Circulation through atmospheric circulation change

SHERRIFF-TADANO, Sam[1*] ; ABE-OUCHI, Ayako[1] ; YOSHIMORI, Masakazu[1] ; CHAN, Wing-le[1]

[1]Atmosphere and Ocean Research Institute, University of Tokyo

In glacial period, huge ice sheet covered the North America and the Northern Europe. Also, the Antarctica Ice sheet had expanded and increased its altitude. It is well known that these ice sheets (hereafter glacial ice sheets) have large influence on climate, for example atmospheric circulation, surface air temperature, and sea surface temperature. On the other hand, recent studies showed that wind stress changes play a crucial role on the AMOC under glacial climate. Moreover, increasing evidence suggests that glacial ice sheets have large influence on the Atlantic Meridional Overturning Circulation (AMOC). However the process how the ice sheets cause such a large impact on the AMOC is yet fully understood. Thus, in this study, we aim to reveal the detailed process of the ice sheet affecting the AMOC through atmospheric circulation change.

Commonly, the Atmosphere-Ocean General Circulation Model (AOGCM) is used to assess the influence of the ice sheet on the AMOC. However, as the atmospheric general circulation model (AGCM) and ocean general circulation model (OGCM) interacts in this model, the wind change as well as other process affect the AMOC. Therefore, it is difficult to divide each effect. Using the AGCM and the OGCM separately can overcome this problem because in this manner, they do not interact and the wind stress or other process can be treated as a boundary condition for the OGCM. This method consists of 2 steps. First, by using the AGCM, the effect of glacial ice sheets on the surface wind stress are evaluated by adding glacial ice sheets as a boundary condition. Second, by using the wind stress result as a boundary condition for the OGCM, the influence of the wind stress change on AMOC is estimated. In addition, by analyzing the results from each model, the underlying mechanism is explored.

As a result, glacial ice sheets largely intensified the AMOC under glacial climate. It was also found that the wind stress change at North Atlantic was important, thus glacial ice sheets at northern hemisphere were important. On the other hand, the AMOC was hardly influenced by wind stress change at Southern Ocean, which is mainly induced by the change in the Antarctica Ice sheet. Therefore change in the Antarctica Ice sheet had small impact on AMOC through surface wind stress change.

By analyzing the results from the AGCM and OGCM, it revealed that two processes were crucial; first, the strengthening of the northward salt transport, which resulted from enhanced westerly due to the North America Ice sheet. Second, the northward sea ice transport due to the southerly wind at Norwegian Sea forced by the Northern Europe Ice sheet. These two processes were found to drastically intensify the AMOC through affecting the sea ice distribution and shifting the NADW formation region.

Reconstruction of paleo-vegetation distribution by using an atmosphere ocean coupled GCM and a DGVM

O'ISHI, Ryouta[1*] ; CHAN, Wing-le[2] ; ABE-OUCHI, Ayako[2]

[1]National Institute of Polar Research, [2]Atmosphere and Ocean Research Institute, the University of Tokyo, [3]JAMSTEC

" The replacement of Neanderthals by Modern Humans has been considered to have occurred during 60,000-30,000 BP, which is also characterized by millennial scale climate change known as the Dansgaard?Oeschger events. The distribution of Neanderthals and Modern Humans during this period suggests correlation with that of paleo-vegetation and animals. This relation reflects the difference between the adaptabilities of Neanderthals and Modern Humans to environmental changes by way of their ability to hunt animals as food resources. Hence, it is important for the RNMH project to predict distribution of fauna, flora and climate change during this period. When estimating fauna distribution of the past, it is necessary to evaluate the changes in flora and thus changes in climate of the past. This can be directly achieved by examining data from sediment proxies, e.g. pollen records and isotopes. However, the availability of such proxies to reproduce the distribution of flora and climate changes is limited.

In the present study, we tried to reconstruct the vegetation distribution across North Africa, the Mediterranean and Europe during 60,000-30,000 BP from the results of a paleo-climate reconstruction by using a general circulation model as input for a dynamical global vegetation model. GCMs consume huge amounts of computational resources and so experiments are usually run using lower resolution models whose grid sizes are not sufficiently small for anthropological studies. In this study, we developed an " anomaly procedure " in order to incorporate features from both a high-resolution model and paleoclimate information. As a result of this new method, we successfully obtained a high-resolution vegetation distribution for a specific period of the past. However, it is not yet clear how these results can be validated against paleovegetation records. We need further discussions on how the appropriate paleoclimate can be reproduced by the GCM and how the vegetation model results can make a robust contribution toward the RNMH project.

Arctic amplification and the Greenland ice sheet at the Last Interglacial: the role of vegetation feedback

ABE-OUCHI, Ayako[1*] ; O'ISHI, Ryouta[1] ; TAKAHASHI, Kunio[2] ; SAITO, Fuyuki[2]

[1]University of Tokyo AORI, [2]JAMSTEC

We calculated the climatic conditions, mass balance and the transient volume of the Greenland ice sheet in the last interglacial period using the atmosphere slab-ocean vegetation general circulation model ASVGCM MIROC-LPJ and IciES ice sheet model. Taking into account the vegetation feedback, the annual mean temperature anomaly increases from +1 K to +2 K, and of summer temperature anomaly from +4 K to +6 K in central Greenland. This is close to the +5 K at NGRIP and +8 K at NEEM as inferred from ice core isotope data, which takes into account that summer precipitation contributes more to oxygen isotope values{reference}. The vegetation feedback, also increases precipitation by 20% averaged over the entire ice sheet and by 30 % in northwestern Greenland. The combination of the sea ice-temperature feedback and the vegetation feedback amplifies both the temperature and precipitation changes in the Eemian.

The increased ablation caused by high temperatures in central Greenland is partly compensated by the increased precipitation. The ice volume loss of Greenland in the Eemian compares to present day amounts to 1 to 2.5 meters sea level equivalent depending on the inferred present day reference climate and model parameters, such as lapse rate. The spatial pattern of increased temperature and increased precipitation is supported by the fact, that the modeled Eemian Greenalnd ice sheet covers all locations of ice core cites (GRIP/GISP, NGRIP, NEEM and Dye3), for which the existence of Eemian ice is confirmed. The reconstructed sea level elevations in the Eemian range from 6 to 9 m{references} above present day sea level. Thus, our results imply that the larger part of the difference in sea level between Eemian and present day stems from the Antarctica ice sheet.

Sensitivity of Greenland ice sheet to climatic parameters during the last interglacial

TAKAHASHI, Kunio[1*] ; ABE-OUCHI, Ayako[2] ; SAITO, Fuyuki[1] ; O'ISHI, Ryouta[3]

[1]Japan Agency for Marine-Earth Science and Technology, [2]Atmosphere Ocean Research Institute, University of Tokyo, [3]National Institute of Polar research

In the last interglacial (LIG), sea level was 5 to 9 m above present, including contribution from Antarctica. Whole melting of the Greenland ice sheet (GIS) can contribute to the global sea-level rise of up to 7 m. It is important source of sea-level change. In the previous IPCC report in 2007 (IPCC AR4), estimates the GIS contribution to sea-level change during LIG range between 4 to 6 m. New IPCC AR5 points out that based on ice-sheet model simulations consistent with elevation changes derived form a new Greenland ice core, the Greenland ice sheet *very likely* contributed between 1.4 to 4.3 m sea level equivalent.

In this study, we present numerical experiments of GIS from 140 ka to 110 ka by using anomaly approach (present-day climate + perturbation obtained from MIROC-AGCM simulations including dynamic vegetation). We focus on the influence of the climatic parameters such as AMOC or northern hemisphere ice sheets. Our results are consistent with IPCC AR5. Considering of transient response to transient climate change are important to moderate ice melting. Several uncertainties remain however, such as the reference climate condition (influence melt from south, north or both?). and related the ice sheet model itself, more numerical studies are required.

We study the implications of a recently published ice sheet history in Northern hemisphere and Greenland ice sheet, derived from the 3D thermo-mechanical ice sheet model (Ice Sheet for Integrated Earth system Studies: IcIES developed by Abe-Ouchi et al. 2013). To characterize the effects of this glaciologically consistent ice sheet history, we examine the time-variations of various geophysical quantities in response to the ice and water mass redistributions. They include vertical uplift and subsidence, global patterns of sea-level change, and regional sea-level variations along the coasts of Greenland. Relative sea-level (RSL) changes in response to past ice and water load variations are obtained solving the sea-level equation, which accounts for the crustal deformation due to glacio-isostatic adjustment (GIA). In this study, we report the predictions of RSL and geodetic signals in Greenland induced by GIA process based on the glaciologically and climatologically consistent ice loading history. And also, we show the temporal and spatial characteristics of predicted geophysical signals in Greenland in comparison with these observations. We expect that using the ice sheet histories derived from IcIES as input in GIA model may put better constraints on postglacial rebound and current rates of crustal deformation.

Chemical compositions of non-volatile particles in NEEM (Greenland) ice core over the last 100,000 years

OYABU, Ikumi[1*] ; IIZUKA, Yoshinori[2] ; KARLIN, Torbjorn[3] ; FUKUI, Manabu[2] ; HANSSON, Margareta[3]

[1]Graduate school of Environmental Science, Hokkaido University, [2]Institute of Low Temperature Science, [3]Department of Physical Geograohy and Quaternary Geology, Stockholm University, Sweden

The polar ice cores provide us with information of past atmospheric aerosols. Soluble aerosols in polar ice cores are well discussed by using proxies of ion concentration/flux, however, there are few studies about chemical compositions of soluble aerosols in ice cores. Using a sublimation method, we show differences in the compositions of non-volatile aerosols over the last 100,000 years in the NEEM ice core, which was drilled during 2008?2012 on the northwest ridge line of Greenland ice sheet (77 ′ 27 ″ N, 51 ′ 03 ″ W).

A total of 86 samples were distributed from NEEM ice core sections from 220 to 2195 m, which covers from late Holocene to Dansgaard-Oeschger event 24. Non-volatile particles were extracted from the ice by sublimation system [Iizuka et al., 2009]. Constituent elements of each non-volatile particle were measured by a scanning electron micro scope and energy dispersive X-ray spectroscopy. We made a classification of non-volatile particles into insoluble dust, soluble sulfate salts and soluble chloride salts as following; if Si found in a particle, we regard the particle as dust (Silicates); if S found, we regard the particle as sulfate; if Cl found, we regard the particle as chloride salt. For the sulfate salt, we did further classification that a particle containing Ca and S are assumed as CaSO4, Na and S are Na2SO4, Mg and S are MgSO4, K and S are K2SO4, the residual sulfate particles are " the other sulfate salt (other-S) " . In the same way, for chloride salts, we assumed NaCl, CaCl2, MgCl2, KCl and the other chloride salt (other-Cl).

The number ratio of soluble salts to total particles is 9±6 % during Dansgaard?Oeschger (DO) events. In Last Glacial Maximum (LGM), the ratio decreased in 3±2%. In Bolling-Allerod (BA), ratio of soluble salts slightly increased (10±5%). In Younger Dryas (YD), the ratio decreased again (6±3%). After Holocene, the ratio increased (16±10 %). In summary, more than 90 % of particles contain insoluble dust during the cold stages. These ratios suggest that during cold periods, insoluble dust concentration is higher contribution to total non-volatile particles than that in warm periods.

We examined chemical characteristics of non-volatile particles by dividing into 7 climatic stages (Late Holocene; LH, Early Holocene; EH, YD, BA, LGM, DO events-warm; DO-W and DO events-cold; DO-C). The 7 stages can be sorted into 2 types; interglacial-type (LH, EH and BA) and glacial-type (YD, LGM, DO-W and DO-C). For the interglacial-type, number of Na-containing particles is larger than that of Ca-containing particles (Na:Ca = 4:3). On the other hand, for the glacial-type, number of Ca-containing particles is larger than that of Na-containing particles (Na:Ca = 5:9). Ca-containing particles is suggested to mainly comes from terrestrial materials and Na-containing particles is mainly comes from sea-salt [Steffense et al., 1997]. Our results of the ratio of Ca and Na particles may be explained by not only absolute concentration of dust and sea-salt but also relative valance of those concentrations. In the three interglacial-type, the ratio of other-S and other-Cl, those are sulfate and chloride salts without Na, Mg, K, nor Ca, during the LH are relatively higher than the other stages. Since NH4+ concentration increased due to increasing of vegetation area and biological activity by warming in LH [Fuhrer and Legrand, 1997], other-S and ?Cl might be ammonium sulfate and ammonium chloride, respectively. Focusing on Ca-particles more in detail in the four glacial-type, number of Ca-containing particles without S and Cl is higher in LGM (11%) and DO-C (12%) than that in YD (6%) and DO-W (7%). Since the X-ray spectroscopy cannot detect carbon, the Ca-containing particles may be CaCO3 in the LGM and DO-C because CaCO3 was founded during the LGM by single particle measurement in the GRIP (Greenland) ice core [Sakurai et al., 2009].

Modelling the climate and the terrestrial carbon cycle for the last millennia

ABE-OUCHI, Ayako[1*] ; O'ISHI, Ryouta[1] ; YOSHIMORI, Masakazu[1]

[1]University of Tokyo AORI

Climate-induced changes in the terrestrial biosphere and the ocean modulate the release and uptake of carbon dioxide and this, in turn, alters atmospheric composition and influences the climate. This is known as the climate-carbon cycle feedback. The Coupled Carbon Cycle Climate Model Intercomparison Project (C4MIP), using models of the ?terrestrial and ocean carbon cycles inside ocean-atmosphere general circulation models, has shown that the carbon cycle-climate feedback appears to be positive BUT there is great uncertainty about the magnitude. It is important to know the magnitude of this feedback because it affects the amount of carbon dioxide that can be emitted in the future in order to stabilize the concentration of CO2 at a given level. There are projects attempting to reduce these uncertainties through systematic evaluation of carbon cycle models against observations of the contemporary carbon cycle. An alternative approach is to use knowledge about past variations in climate and CO2 to provide additional constraints. Here we therefore work on the last millennium (LM) climate-carbon modeling and examine the factors that contribute to atmospheric CO2 change. Ice core is the only proxy that provides the CO2 content in detail for the last millennium and it shows up to 10ppm change around the Little Ice Age and during the LM. Several LM experiments by AOGCM are used to drive the terrestrial carbon cycle model LPJ. We investigate the role of external forcing of climate such as volcano and solar forcing as well as that of internal variability of climate in an unforced experiment of decadal to centennial time scale. We show that the CO2 changes in the same order of magnitude in the unforced experiment as in the forced experiment.

Concentration and Potential Mobility of Trace Metals in Surface Sediment of the North Pacific Ocean By BCR Sequential

ANDREAS, Roy[1*] ; ZHANG, Jing[1]

[1]Graduated school of science and engineeringUniversity of Toyama

Metals can accumulated in sediment, sludge and soil may therefore pose an environmental problem concerning possible metal transfer from sediment to the aquatic system and including them in the food chain. European Community Bureau of Reference (BCR)sequential methods commonly used to trace metals in the sediment or soil samples and can be provide information about bio-availability, mobility or toxicity which are basically depend on the chemical bonding between metals and solid phases of the samples.

Geochemical fractionation of Cadmium (Cd), Lead (Pb), Cobalt (Co), Zinc (Zn), Iron (Fe) and Manganese (Mn) in sediment of the North Pacific Ocean were determined using four-stages of modified BCR sequential extraction methods combination with ICP-MS. Also the contamination factors and risk assessment code effects on surface sediment samples are discussed.

The mean contents of the trace metals in surface sediment of the North Pacific Ocean were: Cd: 0.00; Pb: 13.94; Mn: 2732.94; Fe: 29795.10; Co: 22.16; and Zn:76.75 $\mu g.g^{-1}$, allowing to arrange the trace metals concentration from higher to lower were in the following order: Fe › Mn › Zn › Co › Pb › Cd. Pb was distributed in three fractions (acid soluble, reducible, and residual). Mn and Co were found in a group with mainly reducible fraction, while Fe and Zn were mainly in residual fraction. The high contamination factor was obtained for Mn and Co in the sediment samples, while the lowest was found for Fe. The result showed non risk for Fe, Co, Pb and Cd, while low risk is indicated for Mn and Zn at all stations.

Leaching Properties of Naturally Occurring Heavy Metals from the Soils around Abandoned Metal Mines

ZHANG, Ming[1*] ; HOSHINO, Mihoko[1] ; HARA, Junko[1] ; SUGITA, Hajime[1] ; YOSHIKAWA, Miho[2] ; IMOTO, Yukari[1]

[1]AIST, [2]Chemical Grouting Co., LTD

The major threats to human health from heavy metals are associated with exposure to lead, cadmium, mercury, chromium, arsenic, as well as selenium, fluorine and boron. The effects of such heavy metals on human health have been extensively studies and officially reviewed by international organizations such as the WHO and heavy metal pollutions have been regulated by national environmental standards and/or laws such as the Soil Contamination Countermeasures Act in Japan.

Leaching of naturally occurring heavy metals from the soils around abandoned metal mines into surrounding water systems, either groundwater or surface water systems, is one of the major pathways of exposure. Therefore, understanding the leaching properties of toxic heavy metals from naturally polluted soils is of fundamentally importance for managing abandoned metal mines, excavated rocks discharged from tunneling and/or selecting a pertinent countermeasure against pollution when it is necessary.

In this study, soil samples taken from the surroundings of abandoned metal mines in Tochigi, Miyagi, Yamagata, Akita and Iwate prefectures in Kanto and Tohoku regions were collected and analyzed. The samples contained multiple heavy metals such as lead, arsenic and chromium. Standard leaching test and sequential leaching test considering different forms of contaminants, such as trivalent and pentavalent arsenics, and trivalent and hexavalent chromiums, together with X-ray Fluorescence Analysis (XRF), X-ray diffraction analysis (XRD) and Cation Exchange Capacity (CEC) tests were performed. This presentation illustrates the details of the above experimental study, discusses the relationships among leaching properties, and chemical and mineral compositions, indicates the difficulties associated with remediation of naturally polluted sites, and emphasizes the importance of risk-based countermeasures against naturally occurring heavy metals.

Self-potential inversion for the estimation of hydraulic conductivity in the presence of unsaturated zone

OZAKI, Yusuke[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1]

[1]Graduate School of Engineering, Kyoto University

Self-potential (SP) is the electrical potential naturally generated in and on the earth. The positive electrical charge in the diffuse layer of the electrical double layer is conveyed by the groundwater flow. The electrical potential is generated when the groundwater flow through the porous medium. This electrical potential directly reflects on the Darcy velocity in the porous material, and therefore the hydraulic conductivity can be estimated from the SP data. The hydraulic conductivity has non-linear characteristics as functions of the water saturation, and so does SP. These features suggest that the effect of the unsaturated zone should be considered for much quantitative analysis of SP. However, the dependency of the SP on the water saturation makes the development of inversion difficult. We solved this problem with the adjoint state method for the calculation of the sensitivity matrix that could save the calculation time. The characteristic of water saturation in SP based on Van-Genuichen model is adapted to our inversion. We applied our inversion to a synthetic SP profile to test the performance of our inversion scheme to compare the results with and without the consideration to unsaturated zone. When the effects of the unsaturated zone are not considered, the value of estimated hydraulic conductivity is underestimated. On the other hands, more accurate image could be derived from the inversion with the consideration to the unsaturated zone. Therefore, our inversion technique would allow us to obtain the accurate hydraulic conductivity structure from SP data at the ground surface, although the SP is affected by the distribution of saturation.

Root Water Uptake and Soil Water Storage in a Karst Savanna on the Edwards Plateau, Texas, USA

TOKUMOTO, Ieyasu[1*]

[1]Arid Land Research Center, Tottori University

Woody plants, especially Ashe juniper (Juniperus ashei) and honey mesquite (Prosopis glandulosa), are encroaching into a karst savanna on the Edwards Plateau in central Texas. However, their impact on hydrology is unclear because of high variability in soil depth and uncertainties about shallow and deep root contributions to water uptake in rocky soil overlying bedrock or other substrates that limit water storage capacity and root growth, and create high spatial variability in plant available water. This complex below-ground structure, while not uncommon, has of not been adequately characterized by most hydrological models. We evaluated root water uptake and water storage in the karst of the Edwards Plateau, at a typical savanna site with ˜50% woody cover, mainly Ashe juniper (Juniperus ashei) and honey mesquite (Prosopis glandulosa). Water content profiles to a depth of 1.6 m were measured by neutron thermalization and time domain reflectometry at 36 locations in a 25-by-25 m grid (5 m node spacing). Bulk density profiles were measured by gamma densitometry. Temporal changes in water storage were compared with eddy covariance measurements of evapotranspiration (ET) to evaluate relative amounts of ET originating from root water uptake at various depths. Water storage capacity in the measurement grid ranged from 185 to 401 mm, and coupled with heterogeneous distribution of trees created high spatial variability in root water uptake. Water uptake was higher beneath trees than beneath grass, in part because tree roots were able to extract water from regions of the root zone with high rock density. On average, 81% of the water uptake occurred from the upper 1 m of the profile with the greatest uptake occurring at depths of 0.4 to 0.8 m. An estimated 10% of the uptake occurred from below the maximum measurement depth of 1.6 m. While this result confirms the hypothesis that trees on rocky substrates take up water from greater depths compared to similar ecosystems on soil, it also refutes the view that trees in karst regions have greater access to groundwater.

Estimation of Water Flux in Andisol with a Penta-Needle Heat Pulse Probe

SAKAI, Masaru[1*] ; KONDO, Naho[1] ; JONES, Scott[2]

[1]Graduate school of Bioresources, Mie University, [2]Department of Plants, Soils, and Climate, Utah State University

The potential for using heat pulse probes for estimating soil water flux as well as soil thermal properties has received more attention this past decade. Although many studies were carried out to validate water flux estimation using heat pulse probes in sandy soils, few studies were reported for other soils. The purpose of this study was to estimate water fluxes in an aggregated Andisol using a heat pulse probe, and investigate the applicability with hydrodynamic dispersion in a soil.

The Penta-needle heat pulse probe, which has a central heater needle surrounded by two pairs of orthogonally arranged thermistors, was used to estimate two directional water flux. Steady-state saturated water flow and unit-gradient unsaturated water flow experiments were conducted in Mie Andisol. To achieve saturated conditions, the Andisol was packed in the column with a bulk density of 0.85 g/cm^3 and afterward it was saturated by applying water from column bottom. A glass filter was located at the bottom of the column. $CaCl_2$ solutions were applied from the top of the column at fixed rates using a peristaltic pump, and outflows from the bottom were measured by a scale. The flow rates were decreased stepwise from fast (around 350 cm/day) to slow rates (around 5 cm/day). Using faster flow steps, steady state saturated water flows were developed. Steady state conditions for unit-gradient - unsaturated water flow were developed by controlling suction at the column bottom, in which water contents were uniform and water flowed by gravity. At each flow steps, heat pulse measurements were conducted, and the influent solution concentrations were changed to obtain breakthrough curves (BTCs) by measuring soil electrical conductivities with four-probe salinity sensors. Water fluxes were estimated by applying an analytical solution to temperature rise data. Dispersivities were determined by applying the convection-dispersion equation to BTCs. Each experiment, including packing soil and water flow testing, were repeated a few times.

In saturated conditions, water fluxes estimated by the heat pulse probe agreed well with independently measured water fluxes in one experiment and underestimations were found in two cases. For unsaturated conditions, estimated water fluxes agreed well with actual fluxes even in the experiment with disagreement in saturated conditions. The flux estimation errors were compared with dispersivities which can be interpreted as the scale of water flow spreading from mean displacement position. Large estimation errors were found for experiments with large dispersivities (λ >1.5 cm), while errors were relatively small for conditions with smaller dispersivities both in saturated and unsaturated water flows. Generally, dispersivity values in aggregated Andisol is larger in saturated condition than in unsaturated condition. The experimental results in this study indicates that the applicability of heat pulse probe to aggregated soils potentially results in better water flux estimation in unsaturated conditions.

Keywords: soil water flux, heat pulse probe, Andisol, dispersivity

Geostatistical Interpolation of Thermal Properties of Boring Core Samples

MUTO, Hirou[1*] ; SAITO, Hirotaka[1]

[1]Tokyo University of Agriculture and Technology, [2]CREST, JST

Ground source heat pump systems (GSHP) that use ground or groundwater as a heat source can achieve much higher coefficient of performance (COP) than conventional air source heat pump systems. Although use of GSHP systems has been rapidly increasing worldwide, environmental impacts by GSHP systems have not been fully investigated. To rigorously assess GSHP impact on the subsurface environment, instead of relying on ”effective” properties, ground thermal properties including thermal conductivity and heat capacity need to be accurately characterized.

A geostatistical least-square interpolation method, known as kriging, has been used to characterize the spatial distribution of soil (or ground) physical (both hydrological and thermal) properties in one, two, and three dimensional domains. Kriging can estimate not only the values of an attribute at un-sampled locations accounting for spatial correlations between variables but also their uncertainties in terms of an error variance. Ordinary kriging (OK) which estimates unknown value as a linear combination of neighboring observations is one of the most commonly used kriging estimators. A secondary variable which is spatially cross-correlated with the primary variable can be used to reduce the estimation variance for the primary variable. Such method is known as cokriging. Ordinary cokriging (OCK) is one of the most commonly used cokriging estimator. The objective of this study was to compare OK and OCK in terms of estimating soil thermal properties along 50-m boreholes through the cross validation. Water content and sand content, which are relatively easy to measur, were used as the secondary attributes in cokriging.

In this study, undisturbed boring core samples were collected from two 50-m long boreholes at the campus of Tokyo University of Agriculture and Technology in Tokyo. Volumetric heat capacity (HC), thermal conductivity (TC), gravimetric water content (WC) and volumetric sand content (SC) were measured every 10-20 cm along the cores. The impact of sampling intensity on prediction errors were investigated by drawing random subsets of increasing size and using them to predict thermal properties at the remaining locations (jackknife approach). Then, subsets of N data were selected randomly or randomly per 10-m depth from the entire data set. For both sampling approaches, 50 different random subsets were selected to account for sampling fluctuations. Thermal properties at the remaining locations were then predicted.

This study showed that increasing the size of the subset leads to smaller mean absolute error. It was also found that kriging with random subsets per every 10-m depth yields lower mean absolute error than that with random subsets. Prediction errrors by OCK were smaller than those by OK when the sampling intensity was the same.

Evaluation of Tangential Model Parameters with Respect to Various Soil Types

THIAM, Magatt[1*] ; KOHGO, Yuji[2] ; SAITO, Hirotaka[3]

[1]PhD Student, United Graduate School of Agriculture, Tokyo University of Agriculture and Technology, [2]IEAS, Graduate School of Agriculture, Tokyo University of Agriculture and Technology, [3]Department of Ecoregion Science, Tokyo University of Agriculture and Technology

Usage of Tangential model (Kohgo, 1995) for Soil Water Retention Curves (SWRCs) fitting requires knowing its parameters which are the numerical values of the coordinates of 3 tree points that are selected on the SWRC obtained from an experiment. Performing such an operation might be time consuming and may also lead to errors in the parameter estimation. This study aims to estimate these parameters and investigate possible relations between the parameters and some basic soil properties. SWRCs data and their corresponding hydraulic and physical properties were taken from the Unsaturated Soil Hydraulic Properties Database (UNSODA). The selected data consisted of 458 soils; among them: sand, sandy loams, loamy sands, sandy clay loams, silty loams, silty clay loams and silty clays. These SWRCs were fitted to Tangential model using nonlinear regression analysis with solver, the in-built Microsoft Excel tool. The iteration procedure, in solver, was the Generalized Reduced Gradient method. Results showed that the model performed well. The sum of the squared residuals (SSR) varied between 0.00011 and 0.2114 for sand and sandy soils, while it ranged between 0.021 and 0.00017 for all the others. Highest SSR values were noted with coarse sandy soils while the lower SSR values were noted with materials of finer structure. This suggests that this model is more adapted to fine structured soils. An attempt is being made in order to predict the Tangential model parameters, through multiple linear regression analysis, by using the soil bulk density values, saturated volumetric water content and the soil grain size distribution data.

Quantification of soil pollution concentration of plating metals by bioassay using luminous bacteria

SUGITA, Hajime[1*] ; KOMAI, Takeshi[2] ; HARA, Junko[1] ; IMOTO, Yukari[1] ; ZHANG, Ming[1]

[1]National Institute of Advanced Industrial Science and Technology (AIST), [2]Tohoku University

Cd, Cr(6+), Pb, As and CN are substances which closely related to metal plating. These are regulated as Class II Specified Chemical Substances by Soil Contamination Countermeasures Act. However, many other plating metals have not been subject to this law. Some heavy metals, which are used as plating metals, may be harmful to the human body if taken in excess. They must be also assessed risk in the same way as a Class II Specified Chemical Substances.

On the other hand, there is a bioassay using luminous bacteria as one of the acute toxicity evaluation test on hazardous substances. Since there is normally correlation between the concentration of hazardous substances and the intensity of the acute toxicity, it may be possible to estimate the concentration of harmful substances from the intensity of the acute toxic effects.

Focusing on Fe, Ni, Cu, Zn, Ag and Sn which are widely used as common plating metals, in this study, systematic bioassay tests using luminous bacteria (Vibrio fischeri) were performed. Based on the data obtained in the experiments, quantification of the correlation between the concentration of the plating metals and the intensity of the acute toxicity was attempted.

Subsurface temperature increase (”subsurface warming”) has been documented below many large cities worldwide. The observed subsurface temperature increase has shown close relations with surface warming effects due to global warming and urbanization. Recently, ground source heat pump (GSHP) systems have become popular as a renewable energy technology for space cooling and heating. Operation of GSHP systems for space cooling discharges waste heat into the subsurface environment and, thus, induces additional subsurface temperature increase. However, any potentially negative impacts of GSHP-induced temperature increase on the subsurface environment have not been studied in detail. The objective of this study was therefore to investigate the effects of in-situ, long-term thermal loading on groundwater quality.

A GSHP system was installed in a 50-m deep borehole with a corresponding 50-m long U-tube heat exchanger at the campus of Saitama University in the Arakawa Lowland, Japan. Four groundwater monitoring wells were installed in a marine sand sediment aquifer (around 17-m depth) at 1-m (W1), 2-m (W2), 5-m (W5), and 10-m (W10) distance from the U-tube. At each monitoring well, temperature detectors were placed in 10 depths at approximately 5-m interval, and the subsurface temperature was monitored before and during thermal loading. For the thermal loading, approximately 40 ℃ water was circulated inside the U-tube heat exchanger for 13 months, and groundwater was frequently sampled from all four monitoring wells every 1 to 2 weeks. A wide spectrum of chemical properties (including pH, EC, DO, ORP ”oxidation-reduction potential”, dissolved gases, dissolved organic carbon, inorganic ions, and trace elements) were measured to characterize groundwater quality.

The subsurface temperature at the nearest monitoring well (W1) increased gradually with approximately 8 ℃ from 17 ℃ (base-line) to 25 ℃ during 13 months of thermal loading. In contrast, at the farthest monitoring well (W10), there was no significant change in subsurface temperature, and W10 was therefore selected as a reference (non-temperature affected) monitoring well. A number of chemical components in the groundwater, including boron and potassium, increased markedly at W1 compared to W10. Since marine sediments typically contain high concentrations of chemical components including boron and potassium, the observed increase in groundwater concentration is likely due to thermally-induced dissolution and/or desorption from the marine sediment. The possible mechanisms behind the observed concentration increases will be discussed.

Characterization of water repellency parameters in soil water repellency characteristic curves for JP and NZ soils

WIJEWARDANA, Senani[1*] ; KAWAMOTO, Ken[1] ; MULLER, Karin[2] ; CLOTHIER, Brent[3] ; HIRADATE, Syuntaro[4] ; KOMATSU, Toshiko[1] ; MOLDRUP, Per[5]

[1]Graduate School of Science and Engineering, Saitama University, Japan, [2]Plant & Food Research Institute, Ruakura Research Centre, New Zealand, [3]Plant & Food Research Institute, Palmerston North, New Zealand, [4]Biodiversity Division, National Institute for Agro-Environmental Sciences (NIAES) Japan, [5]Department of Civil Engineering, Aalborg University, Denmark

Soil water repellency (SWR) is the phenomenon where soil does not wet when water is applied to its surface. Characterization of water repellency in natural soil is very important to understand the soil hydrological processes, surface flow and infiltration rates. Objectives of this study were (i) to characterize SWR using molarity of ethanol droplet (MED) test, sessile drop method (SDM) and water drop penetration time (WDPT) test, and (ii) to identify the relationships between the determined SWR parameters and soil organic carbon (SOC) contents. Soil samples were collected from different soil depths of representative Andosols and Cambisols in Japan (Nishigo, Hiruzen and Nikko; all sites under forest) and New Zealand (Ngahinapouri, Wahihora and Whatawhata; all sites under pasture). The soil-water contact angle was directly measured using SDM, and indirectly derived from MED and WDPT measurements. All the A horizons of the Japanese soils showed water repellency, and the New Zealand soils were also water repellent at all depths except the Ngahinapouri, B horizon. Then, soil water repellency characteristic curves (SWRCCs) were obtained for water repellent (WR) soils, i.e., soil-water contact angle / degree of WR as a function of the volumetric water content (θ). Three WR parameters were determined from the SWRCCs. They are (i) the integrated areas below a SWRCC, $S_{WR(}\theta), (ii) the soil water content at maximum (\theta_{WR-Max})$ and (iii) minimum (θ_{WR-Min}) WR. Further, WR parameters were studied with soil organic carbon (SOC) contents. These relationships were agreed well with recently published work of Kawamoto *et al*. (2007) and Karunarathna *et al*. (2010). The SOC contents of New Zealand soils varied between 1.4% (WR) to 12.1% (WR), for the Japanese soils they ranged between 2.6% (Non-WR) and 26.3% (WR). Although the Japanese soils had high SOC contents in >10 cm depths, they were not WR (for Nikko >5 cm depth-Not WR). Therefore, further studies are needed to assess SWR as affected by SOC.

A result of Cs redistribution in a forest soil after FNP-I accident.

NISHIMURA, Taku[1*]

[1]The University of Tokyo

Cesium is a large atom which does not likely to hydrate. Similar to potassium and ammonium cation it prefers to site at siloxane ditrigonal cavity of silica sheet of phyllosilicates. Cesium is strongly, almost irreversibly, captured at frayed edge site of layered clay particles. These facts may make partition coefficient of cesium to be very large. The large partition coefficient may produce larger retardation of cesium transport with percolating water. At the same time large partition coefficient may cause enhance in migration of Cs with moving colloids. A comparison of Cs content distribution of near surface soil of between cleared forestry and a forestry with 5cm litter layer in Iitate village, Fukushima suggested organic colloids could be a transporter of Cs at litter covered forest. Soil total carbon content as well as C/N ratio had relation with soil Cs content. A depth where soil had higher organic carbon and lower C/N ratio tended to show high Cs content.

Observation of Pore Structure for Differently Compacted Landfill Final Cover Soils Using Microfocus X-ray CT

BANIYA, Arjun[1*] ; KOIKE, Takuya[1] ; WATANABE, Kai[2] ; HAMAMOTO, Shoichiro[3] ; KAWAMOTO, Ken[1]

[1]Graduate School of Science and Engineering, Saitama University, Japan, [2]Department of Civil and Environmental Engineering Saitama University, Japan, [3]Graduate School of Agricultural and life Sciences, University of Tokyo, Japan, [4]Institute of Environmental Science and Technology, Saitama university, Japan

The final cover soil on a solid waste landfill consists of many layers of materials and is highly compacted. It is used to prevent rain/surface water infiltration in to the waste layer. On the otherhand, the landfill site has a significant emission source of greenhouse gases. Gas and mass transport in soils occurs through the soil pore network, which is highly affected by soil physical properties including compaction, particle size, moisture content and total porosity. However, there are a limited number of studies on visualization and quantification of soil pore network for highly compacted soil like final cover soil. The objectives of this study were setting of microfocus X-ray Computed tomography (CT) for scanning landfill final cover soils in conjunction with 3-D image analysis techniques and analyzing the soil pore structure parameters. In this study, soil samples were collected from landfill site in Saitama prefecture, Japan. Soil pore structure was analyzed using micro focus X-ray CT (Shimadazu inspeXio SMX-90CT, Shimadzu Corporation) for air dried final cover soil samples of particle size (d$\leq$2mm) with different dry densities 1.4, 1.55 and 1.65 gcm^{-3} by a hand compaction. The tested soil texture was silty sand. The scanned images were taken by the micro focus X-ray CT. Then, by the use of software VGStudio MAX, they were reconstructed in 3-D images. Finally, using software of EXFact analysis they were analyzed to obtain pore structure parameters such as pore size distribution, coordination number, specific area and pore-network tortuosity. For determining suitable scanned images for soil pore structure and network, several scanning conditions for the microfocus X-ray CT have been tested i.e. different combinations of voxel size (10, 30 and 50 μmm), scan number, view number, field of view(FOV), region of interest(ROI), and percent of interior pore for pore structure analysis. Base on the results from the tested conditions, we will propose a suitable condition on the microfocus X-ray CT scanning for macropore network (typically, effective pore diameter $>$100 μmm) in differently compacted final cover soils.

Consolidation characteristics of landfilling waste samples in Japan: Effects of waste compositions and various mixing pr

IQBAL, Muhammad rashid[1*] ; OOHATA, Hiroyuki[1]

[1]Graduate School of Science and Engineering, Saitama University, Japan, [2]Graduate School of Agricultural and Life Sciences, the University of Tokyo, Japan, [3]Institute for Environmental Science and Technology, Saitama University, Japan, [4]Center for Material Cycles and Waste Management Research, NIES, Japan

Solid waste materials are highly heterogeneous depending on various waste compositions, making it difficult to understand their consolidation characteristics. The purpose of study is to find out effects of waste compositions and mixing proportions on the consolidation characteristics of compacted solid waste materials. In this study, totally 6 different waste materials, un-burnable domestic waste, un-burnable industrial waste, incineration ash, crushed concrete, organic sludge and inorganic sludge, were used as tested materials.

By using the standard proctor test, compaction curves and maximum dry bulk densities were determined for each sample. Compaction results showed that maximum dry bulk densities of the Incineration ash (1.65 g/cm3) and crushed concrete (1.45g/cm3) were higher than the inorganic sludge (0.90 g/cm3) and organic sludge (0.742 g/cm3) respectively. The maximum dry bulk densities for mixed sample of inorganic sludge, concrete and incineration ash were larger than each independent waste sample. In especial, the maximum dry bulk density for the mixed sample with ratio 1:1:1 (dry mass basis) was 1.48 times larger than that for inorganic sludge.

Consolidation tests were carried out for selected pre-compacted waste samples with degree of compaction higher than 90 % after the compaction tests. For the consolidation tests, oedometer test apparatus which dimension of 10 cm diameter and 10 cm height was used for the waste materials with particle size larger than 2mm. Results of each independent sample showed that the coefficient of consolidation (Cv) for crushed concrete and incineration ash was higher than organic and inorganic sludge wastes while compressibility of un-burnable industrial waste was higher than the other materials due to a presence of compressible material. As the mixing ratio of crushed concrete in the mixed samples increased, the compression index (Cc) decreased. When the inorganic sludge and crushed concrete are mixed with the ratio 1:3, the Cc value of the mixed sample decreased up to 75% as compared to the one for only inorganic sludge. In addition, by mixing the inorganic sludge with the crushed concrete, the Cv values for mixed samples increased in the order of 10^{1}~10^{2}. Effect of mixed proportion of the various wastes on consolidation parameters will be further investigated.

Remediation of a Tsunami affected saline and sodic soil by calsium carbonate and rice straw

ISHIBASHI, Sakuya[1*] ; NISHIMURA, Taku[1] ; HAMAMOTO, Shoichiro[1] ; IMOTO, Hiromi[1]

[1]Graduate School of Agricultural and Life Sciences, The University of Tokyo

Japanese government recommends leaching of soluble salts as well as adding calcium amendments for remediating saline and sodic soil after Tsunami by the earthquake on March 11, 2011,. Application of calcium carbonate ($CaCO_3$) is recommended for soils having pH lower than 6 and calcium sulfate ($CaSO_4$) is that for pH higher than 6. However, since $CaCO_3$ has low solubility to water, it has not been often used in reclamation of sodic soils (Shainberg et al, 1989).

Solubility of CaCO3 is controlled by CO_2-H_2O-$CaCO_3$ equilibrium in water. The concentration of calcium ion in $CaCO_3$ solution is affected by CO_2 concentration (partial pressure) of air phase. The higher partial pressure of CO_2 causes the higher concentration of Ca^{2+}. In general, addition of organic matter may enhance soil respiration and increase partial pressure of CO_2 in soil. This might potentially enhance solubility of $CaCO_3$ and increase Ca^{2+} concentration in soil solution.

Increase in Ca^{2+} concentration in soil decreases exchangeable sodium percentage (ESP) of the soil. Lower ESP may inhibit soil dispersion and help to keep aggregation. Stability of aggregates has a role on soil permeability, and it affects efficiency of leaching practice.

Objective of this study was to investigate the effect of changes in partial pressure of CO_2 by organic matter decomposition on dissolution of $CaCO_3$, and subsequent Na^+-Ca^{2+} ion exchange of a Tsunami affected soil.

Soil was collected at a former paddy field at Terashima, Miyagi, Japan, where was damaged by Tsunami at the Great East Japan Earthquake. EC (1:5) of the soil was 5.2dS m^{-1}. The soil was mixed with rice straw and/or $CaCO_3$, and then packed into plastic columns of an inner diameter of 8.5cm and 20cm-high with the bulk density of 0.95g cm^{-3}. Amount of rice straw and $CaCO_3$ application was 10t ha^{-1} and 1t ha^{-1}, respectively. The soil columns were incubated for 23 days. During the incubation, 18mm of water was supplied for each three days. The temperature inside and around the columns, and soil water pressure were continuously monitored. The CO_2 concentration in soil air phase was measured at 5-days interval.

After the incubation, the columns were leached by 4 pore volumes of 4mmol L^{-1} KCl solution with. The leachate was collected for further analysis of EC, pH and concentration of cations. After the leaching, the soil columns were separated to 3cm thick layers. Each 3cm thick soil sample was used to measure EC, pH, soluble cations, and exchangeable cations of the soil.

In average, soil CO_2 concentration inside the column was high under the rice straw treatment regardless of $CaCO_3$ application. The CO_2 concentration rose at the periodical water application, and gradually decreased with time. Rise in CO_2 concentration could be due to the enhanced organic matter decomposition and the restricted CO_2 diffusion by higher soil water content following the water application.

Exchangeable cations of the column soil were measured after the leaching. Exchangeable Ca^{2+} slightly increased at whole layer of the four treatment. Increase in exchangeable K^+ coincided with decrease in exchangeable Na^+, suggesting ion exchange between Na^+ and K^+ was a dominant reaction during the leaching.

In this experiment, the effect of organic matter and $CaCO_3$ application on remediation of the Tsunami affected saline and sodic soil was not clear. With fluctuating soil water content, soil CO_2 concentration was not always high during the column incubation experiment. It is expected that depression of soil CO_2 concentration with decrease in soil moisture after water application could not enhance dissolution of applied $CaCO_3$.

Enhancing Radioactive Fallout Removal from the Surface Soils by using artficial macropore transport system

SATO, Naoki[1*] ; MIYAMOTO, Tamami[2] ; MORI, Yasushi[1] ; INAO, Eiko[3] ; NOBORIO, Kousuke[4]

[1]Faculty of Environmental Science and Technology,Okayama University, [2]Graduate School of Environmental and Life Science,Okayama University, [3]Miyagi Prefectural Institute of Agriculture and Horticulture, [4]Faculty of Agriculture,Meiji Unversity

Fukushima nuclear power plant damaged by the East Japan Great Earthquake caused radioactive fallout around the Tohoku-region. Because radioactive fallout was positively charged,it was reported to be absorbed to soil surface. Surface soil scraper and deep plowing would be,therefore effective for the removal of radioactive materials. However,these techniques were available for flat and wide area like school yard or farm land.

in many orchards,fruit absorbed radioactive Cesium, which indicated radioactive fallout did not immediately absorb to soil surface but stayed as exchangeable ion for a while and was absorbed by plant root. therefore the technique for sloped land is also needed for better management for radioactive fallout.

we applied artificial macropores to effectively remove radioactive fallout from the surface soil. artificial macropore filled with bamboo fiber was made in siol(Field:d=1 length=50cm,Lab:d=0.6cm,length=20cm). Zeolite was placed at the bottom of the macropores(Field:50cm,Lab:20cm)to absorb transported Cesium.Four treatments were prepared for field experiments,such as macropore with ammounium sulfate,no macropore and no macropore with ammonium sulfate. In the lab experiments, Potassium was used for safety reason and a 400mm artficial rainfall was applied for one month. Results showed artificial macropore effectively transported radioactive Cesium/Potassium to deeper profile. In the lab experiment, artificial ,macropore successfully delivered Potassium to deeper profile while no radioactive Cesium was observed from the drainage water.

A Design of Artificial Macropore for Improving Infiltration Process in Degraded Soils

SAKIKAWA, Kazuki[1*] ; MORI, Yasushi[1] ; SUETSUGU, Atsushi[1]

[1]Okayama university

Soil is largest carbon storage body in all terrestrial medium such as vegetation and the atmosphere. However, these days, soils could not show its function as water storage layer or culture medium for plant, because of climate change or rough management. In this study, artificial macropores are introduced in soils for purposing enhancing infiltration without cultivation. Fibrous material was inserted so that it reinforced the macropore structure. Moreover, capillary force caused by fibers drag the surface water into the deeper soil prior to saturation. Capillary force caused by fabric introduced vertical transport, while micropore(matrix) enhanced horizontal flow. It makes it possible effective infiltration than empty macropores. In the experiment, an ideal design of artificial macropore was searched. The density of fibrous material was altered as 0.2 0.3 0.5 g/100cm3-soil. Artificial rainfall of 2 (weak rain) and 20 (stormy rain) mm h-1 were applied on the soil column (D=5cm, H=30cm). Results showed that retention curve has gradually changed as we changed the density of fibrous material. Thus, the capillary force was effectively created according to the densities surface water was effectively collected by dense artificial macropore when weak rainfall was applied, while stormy rain was effectively drained by light artificial macropore.

Artificial Macropore installation effect on organic matter storage at a degraded land.

MORIWAKE, Shuichi[1*] ; MORI, Yasushi[1] ; SUETSUGU, Atsushi[1]

[1]Okayama University

At ill-drained lands, heavy rain would cause erosion which enhances degradation process much faster.According to our previous study, artificial macropore successfully enhanced vertical infiltration and increased organic matter contents. However,there was a concern that infiltrated fresh soil water transported nutrient and oxygen at the same time, resulting decomposition of the organic matter.

In this experiment,we prepared sandy soil column(D=50mm,H=300mm)with Cellulose, for which artificial rainfall of 210mL with nutrients (N,P,K)were applied on the surface soils. Then columns were placed at 30 oC constant temperature room to enhance organic matter decomposition. In order to observe structural difference for carbon storage,three treatments were prepared such as, cultivation,artificial macropore and control,respectively.

Results showed that evaporation was significant for cultivation column, which meant traditional agricultural practice had disadvantage for conservation of soil water conservation. On the other hand,artificial macropore column showed similar evaporation rate for control column in spite of their well-drained structure.Affected by water content,vertical profiles for carbon contents were different for three treatments. Standard deviations for vertical profiles were small for control column,and larger for macropore column and cultivation column.

Modelling of Critical Loads for Heavy Metals in Terrestrial Ecosystem in Slovenia

SVETINA VEDER, Marta[1*]

[1]RCE, marta.svetina@rce.si

In Slovenia a modelling application of As, Cd, Co, Cr, Cu, Hg, Mo, Ni, Pb and Zn critical loads in soil were performed. The calculation in the Salek Valley involved 30 research areas in the town Velenje area on a 500 x 500 m grid, where the chemical analyses of precipitation and soil were made.

The aim was application of theoretical models for determination the maximum critical levels of heavy metals in terrestrial ecosystem with empirical data. The basis for calculation was an effect-based approach, which limits are based on adverse effects on the ecosystem and the heavy metal concentrations should stay below those limits. As receptor was used a human health trough the eco toxicological risks with use of ground water for drinking water and/or consume crops that are grown on the soil. The simple model based on dynamic mass balance of heavy metals in soil was used for calculation. It was estimated that the critical time well illustrates the acute danger of soil pollution and is recommended as the draft estimation of actual condition in soil which could be valued with few data.

Two different soil conditions at the actual atmospheric input were used in calculation: unpleasant and average. The unpleasant condition was simulated for the surface soil to depth of 5 cm, and the advanced to soil depth of 20 cm and density of 1.500 kg/m3. The critical time for both conditions is calculated for As, Cd, Co, Cr, Cu, Hg, Mo, Ni, Pb, Zn. The comparison between heavy metals indicates high accumulation of As and Hg, and thus their quit fast approach to the critical loads. In second rang of atmospheric input are Cd, Pb and Zn which are accumulated much slowly, followed by Mo, Ni, and Co, and the slowest progress make Cr. The estimated periods to reach the permitted Slovene limits in surface soil are calculated for As, Hg 100, Cd 140, Pb 230, Zn 350, Cu 830, Mo 1.700, Ni 1.800, Co 1.900, and for Cr 6.000 years.

Predicting soil moisture in arable land under climate change with soil-profile physical properties database

KATO, Chihiro[1*] ; NISHIMURA, Taku[2]

[1]Faculty of Agriculture and Life Science, Hirosaki University, [2]Graduate school of Agricultural and Life Sciences, the University of Tokyo

Soil is foundation of agriculture and ecosystems. Soil physical condition such as soil moisture and temperature directly and indirectly affects yields and quality of crop production. Therefore predicting soil moisture of arable lands under climate change is important and valuable for yield prediction and adaptation under climate change. For predicting soil moisture condition of agricultural lands in arbitrary areas, use of soil database and datasets of General Circulation Model (GCM) projections should be useful since physical properties of soils and meteorological condition vary with location. Most of available GCM projections have spatial and temporal resolution of 100 km and a month. However, using GCM projections as input data for soil moisture and temperature prediction, temporal and spatial scale of the input data is favorable to be small since effective surface soil layer of agricultural production is generally shallow. In this study we investigated possibility of predicting soil moisture of arable lands in arbitrary areas with local-scale (approximately 20km×20km) daily GCM projection dataset " ELPIS-JP " (Iizumi et al., 2012) and the agricultural soil-profile physical properties database, Japan, " Solphy " (Eguchi et al., 2010).

In this study, soybean fields of Yoshioka and Ookubo, which are located in neighbors (approximately 2 ~ 3km), in Toyama city were chosen as experimental sites and scenario studies were done for predicting soil moisture condition with HYDRUS model (Simunek et al., 2008) under climate change in the future (2071 ~ 2090). Soil physical properties of each site were determined with water retention data in the SolphyJ database by using RETC program (Yates et al., 1992). Before the scenario studies, validation of HYDRUS model and soil physical properties which are obtained with SolphyJ database was conducted by comparing observed and simulated soil moisture of the Yoshioka field. The projection of MIROC-hires 3.2 A1B scenario was chosen among 26 (10 GCMs × 3 Special Report of Emission Scenario) ELPIS-JP scenario datasets. For preparing input data for numerical simulation of soil water movement, daily ELPIS-JP datasets were temporally downscaled to hourly or minutes scale by using weather generator " CLIGEN " (Nicks et al., 1995)

Simulated results suggested that the duration of excess soil moisture condition following heavy rainfall events are more likely at Ookubo than Yoshioka even though they are located in neighbors and have similar soil textures. Increase in surface runoff fluxes is possible to be larger in Ookubo than in Yoshioka as well. These results imply that even in a small watershed it is important to consider soil spatial distribution in predicting effects of climate change on agricultural production. Also, combination of temporally downscaled GCM projection dataset and agricultural soil-profile physical properties database may be useful for predicting soil moisture in arbitrary areas.

A Case Study of Combining Geophysics Prospecting Techniques to a Soil Contaminated Site

WANG, Tzu-pin[1*] ; CHEN, Chien-chih[1] ; DONG, Tien-hsing[4] ; CHEN, Yi-chieh[3] ; LIU, Hsin-chang[2] ; LIN, Chih-ping[5] ; HUNG, Hao-chun[6] ; HO, Ching-jen[6]

[1]Dep. of Earth Sciences and Graduate Institute of Geophysics, National Central University, Taiwan, [2]Disaster Reduction Research Center, Chien Hsin University of Science and Technology, Taiwan, [3]Geophysical Technology and Engineering Co.,Ltd. R.O.C, [4]Apollo Technology Co.,Ltd. R.O.C., [5]D.P.W.E. National Chiao Tung University, Taiwan, [6]Environmental Protection Administration, Taiwan

This study utilizes a combination methods of Electrical Reisitivity Tomography (ERT), Ground Penetrating Radar (GPR), and Horizontal Loop Electromagnetic (HLEM) to examine a heavy-metal contaminated site before and after the remediation. It was a processed sludge tacking site of a smelting plant. The sludge is homogeneous red, and the main pollutants are chromium, arsenic and lead. The plant has been closed for more than twenty years. At the time when it was shut down, instead of removing the stacked sludge and underground structures (tank), the site was leveled directly and planted with lawns. Now, it is difficult to know the distribution of the sludge, the depth of its cover, and the correct location of the underground structures.

The pre-remediation investigation conducted with the application of geophysical prospecting techniques found that the HLEM could efficiently define the distribution of sludge efficiently, and ERT could be used to detect the thickness of the sludge and the location of the underground structures, but GPR results failed to meet expectations which may due to a significant attenuation of electromagnetic energy caused by the nature of the sludge. The post-remediation examination shows obvious different morphologies of the site than it was before the remediation. The results can be used to assess the effectiveness of remediation, and to check if any sludge remains.

Cs migration to rice crop from soil after stripping the contaminated top soil at Iitate Village in Fukushima Prefecture.

NISHIWAKI, Junko[1*] ; ASAGI, Naomi[1] ; KOMATSUZAKI, Masakazu[1] ; MIZOGUCHI, Masaru[2] ; NOBORIO, Kosuke[3]

[1]College of Agriculture, Ibaraki University, [2]Graduate school of Agricultural and Life Sciences, The University of Tokyo, [3]School of Agriculture, Meiji University

Iitate Village is at about 40 km northwest from a Fukushima Daiichi nuclear power plant. An agricultural fertile layer in agricultural fields was contaminated by radionuclides, e.g., 134-Cs, 137-Cs, and 90-Sr, just after the accident of the Fukushima Daiichi Nuclear Power Plant in 2011. The decontamination work is an important subject for villagers to return to a village and live there again. Three decontamination methods are proposed by a Ministry of Agriculture, Forestry and Fisheries. They are 1) Stripping the top soil off, 2) Removal of fine particles after soil and water mixing, and 3) Tillage reversal. By the report of the Ministry of Agriculture, Forestry, and Fishery, 90% of radioactive contaminant has been removed by the method of stripping the contaminated top soil off. In this time, we examine the Cs migration to rice crop from soil after stripping the contaminated top soil off.

We used ˜4∗20 m paddy field at Iitate Village in Fukushima Prefecture. At first we decontaminated the site using the method of stripping 5 cm top soil off. After that potassium chloride (KCl) was put in all area as basal fertilizer on June 8, 2013. We comparted the area and made three kinds of treatments such as (1) mixed with rice straw that was harvested last year here, (2) only decontaminated, and (3) mixed with farmyard manure, and transplanted rice crop (rice cultivar is hitomebore) on June 9, 2013. We had sampled top soils at three points from each plot twice a month and the 134-Cs, 137-Cs, and 40-K concentration in soils were analyzed using a Ge semiconductor detector. The concentration of 134-Cs, 137-Cs, and 40-K in rice crop was analyzed by a NaI scintillation counter after harvest.

As a result, 134-Cs is about half of 137-Cs. Since the half-life of 34-Cs is two years, it has become approximately a half. Changes of Cs and K concentrations in soil were not observed during a rice cultivation period. The concentrations of radionuclides in mixed rice crop were 572.93±8.05 Bq/kg-dry / Cs-134, 1089.35±11.41 Bq/kg-dry/ Cs-137, and 127.29±27.59 Bq/kg-dry/ K-40. Although these values were comparatively high, soil did not show the high dose. The reason of that would be the volume of mixed rice straw was small and migration of caesium from the rice straw to the soil was hardly happened. The soil dose mixed with manure had been high through the whole cropping period. It might be the original manure dose was high, but the analysis of the manure has not completed yet. The concentration of radionuclides in rice crop below a detection limit of the NaI scintillation counter and it is below the regulation value defined in our country.

Nitrogen removal and effect of chemical oxygen demand on removal of nitrogen in Coir Fiber Biofilm Treatment System

DHARMARATHNE, Nirmala kumuduni[1*] ; SATO, Naofumi[3] ; KAWAMOTO, Ken[1] ; TAKAHIRO, Koide[2] ; SATO, Hiroyasu[4] ; TANAKA, Norio[1]

[1]Graduate School of Science and Engineering, Saitama University, Japan, [2]Institute of Environmental science and Technology,Saitama University,Japan, [3]Kokusai Kogyo Co., Ltd, [4]Graduate School of Frontier Sciences, University of Tokyo,Japan

Biological treatment is the most useful process to remove nitrogen from water and wastewater. In this process, ammonium is first oxidized to nitrate by aerobic autotrophic nitrifying microorganisms. Nitrate is then reduced to nitrogen gas by heterotrophic denitrifying bacteria under anoxic conditions. Oxygen and organic carbon must be supplied to act as electron acceptor in nitrification and electron donor in denitrification. This study has carried out microcosm experiments in the laboratory for evaluating wastewater treatment mechanism and efficiency in the Coir Fiber Biofilm Treatment System (COTS). Coconut fiber was used to encourage the development of contaminant-degrading biofilms. A string of coconut-fiber (0.2-m length) was used as a biofilm support media and experiments were carried out using synthetic wastewater. The string of coconut-fiber was put inside the treatment container (0.012-m3 volume) with two conditions: low fiber density (LFD; single string per a container) and high fiber density (HFD; two strings per a container). As a control condition, a blank container without a coconut-fiber string was also used in the experiment. The flow rate is about 870 cm3/day (two-weeks retention time)

The inflow ammonium nitrogen concentration was 500 mg/l- 640 mg/l and the average nitrate nitrogen concentration in influent was 5.9 mg/l- 6.5 mg/l (low nitrate nitrogen loading rate). Dissolved Oxygen (DO) value of the treatment tanks were range between 0-0.3 mg/l. DO concentration in LFD and HFD treatment tanks were slightly lower than the inflow and blank tank during the whole experimental period. The maximum ammonium nitrogen removal efficiency was recorded in the 14 days of startup. It was approximately 45% and 30% in HFD and LFD treatment tank respectively. After that, ammonium nitrogen removal efficiency shows the slightly decreasing trend over the time. The maximum nitrate nitrogen removal was observed for 70 days of operation. It was around 90% and 72% in HFD and LFD tank respectively. Over the duration of the experiment, very low concentrations of Nitrite Nitrogen were observed and it was below 1 mg/l. low nitrite nitrogen is evident that the oxygen limited anaerobic nitrification-denitrification process leads to removal of ammonium nitrogen in this system. This process involves two-step as partial nitrification and Anammox. One of the most critical parameters of the nitrification process is the influent chemical oxygen demand (COD), because it directly influences the growth competition between autotrophic and heterotrophic microorganism population. The average inflow COD concentration in influent was 18300 mg/l- 19800 mg/l. Ammonium nitrogen removal efficiency decreased with the increasing of COD removal efficiency in both LFD and HFD treatment tanks. So there is a negative relationship between organic carbon concentration and biological ammonia removal. High organic loading can result in decreased nitrification due to faster growing heterotrophic bacteria dominating the surface of the biofilm, and leads to oxygen limitations for the nitrifying bacteria growing deeper inside the biofilm. As considering the results obtained from the microcosm system it can be conclude that partial nitrification and the subsequent anaerobic ammonium oxidation (Anammox) are the major process associated with the removal of ammonium nitrogen. This process is a shortcut biological nitrogen removal without increasing nitrite and nitrate concentration in the system. At the same time treatment tank with HFD always tend to eliminate significant amount of ammonium nitrogen than the LFD tank. Difference between results in HFD and LFD treatment tank indicating that surface provided for growth of biofilms is a major factor for improving biodegradation rates. COTS has effect on remove nitrate nitrogen effectively at low nitrate loading rate from the wastewater.

Estimation of water film thickness in geological media based on electric double layer interactions

NISHIYAMA, Naoki[1*] ; YOKOYAMA, Tadashi[1]

[1]Department of Earth and Space Science, Osaka University

Water film plays an important role in mineral-water interactions and mass transport in geological media under water-unsaturated conditions (Nishiyama and Yokoyama, 2013, Geochim. Cosmochim. Acta). To quantify such reactive-transport in water film, the understanding of the properties of water film is essential. Water film is retained on grain surfaces due to the action of electric double layer force associated with the compression of diffuse layers developed from mineral-water and water-air interfaces. In this study, we focused on the thickness of water film and developed a model to estimate the thickness taking into consideration the effect of ion concentration, pH, and electric double layers overlapping.

The surface charge density and electric potential at mineral-water and water-air interfaces depend on the amount of adsorption-desorption of proton and ions. When two diffuse layers developed from the opposite interfaces overlap, the concentration of ions in diffuse layers changes and consequently the adsorption-desorption reactions at the interfaces achieve a new equilibrium state. To take into account this process, we used a triple-layer model and a double-layer model to numerically solve the Poisson-Boltzmann equation describing the ion distribution in diffuse layer between the interfaces. We considered water film on quartz grains and calculated water film thickness as a function of pH and ion concentration. The results show that water film thickens with decreasing ion concentration and increasing pH. The model presented in this study allows film thickness to be estimated as a function of mineral type, ion concentration, and pH. Such model would be useful for considering the reactive-transport under unsaturated conditions including the geological storage of carbon dioxide and soil formation.

Coastline as triple boundary among atmosphere, ocean and earth

YAMANAKA, Manabu D.[1*]

[1]JAMSTEC/Kobe U

Coastline is the boundary between ocean and land (earth beyond the sea level), and the liquid-solid heat contrast there produces monsoon or sea-land breeze circulation responding revolution (annual) and rotation (diurnal) periodicity of solar heating. The coastline is also the intersection between ocean surface and bottom, and its location is determined by water budget and erosion-orogeny balance. Furthermore, the coastline is the most active ecological (and also anthropogenic) zone. Based on these geoscientific meanings of coastline, we discuss climatological characteristics of land-sea coexisting planet such as earth.

Keywords: atmosphere-ocean-land interaction, monsoon and local circulation interaction

Cold surge event observed by the research vessele Hakuho-maru over the Pacific in December 2012

OGINO, Shin-ya[1*] ; WU, Peiming[1] ; HATTORI, Miki[1] ; ENDO, Nobuhiko[1] ; KUBOTA, Hisayuki[1] ; INOUE, Tomoshige[1] ; MATSUMOTO, Jun[1]

[1]JAMSTEC, [2]Graduate School of Science, Kobe University, [3]Tokyo Metropolitan University

1. Introduction

A cold surge from the Siberian High is the typical phenomenon of the Asian winter-monsoon that sometimes reaches the southeast Asian regions, such as Philippines and the Indochina Peninsula, across the Pacific and resulted in heavy rainfall there. Airmass transformation is one of the key processes for this phenomenon. However, the quantitative evaluation based on the observation has not yet been done so far. We succeeded in observing a cold surge event by radiosondes from the research vessel over the Philippines Sea in the end of December 2012. The preliminary results are reported in this paper.

2. Observation and data

We conducted radiosonde observations on board the research vessel ”Hakuho-maru” during December 21, 2012 and January 4, 2013. Figure 1 shows the observation points and the launch time of the radiosondes. We launched radiosondes with 6-hour or 12-hour intervals during 23 to 24 December between 21N and 29N along the cruise from north to south. At the southernmost point (21N, 133E), we further carried out the fixed-point observation of 3-hour intervals for about 1.5 days during 24 to 25 December.

3. Synoptic fields

The cold surge from the Siberian High was intensified during December 20 to 26. Northwesterly winds were intensified around Japan and the northeasterly was strengthened in the Pacific Ocean and the Philippine Sea. Convections were activated over the Philippines, and the precipitation also became strong in the coastal area. The cyclonic disturbance propagated westward near the equatorial region over the western Pacific. The easterly flow at the northern edge of the disturbance and the northeasterly by the cold surge formed convergence zone over the offshore of Philippines.

4. Results

Latitude-height section of potential temperature and water vapor mixing ratio obtained by the moving observation during 23 to 24 December revealed the cold air intrusion was observed in the lower layer from the surface to 2 km height. The stable layer was formed at the top of the cold air intrusion (about 2 km height). The temperature and humidity were higher in the southern area. Time-height section of potential temperature and water vapor mixing ratio obtained by the fixed-point observation during 24 to 25 December showed that the stable layer around 2 km height were gradually intensified and that below the stable layer both the potential temperature and the water vapor mixing ratio had the uniform vertical distributions, which is consistent with the well-mixed layer during the cold surge event. The transition to such a typical mixed-layer structure was captured by high temporal resolution observation.

With the help of the operational radiosonde data at Minami-daitojima and at Chichijima, we performed a thermodynamic energy budget analysis and evaluated the transfer of thermodynamic energy between the atmosphere and the ocean. The result indicates that the amount of the energy transfer from the ocean to the atmosphere was even large over the Pacific remote from the Eurasian continent and compares with the one that observed near-continent area over the East China Sea by the AMTEX project (Ninomiya, 1975, JMSJ). The effect of the energy transfer to the precipitation over the Philippine area will be discussed.

Acknowledgement

We would like to thank Dr. Hodaka Kawahata (The University of Tokyo), Mr. Katsura Kameo (The University of Tokyo), Mr. Ei Hatakeyama (Marine Works Japan LTD) and all the crews of Hakuho-maru for their great help with conducting the radiosonde observation on board the research vessel. We wish to express our gratitude in Drs. Kaoru Sato (The University of Tokyo), Naohiko Hirasawa and Yoshihiro Tomikawa (National Institute of Polar Research) for permitting us to use their launch

device. Part of this study is supported by The Green Network of Excellence (GRENE) program of the Japanese Ministry of Education, Culture, Sports, Science and Technology.

Lightning climatology around Jakarta, Indonesia, based on 13-years SYNOP observation and GSMaP rainfall data

MORI, Shuichi[1*] ; ARBAIN, Ardhi[2] ; SYAMSUDIN, Fadli[2] ; YAMASHITA, Kozo[3] ; TAKAHASHI, Yukihiro[4] ; YAMANAKA, Manabu D.[5]

[1]JAMSTEC, [2]BPPT, Indonesia, [3]Dept.Electrical Engineering, Salesian Polytechnic, [4]Department of Cosmosciences, Graduate School of Science, Hokkaido University, [5]JAMSTEC/Graduate School of Science, Kobe University

Operational observation in Indonesia, where has much amount of active convections under the tropical maritime climate with high atmospheric and sea surface temperatures and abundant water vapor supply, showed more than 100-200 days of lightning a year and more than 10 times/km2/year of lightning density. Developed convective systems with lightning (thunderstorms) often generates severe mesoscale phenomena of heavy rainfall, gusty wind, and tornados, as well as lightning strikes at the ground. Indeed, much amount and kinds of serious damages caused by thunderstorms have been reported in Indonesia, e.g., massive blackout and serious damage on electrical devices in urban areas, and forest fires and burn-out of high voltage power lines in rural regions. Although Virts et al. (2013a, 2013b) clearly documented lightning climatology over Indonesia based on TRMM LIS and the World Wide Lightning Location Network (WWLLN) observations, temporal and spatial distributions of lightning activity and their dynamics have not been examined in detail because ground-based radar and lightning locating observations are not well organized and satellite observations have deficiencies in their spatial resolution and sampling frequency.

We started three years (JFY2013-2015) program to study lightning activity mainly over Jakarta, where is the capital megacity in Indonesia and has much risk to be damaged seriously by thunderstorms especially in the social sector, to clarify its characteristics from both the points of precipitation climatological and mesoscale meteorological views based on three approaches as follows: 1) statistical analyses for lightning activity by using operational surface observation and TRMM satellite, 2) case studies on environmental conditions for severe thunderstorms based on a C-band radar and surface observation data already obtained, and 3) campaign observation by using X-band dual-polarimetric radar, VLF receiver network, and hydrometeor video soundings.

We examined 13-years SYNOP data for statistical analysis of lightning activity around Jakarta and its relation to rainfall variation based on GSMaP data as the first step. Seasonal variation of lightning frequency shows two peaks in April and November, which correspond to periods just before and after the peak of the rainy season in February around Jakarta, at most of the stations over the inland region. However, these peaks are not clearly shown at stations close to the coastline of Java Sea and one peak in February is more predominant. Because previous studies (e.g, Hattori et al. 2011, Wu et al 2007) suggested the cross equatorial northerly surge (CENS) intensify local convection around Jakarta in the boreal winter season, the effect of CENS to generate thunderstorms was limited only along the coastal region but not for inland in February. Intraseasonal variation of lightning activity based on MJO index clearly shows a major peak in the MJO phases 3 (eastern Indian Ocean) and minor one in phase 7 (western Pacific). It suggested the lightning activity was intensified at the leading and trailing edges of MJO large scale disturbance which is consistent with previous studies (e.g., Morita et al. 2006). Whereas, GSMaP data show a peak of rainfall around Jakarta in the phase 3 at the same time of lightning peak, though the previous studies showed the rainfall was peaked in the phases 4-5 (maritime continent).

We plan to examine lightning characteristics more focused around Jakarta and its relation to rainfall quantitatively by adapting the rain-yields per flash (RPF) (Williams et al 1992, Takayabu 2006) and the other parameters. More than 15-years TRMM LIS and PR data shall be used in our future study as well as Asia VLF network (AVON) and WWLLN datasets.

Interannual variability of rainy seasons onset over the eastern Indochina Peninsula

NGUYEN-LE, Dzung[1] ; MATSUMOTO, Jun[1*] ; NGO-DUC, Thanh[2]

[1]Tokyo Metropolitan University, [2]Vietnam National University

The onset dates of rainy seasons over eastern Indochina Peninsula (8.5o-23.5oN, 100o-110oE) for individual years from 1958 to 2007 were objectively determined by the principal component of two first dominant empirical orthogonal (EOF) modes of the precipitation data. It is found that onset of summer rainy season (SRS), which is described by the EOF1, is in 6 May on the average, with a standard deviation of 13 days. Meanwhile, the autumn rainy season (ARS) indicated by the EOF2 has the climatological onset and standard deviation is 16 Sep and 12 days, respectively. The SRS starts simultaneously with the eastward shift of the Western North Pacific sub-tropical high (WPSH) and the evolution of summer monsoon westerlies. On the contrary, the retreat of summer monsoon over northern and central Indochina in boreal autumn indeed signifies the onset of ARS. The relationship between the onset and intraseasonal variations (ISVs): the 30?60-day (30?60DV) and the 10?20-day variation (10?20DV), are identified.

The results also insisted that ENSO has considerable influence on the onset of rainy season in the Indochina. In general, La Nina (EL Nino) years with warm (cold) sea surface temperature (SST) anomalies in the western Pacific and cold (warm) SST anomalies in the central?eastern Pacific in the preceding winter-spring have early (late) SRS onset. For an early onset year, the equatorial easterly winds are observed be stronger. Strong convective activities also occur over the southern Indochina Peninsula and the SCS in the preceding winter and spring. Whereas, the early onset of ARS is likely related to El Nino years with weaken equatorial easterly winds. It could be explained by the earlier retreat of westerlies monsoon and farther westward extension of the WPSH. Finally, the differences of ISV between early-late onset years of two rainy seasons are also discussed.

How did North Atlantic Oscillation (NAO) cause drought in northwestern China at the multi-decadal to centennial scales?

LEE, Harry[1*]

[1]The University of Hong Kong

North Atlantic Oscillation (NAO) plays an important role in the Northern Hemisphere climate system. Although there is growing interest in the connection between NAO and precipitation change in China, there are few studies concerning that connection in northwestern China. Based on fine-grained historical drought disaster records and NAO proxies, we explored quantitatively their possible connection in northwestern China over the past millennium at the multi-decadal to centennial timescales. Statistical results show that NAO and drought disaster were negatively correlated, as positive modes of NAO caused northward-displaced, stronger-than average mid-latitude Westerlies with an enhanced latitudinal water vapor gradient into the central Asian drylands, resulting in reduced drought frequency and intensity in northwestern China. But, their correlation was out-of-phase during the Little Ice Age because of the southward shifting of monsoon, Westerlies, and the East Asian Jet Stream brought by long-term land surface cooling. As it has been indicated that the precipitation in northwestern China is also determined by El Nino-Southern Oscillation and North Atlantic sea surface and air temperature aside from NAO, further studies are needed to evaluate their individual roles and combined impacts upon the drought disaster there.

Identifying Precipitation Sources in Northern Mongolia using Back Trajectory Analysis

KOIKE, Yuriko[1] ; ASANUMA, Jun[2*] ; DAVAA, G.[3]

[1]Graduate school of Life and Environmental Sciences, University of Tsukuba, Japan, [2]Center for Research in Isotopes and Environmental Dtnamics, University of Tsukuba, Japan, [3]National Agency for Monitoring for Environment and Meteorology, Mongolia

Prediction of precipitation variability and understanding of its mechanisms are essential in Northern Asia [Yatagai and Yasunari, 1994]. The objective of this study is to investigate linkages between the interannual variability of precipitation sources and that of precipitation amount in this area.

For this purpose, a back-trajectory model [Merrill et al., 1986] of atmospheric water vapor was developed and applied to the rainfall during the warm season from 2003 to 2009 at semi-arid grassland Kherlenbayan-Ulaan (KBU) in northern Mongolia, where an air parcel is tagged with the ambient potential temperature where it is precipitated, and is tracked adiabatically above the planetary boundary layer (PBL). When a parcel is tracked back into the PBL, its potential temperature is adjusted to the value at the top of PBL. In addition, diffusion process of water vapor evaporated from the ground surface into the atmosphere and the altitude raindrops are formed are calculated using the Monte Carlo simulation [Dirmeyer and Brubaker, 1999]. The model uses JRA-25/JCDAS [Onogi et al., 2007] reanalysis data set with 6hour intervals.

The results show that the major precipitation sources of rainwater at KBU are the local area of Mongolia and the central and the western Asia. Water vapor evaporated from the local area of Mongolia is approximately 20% of the total summer precipitation, and this ratio is particularly higher in Mongolia in compared with the other area on the globe [Dirmeyer et al., 2009]. This result consists with Yatagai and Yasunari, [1995] which suggested that the variability of precipitation in the arid areas in the northeastern Asia has higher correlation with the local atmospheric circulation, and Sato et al., [2007]. Moreover, this paper clearly exhibits that this ratio is fairly constant over the years in spite that the total precipitation varies.

Moreover, it was found that water vapor supply from the central and the western Asia is approximately 30% of the total summer precipitation at the target point, and therefore, the central and the western Asia may explain a major portion of the summer total precipitation.

In addition, the year 2003 and 2004 were found to here, anomalous relation. It is discovered that larger precipitation in the autumn of 2003 [Hirata et al., 2008] was followed by the increased contribution of the local evaporation to the precipitation in the following 2004. Shinoda et al., [2011] claimed that the cold season climate with low evapotranspiration and strong soil freezing acts to prolong the decay time scale of autumn soil moisture anomalies to the next spring over the eastern part of Mongolia. Therefore, it is considered that soil moisture at the local region in the autumn may be preserved during the winter up to the next spring and contribute to precipitation in summer in northern Mongolia.

Philippine summer monsoon onset -Intensive observation PALAU2013 and data rescue for 109 years-

KUBOTA, Hisayuki[1*] ; SHIROOKA, Ryuichi[1] ; MATSUMOTO, Jun[2] ; CAYANAN, Esperanza[3] ; HILARIO, Flaviana[3]

[1]Japan Agency for Marine-Earth Science and Technology, [2]Tokyo Metropolitan University, [3]Philippine Atmospheric, Geophysical and Astronomical Services Administration

The Philippines is an archipelago country which is located in the western side of tropical western Pacific. There are distinct summer monsoon in the western side and winter monsoon in the eastern side of the country. This study focuses on the onset of summer monsoon in the western Philippines during May to July. Intensive observation of Pacific Area Long-term Atmospheric observation for Understanding of climate change (PALAU2013) was conducted by launching additional upper-air observation in Cebu, Laoag, and Puerto Princesa during May to August 2013. We captured the onset of summer monsoon in June 10, 2013. Low level strong southwesterly wind associated with moistening air was penetrated in the central Philippines during the onset. We compared the behavior of Philippines summer monsoon onset when there was no continuous upper-air observation in reanalysis data. The recovery of historical station back to 1903 called 'Data rescue' was performed using Monthly Bulletins of Philippine Weather Bureau from 1903 to 1940. We created rainfall dataset in the Philippines from 1903 to 2012 by connecting recovered data and PAGASA station data. Summer monsoon onset was defined by using 8 station rainfall data in the western Philippines. The onset date becomes earlier after 1990s and tends to occur in middle May. Early onsets were also seen in early 20th century.

Relationships between heavy rainfall in East/Southeast Asia and track, intensity, duration patterns of tropical cyclones

ISERI, Yoshihiko[1*] ; KANAE, Shinjiro[1]

[1]Graduate School of Science and Engineering, Tokyo Institute of Technology

Tropical cyclones (TCs) have considerable impacts to many areas in East/Southeast Asia. For instance, TCs accompanied with heavy precipitation could cause floods, and the strong winds of TC also could induce huge damages on their track and surrounding environment. In addition, Intergovernmental Panel on Climate Change (IPCC) 5th assessment report mentions possible increasing of both global mean tropical cyclone maximum wind speed and rain rates. Thereby, it would be very important to deepen our understanding on the relation between TCs and their impacts to local climate in East/Southeast Asia.

This study aims to extract observed TC patterns by employing a nonlinear classification method, and also examine relations between extracted TC patterns and heavy rainfall in East/Southeast Asian cities. The classification method used in this study is the self-organizing maps (SOM). The SOM has been recently used in climate science and have shown significant performance for analysis of high dimensional climate data.

In this study, we utilized the TC data provided by JTWC (Joint Typhoon Warning Center). The data period used in this study is 62 years from 1951-2012. Then, we extracted longitude, latitude, maximum sustained wind speed, and duration from TC genesis in order to make input for the SOM. Consequently, each TC is represented as 39 dimension vector, and total 1,837 TCs are utilized as input for the clustering by the SOM. We set the map size of the SOM as 3x3 hexagonal grids.

By the SOM algorithm, total 1,837 TCs were classified in nine nodes (i.e. nine patterns). As a result, several distinguishable TC patterns were extracted by the SOM, according to their track, intensity and duration. Then, we extracted the TCs classified in each pattern, and subsequently examined relations between the extracted TC patterns and rainfall at 21 meteorological stations in East/Southeast Asian cities. Our analysis confirmed clustering method is quite useful in identifying TC properties. The result also suggested extracted TC patterns are highly related with heavy rainfall in some of the target cities.

Application of pseudo global warming method and dynamic downscaling for typhoons approaching to Japan

TANIGUCHI, Kenji[1*] ; HOSOI, Mari[2]

[1]Faculty of Environmental Design, Kanazawa University, [2]School of Environmental Design, Kanazawa University

Results of global warming experiments indicate that an intensity of typhoon will be magnified in future climate. In this study, reproductive simulation of typhoons which approach to Japan are made. At the same time, pseudo global warming conditions are composed of a reanalysis product and multiple global warming experiments. Then, numerical simulations using the pseudo global warming conditions were conducted for each actual typhoon and variations of typhoons in future climate were investigated by comparing the reproductive simulation and the runs with pseudo global warming conditions. Results of a typhoon in summer showed significant variations in tracks. When a track deflects eastward, a typhoon goes over the ocean and its center pressure remarkably decreases. In addition, wind speed around the typhoon increases very much. Geopotential height in lower troposphere showed lower anomaly over the Pacific Ocean. Decreasing Pacific high is thought to be a cause of the change in typhoon tracks. In another typhoon in summer, although variations in tracks and center pressure were smaller, total precipitation in the typhoon increased in future. However, another typhoon in summer showed decreasing precipitation with small variation in tracks and center pressure. Results for another typhoon in autumn showed smaller variation in tracks and center pressures, and total precipitation increases in results of future climate. Such characteristics in future variations were found in other typhoons in autumn. On the other hand, hourly precipitations were not necessarily increased in future climate both in summer and autumn. These results indicate that extremely strong rainfall does not necessarily occur in short time, but modestly strong rainfall continues longer time. Even if no significant variation in center pressure, or intensity is similar to current climate, precipitation will increase in future climate.

Assessment of GSMaP satellite rainfall products in Asian monsoon region

KAMIMERA, Hideyuki[1*] ; NABESAKA, Seishi[1] ; SYAMSUDIN, Fadli[2] ; NGO-DUC, Thanh[3] ; LE VIET, Xe[4] ; HERNANDO, Hilton T.[5] ; MATSUMOTO, Jun[6] ; USHIO, Tomoo[7] ; IWAMI, Yoichi[1]

[1]International Centre for Water Hazard and Risk Management, Japan, [2]Agency for the Assessment and Application of Technology, Indonesia, [3]Vietnam National University at Ha Noi, Vietnam, [4]National Hydro-Meteorological Service, Vietnam, [5]Philippine Atmospheric, Geophysical and Astronomical Services Administration, the Philippines, [6]Tokyo Metropolitan University, Japan, also at Japan Agency for Marine-Earth Science and Technology, [7]Osaka University, Japan

Satellite rainfall products provide the spatial and temporal distribution of rainfall estimates over the ungauged regions where no ground-based measurements with rain gauges and/or meteorological radars are available. For the regions, the satellite products have special importance in, for example, hydrological and agricultural applications such as flood forecasting/warning and water resources management. The Global Satellite Mapping of Precipitation (GSMaP) products have high resolution in space and time (0.1 deg. and 1 h); besides the near-real-time version of GSMaP opens to the public within four hours after measurements. They are thus highly expected to be in operational use in many countries and regions. There are the problems in accuracy and precision of the products due to the limitations on measuring principles, time intervals of sampling and others. However, the above-mentioned strengths of the products are considerable. Therefore, the performance of the GSMaP products needs to be investigated in various areas for the appropriate and effective use; moreover, through the investigation, it can be expected that the knowledge useful for improving the performance will be obtained. The present study investigates the performance of two GSMaP products, GSMaP_MVK and GSMaP_Gauge (a gauge-adjusted GSMaP_MVK), in the four river basins located from the tropics to mid-latitudes in the Asian monsoon region, including: the Solo Basin (16,100 km^2) in Jawa, Indonesia; the Thu Bon – Vu Gia Basin (10,350 km^2) in central Vietnam; the Pampanga Basin (9,759 km^2) in Luzon, the Philippines; and the Tone Basin (16,840 km^2), Japan. The study is ongoing and intermediate results mainly for the Solo and Thu Bon – Vu Gia river basins are discussed at this session.

INTERIOR FLOOD DAMAGE IN JAPAN: PRESENT AND FUTURE

BHATTARAI, Rajan[1*] ; YOSHIMURA, Kei[1] ; KIGUCHI, Mashasi[1] ; NODA, Keigo[1] ; NAKAMURA, Shinichiro[1] ; OKI, Taikan[1]

[1]Depart. of Civil Engineering, The University of Tokyo

The assessment of flood risk and its future prediction under anthropogenic climate change are important to policy makers for future preparedness and adaptation planning. Almost all countries in the world including major cities suffer from flood damage every year due to large exposed population and property. The intensity of damage amount varies as per the level of their preparedness. The case of Japan is also similar, having about 100 billion yen annual damage due to interior flood. Flood losses are increasing more rapidly during late 20c and is expected to increase in future too. Another major factor contributes to future climate events like floods and its losses will be anthropogenic climate change. But due to lack of robust analytical framework to estimate future losses and lack of long term damage data; future projections of flood loss still have many uncertainties.

Most studies regarding flood damage assessment have been done for river flood which always excludes interior flood damage usually caused by rainfall inside city area due to poor or insufficient drainage facilities. Also some extreme events corresponding to large return period is usually taken for damage assessment, which always exclude the damages caused by high frequency events, but reported as equal as an extreme event. In this study, we present a robust methodology for interior flood damage assessment exclusively; taking all daily rainfall events into account and its application to future climate.

We use recorded historical daily damage data in Japan that was archived in Ministry of Land, Infrastructure, Transport and Tourism (MLIT) of Government of Japan to produce functions namely damage occurrence probability function and damage cost function. Our statistical approach gives the probability of damage following every daily rainfall event and thereby the annual damage as a function of rainfall, population density, topographical slope, and gross domestic product. Our results for Japan show reasonable agreement with area-averaged annual national damage for period 1993?2002 in calibration and 2003-2009 in validation. The flexibility of this method leads to future projection of interior flood damage in Japan.

Multiple climate models in different resolution with different convective schemes, sea surface temperature (SSTs) and future climate scenarios to predict the future interior flood damage amount in monetary term are being used. For Japan, we use high resolution Meteorological Research Institute (MRI) atmospheric general circulation models (MRI-AGCM) for present and future precipitation. The precipitation parameters are calculated from 1979-2009 in present and 2075-2099 in future using MRI-AGCM with two mesh sizes (20 km and 60 km) and three different convective schemes (Yoshimura Scheme, Arakawa-Schubert scheme & Kain-Fritsch scheme) which give multi-physics ensemble. The future sea surface temperature (SST) is as per the multi-model ensemble mean change of CMIP3 and CMIP5 with A1B and RCP8.5 scenario respectively. Moreover to consider uncertainty of future SST due to geographical SST distribution, three different clusters SST are also taken for future damage assessment.

Initial results for annual average interior flood damage in Japan shows 13.25% increase in average for future [2083- 2099] from the base period [1993-2009] for A1B scenario and 10.08 % increase for RCP8.5 scenario. The range of future estimate of average annual interior flood damage for A1B scenario is 68.17 billion yen to 117.81 billion yen and for RCP8.5 scenario, it is 78.93 billion yen to 119.06 billion yen in 2005 price. Another important notice in the result is future largest annual damage in A1B scenario seems quite same as present largest annual damage, but for RCP8.5, some year shows the largest damage will double than the present.

We will add different models and CMIP5 results and will describe more features of future interior flood damage in our presentation.

Application of performance metrics to climate models to project future river discharge in the Chao Phraya River basin

WATANABE, Satoshi[1*] ; HIRABAYASHI, Yukiko[1] ; KANAE, Shinjiro[2]

[1]the University of Tokyo, [2]Tokyo Institute of Technology

Future river discharge in the Chao Phraya River basin was projected, taking into account the performance of multiple General Circulation Models (GCMs). Future hydrological simulations using outputs from multiple GCMs are important for assessing the uncertainty in the projections. In addition, consideration of the spread of GCM projections should be included in the analysis to appropriately evaluate extremes, as there can be significant differences among projections. This study, therefore, developed a bias-corrected dataset for multiple GCMs outputs and a performance metrics to evaluate each GCM in order to project future river discharge more appropriately.

To develop a bias-corrected future climate dataset, an advanced bias correction method is applied, in which the trend of variables from the reference to the projection period is preserved. Then, future river discharge was projected by the H08 hydrological model. The newly developed future climate dataset enabled us to conduct a projection that considered the spread of projection derived from multiple GCMs.

Several metrics to evaluate the performance of each GCM to reproduce monsoon precipitation were proposed to estimate performance-based projection because evaluation of GCM performance in simulating monsoon behavior is important for projecting future discharge in the Chao Phraya River basin. This study was performed to investigate the effects of performance metrics and to estimate the spread of projections derived from the differences in multiple performance metrics.

Multiple future projections using available GCM outputs were conducted in the Chao Phraya River basin and multiple weighted ensemble means were obtained using the proposed multiple metrics related to monsoon precipitation. We compared the projected results obtained and discuss the characteristics of each projection. The performance-based projections indicated that the future river discharge in September is increased by 60%?90% of the retrospective simulation. Our results highlight the importance of appropriate evaluation for the performance of GCMs.

Variation of the South China Sea Summer Monsoon onset

IMAKAWA, Shin[1*] ; HIGUCHI, Atsushi[2]

[1]Graduate School of Science, Chiba University, [2]CEReS, Chiba University

In this study, we reveal factors of variation of the South China Sea Summer Monsoon(SCSSM) onset. The study area of South China Sea(SCS) is 5-15N, 110-120E. We use the data set of JRA-25/JCDAS, and, calculate the SCSSM onset date for 30 years, 1979-2008, defined as the zonal wind. In Kajikawa and Wang(2012), the authors point out an advance in the SCSSM onset date around 1993/94. Then, we divide the 30 years into 2 groups , before 1993(Prior) and after 1994(Later). Moreover, we pick out the advanced and delayed onset date for 3 years in each groups, after all, classify 30 years into 4 groups(Prior-Advanced, Prior-Delayed, Later-Advanced, Later-Delayed).

Focusing on time-changes of Sea Surface Temperature(SST), it is difference between Prior groups(P-A, P-D) and Later groups(L-A, L-D) for SST over the Philippine Sea(PS: 0-15N, 125-140E). The SST for Prior is higher about 0.5 degrees than that for Later. On the other hand, over the SCS, the SST is higher Advanced groups(P-A, L-A) than Delayed groups(A-D, L-D). This is reason why the strength of meridional surface wind over the SCS before April. Therefore, an effect of the SST to the SCSSM onset date is difference between over the SCS and over the PS. The SST over the SCS affect the annual variation of the SCSSM onset, and, the SST over the PS affect the 93/94 change.

The SCSSM onset is affected by a warming of the Tibetan Plateau(TP: 30-35N, 80-100E) too. In Ueda and Yasunari(1998), they reveal that the onset of summer monsoon over the Bay of Bengal and the SCS coincide with a time of rapidly increase in the thermal contrast the TP and surrounding ocean. We calculate the warming over the TP by a difference of geopotential height between 200hPa and 500hPa. Comparing the time-change of warming in 4 groups, we examine the difference of the period of rapidly warming over the TP in each groups. It is consider a relation between variation of the SCSSM onset and variation of the warming over the TP.

Then, we compare the anomaly of SCSSM onset date defined by the zonal wind, the anomaly of a time of rapidly warming over the TP, and, the anomaly of SST contrast between over the SCS and over the PS in April. As a results, the annual variation of SCSSM onset correlate clearly with the variation of the warming over the TP. Moreover, the low(high) SST difference in over the SCS and over the PS and the advanced(delayed) warming over the TP cause the advanced(delayed) SCSSM onset date.

Recent changes in heavy precipitation occurrences along the eastern coast of the Indochina Peninsula

FUKUTOMI, Yoshiki[1*] ; WU, Peiming[1] ; MATSUMOTO, Jun[2]

[1]JAMSTEC, [2]Tokyo Metropolitan University

Long-term changes of the frequency of heavy precipitation occurrence along the eastern coast of the Indochina Peninsula were analyzed using daily data from six Vietnamese meteorological stations for the period September–November of 1961–2010. The heavy precipitation days were defined by the 50 and 100 mm/day threshold values. The frequency of the coastal heavy precipitation days were decomposed into tropical cyclone (TC)-induced heavy precipitation days and non-TC heavy precipitation days, and their contribution to a recent increase in the coastal precipitation was examined. Over the 50-yr period, heavy precipitation occurrence indices show a significant increasing trend that is linked to an increasing trend in seasonal amount of the coastal precipitation. A rapid increase in the coastal heavy precipitation days was found from the mid-1990s through the 2000s. This marked increase is basically due to non-TC heavy precipitation events, suggesting that TC passages do not play a role in the recent increase in the seasonal precipitation amount and the heavy precipitation events. A role of tropical synoptic-scale disturbances (TSDs) as non-developing disturbances for TC formation in the non-TC heavy precipitation events was also explored. About 70% of the non-TC heavy precipitation events are associated with TSDs originated from the western North Pacific–South China Sea region. TSD passages are responsible for the recent increase in non-TC heavy precipitation events.

Climatology of explosively developing extratropical cyclones over the Kurosio Front

NAGAI, Masaki[1*] ; HIGUCHI, Atsushi[2]

[1]Graduate School of Science, Chiba University, [2]CEReS, Chiba University

When the East Asian winter monsoon is strong, the explosive cyclone activity tends to concentrate in the Kurosio Current(Yoshiike and Kawamura,2009). It is important to understand the relationship between the heat supply from the Kurosio extension region and the development process of cyclones. The purpose of this research is to reveal meteorological and oceanic environments that can provide deferences of the cyclone path or the rapid development.

Composite analysis for cyclones developed over the westerly(TypeW_P) or easterly(TypeE_P) Kurosio extension region was conducted. The Result suggests the existence of mesoscale circulation over the Sea of Japan is important to northwardly path of the TypeW_P cyclone. In addition, before the maximum deepning of the TypeW_P cyclone, latant heat flux clearly increased at the Kurosio extention region. It was result of easterly winds, to blow in front of a warm front of cyclone. The Kurosio extension region, which was meander north and south direction, responded to the winds. These results not appear in composite analysis for the TypeE_P cyclone. The influence on weather of Kanto region are also investegated. the results show the TypeW_P cyclone tend to provide heavy rain or snow, and the TypeE_P cyclones provide severe winds on that region. These results show the important contribution of water vapour provided from the Kurosio extension region to the TypeW_P cyclone. We conducted more composite analysis for that cyclones. Composite analysis at the cyclone center revealed some difference in advection of water vapour. The water vapor flux, blow from southeast quadrant to cyclone center, was more stronger in the TypeE_P, but The precipitable water that extend to south of cyclones was greater in the TypeW_P. As the result of strong water vapor advection, development of the TypeE_P cyclone was assisted. On the other hand, more humidity air masses cotributed to development of the TypeW_P cyclone. These experiments were conducted for cyclones that developed over the westerly or Easterly Subarctic frontal zone of the northwstern Atrantic(TypeW_A and TypeE_A, respectively). But no clear difference appeared in low-level environment associated with the TypeW_A or the TypeE_A cyclone. These results suggests that the deferences of low-level fields associated with the difference of the maximum deepning position are particular phenomenon in the Kurosio extention resion. In addition, the contribution of water vapour advection to the cyclone center was stronger for cyclones developed over the kurosio extension region.

Variability of GPS precipitable water vapor over the northeast Bangladesh

MURATA, Fumie[1*] ; TABEI, Takao[1] ; TERAO, Toru[2] ; HAYASHI, Taiichi[3] ; CHOUDHURY, S. A.[4]

[1]Kochi University, [2]Kagawa University, [3]Kyoto University, [4]Bangladesh Meteorological Department

Precipitable water vapor (PWV) derived from Global Positioning System (GPS) which were installed in the northeast Bangladesh was analyzed for different seasons. A GPS utilized for the analysis of pre-monsoon (May 2011) was installed at Sylhet. Two GPS utilized for the analysis of monsoon (July 2007) and winter seasons(December 2007) were installed by UNAVCO at Jamalpur and Jaflong. The simultaneous observation with GPS and radiosondes were conducted in May 2011. The PWV derived from GPS was well corresponded with that derived from radiosondes. A sharp PWV increase frequently observed during the passage of severe storms during the pre-monsoon season. The active and break monsoon periods in July 2007 showed average PWV of 67 mm and 62 mm, respectively. Severe flood occurred over Sylhet area during the active period. The PWV in the winter season showed 10-15-day periodicity in PWV between 15 mm in minimum and 25 mm in maximum. The amplitude of diurnal variation was larger in the break monsoon period than the active monsoon period. The nocturnal maximum and early afternoon minimum were remarkable in the diurnal variation of PWV in the monsoon period. The amplitude of diurnal variation was also large in winter. The phase in the diurnal variation was different in the two GPS stations. The PWV was increase on 12-18 LT at Jaflong, but the PWV had minimum on the same period of time at Jamalpur.

Distributed hydrological model simulation on the diurnal-cycle of Ciliwung River basin

SULISTYOWATI, Reni[1*] ; HAPSARI, Ratih indri[2] ; MORI, Shuichi[3] ; SYAMSUDIN, Fadli[4] ; OISHI, Satoru[1] ; YAMANAKA, Manabu D.[1]

[1]Kobe University, [2]State Polytechnic of Malang, [3]JAMSTEC, [4]BPPT

A systematic diurnal-cycle of water level is persistently generated over Ciliwung River basin during the Intensive Observational Period of HARIMAU2010 (15 January to 15 February 2010). It is almost uniquely explained by diurnal-cycle of rainfall observed with weather radar (C-band Doppler Radar) over Jakarta and surrounding area.

In this study, we have shown a simulation of the diurnal cycle of Ciliwung River water level by distributed hydrological model (the CDRMV3 model). Using the CDR rainfall data, river discharge is simulated both for short period and one-month period in two station, i.e. Manggarai (downstream outlet) and Katulampa (upstream outlet), and verified by comparing with the observation discharge from those two station.

Further improvement of the simulation scheme for the diurnal-cycle rainfall is also discussed.

Introduction of the SCOSTEP's VarSITI program - Variability of the Sun and Its Terrestrial Impact

SHIOKAWA, Kazuo[1*] ; GEORGIEVA, Katya[2]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Space Research and Technologies Institute, Bulgarian Academy of Sciences

The Scientific Committee on Solar Terrestrial Physics (SCOSTEP) is an interdisciplinary body of the International Council for Science (ICSU) to run international interdisciplinary scientific programs and promotes solar-terrestrial physics research. The last solar minimum in 2008-2009 and the current solar maximum of sunspot cycle 24 show much lower activities compared with the previous two solar cycles 22 and 23. The scientists in the solar-terrestrial physics are watching very low solar activities and their consequences on Earth, which have never been observed since modern scientific measurements become available. The SCOSTEP program "Variability of the Sun and Its Terrestrial Impact (VarSITI)" (2014-2018) will focus on this particular low solar activity and their consequences on Earth, for various times scales from the order of thousands years to milliseconds, and for various locations and their connections from the solar interior to the Earth's atmosphere. In order to elucidate various sun-earth connections, we encourage communication between solar scientists (solar interior, sun, and the heliosphere) and geospace scientists (magnetosphere, ionosphere, and atmosphere). Campaign observations will be promoted for particular interval in collaboration with relevant satellite and ground-based missions as well as modeling efforts. Four scientific projects will be carried out in VarSITI as (1) Solar Evolution and Extrema (SEE), (2) International Study of Earth-Affecting Solar Transients (ISEST/Minimax24), (3) Specification and Prediction of the Coupled Inner-Magnetospheric Environment (SPeCIMEN), and (4) Role Of the Sun and the Middle atmosphere/thermosphere/ionosphere In Climate (ROSMIC). In this presentation we introduce the VarSITI program and its four projects to promote interdisciplinary studies among different fields.

California Nino/Nina in boreal summer

YUAN, Chaoxia[1*] ; YAMAGATA, Toshio[1]

[1]APL, JAMSTEC

Anomalous warming/cooling in the coastal ocean off Baja and Alta California has attracted broad attention due to its significant impacts on the coastal marine ecosystem. The anomalous warming/cooling has been attributed, especially in boreal winter, to the remote forcing of the tropical El Nino/Southern Oscillation (ENSO) through both oceanic and atmospheric teleconnections and/or the ENSO-independent basin-wide atmospheric circulation anomalies in mid-latitudes. In the present study, we show for the first time the existence of coastal air-sea coupled phenomenon in the coastal ocean off Baja and Alta California in boreal summer. An initial decrease/increase in the southward alongshore surface winds along the coast weakens/strengthens the coastal upwelling and raises/lowers the coastal sea surface temperatures (SSTs) through oceanic mixed-layer processes. The resultant coastal warming/cooling, in turn, heats/cools the overlying atmosphere anomalously, decreases/increases the atmospheric pressure in the lower troposphere, generates an anomalous cross-shore pressure gradient, and thus reinforces or maintains the alongshore surface wind anomalies. The air-sea coupled phenomenon is analogous to the well-known ENSO in the tropical Pacific but with much smaller time and space scales, and referred to as California Nino/Nina (CAN) after the pioneer work that describe the warming events in the coastal ocean off Baja and Alta California as California El Nino.

River discharges, ocean circulation and material transport in Japanese coastal waters: simulation with JCOPE ocean model

VARLAMOV, Sergey[1*] ; MIYAZAWA, Yasumasa[1] ; YAMASHIKI, Yosuke[2] ; SASAKI, Toshiaki[2]

[1]Japan Agency for Marine-Earth Science and Technlogy, [2]Graduate School of Advanced Integrated Studies in Human Survivability, Kyoto University

The total volume of fresh water discharged by rivers into the word ocean is incompatible with the total mass of ocean waters; however these discharges contribute significantly into formation of fresher coastal waters and details of coastal ocean circulation.

This impact is not local, and supports presence of lower salinity waters in wide coastal areas along Japanese coast. In an absence of rivers in ocean model for appropriate reproducibility of ocean surface salinity it is often required to apply salinity restoration approach. Additionally, rivers could bring to ocean surface-floating, suspended and dissolved substances, some of which are hazardous, like radioactive materials initially dropped on the ground following such disasters as Fukushima Dai-Ichi nuclear power plant accident. These could be washed to rivers by strong rainfalls.

Method of counting inflow of fresh water from rivers as horizontal fluxes to the designated model cells is used. Demonstrated are direct impacts of rivers on formation of fresher waters along the coast of Japan and some cases of induced by discharges local ocean circulation patterns near the river mouth locations. A preliminary experiment when the model utilizes the hourly information on the amount of river discharges demonstrates an importance of such approach for the correct simulation of transport processes in extreme conditions like the typhoon-induced precipitations that often take place in Japan and East Asia. For achieving of this capacity, we are looking for utilization of simple land waters hydrological models for main river basins that could transfer the detailed meteorological precipitation forecast information into the approximate forecasts of river discharges.

The recent great earthquake of magnitude 9.0 on 11 March 2011 followed by TSUNAMI and fire in Japan has resulted in serious environmental problems in and around Japan. A huge amount of materials has been discharged into the ocean after the tremendous flood damage by TSUNAMI. A research group of the National Institute of Advanced Industrial Science and Technology has sampled the perfluoroalkyl substances (PFAs), which are chemical materials included in the industrial products, in the Western North Pacific for past a few years. They found some evidences showing an abrupt increase of the PFAs concentration east of Japan in 2011 after the great earthquake. To confirm the anomalous input of two typical PFAs (PFOA and PFOS) from the Japanese coast into the ocean, we conducted a series of chemical tracer simulations using an eddy-resolving ocean reanalysis product, JCOPE2, by assuming the oceanic dispersion of the PFAs dissolved in sea water mainly driven by the ocean current. Comparison of the simulation results with the observation actually indicates a spike-like input of PFOA into the Western North Pacific after the great earthquake; however, the simulations could not well explain the observed distribution of PFOS, suggesting some differences in the oceanic dispersion processes between PFOA and PFOS. We discuss estimates of the total emission amounts of PFOA and PFOS based on a simple process representing the TSUNAMI effect on the emission from the land.

Super high resolution experiments of torrential rainfall events with the K super computer

OIZUMI, Tsutao[1*] ; KURODA, Tohru[1] ; SAITO, Kazuo[2]

[1]Japan Agency for Marine-Earth Science and Technology, [2]Meteorological Research Institute / JAMSTEC

In Japan, localized torrential rainfalls sometimes cause severe disasters which impact on the society. (e.g., the urban flash flood disaster at the Toga-gawa River in Kobe in July 2008, and the debris flow disaster in Izu Ohshima Island in 2013). In these events, the precipitation amountswere very different in the small areas, and they were likely strongly affected by geographical features. In the Kobe event case, about 70 % of the initial flow of the flash flood is from the urban area that covers only about 30 % of the entire catchment area (14 square kilo meters). In the Izu Ohoshima case, two meteorological observation stations are in the northern part and the middle part (near the damaged area) in the island, and the distance between the two stations is only 4 km. However, the quantity of observed precipitation in the middle in island was about twice as much as north.

To understand these phenomena, high resolution (several hundred meter scale resolution) numerical weather simulation is necessary. Super high resolution experiments have been made by previous studies such as tornado for limited domains, however, a numerical weather simulation with wide domain is very few due to limitation of the computational resources. We conduct super high resolution numerical weather experiments for Japan area with the K computer and JMA nonhydrostatic model.

Interannual variability of Kuroshio nitrate flux and transport along western boundary in the North Pacific

SASAI, Yoshikazu[1*] ; SASAKI, Hideharu[1] ; NONAKA, Masami[1]

[1]JAMSTEC

An eddy-resolving coupled physical-biological ocean model has been employed to examine the interannual variability of nitrate flux and transport mechanism by the Kuroshio during 1995-2012. The Kuroshio provides an advective flux of nitrate carried in subsurface waters, redistributing nitrate from the tropics to the mid-latitude. Some observed data capture the nitrate flux and transport in the subsurface layers by the Kuroshio. The maximum nitrate flux core appears about 400 m depth in the East China Sea, and the nitrate transport by the Kuroshio had a mean of 170 kmol s-1. The model reproduces the maximum nitrate flux core in the subsurface layer from the Luzon strait to the Kuroshio Extension with the downstream. Along the vertical section of east side of Taiwan (24N), west side of Okinawa (28N), south of Kagoshima (130E), the time series of nitrate flux, volume transport, and nitrate concentration show the interannual variation. The variability of nitrate flux is strongly correlated with the variability of Kuroshio volume transport, but the nitrate concentration shows the increasing trend between 1995 and 2008. This trend may be related to the variability of nitrate concentration in the upstream of Kuroshio.

High Resolution, Terrain Independent Radiation Mapping

SCOTT, Thomas[1*]

[1]Interface Analysis Centre School of Physics University of Bristol

The University of Bristol has developed a terrain-independent, wide area radiation mapping system using an UAV (Unmanned Aerial Vehicle). At the heart of the system is a micro computer, carried by a semi-autonomous multi-rotor copter (drone), combining data from a lightweight gamma spectrometer, laser range finder, and GPS, to geospatially map radioactive anomalies.

Aerial vehicles can be purpose built, according to range/flight time required, payload/sensing strategy and operational environment. For example, an unmanned vehicle could be tailored for mapping over both land and sea areas, where it could land in the sea at different locations to make water based gamma measurements. The system is also adaptable for use on ground vehicles, or handheld, walking surveys.

Information is streamed in real-time, providing high resolution detail on source isotopes, intensity and location of the radiation anomaly. More than just a flying Geiger counter, the system can differentiate between natural and man-made anomalies - such as types of nuclear fuel, radioactive waste or spent munitions.

This is all achieved from a safe distance, keeping people and manned aircraft away from hazardous environments.

Examples of uses include;

∗Rapid disaster response monitoring of nuclear events, providing real-time data on spread, source and intensity. This could range from site incidents to terrorist events.

∗Routine monitoring of nuclear sites (internally and externally), mining operations and oil and gas facilities.

∗Nuclear plants - new build: site survey and characterisation of pre and post construction and monitoring during plant life time.

∗Environmental monitoring for site decommissioning.

∗Environmental monitoring of war zones for spent depleted uranium munitions.

∗Homeland security and nuclear material detection.

The instrument securely transmits the location, identity and intensity of radionuclide contamination to a remote operator or base station. Sub metre resolution is attainable by flying slowly, even to the point of a fixed hover, relatively close to the ground.

It can be operated manually, using traditional radio-controls or semi autonomously via programmed GPS waypoints. Grid lines are used to create survey routes that provide detailed geographical coverage of a designated area. Programming can include automated landing and take-off, such that the device can gather long exposure spectra of the region of interest.

Heat budget analysis on cooling events associated with typhoon passages in Seto Inland Sea, Japan

UCHIYAMA, Yusuke[1*] ; NISHII, Tatsuya[1]

[1]Graduate School of Engineering, Kobe University

Typhoons alter coastal oceans significantly through several mechanisms including the enhanced vertical mixing through increased surface wind and waves, resulting in extensive cooling of the upper oceans. In the present study, we investigate impacts of typhoon passages with a detailed ocean modeling in particular on the temperature structure in Seto Inland Sea, the largest semi-enclosed estuary in Japan. We develop a synoptic, double nested downscaling ROMS model (Shchepetkin and McWilliams, 2005; 2008) forced by the assimilative JCOPES oceanic reanalysis (Miyazawa *et al*., 2009) and JMA GPV-MSM atmospheric reanalysis for the surface momentum, heat and radiation fluxes by exploiting a bulk formula developed for COAMPS. The horizontal grid refinement occurs from 1/12 degree (JCOPE2) to 2 km (ROMS-L1) and to 600 m (ROMS-L2), where the L2 model running for about two years (2012-2013) is our test bed for the comprehensive heat budget analysis. The persistent clockwise estuarine circulation and the eastward-flowing Kuroshio are key features that cause the overall circulations of the estuary.

In the fall 2012, SST is found to decrease about two degrees for a two-week period during three consecutive typhoons passing nearby. The first EOF mode of the modeled SST corresponds to the seasonal cooling along with mixed-layer deepening, whereas the effects of the typhoons appear in higher modes. Kuroshio interacts with the topography to form standing cyclonic cold-core eddies as extracted in the second mode, resulting in intermittent eastward cold-water transport beyond the headlands. The third and forth modes jointly represent cold water formation associated with storm-driven coastal upwelling that propagates with the estuarine circulation. Similar EOF modes are detected in the SST during the fall 2013 when two typhoons attacked the study area.

In the falls in 2012 and 2013 after the mid September when a series of typhoons pass by the estuary, the heat budget analysis exhibits that the net heat flux at surface becomes negative to induce prominent surface cooling and cold-water formation in the upper ocean. Whereas divergence of the horizontal advective heat flux is crucial in the daily-averaged heat budget, the surface net heat flux is essential to long-term temperature variation. Latent heat flux is found to play a primary role in the negative net surface flux as well as decrease of downward shortwave (solar) radiation. Unstable lowest atmospheric planetary boundary layer leads to pronounced changes in the latent heat flux in response to surface wind and abrupt decrease of the near-surface humidity after the typhoon passages.

Development of a hydro-ocean coupled model

KIDA, Shinichiro[1*] ; YAMASHIKI, Yosuke[2]

[1]Japan Agency for Marine-Earth Science and Technology, [2]Kyoto University

A new hydro-oceanic coupled model is developed for examining the basic dynamics of river-ocean interaction in estuary zones during high water discharge events. These high frequency and vigorous events are not reproduced in climatological river transport data sets that are often used in ocean circulation models. The new hydro-oceanic model is based on an isopycnal layer model. It treats continental and oceanic water with separate layers but allows dynamical interaction between the two. Mixing between the two layers occurs through a Richardson number criterion. When the model is forced with Radar-Rain gauge analyzed precipitation data around eastern Japan, the model simulates the river discharge of Abukuma river basin that is analogous to observations. The abrupt changes in the water mass transport at upstream and downstream locations are well captured, showing its applicability for hydrological basin analysis. Freshwater plumes that hug along the oceanic coasts are also well captured. We find the model, based on single dynamical core, useful for both hydrological catchment and estuary mixing zone and can be used for examining the impact of weather related events.

FIELD OBSERVATION ON PHYSICAL CHARACTERISTICS OF ABUKUMA RIVER ESTUARY IN SENDAI BAY

YAMASHIKI, Yosuke[1*] ; PRATAMA, Adhiraga[3] ; VARLAMOV, Sergey[4] ; MIYAZAWA, Yasumasa[4] ; YAMAZAKI, Hideo[5] ; ISHIDA, Masanobu[5] ; NIWA, Yoshihiro[6]

[1]GSAIS, Kyoto University, [2]Application Laboratory, JAMSTEC, [3]GSE, Kyoto University, [4]RCGC, JAMSTEC, [5]Kinki University, [6]EPS, The University of Tokyo

Higher amount of radiocaesium transport from Abukuma river into Pacific Ocean, especially during the extreme events, has already estimated. The current study aims to clarify the following: i)to survey estuary mixing processes during freshwater and turbidity intrusion from Abukuma river mouth, largest river basin affected fallout, where annual radiocaesium flux reached 10 Terabecquerel during our observation in 2011-2012; ii) To identify bottom-sediment contamination along the river mouth by sediment sampling. Field observation was conducted both in March 18 and September 2-3 in 2013 in Sendai Bay. Vertical temperature and turbidity, together with the salinity field are observed using fishing vessel. We analyzed also vertical velocity profile using ADCP to identify the current movement of the bay. The velocity fields in Sendai Bay of the observation date are illustrated using JCOPE2 program.Figures 1 illustrates observation points, vertical salinity, turbidity and temperature field in each points, and vertical velocity profile observed in 18 March 2013 . The eastward surface current was observed in each transection line. At near bottom of the sea, westward current was observed, indicating estuary circulation. Southward surface current was observed in most of latitudinal section, weak northward bottom current was also found Freshwater intrusion was observed on some of the stations in transection A which is located near the mouth of Abukuma River.In most of the station, turbidity peak was observed in near bottom of the sea, except in some station in transection A where the peak of turbidity was found in surface similar to the location of freshwater intrusion. Higher concentration of radiocaesium in the bottom sediment near the Abukuma river mouth is observed where fine argilliferous soil are found, much higher than that in surrounded area, giving important evidence of radiocaesium in particulate form supplied from Abukuma River. Peaks of turbidity near the river mouth were found at slightly lower position than the freshwater-saline boundary at stations 1 and 3 (March 20), implying that the occurrence of coagulation of suspended particulate matter through mixing with saline water, supporting the observed concentration found in (1).

Development of Satellite data manipulator for geography analysis

NAKANO, Fujio[1*]

[1]Japan Aerospace Exploration Agency, [2]Kyoto University

Development of Satellite data manipulator for geography analysis

ALOS (Advanced Land Observing Satellite: common name ”Daichi”) carried the sensor PRISM which can observe earth surface in high accuracy, and enabled acquisition of DSM (Digital Surface Model) data. By utilizing the data acquired by such an advanced sensor, it becomes possible to display high-precision three-dimensional satellite data. Using satellite data as three dimensions means expansion of the utilization range, and it can expect unprecedented multi-functionalization. Furthermore, three-dimensional satellite data was displayed on iPad interlocked with GPS in various satellite data including ALOS data, and ”Geo-Sim” which can be used also in area without communication environment was developed. Thereby, the generating situation of a mudflow or the ancient coastline is reproduced by CG, and the matching operation on-site becomes possible.

Land-Ocean Mutual Interaction: Sediment Transportation Processes in Coastal Zone Induced by Abukuma River Mouth Runoff

TROSELJ, Josko[1*] ; YAMASHIKI, Yosuke[2] ; TAKARA, Kaoru[3]

[1]Graduate School of Engineering, Kyoto University, [2]Graduate School of Advanced Integrated Studies in Human Survivability, Kyoto University, [3]Disaster Prevention Research Institute, Kyoto University

1. Introduction

Modeling of a contact zone between a river coming from potentially contaminated basin and an ocean is especially sensitive case for Land-Ocean coupling interaction due to significant risk of major environmental disaster which can occur in the case of contamination of the coastal zone. Therefore, it is of great importance to study and develop integrated modeling approach to comprehend the complex interaction processes in the contact zone in order to minimize disaster risk potential, which can consequently cause undesirable social and economical costs.

2. Objectives

The focus of this study is to promote relevant numerical simulation on Land-Ocean coupling modeling approach applicable for the bay and estuary zone affected by river inflow and associated sediment transportation from the Abukuma river basin in Japan. By conducting several field observations, we found interesting and unusual temporal and spatial distribution of radionuclides within the coastal zone near the river mouth. Sediment transportation processes which have led to the distribution as well as influence of near-shore bathymetry to sediment dispersion are of close interest for the study. Calculation was conducted by simulating stages and conditions for mechanisms of sediment transport in the coastal zone, from initial deposition onto river bed to final deposition onto ocean floor, with special focus on processes which are occurring during high water periods.

3. Model Description

The modeling approach has been studied by combining river mouth runoff boundary conditions by using Lagrangian particle tracking model for simulating sediment transportation, with coupled atmosphere-ocean-land model (MSSG model, JAMSTEC) which used fine resolution grid, and associated downscaling techniques for oceanic boundary conditions (JCOPE2 model, JAMSTEC) which used coarse resolution grid. We have simulated two different cases, at first circulation of ocean itself in non-equilibrium quasi stationary state, where its dynamics was induced only by its own temperature and salinity data differences among adjacent cells, and at second response of the ocean circulation to inflow from the river outlet, simulated under various boundary conditions and external effects.

ETOPO1, 1 Arc Minute Global Relief Model was chosen as initial database for bathymetry data, while World Ocean Atlas 2005 database was chosen as initial 3D database for temperature, salinity, pressure, and velocity field data. Incompressive Navier-Stokes equation and Yin-Yang grid were used in the calculation of the flow field.

4. Conclusions and follow up

The study is continuous part of the PhD study of the first author, so the results are about to be improved as the course will continue. So far, results neither confirmed nor denied the hypothesis that near-shore bathymetry may have important role in spatial dispersion of radionuclides, so the question still remains open and subject for discussion. Our assumption is that using fine resolution grid within the contact zone between two different fluids should give us better insight into the problem, while simultaneously proper downscaling of outer oceanic boundary conditions and proper coupling with sediment transportation model are needed to be done in order to maintain satisfactory level of simulated physics of processes during the calculation. In follow up of the study, we will try to simulate hydrograph based water wave rather than constant inflow from the river mouth, as well as try to put ocean side into initial dynamic state rather than non-equilibrium quasi stationary state. Also, more focus will be aimed to the physical processes behind mechanisms of radionuclide transportation from the basin towards the river mouth.

modelling of radiocesium movement in catchment area of abukuma river, japan

PRATAMA, Mochamad adhiraga[1*] ; YAMASHIKI, Yosuke[2] ; YONEDA, Minoru[1]

[1]Department of Environmental Engineering, Kyoto University, [2]Graduate School of Advanced Integrated Studies in Human Survivability, Kyoto University

The great earthquake on March of 2011 followed by tsunami caused Fukushima Dai-ichi reactor meltdown which led to explosion and emission of radioactive substances into environment. As a result, Abukuma River, one of the most important rivers in Japan and its catchment area, received up to 2.25 x 10^6 Bq/m^2 of radiocesium. Previous study found that 80-90% of radiocesium influx to Abukuma River was in particulate form and it was estimated that 10 TBq of the radionuclide was released into the end point of the river, coastal sea of Sendai Bay. A lot of models of radionuclides movement had been developed, however just few models that account solid wash off process in catchment area . This study tried to simulate the influx of radiocesium into Abukuma River from its catchment area by modifying MOIRA model with addition on solid transport which was calculated with SWAT model. Deposition of the radiocesium was used as an input of the model. Then after, fixation process into surface ground, liquid wash-off by surface run off, and solid wash off by erosion are the mechanisms which govern the dynamic of the radiocesium in this model. The result at the model shows an agreement compared to the observed data. With R^2 value of 0.8 showed that the model could explain seasonal variability of observed data. However, as several uncertainties were observed such as quantification of storm effect and decontamination activities, further study to optimize and improve the result of the model is deemed necessary

A Study of Contribution of ”Nanohana Project” and Agricultural restoration in Sukagawa, Fukushima, Japan

KIMURA, Naoko[1*]

[1]GSGES, Kyoto University

This paper explores for what and to what extent ”Nanohana Project” contributes to restoration in Sukagawa, Fukushima Prefecture, Japan. Since the huge earthquake and tsunami occurred in March 2011, agricultural fields in these cities have been suffering damages caused by radionuclides classified as nuclear-fission products from the Fukushima No.1 Nuclear Power Plant (Tokyo Electricity Power Company (TEPCO)) due to the accident. Agricultural field restoration, especially decontamination of radionuclides from the soil, is one of the most important issues to be tackled for local farmers. This research reviews literatures regarding and conducted an interview to an agricultural production corporation in Sukagawa in order to grasp what initiatives has been taken to reduce radionuclides in their products as well as to fight to bad rumors among general public. ”Nanohana Project” has been implemented with local stakeholders in Sukagawa since 2007. They grow Nanohana (rapeseed flower or colza, Brassica Napus) and produce Biodiesel fuel (BDF) from seeds as well as biogas (BG) out of the pomace (leaves and stems after producing BDF), and they use the BDF and BG in the local area. The Nanohana absorbs some radionuclides in the soil in its growing process, and there was attention to it after disaster, however some scientific researches found that the absorption amount is limited and may not be a remedy itself for decontamination of radionuclides. Nevertheless, ”Nanohana Project” has been ongoing and the network is expanding in Sukagawa. This paper discusses contribution of ”Nanohana Project” and initiatives by an agricultural production corporation for restoration through qualitative analysis of interview and some key figures in order to speculate the Project’s possible roles for future reconstruction in the region.

The relationship between monthly and yearly trend of Ammonia and SS loading at Rhine River and land use change

TERAMOTO, Tomoko[1] ; YAMASHIKI, Yosuke[2*] ; TAKARA, Kaoru[3]

[1]Department of Environmental Engineering Graduate School of Engineering Kyoto University, [2]Graduate School of Advanced Integrated Studies in Human Survivability Kyoto University, [3]Disaster Prevention Research Institute, Kyoto University

Rhine River is the international river, which flows through several countries, so it is important to know and maintain the water quality. To estimate the gross loading to the marine environment is necessary for assessment of the current status of the coastal zone, especially for the water quality of Bays and Estuary zone.

In this study, we estimate Ammonia SS loading at Rhine River by using GEMS/Water (Global Environment Monitoring System/ Water) Dataset and GRDC (Global Runoff Data Centre) Dataset.

The procedure of this research is three steps. First, we have used the set of discharge data obtained from GRDC to be used for the loading estimation based on the observed data. Second, the locations of GEMS/Water and GRDC station have been compared to identify appropriate station to set the calculation loading. Finally, we have multiplied concentration and discharge to get the loading.

The characteristics land use of Rhine River basin has been analyzed using the Global Land Cover Characterization dataset prepared by USGS.

For land use change of Rhine River basin has been analyzed by using landsat5 and landsat7 images.

The concentration and loading results show seven things :(1) From December to February, Ammonia concentration was higher than other months. (2) From January to march, Ammonia loading was higher than other months. (3) Ammonia concentration was gradually decreasing except through1983 to 1987. (4) Ammonia loading was decreasing and the number suddenly dropped at 1989 (5) SS concentration was stable through 1979 to 1994 except 1983, 1984 and 1995. (6) From December to February SS loading was higher than other months. (7) SS loading was gradually decreasing and the number suddenly dropped at 1989.

The Rhine river watershed is mainly forest and grassland by analyzing land use from USGS data. This land use affects water quality

NASA Earth Science and Applications

FREILICH, Michael[1*]

[1]Director, Earth Science Div. NASA Headquarters

Earth is a complex, dynamic system we do not yet fully understand. The Earth system, like the human body, comprises diverse components that interact in complex ways. We need to understand the Earth's atmosphere, lithosphere, hydrosphere, cryosphere, and biosphere as a single connected system. Our planet is changing on all spatial and temporal scales. The purpose of NASA's Earth science program is to develop a scientific understanding of Earth's system and its response to natural or human-induced changes, and to improve prediction of climate, weather, and natural hazards. A major component of NASA's Earth Science Division is a coordinated series of satellite and airborne missions for long-term global observations of the land surface, biosphere, solid Earth, atmosphere, and oceans. This coordinated approach enables an improved understanding of the Earth as an integrated system.

Over the coming decades, NASA and the Agency's research partners will continue to pioneer the use of both spaceborne and aircraft measurements to characterize, understand, and predict variability and trends in Earth's system for both research and applications. NASA Earth System Science conducts and sponsors research, collects new observations, develops technologies and extends science and technology education to learners of all ages. We work closely with our global partners in government, industry, and the public to enhance economic security, and environmental stewardship, benefiting society in many tangible ways. We conduct and sponsor research to answer fundamental science questions about the changes we see in climate, weather, and natural hazards, and deliver sound science that helps decision-makers make informed decisions. We inspire the next generation of explorers by providing opportunities for learners of all ages to investigate the Earth system using unique NASA resources, and our Earth System research is strengthening science, technology, engineering and mathematics education nationwide.

JAXA's Earth Observation Missions

NAKAMURA, Kenji[1*] ; FUKUDA, Toru[2]

[1]Earth Observation Research Center, Japan Aerospace Exploration Agency/Dokkyo University, [2]Earth Observation Research Center, Japan Aerospace Exploration Agency

The Japan Aerospace Exploration Agency (JAXA) is promoting the Earth observation from space. JAXA is now operating GOSAT (the Green House Gases Observing Satellite) and GCOM-W1 (the Global Change Observation Mission 1st-Water). The GOSAT mission is a joint effort of JAXA, the National Institute for Environmental Studies (NIES) and the Ministry of the Environment (MOE). GOSAT has been launched in January 2009, and is equipped with the Fourier Transform Spectrometer and the Cloud Aerosol Imager providing global distribution of carbon dioxide and methane with seasonal changes. GCOM-W1 was launched in May 2012 for global water cycle observation and has the AMSR-2 (Advanced Microwave Scanning Radiometer 2). AMSR-2 follows the design of AMSR which was aboard ADEOS-2 satellite, but with improvements in antenna size and onboard calibration, etc. JAXA is also operating the Precipitation Radar (PR) aboard the TRMM (Tropical Rainfall Measuring Mission) satellite and Advanced Microwave Scanning Radiometer (AMSR-E) aboard Aqua satellite of the National Aeronautics and Space Administration (NASA). TRMM is a joint venture of JAXA and NASA. The TRMM satellite was launched in 1997 and is still in operation. The Precipitation Radar (PR) aboard the TRMM satellite is the first spaceborne radar dedicated for precipitation observation developed by JAXA and the National Institute of Information and Communications Technology, Japan (NICT). The data from PR for more than 16 years contributed much for better understanding the precipitation system climatology over tropical and subtropical regions. The Global Precipitation Measurement (GPM) which is led by JAXA and NASA with international collaboration is a multi-satellite system dedicated for the global precipitation observation. The core satellite of GPM will be launched by JAXA at the end of February 2014. JAXA has developed the dual-wavelength radar (DPR) with NICT for the GPM core satellite. DPR will observe rain including solid precipitation with better accuracy than TRMM PR. The ALOS-2 (Advanced Lang Observing Satellite-2) which is equipped with an L-band Synthetic Aperture Radar (PALSAR) is scheduled to launch in 2014. ALOS-2 is a follow-on mission from ALOS contributing to cartography, disaster monitoring, resource survey, etc. EarthCARE for cloud and aerosol observation is a collaboration mission with the European Space Agency (ESA). JAXA has developed a W-band Cloud Profiling Radar (CPR) with NICT for EarthCARE. CPR has high sensitivity to clouds with Doppler function. Using the Doppler function CPR can measure the vertical movement of clouds which is important to understand the cloudy systems. JAXA is also developing GCOM-C1 (the Global Change Observation Mission 1st-Climate) which is for surface and atmospheric measurements related to the carbon cycle and radiation budget. An SGLI (Second Generation Global Imager) will be aboard the satellite. JAXA is also studying future sensors including small sensors for the International Space Station (ISS).

Greenhouse gas observation by GOSAT during its five-year nominal operation period

YOKOTA, Tatsuya[1*] ; KIKUCHI, Nobuhiro[1] ; YOSHIDA, Yukio[1] ; BRIL, Andrey[1] ; OSHCHEPKOV, Sergey[1] ; INOUE, Makoto[1] ; MORINO, Isamu[1] ; UCHINO, Osamu[1] ; KIM, Heon-sook[1] ; TAKAGI, Hiroshi[1] ; SAITO, Makoto[1] ; MAKSYUTOV, Shamil[1] ; YUKI, Akira[1] ; KANEKON, Sayaka[1] ; KAWAZOE, Fumie[1] ; AJIRO, Masataka[1]

[1]National Institute for Environmental Studies

The Greenhouse gases Observing SATellite (GOSAT) recently completed its planned nominal operation period of five years on 23 January 2014, and it now entered the phase of extended operation. During the past five years, almost all of the GOSAT standard data products were opened to general users. These data products are publicly available and can be obtained through the GOSAT User Interface Gateway (GUIG, http://www.data.gosat.nies.go.jp/). From the spectral data that GOSAT collected, the concentrations of major greenhouse gases (GHGs), namely carbon dioxide (CO_2) and methane (CH_4), were retrieved, and their precisions are now at the level of much less than 1%. These concentration data are used to estimate the monthly surface fluxes of CO_2 and CH_4 on sub-continental and ocean-basin scales. The data are also utilized to monitor GHGs' temporal and spatial changes. Various reports on the results of GOSAT data analysis have appeared in peer-reviewed journals so far. The topics reported include the detection of large GHG point sources and anomalies in the inter-annual trend of CO_2 uptake by terrestrial biosphere.

In this presentation, we will summarize the five-year-long GHG observation by GOSAT and present the global distributions of the GHG concentrations and the surface flux estimates. Also, we will touch on the current status of researches conducted within the framework of the GOSAT Research Announcement.

The NASA Orbiting Carbon Observatory - 2 (OCO-2), the next step in CO2 measurements from space

CRISP, David[1*]

[1]Jet Propulsion Laboratory, Caltech

Global, space-based remote sensing observations of atmospheric carbon dioxide (CO_2) and methane (CH_4) hold substantial promise for future, long-term monitoring of these important greenhouse gases. These measurements will complement those from the existing ground based greenhouse gas monitoring network with increased spatial coverage and sampling resolution. The principle challenge for this approach is the high precision and accuracy needed to resolve the small (<0.3 percent) variations in the background distributions of these gases associated with their emission sources and natural sinks. The European Space Agency (ESA) EnviSat SCIAMACHY and Japanese Greenhouse Gases Observing Satellite (GOSAT) TANSO-FTS were the first two space-based sensors designed to return high resolution spectra of the reflected sunlight in molecular oxygen (O_2), CO_2, and CH_4 bands at near-infrared wavelengths. These spectra are being analyzed to yield spatially resolved estimates of the column-averaged CO_2 and CH_4 dry air mole fractions (X_{CO2}, X_{CH4}) over the sunlit hemisphere. The availability of these data has already enabled substantial improvements in instrument calibration techniques, remote sensing retrieval algorithms, and data validation techniques. However, sensors with greater sensitivity, coverage, and resolution are needed to implement the space-based segment of a global greenhouse gas monitoring system.

In July of 2014, these space-based greenhouse gas pathfinders will be joined by the NASA Orbiting Carbon Observatory-2 (OCO-2). This satellite will fly at the front of the 705-km Afternoon Constellation (A-Train), along an orbit track aligned with the ground footprints of the CloudSat radar and CALIPSO lidar. Its 3-channel, imaging, grating spectrometer has been optimized to record high resolution spectra of reflected sunlight in the 765 nm O_2 A-band and in the 1610 and 2060 nm CO_2 bands. Coincident O_2 and CO_2 spectra are combined into soundings that are analyzed with a full-physics retrieval algorithm to yield estimates of X_{CO2} with accuracies exceeding 0.3 percent over most of the Earth. The OCO-2 spectrometer will collect up to 1 million of these soundings each day along a narrow ground track as it flies over the sunlit hemisphere. Between 20 and 30% of these soundings are expected to be sufficiently cloud free to yield full-column estimates of X_{CO2}. Even with these assets, OCO-2 is still only a research satellite, designed to validate a space-based CO_2 measurement approach. A coordinated network of satellites with similar capabilities will be needed to discriminate and quantify the CO_2 emissions from fossil fuel combustion, land use practices, and other human activities in the presence of the much larger CO_2 fluxes associated with the natural carbon cycle.

Development of a 3D solar induced chlorophyll fluorescence simulator for satellite fluorescence observation

KOBAYASHI, Hideki[1*] ; NAGAI, Shin[1] ; INOUE, Tomoharu[1] ; ICHII, Kazuhito[1]

[1]Japan Agency for Marine-Earth Science and Technology

Recent studies show that the vegetation canopy scale chlorophyll fluorescence can be observed from satellite, such as GOSAT and OCO-2, using Fraunhofer lines (e.g. Frankenberg et al., 2011). Satellite-based fluorescence can be used to infer the photosynthetic capacity of plant canopy. To understand how the canopy scale bidirectional fluorescence observations are related to three-dimensional fluorescence distribution within a plant canopy, it is necessary to evaluate canopy scale fluorescence emission using a detail plant canopy radiative transfer model. In this study, we developed a three-dimensional plant canopy radiative transfer model that can simulate the bidirectional chlorophyll fluorescence radiance. This modeling was based on the 3D radiative transfer model, forest light environmental simulator (FLiES) (Kobayashi and Iwabuchi, 2008). FLiES is a Monte Carlo ray-tracing model to simulate radiative field in shortwave (solar domain) and long-wave (thermal infrared) radiation in 3D landscape. To realize individual tree crown shapes, the original FLiES model used geometric objects such as cone, cylinder, and spheroid. Recently, FLiES has been extending to utilize voxel-based tree crown datasets, which are favorable to LiDAR based tree crown data sets. In this presentation, we show the current status of the development of the 3D chlorophyll fluorescence simulator.

Orbital checkout status of the DPR on the GPM core spacecraft

KOJIMA, Masahiro[1*] ; FURUKAWA, Kinji[1] ; MIURA, Takeshi[1] ; HYAKUSOKU, Yasutoshi[1] ; KAI, Hiroki[1] ; ISHIKIRI, Takayuki[1] ; IGUCHI, Toshio[2] ; HANADO, Hiroshi[2] ; NAKAGAWA, Katsuhiro[2] ; OKUMURA, Minoru[3]

[1]Japan Aerospace Exploration Agency, [2]National Institute of Information and Communications Technology, [3]NEC TOSHIBA Space systems

The Dual-frequency Precipitation Radar (DPR) on the Global Precipitation Measurement (GPM) core satellite was developed by Japan Aerospace Exploration Agency (JAXA) and National Institute of Information and Communications Technology (NICT). The GPM is a follow-on mission of the Tropical Rainfall Measuring Mission (TRMM). The objectives of the GPM mission are to observe global precipitation more frequently and accurately than TRMM. The frequent precipitation measurement about every three hours will be achieved by some constellation satellites with microwave radiometers (MWRs) or microwave sounders (MWSs), which will be developed by various countries. The accurate measurement of precipitation in mid-high latitudes will be achieved by the DPR. The GPM core satellite is a joint product of National Aeronautics and Space Administration (NASA), JAXA and NICT. NASA developed the satellite bus and the GPM microwave radiometer (GMI), and JAXA and NICT developed the DPR. JAXA and NICT developed the DPR through procurement. The contract for DPR was awarded to NEC TOSHIBA Space Systems, Ltd.

The configuration of precipitation measurement using an active radar and a passive radiometer is similar to TRMM. The major difference is that DPR is used in GPM instead of the precipitation radar (PR) in TRMM. The inclination of the core satellite is 65 degrees, and the flight altitude is about 407 km. The non-sun-synchronous circular orbit is necessary for measuring the diurnal change of rainfall similarly to TRMM. The DPR consists of two radars, which are Ku-band (13.6 GHz) precipitation radar (KuPR) and Ka-band (35.5 GHz) precipitation radar (KaPR). The objectives of the DPR are

(1) to provide three-dimensional precipitation structure including snowfall over both ocean and land,
(2) to improve the sensitivity and accuracy of precipitation measurement,
(3) to calibrate the estimated precipitation amount by MWRs and MWSs on the constellation satellites.

The DPR consists of Ku-band (13.6 GHz) precipitation radar (KuPR) and Ka-band (35.5 GHz) precipitation radar (KaPR). The KuPR unit will measure 2.6m X 2.4m X 0.7m in size. The KaPR unit will measure 1.3m X 1.5m X 0.8m in size. Both KuPR and KaPR have almost the same design as TRMM PR. The DPR system design and performance were verified through the development test and the proto flight test. DPR has handed over to NASA and integration of the DPR to the GPM core spacecraft have completed in May 2012. GPM core spacecraft satellite system test has completed in November 2013. The results of the satellite system test concerning to the DPR satisfied system requirements.

GPM core observatory was shipped to Tanegashima Space Center, JAPAN and Launch Site Operations has started on November 2013 and GPM core observatory will be launched in February 2014. DPR orbital check out will be started in March 2014 and it will be completed in April 2014. The orbital check out status of DPR will be reported .

The Global Precipitation Measurement (GPM) mission is a satellite program led by Japan and the U.S., to measure the global distribution of precipitation accurately in a sufficient frequency so that the information provided by this program can drastically improve hydrological predictions, climate modeling, and understanding of water cycles. The GPM Core Observatory carries the Dual-frequency Precipitation Radar (DPR) developed by Japan Aerospace Exploration Agency (JAXA) and the National Institute of Information and Communications Technology (NICT), and the GPM Microwave Imager (GMI) developed by the National Aeronautics and Space Administration (NASA). The frequent precipitation measurement about every three hours will be achieved by constellation satellites with microwave radiometers or microwave sounders, which will be developed by international partners. JAXA also provides the Global Change Observation Mission (GCOM) 1st ? Water (GCOM-W1) named ”SHIZUKU,” launched on May 18, 2012, as one of constellation satellites.

The Japanese GPM research project conducts scientific activities on algorithm development, ground validation, application research including production of research products. In addition to those activities, we promote collaboration studies in Japan and Asian countries, and seek potential users of satellite precipitation products. JAXA develops the DPR Level 1 algorithm, and the NASA-JAXA Joint Algorithm Team develops the DPR Level 2 and DPR-GMI combined Level2 algorithms. JAXA also develops the Global Rainfall Map algorithm, which is a new version of the Global Satellite Mapping of Precipitation (GSMaP), as one of national products to distribute hourly and 0.1-degree horizontal resolution rainfall map. In the GPM era, the GSMaP algorithm will be improved by refining rainfall retrievals over land, considered the orographic rainfall effects, added the rain gauge corrected rainfall product. In the future, information from the Dual-frequency Precipitation Radar (DPR) will be compiled as a database to improve the retrieval accuracy of weak rainfall in mid-to-high latitudes.

The GPM Core Observatory is scheduled to be launched from the JAXA Takengashima Space Center by the H-IIA F23 rocket around 3:07 a.m. thru 5:07 a.m. (JST) on February 28 (Fri.,) 2014. After the initial checkout (about 2-month,) calibration and validation of the DPR, GMI and other products will be implemented toward the public release of all products to general users. Data release date is currently scheduled to be 6-month after the launch.

[1]Japan Aerospace Exploration Agency, [2]National Institute of Information and Communications Technology, [3]Nagasaki University, [4]Tokai University, [5]Remote Sensing Technology Center of Japan

The Global Precipitation Measurement (GPM) Mission consists of a Tropical Rainfall Measuring Mission (TRMM)-like non-sun-synchronous orbiting satellite (GPM Core Observatory) and a constellation of satellites carrying microwave radiometer instruments. The GPM Core Observatory, which will be launched in 28 February 2014, carries the Dual-frequency Precipitation Radar (DPR) developed by the Japan Aerospace Exploration Agency (JAXA) and the National Institute of Information and Communications Technology (NICT). The DPR consists of two radars; Ku-band (13.6 GHz) precipitation radar (KuPR) and Ka-band (35.55 GHz) radar (KaPR). The DPR is expected to advance precipitation science by expanding the coverage of observations to higher latitudes than those obtained by the TRMM Precipitation Radar (PR), by measuring snow and light rain via high-sensitivity observations from the KaPR, and by providing drop size distribution (DSD) information based on the differential scattering properties of the two frequencies. For operational productions of precipitation datasets, it is necessary to develop computationally efficient, fast-processing DPR Level-2 (L2) algorithms that can provide estimated precipitation rates, radar reflectivity factors, and precipitation information, such as the DSD and precipitation type. The L2 algorithms have been developed by the DPR Algorithm Development Team under the NASA-JAXA Joint Algorithm Team.

Before the launch of the GPM Core Observatory, synthetic DPR Level-1 (L1) data are needed as a test bed for the DPR L2 algorithms. In this work, we use data simulated from the TRMM/PR. The primary advantage is that measured Ku-band data from the TRMM/PR, obtained under a wide variety of meteorological conditions, forms the basis of the simulation. As such, the results can be compared directly to the standard TRMM/PR retrievals. Thus, ”at-launch” codes of DPR precipitation algorithms, which will be used in GPM ground systems at launch, were evaluated using synthetic data based upon the TRMM/PR data. Results from the codes (Version 4.20131010) of the KuPR-only, KaPR-only, and DPR algorithms were compared with ”true values” calculated based upon drop size distributions assumed in the synthetic data and standard results from the TRMM algorithms at an altitude of 2 km over the ocean. The results indicate that the total precipitation amounts during April 2011 from the KuPR and DPR algorithms are similar to the true values, while the estimates from the KaPR data are underestimated. By analysis results, the underestimation of the KaPR can be caused by a problem in the attenuation correction method. This was verified by the improved codes (Version 4.20131129), and so this problem has been resolved in the latest version.

After the launch, calibration and validation of the DPR products will be implemented toward the public release of all products to general users. Data release date is currently scheduled to be 6-month after the launch. In this work, we introduce initial validation results of the DPR-L2 product, mainly based upon comparisons of the TRMM/PR product.

Expectations for the Global Precipitation Measurements for Precipitation Sciences

TAKAYABU, Yukari[1*] ; OKI, Riko[2] ; IGUCHI, Toshio[3] ; AONASHI, Kazumasa[4] ; KACHI, Misako[2] ; KUBOTA, Takuji[2] ; HAMADA, Atsushi[1] ; TAKAHASHI, Nobuhiro[3] ; NAKAMURA, Kenji[5]

[1]The University of Tokyo, [2]Japan Aerospace Exploration Agency, [3]National Institute of Information and Communications Technology, [4]Meteorological Research Institute, Japan Meteorological Agency, [5]Dokkyo University

Three dimensional precipitation data observed with Ku (13.8GHz) band Precipitation Radar (PR) on board the Tropical Rainfall Measurement Mission (TRMM) satellite have enabled us to discover various precipitation characteristics over the tropics and subtropics between 36N and 36S. Precipitation system regimes are estimated with precipitation characteristics. The multiple instrument observations of TRMM have also made us quantify the discrepancies between TRMM Microwave Imager (TMI) vs. PR estimated rainfall, and provided us with opportunities to investigate various approaches to improve the rainfall retrieval algorithms.

With the launch of the GPM/DPR, scheduled in February 2014, dual band measurements from space with Ku (13.6GHz) and Ka (35.5GHz) band frequencies will be started. Increasing information of the drop size distributions with DPR should improve the accuracy of precipitation profile structures, which are essential to study precipitation characteristics. GPM/DPR will provide excellent cross calibrations for constellation microwave observations to construct better mapping of precipitation from 65N to 65S, which covers 91% of the earth surface. Weak rainfall measurements will enable us better energy budget calculations after all, as well as more precise examinations of rainfall system lifecycles. We can also expect reexamination and further improvements of TRMM PR rainfall products by comparing Ku-band retrievals with DPR retrievals.

Three dimensional satellite measurement of precipitation at mid-to-high latitudes is a completely new scientific experiment. Since the precipitation systems there are very different from those in the tropics and subtropics, we can certainly expect further scientific discoveries to improve our knowledge of precipitation characteristics with thorough observations from the satellite. Using this outcomes, we also expect to provide useful knowledge to improve the numerical models for weather predictions and climate projections.

The Global Precipitation Measurement (GPM) Mission: Advancing precipitation measurement for science and society

KIRSCHBAUM, Dalia[1*]

[1]NASA Goddard Space Flight Center

Too much or too little rain can serve as a tipping point for triggering catastrophic flooding and landslides or widespread drought. Knowing when, where and how much rain is falling globally is vital to understanding how vulnerable areas may be more or less impacted by these disasters. Global Precipitation Measurement (GPM) is an international satellite mission to provide next-generation observations of rain and snow worldwide every three hours. The foundation of the GPM mission is the Core Observatory satellite provided by NASA and JAXA. This satellite, launching in early 2014, carries advanced instruments that will set a new standard for precipitation measurements from space. The Core satellite will measure rain and snow using two science instruments: the GPM Microwave Imager (GMI) and the Dual-frequency Precipitation Radar (DPR). The GMI captures precipitation intensities and horizontal patterns, while the DPR provides insights into the three dimensional structure of precipitating particles. Together these two instruments provide a database of measurements against which other partner satellites' microwave observations can be meaningfully compared and combined to make a global precipitation dataset.

Data collected from the Core satellite serves as a reference standard that will unify precipitation measurements from research and operational satellites launched by a consortium of GPM partners in the United States, Japan, France, India, and Europe. The GPM constellation of satellites can observe precipitation over the entire globe within 3 hours of acquisition. The GPM mission will help advance our understanding of Earth's water and energy cycles, improve the forecasting of extreme events that cause natural disasters, and extend current capabilities of using satellite precipitation information to directly benefit society.

Development of attenuation correction method for GPM/DPR

SETO, Shinta[1*] ; IGUCHI, Toshio[2]

[1]Graduate School of Engineering, Nagasaki University, [2]National Institute for Information and Communications Technology

A new attenuation correction method is developed for the Dual-frequency Precipitation Radar (DPR) on the core satellite of the Global Precipitation Measurement (GPM) mission. Hitschfeld and Bordan's attenuation correction method (HB method) assumes relation between the specific attenuation k and the effective radar reflectivity factor Z_e (k-Ze relation) as $k=aZ_e^b$. The new method is based on HB method, but k-Ze relation is modified as $k=eaZ_e^b$ by using dual-frequency ratio of Z_e (DFR) and surface reference technique (SRT). Therefore, the new method is called HB-DFR-SRT method (H-D-S method in short). While the authors' previous attenuation correction method called HB-DFR method (H-D method in short) results in underestimation of precipitation rates for heavy precipitation, H-D-S method and its improved version try to correct the negative bias by means of SRT. When only single-frequency measurement is available, H-D-S method can be easily switched to HB-SRT method (H-S method in short), which is similar to the attenuation correction method used in the TRMM/PR standard algorithm.

The attenuation correction methods are tested with a simple synthetic dataset of DPR. As long as SRT gives the prefect estimates of path integrated attenuation (PIA) and the parameters of k-Ze relation (a and b) are given properly so that e could be vertically constant, H-S method is much better than the dual-frequency methods. In reality, SRT has error and we cannot give the parameters of k-Ze relation properly so that e should be vertically variable. Tests with SRT error and vertical variation of e show that H-D method is better than H-S method for weak precipitation but H-S method is better than H-D method for heavy precipitation. It is because SRT is unreliable for weak precipitation and DFR is unreliable for heavy precipitation. H-D-S method shows not the best but stable results for both weak and heavy precipitation, and it may work well for medium precipitation. Quantitative evaluation should be done with real measurement dataset of DPR.

Analysis of rain characteristics by using CloudSat and TRMM/PR

TAKAHASHI, Nobuhiro[1*]

[1]National Institute of Information and Communications Technology

Spaceborne cloud/precipitation radars are suitable for understanding the global climate (especially precipitation in this study) that means both the average figure of the Earth climate and the local climate in the global climate. In terms of precipitation climatology, major parameters are the precipitation amount and its diurnal/seasonal changes as well as the drop size information that is a kind of proxy of the precipitation processes such as warm/cold rain. The purpose of this study is to develop the climate map of precipitation by using CloudSat that equips W-band (94 GHz) radar and TRMM/PR that equips Ku-band (13.8 GHz) radar; rain amount is estimated by the TRMM/PR level 2 product (2A25) and the drop size information is obtained by combining the CloudSat and TRMM/PR. The basic idea of the analysis method is to compare the histograms of radar reflectivity factor (Z) at near-surface range bin at the overlapping Z range (weak to moderate rain echo). Because the both satellites have different orbit, only the statistical approach is available. Since the different Mie scattering effect appears for the different frequency and drop size, the Z value of rainfall is different between w- and Ku-band radar observations and it reflects the difference in the histograms of w- and Ku-band. Based on these characteristics, drop size information is estimated by comparing the histograms. In this study, median diameter (D0) is estimated. For the comparison of the estimation, D0 is estimated by TRMM/PR only.

Climate data are created in 10 x 10 degrees in latitude and longitude boxes and each box consists of the unconditional and conditional rain rate (the former corresponds the rain amount) and D0 (median diameter) both from the CloudSat-TRMM/PR combined analysis and TRMM/PR-only analysis for every seasons (DJF, MAM, JJA, and SON), diurnal cycle (night time/day time orbit) and over land or ocean.

The results show that the general characteristic of global maps of D0 through the year and local time is apparent land-ocean contrast; larger D0 appears over land and smaller D0 appears over ocean except for relatively small D0 over southeastern Asia to China. Also, relatively larger D0 appears in tropical area and mid latitude summer. Diurnal change of D0 can be seen by comparing the day/night time D0; D0 is larger in the night time over ocean while day time D0 is larger over land. Tropical Ocean shows smaller seasonal change, while larger changes are seen over mid-latitude area. Comparison of the two estimates of D0 between CloudSat-TRMM/PR combined estimation and TRMM/PR-only estimation.

Since the Dual-frequency Precipitation Radar (DPR) onboard Global Precipitation Measurement (GPM) core satellite, which is launched in February 2014, can estimate the drop size distribution (DSD), the approach in this study can be useful of evaluation of the algorithm for DSD estimation.

Characteristic differences between the heaviest rainfall and the strongest convection

HAMADA, Atsushi[1*] ; TAKAYABU, Yukari[1]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo

Regional and seasonal differences in the rain characteristics between rain-rate and convection extreme events are examined using 11-yr measurements from the Precipitation Radar (PR) onboard the Tropical Rainfall Measuring Mission (TRMM) satellite. After defining a rainfall event as a set of contiguous rainy pixels of TRMM PR measurements, three different types of regional extreme rainfall events are defined, using the maximum values of near-surface rainfall rate (NSR) and 30-dBZ echo top height (ETH30) in rainfall event; Rainfall events of which the maximum NSR is within top 0.1% at a grid but the ETH30 is not are defined as R-only extreme events, those of which the maximum ETH30 is within top 0.1% but the NSR is not are defined as H-only extreme events, and those of which both of the maximum NSR and maximum ETH30 are within top 0.1% are defined as RH extreme events. This is done on a local basis with 2.5 x 2.5 degree horizontal resolution to examine regional extreme events.

It is shown that the fractional occurrence of RH extreme events are less than 30% in most regions, indicating that only a few dozen percent of convection extremes are related to rain rate extremes. There are robust differences in echo profiles, rainfall characteristics, and local environments between R-only and H-only extreme events. These characteristic differences are basically independent on region and season, except for their seasonal occurrence. R-only extreme events exhibit lower echo-top height than H-only extremes, linear downward increase of radar reflectivity (Ze) below freezing level, and sharp upward decrease of Ze in 5-7 km, whereas H-only extreme events exhibit slight downward decrease of Ze below freezing level. R-only extreme events are almost in phase with mean monthly rainfall, while H-only extremes tend to peak slightly out of phase with rainy season. Local environments related to R-only extremes are less convectively unstable, wetter in the low-middle troposphere, and larger moisture flux convergence in the lowermost troposphere, compared with those related to H-only extremes. The features related to R-only extreme events imply a dominance of warm-rain process.

The next-generation GSMaP MWI precipitation retrieval algorithm

AONASHI, Kazumasa[1*]

[1]Meteorological Research Institute Japan Meteorological Agency

1. Introduction

The current GSMaP Microwave Imager (MWI) precipitation retrieval algorithm degrades retrieval accuracy for weak precipitation areas where MWI brightness temperatures (TBs) are sensitive to physical variables other than precipitation. In order to address this issue, we have been developing a new algorithm that retrieves the physical variables including precipitation from MWI TBs. The basic idea of this algorithm is to derive the statistically optimal values of the physical variables, based on Bayes's theorem (Elsaessar and Kummerow 2008, Boukabara et.al 2011). We adopted an ensemble-based variational method (EnVA) for deriving the optimal values from MWI TBs that are non-linear functions of the physical variables. The retrieval algorithm consists of the precipitation detection part and the retrieval part for physical variables in precipitation areas. In this presentation, we will report the precipitation detection part.

2. Precipitation detection part

In the precipitation detection part, we chose surface temperature (Ts), sea surface wind speed (SWS), precipitable water content (PWC), and cloud liquid water content (CLWC) as the over-sea control variables, Ts and surface emissivity (Es) as the over-land control variables, assuming no precipitation.

The EnVA employed forecasts of a cloud-resolving model (CRM) as the first guess of the physical variables, and estimated the first guess error covariance from CRM ensemble forecast. The EnVA calculated innovations and post-fit residuals of MWI TBs that were then used for the precipitation detection.

Fresh water is one of the most important resources for human. Precipitation is the main source of fresh water. Precipitation is also heating atmosphere by latent heat and one of important energy transport mechanism of atmosphere. Knowledge of world precipitation activity is important information for not only human activity, but also earth science.

Passive Microwave Radiometer (PMR) is a small and low power consumption sensor, thus many space-borne PMRs observe precipitation from low earth orbit. Space-born PMR provides uniform quality and stable observation data all over the world. PMR have become the precipital sensors for global precipitation retrieval, since these emission and scattering signals have a more direct relationship with precipitation rates than infrared radiometer (IR). The Global Satellite Mapping of Precipitation (GSMaP) project is developing PMR algorithm to provide global precipitation map with space-born PMRs. The GSMaP's goal is to develop the algorithm of high precision and eventually to produce a global precipitation map with high temporal (one hour) and special resolution (0.1 degree). PMR swathes, however, do not cover all surface in one hour. Therefore, it is necessary to utilize a gap-filling technique to generate precipitation maps with high temporal resolution. GSMaP derives Moving Vector (MV) from two successive IR images. GSMaP algorithm interpolates precipitation between gaps when PMRs overpass successive swath with MV by Kalman-filter. GSMaP algorithm now produces 0.1-grid-resolution precipitation map every one hour. Some evaluations, however, show the tendency of underestimation compared to some ground based observations, because PMR precipitation estimation over land has difficulty due to emission variability in surface. Rain gauge provides reliable data, and a rain gauge collects precipitation for certain period at a fixed location. PMR observes signals from precipitation instantaneously. We are developing the GSMaP gauge adjusted product (GSMaP Gauge). The GSMaP Gauge algorithm fits the GSMaP precipitation map to NOAA Climate Prediction Center (CPC) global rain gauge data set. The CPC data set is provided daily with low resolution (0.5-grid-degree). Quality of the CPC data set is not uniform (Quality of gauge-based analysis depends on density of rain gauge). We fill the gap of the precipitation estimation between the satellite and rain gauge attributable to the retrieval difficulty, the spatial and temporal resolution difference. The GSMaP Gauge succeeded to reduce the under estimation of the GSMaP algorithm. In this presentation, we introduce the GSMaP Gauge and its performance.

Current Status of the Products of AMSR2 on GCOM-W1 Satellite

OKI, Taikan[1*] ; KACHI, Misako[2] ; NAOKI, Kazuhiro[2] ; HORI, Masahiro[2] ; MAEDA, Takashi[2] ; IMAOKA, Keiji[2]

[1]Institute of Industrial Science, The University of Tokyo, [2]Earth Observation Research Center, Japan Aerospace Exploration Agency

The Advanced Microwave Scanning Radiometer 2 (AMSR2), on board the first generation satellite of Global Change Observation Mission - Water (GCOM-W1 or ”SHIZUKU”) satellite, is multi-frequency, total-power microwave radiometer system with dual polarization channels for all frequency bands. The GCOM-W1 satellite was launched on May 18, 2012 (JST), and has started scientific observation since July 3, 2012. After the calibration and validation phase, which confirmed that all the pre-defined release accuracies are satisfied, the AMSR2 bright temperature product (Level 1) and geophysical parameter product (Level 2) were released to public since January 2013 and May 2013, respectively.

Monitoring and validation of the AMSR2 geophysical parameters have been continued for further improvements of the observation accuracy in future algorithms. For example, the precipitation product is validated by comparing with the Precipitation Radar (PR) on board the Tropical Rainfall Measuring Mission (TRMM) satellite, and relative errors were 48% over ocean and 88 % over land for the period from September 1, 2012 to August 31, 2013.

Quality control (QC) of in-situ data is also improved for the better validation. New QC method for buoy data, which is used in the validation of the sea surface temperature (SST) and sea surface wind speed products, is introduced to remove unreliable in-situ observation data from comparisons, including overlap check, movement speed check, comparison with numerical model, and statistical check by Bayes’ theorem. Those efforts will contribute to improve the algorithm for future version-up.

The AMSR2 standard products have been distributed through the GCOM-W1 Data Providing Service (https://gcom-w1.jaxa.jp/), and quick look of the products, browse images of all AMSR2 brightness temperatures and geophysical parameters are available at the JAXA Satellite Monitoring for Environmental Studies (JASMES) for Water Cycle (http://kuroshio.eorc.jaxa.jp/JASMES/WC.html).

Applications of ocean surface wind direction signals in microwave imager observation for atmospheric humidity analysis

KAZUMORI, Masahiro[1*]

[1]Japan Meteorological Agency

An empirical relative wind direction (RWD) model function was developed to represent azimuthal variations of oceanic microwave brightness temperatures of vertical and horizontal polarizations. The RWD model function was based on measurements of observed brightness temperature from the Advanced Microwave Scanning Radiometer and wind vector from SeaWinds, both on board the Advanced Earth Observing Satellite - II, and Special Sensor Microwave Imager Sounder (SSMIS) first guess departure and wind vector data in European Centre for Medium-Range Weather Forecasts (ECMWF) Integrated Forecasting System. The model function was introduced to a microwave ocean emissivity model; a FAST microwave Emissivity Model (FASTEM) in a radiative transfer model for satellite radiance assimilation. Performances of the RWD model function were much more realistic than present azimuthal model functions in FASTEM for low wind speed and high frequency channels.

An assimilation experiment using the RWD model function was performed in the ECMWF system. The experiment demonstrated reductions of first guess departure biases arising from modelling of the azimuthal variations in areas of high wind speed and low variability of wind direction. For example, bias reductions in ascending and descending SSMIS 19 GHz vertical polarized brightness temperature in Somali jet at the Arabian Sea were approximately 0.6 K and 0.7 K. The bias reductions were found for all assimilated microwave imager channels in a wide wind speed range. Moreover, analysis increments of specific humidity in the lower troposphere were reduced (e.g., 0.3 g kg^{-1} reduction at 1000 hPa in the Somali jet). We found improvements of relative humidity and temperature in short-range forecasts in the lower troposphere. The experiment results clearly showed the importance of modelling the azimuthal variation of emissivity for assimilation of microwave imager observations. The RWD model function should be included in the radiative transfer model used in the microwave radiance assimilation observation operator.

Satellite Microwave remote sensing is the powerful tool to investigate polar regions. The data enables monitoring and surveying ice sheet, sea ice,snow cover conditions for large scale and continuous monitoring in the changing climate, and , and studying their changing mechanisms. Satellite passive microwave observation has almost 30-years long data set which contribute climatological study. The recent GCOM-W data is useful for more precise investigations.

For the Arctic study, GRENE Arctic climate research project(2011-2016) has started by integrating Japanese scientific activities. satellite microwave data is very important to this project since satellite data expands availability of site data to large area and long term. The Arctic project enhances interdisciplinal study and collaboration between modelling and observation. Multi-discipilinaly information and scale-upping by satellite is very important.

Sea-ice production in Antarctic coastal polynyas estimated using AMSR-E data

NIHASHI, Sohey[1*] ; OHSHIMA, Kay I.[2]

[1]Department of Mechanical Engineering, Tomakomai National College of Technolog, [2]Institute of Low Temperature Science, Hokkaido University

Coastal polynyas are newly-forming sea-ice areas formed by divergent ice drift due to prevailing winds and/or ocean currents. In coastal polynyas, huge amounts of heat flux from the ocean to the atmosphere occur because the heat insulation effect of sea-ice is greatly reduced in the case of thin ice, and accordingly sea ice is formed actively. Dense water formed in Antarctic coastal polynyas with the intense sea-ice production is a major source of Antarctic Bottom Water, which is a key player in the global climate system.

In this study, an algorithm for estimating daily thin ice thickness is developed based on a relationship between polarization ratios (PR) of AMSR-E brightness temperatures (TBs) and thermal ice thickness. The TBs at 89 GHz and 36.5 GHz are used. The thermal ice thickness is based on heat flux calculation using ice surface temperatures derived from satellite thermal infrared images. We used cloud-free MODIS images.

In the Antarctic Ocean, landfast sea-ice (fast ice), which is stationary sea ice attached to coastal features such as grounded icebergs, is formed along the coast. Antarctic coastal polynyas tend to be formed adjacent to fast ice. The AMSR-E ice thickness algorithm possibly mis-classifies fast ice as thin ice, because the PR values of thin ice and fast ice are similar. Thus, also the fast ice detection algorithm is developed. Monthly fast ice extent is detected based on microwave characteristics that the horizontally- and vertically-polarized TBs of fast ice tend to be lower than those of thin ice and are similar to those of ice sheet close to the coast.

The spatial resolution of AMSR-E is about 6.25 km, and the pixel density is four times higher than that of SSM/I which has been used in previous studies. This advantage is critical for the coincident detection and monitoring of coastal polynyas and fast ice because their areal extent is fairly small (tens to a hundred kms at most). The accuracy of the created AMSR-E dataset is validated from comparisons with backscatter images acquired by ASAR on Envisat.

Sea-ice production in Antarctic coastal polynyas is estimated based on heat flux calculation using the AMSR-E dataset. For the estimation, it is assumed that heat from the ocean below is negligible and that all of the heat loss to the atmosphere goes towards freezing. The sea-ice production estimated using the AMSR-E data has been improved from the SSM/I ice production because of the finer spatial resolution. First, the AMSR-E data can better resolve the high production area close to the coast. Second, false sea-ice production in the fast ice pixels mis-included by SSM/I is corrected because AMSR-E can detect fast ice that cannot be resolved by SSM/I. In fact, the total sea-ice production in each polynya by AMSR-E does not change much from the SSM/I ice production for many polynyas because these two effects of opposite direction compensate for each other. The AMSR-E dataset presented in this study would give the boundary/validation data of sea-ice production and fast ice for modeling studies.

A proposal of mission combining active and passive microwave sensors and its applications for global water cycle

EBUCHI, Naoto[1*]

[1]Hokkaido University

A mission carrying active and passive microwave sensors is proposed to monitor the global water cycle and air-sea coupling. The passive microwave sensor will be a successor of AMSR2 on GCOM-W2, which was launched by JAXA on 12 May 2012. Channels to observe solid precipitation will also be added to AMSR2. The active sensor will be a scatterometer at operated at Ku- and Ka-bands. The Ka-band scatterometer can measure vector wind fields near the coasts with higher spatial resolution than the Ku-band scatterometer, which is similar to SeaWinds on QuikSCAT and ADEOS-II and OSCAT on Oceansat-2. Merits of the combination of the active and passive microwave sensors will be discussed in aspects of sensor and science synergisms. The microwave radiometer contributes to improve accuracy of vector wind measurements by the scatterometer under rain conditions. The wind direction provided by the scatterometer improves accuracy of the SST, water vapor and precipitation measured by the radiometer. The science synergy includes applications for studies of monsoon, tropical cyclones, air-sea coupling in various scales, global and regional water cycles, sea ice, soil moisture and snow over land.

Upwelling events at the western African coast related to atmospheric structures: An analysis with satellite observations

DESBIOLLES, Fabien[1*] ; BLANKE, Bruno[1] ; BENTAMY, Abderrahim[2]

[1]Laboratoire de Physique des Oceans (LPO), UMR 6523 CNRS-Ifremer-IRD-UBO, Brest, France, [2]Laboratoire d'Oceanographie Spatiale (LOS), IFREMER, centre de Brest, France

Satellite scatterometers provide continuously valuable surface wind speed and direction estimates over the global ocean on a regular grid both in space and time. The Level 3 data derived from the Advanced Scatterometer (ASCAT), available at $1/4^o$ spatial resolution (hereafter AS25), and Quick Scatterometer (QuikSCAT), available on $1/2^o$ and $1/4^o$ horizontal grids (QS50 and QS25 respectively), are studied at regional scales in both the Benguela and Canary upwelling systems. They are compared to the European Center for Medium-Range Weather Forecast surface wind analysis, with insight into their intrinsic and effective spatial resolutions. In the coastal band, the finest spatial patterns are found in the QS25 winds and are O(75km). This demonstrates the sensitivity of the high-resolution satellite-derived winds to coastal processes related to sea surface temperature (SST) perturbations and land-sea transition. More specifically, mesoscale coupling processes between SST and winds play a leading part in structuring the wind stress curl in both the Canary and Benguela upwelling systems. These processes act especially over the upwelling extension zone (O(100km) off the coast). Next, short-lived upwelling episodes (SUEs) calculated from SST anomalies are defined consistently with the QS25 effective resolution. These cold events refer to local, short-lived perturbations that add to seasonal upwelling variability. We characterize concomitant atmospheric synoptic conditions for SUEs identified at chosen latitudes and highlight two subregions in both upwelling systems, with contrasted patterns for the alongshore wind stress component and curl. The complexity of the latter patterns is closely linked to local, short-term SST variability. Closer to the shore, wind stress curl patterns derived from QS25 are only loosely related to SST/wind interactions and, as a working hypothesis, can also be associated with orographic effects that may play an important role in cooling processes. The derivation of a realistic coastal wind drop-off from satellite observations is an almost impossible task, first because a blind zone at the coast, second because the horizontal scales of pure orographic effects (a few tens of kilometers) are finer than the effective resolution of the satellite-derived product (˜75km). However, an alternative assessment can be given by evaluating the ocean response to contrasted coastal wind profiles. Numerical sensitivity experiments show that the imbalance between Ekman transport and Ekman pumping has an impact on ocean dynamics: a reduction of the wind in the QS25 forcing, partly induced by orography, contributes to SST cooling.

The GNSS Ocean Winds and AIS Mission, An Earth Science and Marine Safety Satellite Constellation

ROSE, Randall[1*] ; GLEASON, Scott[1] ; RUF, Christopher[2] ; KITAZAWA, Yukihito[3] ; TANIMOTO, Kazuo[4]

[1]Southwest Research Institute, [2]University of Michigan, [3]IHI Corporation, [4]Meisei Electric Co., Ltd.

Recent developments in electronics and nano-satellite technologies combined with modeling techniques developed over the past 20 years have enabled a new class of remote wave and wind sensing capabilities that offer markedly improved performance over existing observatories while opening avenues to new applications. Most existing space borne ocean wind observatories operate in the C and Ku-bands which obscures key information about the ocean and the global climate. Using GNSS-based bi-static scatterometry performed by a constellation of nano-satellites, ocean wave and wind data can be provided with unprecedented temporal resolution and spatial coverage across the full dynamic range of ocean wind speeds in all precipitating conditions.

The NASA Cyclone Global Navigation Satellite System (CYGNSS) is a space borne mission being developed to study tropical cyclone inner core processes. CYGNSS consists of 8 GPS bi-static radar receivers to be deployed on separate nano-satellites in October 2016. It is anticipated that numerous additional Earth science applications can also benefit from the cost effective high spatial and temporal sampling capabilities of GNSS remote sensing. These applications include monitoring of rough and dangerous sea states, global observations of sea ice cover and extent, meso-scale ocean circulation studies, and near surface soil moisture observations.

The Automatic Identification System (AIS) is a maritime system used for global identification and tracking of ships. It is proposed as part of the GNSS Ocean Winds and AIS (GOWA) nano-satellite constellation concept to combine and improve upon the GNSS remote sensing capability of CYGNSS with a space based AIS system. GOWA will be capable of monitoring both the ocean roughness and the locations of ship traffic at the same time. This will result in both an increase in maritime safety and valuable Earth science measurements of ocean winds, sea ice and land surfaces.

This presentation will present a summary of the CYGNSS mission and plans for future instrument development to increase the number of science observations. The goal of this development is to enable the GOWA mission being proposed for Japanese science and maritime safety applications.

Development of Cloud Profiling Radar (CPR) for Earth Clouds, Aerosols and Radiation Explorer (EarthCARE) mission

SEKI, Yoshihiro[1*] ; TOMITA, Eiichi[1] ; KIMURA, Toshiyoshi[1] ; NAKATSUKA, Hirotaka[1] ; AIDA, Yoshihisa[1] ; OKADA, Kazuyuki[1] ; IIDE, Yoshiya[1] ; KADOSAKI, Gaku[1] ; TAKAHASHI, Nobuhiro[2] ; OHNO, Yuichi[2] ; HORIE, Hiroaki[2] ; SATO, Kenji[2]

[1]Japan Aerospace Exploration Agency, [2]National Institute of Information and Communications Technology

Earth Clouds, Aerosols and Radiation Explorer (EarthCARE) is a Japanese-European collaborative Earth observation satellite mission aimed to deepen understanding of the interaction process between clouds and aerosols and its effects on the Earth's radiation. The outcome of this mission is expected to improve accuracy of the Global Climate Change prediction.

The EarthCARE spacecraft, which weighs approximately 2,250kg and goes along a Sun-Synchronous 400km-hight orbit around the Earth, accommodates four instruments which are to observe the Earth's clouds, aerosols and radiation. The observation data acquired simultaneously by the four sensors will be processed into a variety of synergy products including vertical profiles of clouds and aerosols, microscopic cloud parameters, radiation fluxes and so on. As one of those observatories, the Cloud Profiling Radar (CPR), which has a 2.5m-diameter main reflector and W-band 1.5kW transmitter and receiver, is the world's first space-borne Doppler cloud radar jointly developed by the Japan Aerospace Exploration Agency (JAXA) and the National Institute of Information and Communications Technology (NICT), which provides vertical velocity as well as vertical structure inside clouds. The other payloads on the satellite are the Atmospheric Lidar (ATLID) for vertical structure measurement of clouds and aerosols, the Multi-Spectral Imager (MSI) for horizontal distribution measurement of clouds and aerosols, and the Broad-Band Radiometer (BBR) for measurement of radiation fluxes at top of the atmosphere. ATLID, MSI, BBR and the base-platform of the spacecraft are developed by the European Space Agency (ESA).

In Japan, the critical design review of the CPR has been completed in 2013 and CPR proto-flight model is currently being manufactured, integrated, and tested. After handed-over to ESA, the CPR will be installed onto the EarthCARE satellite together with the other instruments, tested, transported to Guiana Space Center in Kourou, French Guiana and launched by a Soyuz launcher in JFY2016.

Shortwave direct aerosol radiative forcing using CALIOP and MODIS measurements

OIKAWA, Eiji[1*] ; NAKAJIMA, Teruyuki[1] ; WINKER, David[2]

[1]AORI, University of Tokyo, [2]NASA Langley Research Center

The aerosol direct effect occurs by direct scattering and absorption of solar and thermal radiation. Shortwave direct aerosol radiative forcing (SWDARF) under clear-sky condition is estimated about 5 Wm^{-2} from satellite retrievals and model simulations [e.g., *Yu et al*., 2006]. Simultaneous observations of aerosols and clouds are, however, very limited to validate the estimation of SWDARF under cloudy-sky condition. In 2006, the CALIPSO (Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations) satellite was launched with the space-borne lidar, CALIOP (Cloud-Aerosol Lidar with Orthogonal Polarization). This enabled us to get data of the vertical distribution of aerosols and clouds all over the world. *Oikawa et al.* [2013] estimated SWDARF under clear-sky, cloudy-sky, and all-sky conditions using CALIOP Version 2 data and MODIS (Moderate resolution Imaging Spectrometer) data. They investigated four scenarios for evaluating the SWDARF: clear-sky, the case that aerosols exist above clouds (above-cloud case), the case that aerosols exist below high-level clouds (below-cloud case), and the case that aerosols are not detected by CALIOP in cloudy-sky condition. The cloudy-sky SWDARF is, then, estimated by the latter three scenarios. The all-sky SWDARF is the combination of clear-sky and cloudy-sky SWDARF weighted by the cloud occurrence.

We calculated SWDARF from 2007 to 2009 using CALIOP Level 2 Cloud and Aerosol Layer Products Version 2 (V2) and Version 3 (V3) with the method of *Oikawa et al.* [2013]. The procedure of daytime calibration, cloud screening, and aerosol-cloud classification are improved in the V3 algorithms [*Powell et al*., 2010; *Vaughan et al*., 2010; *Liu et al*., 2010]; therefore, the distributions of aerosols and clouds are significantly changed from V2 data. Compared V3 data with V2 data, the total cloud fraction and occurrence probability of above-cloud case decrease. In clear-sky condition, marine aerosols increase and single scattering albedo (SSA) of total aerosols increases over the ocean. In cloudy-sky condition, smoke and polluted dust decrease. Annual zonal averages of SWDARF from 60^oS to 60^oN under clear-sky, cloudy-sky, and all-sky are -2.85, -0.16, and -0.78 Wm^{-2} for V2 data and -3.70, -1.07, and -2.02 Wm^{-2} for V3 data. It indicates that SWDARF largely depends on the retrieval and classification algorithms of aerosols and clouds.

Previous studies reported that the aerosol absorption above clouds cause the underestimation of cloud optical thickness (COT) in the satellite retrievals [*Haywood et al*., 2004; *Coddington et al*., 2010]. We, therefore, have a plan to examine the effect on SWDARF from underestimation of COT.

A new method for estimating biases in multi-spectral cloud parameter retrievals caused by cloud horizontal inhomogeneity

NAGAO, Takashi[1*] ; NAKAJIMA, Takashi[1]

[1]Tokai University

Clouds play an important role in terrestrial atmospheric dynamics, thermodynamics, and radiative transfer and are key elements of the water and energy cycles. Modification of cloud properties, lifetime, and amount by indirect aerosol effects has an effect on radiative forcing in the climate. Cloud observations using satellite-borne multispectral imagers (e.g. Aqua/MODIS, GCOM-C/SGLI and EarthCARE/MSI) provide data sets useful for understanding cloud characteristics and their distributions on a global scale. Previous studies, however, pointed out that cloud parameters (e.g. cloud optical thickness, cloud particle effective radius and cloud top temperature) retrieved from multispectral measurements were significantly impacted by vertical and horizontal inhomogeneities of clouds, bimodal particle size distributions in drizzling clouds, and three-dimensional radiative transfer. In this study, we suggest a new method for estimating bias in multi-spectral-retrieved cloud parameters caused by cloud horizontal inhomogeneity. The impact of cloud horizontal inhomogeneity is considered as a key for interpreting discrepancies between cloud parameters from satellite observations and in-situ measurements or numerical cloud models. The estimation method considers the bias as the combination of the following two impacts: One is the impact of clear-contamination in cloud pixel, which is parameterized by cloud-fraction. The other is the impact of subpixel scale variance of cloud properties (but no clear-contamination), which is parameterized by variance of multi-spectral radiances in sub-pixels, and based on error propagation theory. We evaluate the method by using high-spatial resolution measurements of Landsat 8. Additionally, to apply the method to several multi-spectral imagers (e.g. MODIS, GCOM-C/SGLI and EarthCARE/MSI), we also investigate co-variance matrices of adjacent pixels or sub-pixels obtained from different IFOVs because the accuracy of the method depends on the accuracy of the co-variance matrix.

The purpose of this study is to evaluate the earth radiation budget when data are available from satellite-borne active sensors, i.e. cloud profiling radar (CPR) and lidar, and a multi-spectral imager (MSI) in the project of the Earth Explore/EarthCARE mission. The scientific requirement of the evaluation accuracy is less than 10 Wm-2 for the upward broadband radiative flux for the instantaneous 10kmx10km footprint of CPR (EarthCARE, 2006). For this purpose, we first developed forward and backward 3D Monte Carlo radiative transfer codes called MCsatr that treat a broadband solar flux calculation including thermal infrared emission calculation by k-distribution parameters of Sekiguchi and Nakajima (2008). We have developed Forward and Backward Monte Carlo radiative transfer codes, and we have also developed both of two types for deciding optical mean path by extinction transmittance and scattering transmittance for Forward Monte Carlo radiative transfer code.

In evaluation system, 3D extinction coefficient fields are constructed by two methods: 1) the Minimum Information Deviation Profiling Method (MIDPM) (Barker and Donovan et. al., 2011) and 2) numerical simulation by bin-spectral non-hydrostatic cloud model. In the MIDPM, we first construct a library of pair of observed vertical profiles from active sensors and collocated imager products at the nadir footprint, i.e. spectral imager radiances, cloud optical thickness (COT), effective particle radius (RE) and cloud top temperature (Tc). We select a best matched active sensor-derived vertical profiles from the library for each of off-nadir pixels of the imager where active sensor-derived vertical profile is not available, by minimizing the deviation between library imager parameters and those at the pixel, to construct the 3D cloud field. We applied this method to data of Cloudsat/CPR and AQUA/MODIS for a case of summer stratus cloud of California coast on July 2, 2007.

The second construction of 3D cloud systems is performed by numerical simulation of Californian summer stratus clouds using an non-hyderostatic atmospheric model coupled with a bin-spectral cloud microphysics model based on the NHM+ACBM model (Iguchi et al., 2008; Sato et al., 2009, 2011). Most inner region of a three-fold nesting system is an area of 30km∗30km∗1.5km with horizontal (vertical) grid spacing of 100m (20m) and 300m (20m). Two different cell systems were simulated for small and large cloud condensation nuclei (CCN) concentration. The area mean cloud optical thickness, $<$COT$>$, and standard deviation are 3.0 and 4.3 for pristine case and 8.5 and 7.4 for polluted case.

We then re-calculated the solar radiation field by two types of Fowrad MCstar. We compared flux reflectivities of the 3D atmospheres with those by Plane Parallel Approximation (PPA) and Independent Pixel Approximation (IPA) (Cahalan et al., 1994). As expected, the reflectivity difference between 3D and PPA clouds increases with increasing COT horizontal variability of the 3D clouds. The reflectivity difference between 3D and PPA reaches 0.078 at maximum, which is equivalent to a solar radiative flux error of 70 Wm-2.

On the other hand, the IPA result between the two cases are significantly different. We infer this difference is caused by difference in the spatial characteristic size of inhomogeneity. The mean extinction of the cloud system is of 5 to 8 km-1, so that the kilometer-size clouds in the satellite case are optically dense enough to be approximated by IPA. The difference is less than 0.010 in reflectivity or 10 Wm-2 in upward flux. On the other hand, the model simulation case is optically thin to be approximated by IPA. The error reaches 0.07 at maximum by pristine case. A future work is needed to correct this significant error utilizing the 3D structure of the cloud system.

Synergistic use of the geostationary and the polar orbit satellites for surveying the cloud evolution process: plan

NAKAJIMA, Takashi[1*] ; NAGAO, Takashi[1] ; LETU, Husi[1]

[1]Tokai University

The use of spaceborne radar and imager aboard the CloudSat, Aqua, EarthCARE, GCOM-C1, and the 3rd generation geostationary satellites for investigating cloud evolution process, is suggested. These satellites have been in orbit or will be launched in the middle of 2010-era and contribute for observing aerosols, clouds on the earth system. Since aerosols and clouds exert an important influence on the planet water and energy balances, more understanding of their lifecycle is required. Optical thickness and particle size of clouds are primal information for estimating the cloud evolution process. These parameters are retrieved from multi-spectral imageries obtained from space-borne satellite sensors. Recently, active sensors, such as the CloudSat cloud profiling radar (CPR) and the CALIPSO Lidar present a new epoch of aerosol and cloud observation with the purpose of revealing transition of particles, from cloud condensation nuclei to rain droplets via cloud and drizzle particles. They observe vertical cross section of the cloud system along the satellite footprint. As follow on the CloudSat / CALIPSO, the EarthCARE that has both active and passive sensors is planed by JAXA, NICT, and ESA collaboration. Doppler capability of the EarthCARE CPR will reveals vertical motion of cloud particles. Moreover, the 3rd generation geostationary weather satellite will appear in 2015 and observe aerosol and cloud system in every 10 or 2.5 minutes. Therefore, it is expected that the combined use of polar orbital passive/active sensors and geostationary satellites reveal details of cloud evolution process, statistically and dynamically. In this presentation, we introduce recent progresses of aerosol and cloud observations from satellites, showing the multi-sensor views of cloud growth process obtained from an active radar (CPR) and a passive imager (MODIS).

It is known that atmospheric aerosols have valuable information in many research fields. However estimation of aerosol direct and indirect effects on climate changes in the 5th report of IPCC still involves large uncertainty due to lack of precise aerosol properties.

JAXA (Japanese space agency) is developing the GCOM-C (Global change observing mission?climate) satellite series, which are expected to provide us new aerosol information as well as geo-physical parameters for thirteen years after launch. The first of GCOM-C series will carry the SGLI (second generation global imager) sensor which observes total radiance from near UV to thermal infrared wavelengths including polarization measurements at red and near IR. This work intends to develop an efficient algorithm for aerosol retrieval based on this polarization information to be given by GCOM-C1/SGLI.

Ocean primary production algorithm for the GCOM-C1/SGLI

HIRAWAKE, Toru[1*] ; FUTSUKI, Ryosuke[1] ; SHINMYO, Katuhito[1] ; TAKAO, Shintaro[2] ; FUJIWARA, Amane[3] ; SAITOH, Sei-ichi[1]

[1]Faculty/Graduate School of Fisheries Sciences, Hokkaido University, [2]Faculty of Environmental Earth Science, Hokkaido University, [3]National Institute of Polar Research

One of the objectives of second-generation global imager (SGLI) on the earth observation satellite, Global Change Observation Mission 1st-Climate (GCOM-C1) is to understand the global carbon cycle. Therefore, estimation of column integrated daily net primary production (PP_{eu}) as carbon assimilation by photosynthesis of phytoplankton in the ocean is essential for the objective of SGLI/GCOM-C1 project. Most of the algorithms developed in the past used chlorophyll *a* (chl *a*) concentration. However, estimation of chl *a* concentration from satellite data has uncertainty due to the effect of pigment packaging that leads to underestimation, and the interference of colored dissolved organic matter (CDOM) which leads to overestimation. Another uncertainty is derivation of photosynthetic rate of phytoplankton. Although the vertically generalized productivity model (VGPM) which is one of the frequently used algorithms expressed the maximal photosynthetic rate (${P^B}_{opt}$) as a function of sea surface temperature (SST), the SST derived ${P^B}_{opt}$ had large error, particularly in the polar waters. Furthermore, discussion on the effect of global warming to primary productivity in the ocean using satellite data is facilitated, if the photosynthetic rate is an independent parameter on the SST.

To reduce these issues, light absorption coefficient of phytoplankton (a_{ph}) was used in the algorithm for SGLI/GCOM-C1; product of ${P^B}_{opt}$ and chl *a* in the VGPM, which means productivity at the depth with the maximal photosynthetic rate within a water column, was expressed by photosynthetic available radiation (PAR) absorbed in phytoplankton. In situ primary production and optical data to develop the algorithm were measured in the North Pacific, Japan Sea, East China Sea, Southern Ocean, Chukchi Sea (Arctic Ocean), Bering Sea. Additional datasets of the Bermuda Atlantic Time-series Study (BATS), Hawaii Ocean Time-series (HOT) and The California Cooperative Oceanic Fisheries Investigations (CalCOFI) were also obtained for the development and validation of the algorithm. Accuracy in the estimation of product of ${P^B}_{opt}$ and chl *a* (P_{opt}) and PP_{eu} were fairly well and estimated values from the new algorithms almost satisfied a factor of 2 of the values measured in situ. If accurate value of aph is derived from SGLI data, global estimation of PP_{eu} without the issues of pigments packaging, CDOM and SST are expected.

Global snow and ice cover observations using GCOM-C1/SGLI for studying climate changes

HORI, Masahiro[1*] ; AOKI, Teruo[2] ; STAMNES, Knut[3] ; TANIKAWA, Tomonori[1] ; KUCHIKI, Katsuyuki[2] ; LI, Wei[3] ; CHEN, Nan[3]

[1]Japan Aerospace Exploration Agency, [2]Meteorological Research Institute, [3]Stevens Institute of Technology

The ”Global Change Observation Mission-Climate” (GCOM-C) is a project of Japan Aerospace Exploration Agency (JAXA) for the global observation of the Earth environment. The GCOM-C is a part of the JAXA’s GCOM mission which consists of two satellite series, GCOM-C and GCOM-W (Water). GCOM-C carries a multi-spectral optical radiometer named Second Generation Global Imager (SGLI), which will have special features of wide spectral coverage from 380 nm to 12 micrometer, a high spatial resolution of 250m, a field of view exceeding 1000km, two-direction simultaneous observation, and polarization observation. The GCOM-C mission aims to improve our knowledge on the global carbon cycle and radiation budget through high-accuracy observation of global vegetation, ocean color, temperature, cloud, aerosol, and snow and ice. As for the cryosphere observation, not only snow and ice cover extent but also snow physical parameters are retrieved from SGLI data such as snow grain sizes at shallow layers, temperature, and mass fraction of impurity mixed in snow layer and so on. These snow physical parameters are important factors that determine spectral albedo and radiation budget at the snow surface. Thus it is essential to monitor those parameters from space in order to better understand snow metamorphosis and melting process and also to study the response of snow and sea-ice cover extent in the Polar Regions to a climate forcing such as global warming. In addition, one of important objectives of the GCOM mission is to monitor long-term trend of the geophysical parameters for understanding the mechanism of earth’s climate system. For this purpose, the data from GCOM series satellites are not enough. Thus, JAXA launched a website named ”JAXA Satellite Monitoring for Environmental Studies (JASMES)” for semi-near real-time monitoring of earth’s environmental variables. Through this website JASMES provides users with not only satellite datasets (flat binary) but also information on the current status of the climate variables such as solar radiation reaching the earth’s surface (photosynthetically available radiation: PAR), snow and cloud cover, dryness of vegetation (water stress trend), wild fire and so on. MODIS data since February 2000 are currently processed for this analysis but SGLI data will be used after the launch of GCOM-C. Furthermore, the data from Advanced Very High Resolution Radiometer (AVHRR) onboard polar orbiting satellites operated by the National Oceanic and Atmospheric Administration (NOAA) since 1978 are also under preparation toward establishing a half-century long datasets of remote sensing after the success of the GCOM mission. This presentation will summarize the SGLI cryospheric products and validation plans, and also briefly introduce the JASMES dataset.

Development of GCOM-C1 land surface reflectance product

MURAKAMI, Hiroshi[1*]

[1]JAXA, Earth Observation Research Center

Land-surface reflectance (RSRF) product is one of the essential products of Global Change Observation Mission-Climate 1/ Global Imager (GCOM-C1/SGLI; to be launched in JFY 2016); it is an input of other land algorithms, such as Leaf Area Index (LAI) and land cover classification (LCC), and will be used for surface albedo in the radiation budget, and used as the background of aerosol and cloud estimation. RSRF is estimated by subtracting scattering and absorption of an atmospheric molecule and aerosol from the top-of-atmosphere (TOA) radiance in cloud-free areas observed by the satellite (i.e., atmospheric correction). However, in order to extract the information on aerosols from the TOA radiation, it is necessary to know the information on land surface used as a background beforehand.

Experiential assumption and a candidate model about the spectral characteristic of aerosol and surface reflectance are often used in the presumption. Since the presumption can influence the output results, it is necessary to accumulate the knowledge of the various spectral characteristics and to perform suitable selection. Change of RSRF by the sun and the satellite geometries (BRDF) should be modeled when we preset the land-surface reflectance, because the satellite observes targets from a specific direction.

Candidate models of aerosol in the atmospheric correction (size distribution and vertical distribution, refractive index, etc.) may be able to be consistent with ones in the traditional aerosol-estimation algorithms which use candidate models as well. Since RSRF is used as a background of aerosol estimation, the consistency will be important for the product evaluation and accuracy improvement. There are groups which study aerosol properties by ground observation network, SKYNET, AERONET, etc., their regional characterization, spectral reflectance of the land surface, and observation and modeling (canopy radiation transfer) of the BRDF in the GCOM-C1 science team. The GCOM-C1 science team held a mini-workshop in summer of 2012, and decided that JAXA develops the land-surface atmospheric correction algorithm step by step by integrating their results . We confirmed importance of the consistency with the algorithms, such as LCC, LAI, albedo, etc., which use the estimated RSRF and BRDF.

We plan to develop the algorithm based on the existing knowledge (i.e., a traditional algorithm) for the at-launch version. Gas absorption of SGLI bands by water vapor, ozone, oxygen, and NO2 will be considered by using objective analysis data or Climatology. The surface elevation will be corrected by using objective-analysis sea-level pressure data and high-spatial resolution digital elevation data, DEM. Influence of surface slope will be reduced by using surface normal vector calculated by the DEM and solar vector. GCOM-C1/SGLI has an near-ultra violet (NUV) 380nm band, which will be used for the presumption of surface reflectance in the GCOM-C1 atmospheric correction, because reflectance and its directionality is generally small in the NUV and blue wavelengths. The presumption of the NUV band uses vegetation and land-cover information assumed from near infrared (NIR) and short-wave infrared (SWIR) reflectance, which are not so much affected by aerosols, and RSRF in the previous days by assuming temporal change of RSRF is generally smaller than the change of the atmosphere.

For the future algorithm version after the satellite launch, we expect to improve the presumption by knowledge from the canopy radiation transfer, LCC and vegetation phenology, adopt new aerosol estimation schemes, or use results of the aerosol-transport model to find the optimal aerosol models. SGLI has a polarization radiometer which observes the Stokes vector of red and NIR bands with 45-deg along-track slant view. It may be able to improve atmospheric correction accuracy after accumulation of surface BRDF and polarization knowledge in the future.

Assessing the variations of the Alaskan tundra vegetation using MODIS NDVI 250-m imagery

SETIAWAN, Yudi[1*] ; KUSHIDA, Keiji[1]

[1]College of Bioresource Sci., Nihon Univ. Japan

Improving the understanding of Alaskan tundra vegetation using remote sensing data is a challenging task due to a general lack of consistency and coverage from historical and existing platforms. Furthermore, it should be essential for many aspects of global environmental change research.

Vegetation dynamics of the land surface is an integrated reflection of the vegetation and physical and chemical factors that shape the environment of a given land area and determinants for overall biological diversity patterns. In this paper, we demonstrate an approach for displaying detailed information of the Alaskan tundra ecosystem from the vegetation dynamics point of view. We assumed that locations displaying similar temporal vegetation patterns are inferred to have a similar vegetation and/or environment characteristics. Differences among land cover types as reflected in temporal profiles of NDVI are caused by differences in vegetation type composition and/or in their densities, and their responses to local environmental conditions, consequently, the use of long time-series NDVI will capture such different patterns in seasonal growth cycles.

The clustering method yields sets of clusters, which each cluster represents a significant different NDVI pattern at detailed information in the land cover type. However, the complexity and enormous amount of time-series NDVI datasets may lead to the difficulty of obtaining the actual number of clusters in this study. Therefore, to provide maximum effectiveness of the clustering algorithm, we first consider the number of clusters 15 which correspond to the number of dominant physiognomy of Alaska tundra ecosystem (Raynold et al., 2005). The number of clusters was then evaluated based on a statistical measurement of how separate that pattern is to patterns in its own cluster compared to patterns in other clusters. This separability analysis was applied to discriminate among high detailed significant patterns that were theoretically defined to portray the specific characteristics of each land cover type.

Detection of regional extent of permafrost thawing and waterlog damage area in boreal forest in eastern Siberia during w

IIJIMA, Yoshihiro[1*] ; ABE, Konomi[2] ; ISE, Hajime[2] ; MASUZAWA, Tadashi[2]

[1]JAMSTEC, [2]Regional Environmental Planning Inc.

Wet climate with largely increased in rainfall during summer and snow accumulation during winter had perennially continued since 2004 in eastern Siberia. Soil moisture in the active layer had been rapidly increased corresponding with thawing permafrost near the surface during following years. The perennially water-logged active layer furthermore exacerbated the boreal forest habitat, namely withered and dead forests widely extended in this region. In the present study, we have attempted to extract the region of degraded boreal (larch) forest based on the analysis of satellite data (ALOS-AVNIR2 and PALSAR) in the left and right banks of the central Lena River Basin near Yakutsk, along with expansion of the water-logged forest floor in relation to permafrost degradation.

A potential map of precipitation area using the geostationary meteorological satellite for the GSMaP

HIROSE, Hitoshi[1*] ; HIGUCHI, Atsushi[1] ; USHIO, Tomoo[2] ; MEGA, Tomoaki[2] ; YAMAMOTO, Munehisa[3] ; SHIGE, Shoichi[3] ; SATOMURA, Takehiko[3] ; HAMADA, Atsushi[4]

[1]Center for Environmental Remote Sensing, Chiba University., [2]Division of Electric and Information Engineering, Osaka University., [3]Division of Earth and Planetary Science, Graduate School of Science, Kyoto University., [4]Atmosphere and Ocean Research Institute, Tokyo University.

The Global Satellite Mapping of Precipitation (GSMaP) produces accurate precipitation data with high time and spatial resolution (per 1hour, 0.1 degree) by utilizing the satellite microwave radiometer. At the time and place which all microwave radiometer satellites are not available, the GSMaP estimates where the precipitation area observed before that time will moves by using a cloud moving vector retrieved from the infrared brightness temperature (IR Tb) observed by the geostationary meteorological satellite (GMS) (GSMaP_MVK, GSMaP_NRT; v5.222.1). However this method has some possibility of missing the convective precipitation which develops quickly (Ushio et al. 2009), and uses only IR1 channel (10.5˜11.5μm) of the GMS observation to calculate the cloud moving vector. Therefore, this study made more accurate data of estimated precipitation area by using multi-channel GMS observation, called potential map, and then improved the accuracy of GSMaP_MVK and GSMaP_NRT precipitation areas by utilizing the potential map.

As a precipitation area index of the GMS, we used difference of the Tb between IR1 channel and water vapor (WV) channel (6.5˜7.0μm). This index is based on the assumption which a deep convective cloud with precipitation probably occurs at the area with a small Tb difference of IR1 and WV (Ohsawa et al. 2001). Moreover since almost all of geostationary satellites have the IR1 and WV channel, the index is available globally on a long-term basis. We used near surface rain observed by the precipitation radar of the Tropical Rainfall Measurement Mission (TRMM) (PR; 2A25, V7) and the rainfall intensity retrieved from ground-based precipitation radar of Japan Meteorological Agency (JMA) as the truth of the precipitation area and converted the Tb of the GMS to the probability of precipitation with simultaneous observation between the GMS and the precipitation radar.

At first we compared the precipitation area obtained from the GSMaP and the precipitation radar, and found that the GSMaP_MVK overestimated the precipitation area over the ocean without the microwave observation. And therefore we tried to identify the area which the GSMaP precipitation was less than 1.0 mm per hour and the possibility of precipitation obtained of the potential map was less than 15 % as non-precipitation area. As the result the threat score of the GSMaP_MVK precipitation detection was improved from 0.37 to 0.41 over the ocean without the microwave observation. As it is considered that the threat score of GSMaP_MVK with the microwave observation is 0.45, this improvement is regarded as significant. On the other hand, the GSMaP_NRT underestimated the precipitation area over the land and coast without the microwave observation. And then we identified the area which the potential map was more than 40 % as precipitation area. As the result the threat score of the GSMaP_NRT was much improved from 0.27 to 0.34 over the land and coast without the microwave observation. In these areas and conditions, we can expect that the GSMaP estimates the precipitation area more accurately by utilizing the potential map.

A study of multi-pixel and multi-parameter satellite remote sensing for aerosol properties

HASHIMOTO, Makiko[1*] ; MORIMOTO, Shotaro[1] ; TAKENAKA, Hideaki[1] ; NAKAJIMA, Teruyuki[1]

[1]AORI, the University of Tokyo

We have developed a new satellite remote sensing algorithm to retrieve the aerosol optical characteristics using multi-pixel information of satellite imagers. In this algorithm, the inversion method is a combination of the MAP method (Maximum a posteriori method, Rodgers, 2000) and the Phillips-Twomey method (Phillips, 1962; Twomey, 1963) as a smoothing constraint for the state vector. Retrieved parameters in our algorithm are aerosol optical properties, such as aerosol optical thickness (AOT) of fine mode, sea salt, and dust particles, a volume soot fraction in fine mode particles, and ground surface albedo of each observed wavelength. We simultaneously retrieve all the parameters that characterize pixels in each of horizontal sub-domains consisting the target area. Then we successively apply the retrieval method to all the sub-domains in the target area.

We conducted numerical tests for the retrieval of aerosol properties and ground surface albedo for GOSAT/CAI imager data to test the algorithm for the land area. The result of the experiment showed that AOTs of fine mode and dust particles, soot fraction and ground surface albedo are successfully retrieved within absolute. We discuss the accuracy of the algorithm for various land surface types. Our future work is to extend the algorithm for analysis of AGEOS-II/GLI and GCOM/C-SGLI data.

Estimation of Phytoplankton Group-Specific Primary Production in Kuroshio Waters Using Ocean Colour Remote Sensing

HIRATA, Takafumi[1*] ; SUGIE, Koji[1] ; SUZUKI, Koji[1] ; SAITOH, Hiroaki[2]

[1]Faculty of Environmental Earth Science, Hokkaido University, [2]Tohoku National Fisheries Research Institute, Fisheries Research Agency

The ocean is a major sink of carbon dioxide released into the atmosphere. Phytoplankton conducting primary production plays a significant role on temporal and spatial variability in the absorption of the carbon. Also phytoplankton transfers carbon to higher trophic levels in a marine ecosystem, and the carbon pathways to the higher trophic levels affect vulnerability of food web, or the ecosystem, against external forcings. Tremendous efforts to measure primary productivity of the total phytoplankton community in the global oceans have been made historically. On the other hand, measurements of primary productivity of individual phytoplankton groups composing of the total community are relatively sparse. This is partly due to methodological difficulties to differentiate such productivity of individual groups in situ, on top of practical circumstance that in situ observation requiring ship time is usually expensive. Therefore, it is of great interest if satellite remote sensing can overcome these problems, given that a number of earth observation satellites have been and will be launched. Especially, it is a great advantage of satellite observation that one can hindcast primary productivity of individual phytoplankton groups using historical remote sensing data, once a remote sensing methodology/algorithm is developed. In this presentation, we show a primitive result of development of such methodology to estimate primary productivity of diatoms and haptophytes in Kuroshio waters using ocean colour remote sensing.

NICT Calibration and Validation experiment for DPR/GPM

NAKAGAWA, Katsuhiro[1*] ; HANADO, Hiroshi[1] ; KAWAMURA, Seiji[1] ; IWAI, Hironori[1] ; TAKAHASHI, Nobuhiro[1] ; IGUCHI, Toshio[1]

[1]National Institute of Information and Communications Technology

The GPM core satellite is scheduled to be launched on February 28, 2014. It carries the Dual-Frequency Precipitation Radar (DPR) developed by Japan Aerospace Exploration Agency (JAXA) and National Institute of Information and Communications Technology (NICT), which consists of two radars: Ku-band precipitation radar (KuPR, 13.6 GHz) and Ka-band radar (KaPR, 35.5 GHz). NICT is planning the GPM/DPR onboard calibration experiment at NICT Koganei. The beam matching of two radars will be evaluated. NICT is also planning the post-launch ground validation (product validation) experiment at two locations, NICT Kobe (NICT Advanced ICT Research Institute) and NICT Okinawa (Okinawa Electromagnetic Technology Center). NICT is developing two X-band phased array radars (PANDA: Phased Array radar Network DAta system) and will install at NICT Kobe and Okinawa. PANDA can scan three-dimensionally in thirty seconds. We can compare the radar directly and simultaneously. At NICT Okinawa, the C-band polarimetric Doppler radar (COBRA) is also installed. The differential reflectivity (ZDR) can be used to validate the rain drop size distribution parameter (D_0). The cross-correlation coefficient (ρHV) can be used to validate the melting layer flag. Using the ground-based rain drop size measurements, the two-dimensional Video disdtrometer (2DVD), Joss-type disdrometer, and Laser Optical disdrometr (Parsivel), and so on, the characteristics of DSD itself are analyzed and the k-Z relationship is estimated for evaluation and improvement of the GPM/DPR algorithm.

Ground-based Validation of GPM/DPR

KANEKO, Yuki[1*] ; OKI, Riko[1] ; NAKAGAWA, Katsuhiro[2] ; NAKAMURA, Kenji[3]

[1]Japan Aerospace Exploration Agency (JAXA), [2]National Institute of Information and Communications Technology, [3]Faculty of Economics, Dokkyo University

The Global Precipitation Measurement (GPM) mission is an expanded follow-on mission to TRMM (Tropical Rainfall Measuring Mission) and GPM core satellite carries dual frequency precipitation radar (DPR) and GPM Microwave Imager on board. The DPR is expected to advance precipitation science by expanding the coverage of observations to higher latitudes than those of the TRMM/PR, measuring snow and light rain by the KaPR, and providing drop size distribution information based on the differential attenuation of echoes at two frequencies. After launch of GPM core satellite JAXA will perform evaluation of DPR L2 products, for example, precipitation rate, measured radar reflectivity, and drop size distribution. Those physical values will be compared with ground-based observations. This poster presentation will show the preliminary report of DPR evaluation comparison between DPR products and ground-based instruments during the first 2 months after launch, including a ground-based Ka-band radar system.

Optimal choice of surface reflectance and aerosol types for Multi-Spectral Imager on board EarthCARE

FUKUDA, Satoru[1*] ; NAKAJIMA, Teruyuki[2] ; TAKENAKA, Hideaki[2]

[1]Japan Aerospace Exploration Agency, [2]Atmosphere and Ocean Research Institute, The University of Tokyo

EarthCARE is a satellite which will be launched in 2016. EarhtCARE is a joint mission between Europe and Japan. Four instruments such as CPR, ATLID, MSI and BBR will be equipped. MSI is a multi-spectral imager, and the purpose of it is to get the horizontal structure of aerosol and cloud. We are developing the aerosol retrieval algorithm for MSI. MSI aerosol products are consists of optical thickness over land, optical thickness over ocean, and Angstrom Exponent over ocean. Over ocean we implement two channel method with 0.68 um and 0.86 um (Higurashi and Nakajima, 1999) and we retrieve optical thickness and Angstrom Exponent. Over land we estimate the surface reflectance at 0.68 um from longer wavelength. Kaufman et al (1997) used 2.2 um to estimate the surface reflectance at 0.68 um. In this study we tried to use 1.6 um to estimate the surface reflectance at 0.68 um. This is because there is a possibility to get better estimation than to use 2.2 um and we can use this method for sensors which don't equip 2.2 um such as GOSAT/TANSO-CAI or CAI2. We have made a scatter plot of the reflectance between 0.68 um and 1.6 um. As reflectance data set, we used AERONET data of 0.68 um and GOSAT/TANSO-CAI's reflectance data of 1.6 um. We found that there are some correlations between these two reflectances when we classified by NDVI. The correlation is larger when the NDVI is large. The error induced by this parameterization is calculated. The standard error is 0.009 when 0.5 <NDVI <0.7, and the standard error is 0.007 when 0.7 <NDVI. We also calculated the error as aerosol optical thickness. The error as aerosol optical thickness at 0.5 um is 0.18 when 0.5 <NDVI <0.7, and that is 0.14 when 0.7 <NDVI. We will also develop aerosol models for each area by use of cluster method and linear classifier method.

Keywords: aerosol, remote sensing, EarthCARE

Helicopter-borne observation with portable microwave radiometer in the Southern Ocean and the Sea of Okhotsk

TAMURA, Takeshi[1*] ; OHSHIMA, Keiichiro[2] ; LIESER, Jan[3] ; TOYOTA, Takenobu[2] ; TATEYAMA, Kazutaka[4] ; NOMURA, Daiki[2] ; NAKATA, Kazuki[2] ; FRASER, Alex[2] ; JANSEN, Peter[3] ; NEWBERY, Kym[3] ; MASSOM, Robert[3] ; USHIO, Shuki[1]

[1]National Institute of Polar Research, [2]Institute of Low Temperature Science, [3]ACE CRC, [4]Kitami Institute of Technology

It has been recently recognized that sea ice production in the polar regions is controlled by the thin sea ice area with thickness of less than 0.2 m. Spatial distribution of thin ice area and its variability are important information to better understand the reduction of the sea ice covered region in a changing climate environment. We have developed a thin ice thickness algorithm for satellite passive microwave data of the Advanced Microwave Scanning Radiometer-EOS (AMSR-E) and Special Sensor Microwave Imager (SSM/I). Although the microwave skin depth of bare sea ice is about several cm at most, microwave brightness temperatures correlate with the surface salinity (brine volume fraction), which is sensitive to thin ice thickness. Here, we present in-situ observations using a helicopter-borne portable passive microwave radiometer that has the same specifications as the satellite AMSR-E and AMSR-II sensors (36 GHz-vertical and -horizontal channels), to validate and improve our thin ice thickness algorithm. This study estimates the relationship between the microwave brightness temperatures (both satellite and helicopter-borne portable sensors) and in-situ observations of sea ice thickness.

We present data from two airborne missions, one in early austral spring 2012 during the Sea Ice Physics and Ecosystem eXperiment (SIPEX-2) of the Australian Antarctic Program in East Antarctica, and one from the Sea of Okhotsk in mid-winter 2009. These microwave data are compared with the satellite AMSR-E and AMSR-II data and ice thickness estimated from Moderate-Resolution Imaging Spectroradiometer (MODIS) data, helicopter-borne IR sensor data, and ship-borne downward looking camera data. High-resolution airborne microwave brightness temperatures show good agreement with low AMSR-E and AMSR-II brightness temperatures, despite the significant resolution mismatch. In the thin ice region, the polarization ratio of 36 GHz vertical and horizontal temperatures (PR-36) is found to be well correlated with ice thickness, supporting the validity of the AMSR-E thin ice algorithm which was developed previously by our group. We also discuss the microwave characteristics of fast versus pack ice, with a view to improving a satellite fast ice detection algorithm.

Diatom analysis on the late Pleistocene Takano Formation, Nagano, Japan

NAGAYASU, Koichi[1*] ; OTANI, Hiromi[3] ; KUMON, Fujio[2]

[1]Interdisciplinary Graduate School of Science and Technology, Shinshu University, [2]Department of Environmental Sciences, Faculty of Science, Shinshu University, [3]Faculty of Science, Shinshu University

Diatom analysis has been performed at a 0.5 m interval for a sediment core of 53.88 m length from the late Pleistocene Takano Formation. According to the age-model proposed by Tawara et al. (2006), this core can covers from 170 ka to 40 ka in age and analysis interval correspond to about 1500 years.

From 170 ka to 140 ka, benthoic diatoms such as *Achnanthes* spp. and *Staurosira* spp. are dominant, and diatom abundance is very low (lower than 1.0×10^8valves/g). After 140 ka, planktonic diatoms such as *Cyclotella radiosa*, *Aulacoseira ambigua*, *Cyclotella stelligera*, *Aulacoseira alpigena* are dominant. From 140 ka to 130 ka, *C. radiosa* is dominant, and diatom abundance is low (1.6 - 6.9×10^8 valves/g). From 130 ka to 115 ka, *Aul. alpigena* is dominant, and diatom abundance is high (over 10×10^8 valves/g). From 115 ka to 100 ka, *C. stelligera* is dominant, and diatom abundance varies largely (0.1 - 38.2×10^8 valves/g). From 100 ka to 70 ka, *C. radiosa* is dominant, and diatom abundance is abundant, between 3.2×10^8 valves/g and 56×10^8 valves/g. From 70 ka to 40 ka, *C. radiosa* and *Aul. alpigena* are dominant, and diatom abundance is low, fluctuating a little between 0.9×10^8 valves/g and 20×10^8 valves/g.

These results are compared with the diatoms analysis of the sediment cores from Lake Biwa. After 140 ka, planktonic diatoms are dominant in the Takano Formation, and the diatom assemblage changes synchronously between Takano Formation and Lake Biwa.

Is small Abies mariesii forest in Pseudo-Alpine Zone spreading? :Case study in the Akitakomagatake

KONNO, Asaka[1*]

[1]Miyagi University of Education,MA

Pseudo-Alpine Zone composed of Sasa and shrubs occupies on subalpine zone of mountain along the Sea of Japan in eastern Japan. It is considered that heavy snowfall on those mountains prevents coniferous trees from growing and consequently Pseudo-Alpine Zone exists. But there is Pseudo-Alpine Zone in the part of the Ou Backbone Range which is less snowfall than mountains along the Sea of Japan. On Akitakomagatake, the one of mountains which has Pseudo-Alpine Zone, small Abies mariesii forests are scattered.

This landscape has been hitherto considered that spreading Abies mariesii forest which finally results in matured coniferous forest on the basis of pollen analysis. Perpose of this study is discussing whether small Abies mariesii forest is spreading or not in terms of tree distribution and local environment.

As the result, Abies mariesii seeding is distributed only within the small Abies mariesii forest, not in surrounding Sasa kurilensis and Fagus crenata.In addition, soil moisture is higher in the small Abies mariesii forest than in the surrounding vegetation. These results suggest that the small Abies mariesii forest is not spreading but just being established on appropriate site.

The chemical characteristics of spring and river water in Kamikochi at the Japanese Alps

KURAMOTO, Takayuki[1*] ; SASAKI, Akihiko[1] ; SUZUKI, Keisuke[1]

[1]IMS, Shinshu University

There are much spring waters in the Azusa River which flows through Kamikochi. These spring waters form the branch of the Azusa River. Spring water shows the characteristics reflecting an underground water flow. Therefore, in order to understand the water cycle of Kamikochi, it is important to understand the formation mechanism of spring water. The purpose of this study is to clarify the chemical characteristics of spring and river water in Kamikochi. We set up the thermometer in five places of a basin for the measuring of spring and river water temperature. The water samples were collected in water temperature measuring site and Azusa River. The pH, electric conductivity, major ions (Na^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, $NO_3{}^-$ and $SO_4{}^{2-}$), and stable isotope of water were analyzed with the pH meter, conductivity meter, ion chromatographs, and isotopic water analyzer, respectively. In addition, $HCO_3{}^-$ concentration was measured using the sulfuric acid titration method. At almost observation points, the temperatures of spring and river water showed seasonal change. However, only one site did not have change of spring water temperature through a whole year.

Geo-environmental changes after the fire on the alpine slopes of Mount Shirouma-dake, northern Japanese Alps

SASAKI, Akihiko[1*] ; KARIYA, Yoshihiko[2] ; IKEDA, Atsushi[3] ; SUZUKI, Keisuke[1]

[1]IMS, Shinshu Univ., [2]Senshu Univ., [3]Tsukuba Univ

This is the continuous study to clarify the geo-environmental changes on the post-fire alpine slopes of Mount Shirouma-dake in the Northern Japanese Alps. The fire occurred at May 9, 2009 on the alpine slopes of Mount Shirouma-dake, and the fire spread to the Pinus pumila communities and grasslands. Although the grass had a little damage by the fire, the Pinus pumila received nearly impact of the fire. In the Pinus pumila communities where the leaf burnt, forest floor is exposed and become easy to be affected by atmospheric condition such as rain, wind, snow, and etc.

First, we illustrated a map of micro-landforms, based on geomorphological fieldworks. We observed these micro-landforms repeatedly for four years after the fire. As the results of the observation, it is clear that remarkable changes of these micro-landforms have not occurred but some litters on the forest-floor in the Pinus pumila communities are flushed out to surroundings. The litter layer on the forest-floor in the Pinus pumila communities were 3-4 cm thick in August of 2011, but it became 1-2 cm thick in September of 2013. The Pinus pumila communities established on the slopes consists of angular and sub-angular gravel with openwork texture, which are covered by thin soil layer. Therefore, it is necessary to pay attention to soil erosion following the outflow of the litter.

In addition, we observe the ground temperature and soil moisture, under the fired Pinus pumila communities and the no fired Pinus pumila communities after the fire, to find influence of the fire. The ground temperature sensors were installed into at 1 cm, 10 cm, and 40 cm depth. The soil moisture sensors were installed into at 1 cm and 10 cm depth. The 1 cm depth of the soil on the post-fire slopes, diurnal freeze-thaw cycles occurred in October and November of 2011 and 2012, but it had not occurred in 2009 and 2010. In addition, the period of seasonal frost at 10 cm and 40 cm depth on the post-fire slopes are extended for two weeks. These thermal condition changes are triggered by decrease in the thickness of the litter layer on the fired Pinus pumila communities.

Combining time-lapse photography and multisensor data logging to monitor slope dynamics in the southern Japanese Alps

MATSUOKA, Norikazu[1*]

[1]University of Tsukuba

Onsite time-lapse photography (TLP) is applied to visual monitoring of soil movements and rockfalls in an alpine zone (Mt. Ainodake area) of the southern Japanese Alps. The time-series images greatly improve understanding of slope processes in remote, seasonally inaccessible areas. TLP detects the timing of slope movements at a high time resolution. Stereographic view of successive images displays 3D slope dynamics that indicates the location and magnitude of displacement. When combined with sensor-based data logging, TLP allows more reliable evaluation of thresholds (environmental controls) for slope movements. This presentation demonstrates (1) how visual information improves the interpretation of both slow progressive soil movements (frost creep) and rapid temporary movements (rill erosion and rockfalls) and (2) how highly active is slope dynamics in the southern Japanese Alps that experience deep seasonal frost in winter and heavy rain storms in summer.

Continuous monitoring of a painted line drawn on a debris lobe highlights biannual shallow soil movements, mostly derived from diurnal frost heave by needle ice or shallow ice lens formation and approximated by the potential frost creep. The surface velocity shows a small interannual variation mainly reflecting snow conditions, but an extraordinary velocity is recorded once per decade. This is due to episodic rill erosion released when the topmost frozen soil is rapidly thawed and super-saturated by intensive rainfall during seasonal thawing periods.

Year-round TLP images of a rockslide scarp allows evaluation of the timing and magnitude of rockfalls at different scales. Close-up images of color-painted quadrangles (50 cm square) indicates centimeter- to decimeter-scale spalling events. Spalling activity reach a maximum at the beginning of seasonal thawing, when the rockwall experiences both diurnal freeze-thaw alternations within the outermost 20 cm and progressive warming of the still-frozen substrate. Stereographic view of successive images also identifies block-scale rockfalls. Such an event occurred between 16 h on 7 July and 8 h on 8 July 2011, triggered by nocturnal rainfall (total 33 mm).

Evaluation of long-term variability of rainfall-runoff properties in forested alpine catchment

KOJIMA, Toshiharu[1*] ; ZAINAL, Edwina[2] ; OHASHI, Keisuke[3] ; SHINODA, Seirou[4]

[1]River Basin Research Center, Gifu University, [2]Graduate School of Engineering, Gifu University, [3]Faculty of Engineering, Gifu University, [4]Information and Multimedia Center, Gifu University

The water conservation function of forest, so-called ”Green Dam” in Japan, is recognized as one of the important forest’s functions. However it is often miss-understood by general public such as ”sponge theory”. Water balance in forested catchment is not clear because of its complexity by many hydro processes. The authors investigate the long-term variability of rainfall-runoff properties by forest growth and climate changes in the Gamansawa catchment (3 km^2), Nakatsudawa, Gifu, Japan. The study area has long-term hydrological data acquired by Gifu prefecture and Forestry Agency, Japan from 1984 to 2007. Main forest types are cypress(67%), cider(4%), broad-leaves forest(20%) and so on. The long-term tendency of forest variation is investigated by satellite image analysis with Landsat/MSS, TM and Terra/ASTER images acquired from 1984 to 2010. The mean NDVI over the study area are increasing. Therefore the forest should be growing in the research period. The authors investigate the trend of event based discharge rates f (=total direct discharge at the event / total rainfall at the event). The hydrological data is divided to many rainfall events and event based discharge rates are evaluated. The event based discharge rates are on a slightly decreasing trend with df/dt = -0.006 [y^{-1}]. Moreover the long-term hydrological data is divided to four periods and apply to the 4-layer tank model in order to evaluate the variation of hydrological properties in the study area. We assumed that the long-term variation in forest property is mostly surface soil layer such as soil layer thickness and lateral permeability. Vertical permeability depends on bed rock cracks should not so much increase. Based on this assumption, the model parameter of the bottom hole, which is related to infiltration to aquifer, is fixed. The model parameters of the second and lower tanks are also fixed. And the variability of the model parameters of side holes of the first tank, which are related to direct discharge, is investigated. We obtained the results as the model parameters of the side holes have the tendency of decrease as 0.9 to 0.7[d^{-1}], during the research period. Next, using these model parameters, the test rainfall events are simulated and the following results were obtained. 1) The peak discharge volume is decreased. 2) The event based discharge rates f are decreased as 0.6 to 0.5. This trend is the almost same as the mentioned event based discharge rates with long-term hydrological data analysis. These results suggest the flood mitigation function is increased during this period. On the other hand, although the model parameter of the bottom hole is fixed, total infiltration volume to lower tanks and base flow are increased. This result suggests that water conservation to aquifer also increase without increasing of vertical permeability such as bed cracks. It can be explained as follows. Consider a simple tank has one side hole and one bottom hole. The discharge from the side hole q [mm/d] is defined as $q = ah$, where h [mm] is the storage depth of the tank, a [d^{-1}] is the side hole size. The infiltration from the bottom hole i [mm/d] is defined as $i = bh$, where b [d^{-1}] is the bottom hole size. The time variation of h is defined as $dh/dt = q - i$. We obtain the total infiltration volume I as $I = bC/(a+b)$, where C is a constant of integration. By the above equation, when a is decreased with fixed b, total infiltration is increased. Therefore, it is suggested that increasing of water conservation can be explained with lateral permeability depend on forest growth. Moreover, we simulated two cases about evapotranspiration. First case is considered evapotranspiration with Hammon equation, and second is not considered. Hammon equation estimates probability evapotranspiration based on air temperature and daylight time. The results with two cases are the almost same. It is suggested that influence of climate changes have less effect than other factors.

Canopy photosynthetic and soil respiratory responses to rising temperature in a cool-temperate deciduous forest

MURAOKA, Hiroyuki[1*] ; NOH, Namjin[1] ; NAGAO, Ayaka[1] ; SAITOH, Taku M.[1] ; KURIBAYASHI, Masatoshi[1] ; NODA, Hibiki M.[2] ; ITO, Akihiko[2] ; NAGAI, Shin[3] ; NAKAJI, Tatsuro[4] ; HIURA, Tsutom[4]

[1]Gifu University, [2]National Institute of Environmental Studies, [3]JAMSTEC, [4]Hokkaido University

Prediction of possible influences of global warming on terrestrial ecosystem structure and functions is one of an urgent research tasks in environmental sciences. This paper overviews our challenging research by open-field warming experiments on forest canopy photosynthetic productivity and on soil respiration in a cool-temperate deciduous broadleaf forest at Takayama AsiaFlux and JaLTER site, located on a mountainous landscape in central Japan. Canopy warming experiment is conducted by three open-top canopy chambers (OTCC) on branches of a mature tree of Quercus crispula, one of the dominant canopy species in the forest. The OTCC increased mean daytime air temperature by about 2 degree-C, with midday maximum of about 5 degree-C throughout the growing seasons. Soil warming treatment, with 3 degree-C higher than the control area, was made by installing electric heating cables below the soil surface.

Warming treatment at the canopy-top led (1) expansion of canopy photosynthetically active season in about 10 days by 3-5 days earlier leaf budbreak and expansion and about 5 days delay of leaf senescence, and (2) slightly higher chlorophyll content and photosynthetic capacity of oak leaves. Warming treatment of forest soil showed (1) higher soil respiration throughout the seasons, resulting in 15% higher CO2 efflux from the soil during the growing season, but (2) the temperature response of soil respiration acclimated to the higher temperature condition characterized by lower slope of the response curve. We also examined the possible effects of growing period length on forest canopy and understory vegetation ecosystem CO2 budget under future climate conditions by using canopy-phenology ecosystem carbon cycling combined model. Our simulation indicated that annual total ecosystem GPP, RE and NEP was greater under the future condition than under the current condition by 9-12 %, 9-13% and 12-17%.

Our study demonstrates that open-field warming experiments provide us with useful and insightful knowledge on the ecophysiological responses of both canopy and soil processes to rising temperature, and their critical roles in predicting future changes of forest carbon cycle processes in cool-temperate region in Japan where ecosystem structure, functions and services are subjected to influence of the climate change.

Effects of Open-top Chamber on Soil Oribatid Mites (Acari:Oribatida) at Mt. Kisokoma-gatake

FUKUYAMA, Kenji[1*] ; NAKAMURA, Hiroshi[1] ; KOBAYASHI, Hajime[1] ; TANAKA, Kenta[2]

[1]Faculty of Agriculture, Shinshu University, [2]Sugadaira Montane Research Center, University of Tsukuba

INTRODUCTION

Forest limit ecosystem on high mountains was one of the most vulnerable ecosystems against global warming. We investigated effects of artificial warming using an open-top chamber on forest limit ecosystem (2600m in elevation) of Mt. Kiso-komagatake, Chuo-alps, Nagano, central of Japan. Oribatid mites were useful environmental bio-indicator because they distribute most of all terrestrial soil habitats. Therefore, oribatid fauna were compared between artificial warming sites and control site in the study area. We investigate vertical distribution concerned with elevation of oribatid fauna from 2600m to 1250m. On the other hand, Mortality of oribatid species was investigated under different temperature in incubator.

METHOD

Research sites of vertical distribution were established at 1250m, 1700m, 1900m and 2100m above sea level in Nishikoma Station of Shinshu University. We selected two plots (coniferous forest and broad leaved forest) in each elevation site. Five soil samples were randomly corrected using core sampler (100cc) 5cm depth on 26 July 2012. Oribatid mites were corrected using the Tullgren funnel on same day. Additionally, two soil samples (about 400cc) were corrected at 1250m, 1400m, 1700m, 1800m, 1900m, 2000m, 2100m, 2200m and 2600m above sea level on 28 Aug. 2012.

Nine open-top-chambers (1m X 1m, about 2m in height) were established at 2650m above sea level near Mt. Shogigasira. Two soil samples (100cc, 5cm depth) were corrected using core sampler from each open-top-chamber on 20 Sept. 2013. Also two soil samples were corrected from control site close to each open-top-chamber. Two soil samples were set on one Tullgren funnel in laboratory on same day.

Soil samples (about 5000cc) were corrected from 2100m and 1250m above sea level in Nishikoma station of Shinshu University on 17 July 2013 and each soil sample was softly stirred by hand in laboratory and was divided in 15 nonwoven fabric bags (400cc). Each bag was set in unglazed pottery (11cm in diameter). Five potteries were incubated in incubator under 10 degrees centigrade, 20 degrees centigrade and 30 degrees centigrade from 17 July to 12 Aug. 2013.

RESULTS and DISCUSSION

Results of investigation of vertical distribution show that *Cyrtozetes* sp., *Tectocepheus velatus* and *Phthiracarus japonicus* positively increased their population densities correlated with elevation, and especially, *Cyrtozetes* was only found upper from 1900m above sea level.

Results of comparative study using the open-top-chamber show that *Cyrtozetes* and *Phthiracarus* in the open-top-chamber were significantly decreased instead of *Ghilarobizetes* significantly increased.

These results suggest that *Cyrtozetes* and *Phthiracarus* are good indicators for global warming monitoring in high mountain ecosystem.

On the other hand, mortality rate of *Cyrtozetes* and *Phthiracarus* were not affected by temperature from result of incubation one month after. The reason of no affection of temperature on *Cyrtozetes* is probably its long life cycle. More studies will be needed about it.

The parametric estimation of the amount of CO2 to be stored as HWP of the wooden house, based on the each of tree specie

TAKAMURA, Hideki[1*] ; ASANO, Yoshiharu[1]

[1]Faculty of Engineering, Shinshu University and Institute of Mountain Science, Shinshu University

In the term of the handling of wood in Kyoto Protocol, it has been considered to release carbon accumulated in growing stage immediately into atmosphere at the time of cutting down from forest in the first commitment period. In the second commitment period, it has been considered to fix carbon while it is used as harvest wood products (HWP), and to release carbon into atmosphere at discarded stage. The main utilization of domestic wood is to build wooden house domestically, and it has an important role as a carbon pool of HWP. However, the rate of utilization of domestic wood has been continued to decrease. In order to take concrete strategy to measure rate of increase in utilization of domestic wood in the future, it is important to estimate present amount of utilization by each of tree species and the amount of prospect for increased use in the future.

Future estimation of carbon pool by HWP for all over the country was studied in the past research. In the estimation for all over the country, national total gross floor space, the number of new constructions per year, the number of households, the amount of average for wood utilization are used as basic date, it has not been estimated by each of tree species. Therefore, in order to estimate target amount of increased utilization for each of tree species, it is urgent issue to make calculation flow based on area characteristic by using the amount of tree species used in each material by region, and the amount of carbon stock (hereinafter called carbon balance) for each of tree species by region.

In this study, it was investigated that estimation method of the amount of utilization by each of tree species and the amount of carbon stock which is applicable to wood statistics and all prefectures. Estimation, which is for Nagano, of the amount of utilization for each of tree species and the amount of carbon stock was conducted by using carbon balance for each of tree species in Nagano which was revealed by Yamagata et al. in the past research, and the rate of utilization for each of tree species which was surveyed by Nagano Prefecture.

As a result of estimation, it revealed that the amount of carbon stock would decrease with a peak of 380,000 [t-C] in 2021 (Heisei 33). From the increase in the total gross floor space in the whole area of Nagano by the increase in the average of gross floor space per house, the amount of carbon stock indicated an upward trend until 2021. However, the amount of carbon stock declined by the decrease in the number of new constructions per year and increase in the number of losses of existing houses in 2022 and later. In this research, we conducted the estimation of the case in which 60% of domestic wood utilization that Forestry Agency advocated as a measure against decrease in the amount of carbon stock was achieved. As a result of having changed the domestic wood utilization up to 60% in 2011 and later, the decrease in the amount of carbon stock was not seen until 2038 (Heisei 50).

The estimation revealed necessity to increase supply of domestic wood approximately 50,000m3 per year to achieve 60% of utilization rate for domestic wood. There is sufficient amount of accumulated forest resources in Nagano, however, it is necessary to secure supply capacity. Ido et al. pointed out that it is difficult to adjust the cut of timber from forest since it is difficult to show demand prospect. For this issue, the estimation of this study is very useful and contributes to increase distribution of domestic wood by feeding back the estimation result to supply side. Since there is a distribution of domestic wood between prefectures, it is necessary to estimate by the method of this study in other prefectures. It is important to create road map which raises rate of utilization of domestic wood by planning and grasping the wood distribution of the whole country by obtaining each demand prospect in the future.

Snow patches of Japanese Alps last until late autumn 2013 and their past variations

ASAHI, Katsuhiko[1*]

[1]Institute of Mountain Science, Shinshu University

Variations in glaciers are visible indicators of climate change, especially in mountain region. In Japan, snow patch can be an alternate indicator since glaciers, long years, were not recognized in the Japanese Alps. One characteristic of the Japanese Alps is their extensive distribution of snow patch last until late autumn. A snow patch inventory for this mountain is urgently required, not only for monitoring snow patch variations but also to evaluate water reservoir in the region. Limited number of studies has attempted to complete snow patch atlas in Japan. As a step in this direction, the author has produced an inventory of snow patch lasts before winter 2013 at the entire area of the Japanese Alps. This study addresses the results of snow patch mapping 2013.

The work of compiling a perennial snow patch inventory for the Japanese Alps initially involved oblique aerial photographs taken from a charter flight throughout the Japanese Alps. These photographs were interpreted using a stereoscope. The photographs were taken on 7th and 10th October 2013. The planimetric outline of each perennial snow patch was manually delimited and drawn on 1:25 000 scale topographical maps and successfully compiled the complete set of snow patch inventory of the Japanese Alps in 2013. Then inventory of 2013 thus compiled reveals 579 snow patches with a total surface area of 3.66 km^2. The year 2013 distribution was much extensive rather than that of usual years. The lowest snow patch termini appeared at the altitude of 1070 m on Mt. Inu of the northern Japanese Alps and the southernmost was 35 ^{o} 40 $'$ 30.5 $''$ at Mt. Kita of the southern Japanese Alps. The largest one was the area of 0.184km^2 on Mt. Karamatsu of the Northern Japanese Alps. Ca. 80% of them locate east-facing slopes, where leeward side against winter prevailing NW wind. Latitudinal profile of the terminus altitudes of snow patches shows northward gradients. Winter northwesterly blown from the Siberian High, collecting vapor from warm current on the Sea of Japan, bring orographic heavy snowfall to the northern part of the Japanese Alps. Thereafter, peculiar snow patch distribution last before winter is likely to be a ruling by maldistribution of snowfall in winter.

In the same area, the inventory of 1976/77, compiled by the vertical aerial photograph interpretation, counts 264 with the area of 2.48 km^2. Major distribution concentrated in Mts. Tsurugi and Tateyama, central part of the Northern Japanese Alps. The total area in this mountains were 0.78, 0.77, 0.58, 0.84 km^2 in 1969, 1977, 2009, and 2013, respectively. Snowfall amount in winter and the snow patch area fluctuate largely year-by-year. However, the area fluctuation limits within a range of 30% the total area.

Effects of forest harvesting on winter microcrimate and sedmiment movements in mountainous area

IMAIZUMI, Fumitoshi[1*] ; NISHII, Ryoko[2] ; UENO, Kenichi[2] ; KUROBE, Kousei[3]

[1]Graduate Shool of Agriculture, Shizuoka University, [2]Faculty of Life and Environmental Sciences, University of Tsukuba, [3]Graduate School of Life and Environmental Sciences, University of Tsukuba

Activities of periglacial processes are controlled by the hillslope microclimate (i.e., air and ground temperatures, ground water content) that is highly affected by land cover conditions. Thus, forest harvesting in periglacial areas possibly affects activities of sediment movement (i.e., soil creep, dry ravel) by changing the microclimate of hillslopes. Knowledge on the effect of forest harvesting on sediment movement are needed to protect aquatic ecosystems as well as to develop better mitigation measures for preventing sediment disasters. We also observed difference in the microclimate as well as sediment movement between harvested and non-harvested artificial forests in a periglacial area. The field observation was conducted in Ikawa University Forest, University of Tsukuba, in southern Japanese Alps. In this region, air temperature frequently rises above and falls below 0 degree in winter. Forest harvesting changed both temperature and water condition of hillslopes; diurnal fluctuations in the ground surface temperature in the harvested area (about 15 degree) were much larger than that in the non-harvested area (about 3 degree). In the period without rainfall, water content ratio of soil in the harvested area was lower than that in the non-harvested area. Difference in the freezing and thawing frequency between the harvested and the non-harvested area was also observed by interval cameras. In the period without snow cover, diurnal frost heave was observed almost everyday in the harvested area. In contrast, diurnal frost heave in the non-harvested was observed only several times in one winter. Consequently, forest harvesting changes both microclimate and activities of periglacial processes. Meanwhile, the volume of sediment captured by sediment traps was not clearly different between the harvested and the non-harvested areas. In the harvested area, we found that a large volume of sediment was captured by litters and branches of harvested trees left on the hillslopes. Therefore sediment supply rate from harvested area may be also affected by other factors, such as existence of litters and branches on the ground surface.

Spatial and temporal changes in soil respiration in an old-growth forest on the slope of Mt Hakusan

OHTSUKA, Toshiyuki[1*] ; SUCHEWABORIPONT, Vilanee[1] ; IIMURA, Yasuo[2] ; YOSHITAKE, Shinpei[1]

[1]Gifu University, River basin research center, [2]University of Shiga Prefecture, School of Environmental Science

Structure and function of cool-temperate beech forests have been dramatically altered by disturbance. Especially in old-growth forests, canopy disturbance has important influences on the structure and organization of forest communities. As a result, the complexity of forest structure affects the spatial difference in micro-environmental factors such as soil temperature and soil water content. Therefore, the spatial and temporal changes in soil respiration were studied using soda lime in 1-ha study site, and automated open-close chamber using IRGA (AOCC method) in canopy and gap areas in 2013 in an old-growth beech forest, Mt Hakusan. The spatial pattern with the different vegetation and micro-environmental factors showed the high efflux in canopy and the low efflux in gap. All soil effluxes increased from spring (Jun.-Jul.) to summer (Aug.), and then decreased in autumn (Sep.-Nov.). The seasonal pattern showed the hysteresis loop that soil respiration in spring was greater than that at the same temperature in autumn. Diel soil efflux was greatly controlled by soil temperature but a diel lag between soil respiration and soil temperature led to diurnal hysteresis loop in some season.

Keywords: Soil respiration, cool-temperate region, old-growth forests, carbon cycling, beech forests

Spatial distribution of soil microbial characteristics in a cool-temperate deciduous broad-leaved forest in Takayama

YOSHITAKE, Shinpei[1*] ; YOSHITAKE, Ayako[1] ; IIMURA, Yasuo[2] ; OHTSUKA, Toshiyuki[1]

[1]Gifu University, River Basin Research Center, [2]The University of Siga Prefecture, School of Environmental Science

1. Introduction

Heterotrophic microorganisms have an important role in nutrients cycling and soil formation through the organic matter decomposition. Therefore, it is important to clarify the spatiotemporal variation in quantitative and qualitative characteristics of soil microbial community and the factor(s) affecting such spatiotemporal variation in considering the matter cycling. Takayama Field Station of Gifu University has studied carbon cycling in a cool-temperate deciduous forest for long term and have clarified that various ecological processes such as soil respiration showed significant spatiotemporal variation. However, the information of soil microbial community is largely limited and especially, the spatial variation of microbial characteristics and factors affecting it still remain unclear. Then, we aimed to describe the spatial distribution of microbial characteristics and clarify the relationships between spatial distribution and environmental factors.

2. Materials and Methods

Our study site was cool-temperate deciduous broad-leaved forest on the northwestern slope of Mt. Norikura, central Japan. The site was dominated by oak (*Quercus crispula*) and birch (*Betula ermanii*, *B. Platyphylla*) and the forest floor is covered with a dense dwarf bamboo (*Sasa senaninsis*) community. A permanent plot of 1 ha was set on a west-facing slope and 100 subplots (each 10 m$\times$10 m) are distributed along five microtopographic type: ridge (30), northern slope (25), valley bottom (19), southern slope (19) and western slope (7) (Fig.1). Litter (L layer) and mineral soil (0-5 cm of A layer) samples were collected from 100 subquadrat on early May 2013. Some soil properties (e.g., water content, pH, NH_4^+-N, NO_3^--N) were determined. Microbial respiration rate from mineral soil sample was determined by open-flow method with infrared gas analyzer in laboratory condition.

3. Results, Discussion and future plan

Average value of microbial respiration rate per gram soil was significantly differed among five topographic types (one-way ANOVA, P <0.01) and that in ridge (3.6$\pm$0.81 μg CO_2-C g^{-1} h^{-1}) was significantly higher than that in valley bottom (2.9$\pm$0.78 μg CO_2-C g^{-1} h^{-1}) (Tukey-Kramer test, P <0.05). In this poster presentation, the effects of topography on microbial respiration rate will be discussed based on the differences in environmental factors such as soil water content, litter amount, and soil carbon and nitrogen contents. In addition, soil microbial biomass and community structure will be determined for collected mineral soil samples by phospholipid fatty acid (PLFA) analysis in near future and spatial distribution of microbial biomass, community structure, and respiration activity (respiration rate per biomass) will be clarified.

Global pattern of gene flow in plant species along altitudinal gradients on mountains

HIRAO, Akira[1*]

[1]Sugadaira Montane Research Center, University of Tsukuba

Several studies on mountain plants with wide-altitudinal distributions have found significant genetic differentiation and structuring among populations along altitudinal gradients. In most of the studies, however, the level of genetic differentiation was not highly remarkable. This is somewhat counterintuitive, since one would expect that mountainous species often exhibit heterogenous environments and phenological differences along altitudinal gradients, which should be forces driving genetic differentiation. Understanding how gene flow corresponds with altitudinal gradients can inform process of the genetic structuring. I reviewed published studies to categorize global patterns of gene flow in mountainous plant species. These outcomes can depend on 1) isolation by distance, 2) mobility within similar altitudes, and 3) mobility among dissimilar altitudes, and imply evolutionary processes of the plant populations on mountains.

Frontier of using stable water isotopic information in studies on land-ecological, hydrological, and atmospheric process

YOSHIMURA, Kei[1*]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo

In this study, it was clearly shown that vapor isotope data retrieved by satellite sensors or in situ monitoring networks have the potential to constrain the atmospheric fields. The results of this study can be applied in two directions. The first direction is a better analysis skill in current weather forecasting systems. Though our understanding of the atmosphere is improving, understanding the hydrological cycles of the mid- to upper troposphere and lower stratosphere in association with convective clouds remains difficult. Because it is apparent that water vapor isotopic information has unique characteristics with regard to the atmospheric hydrological cycle and technical improvements in satellite and in situ instruments are occurring rapidly, this direction is indeed quite promising. The second direction, regarding proxy data assimilation, is even more challenging and is significant in several disciplines. In the past, we lacked direct measurements of the Earth and were forced to rely on proxy data. Interpretation of proxy data is important but can be over-simplified. By using data assimilation for proxy data, an objective analysis of the past (specifically before the nineteenth century) can be achieved without simplifying the empirical relationship between proxy data and climate/environment information. Although there are many technical and theoretical obstacles in both directions, the authors strongly believe that scientific benefits can be achieved.

Significance of hyper spectral solar radiation observation

KUME, Atsushi[1*] ; AKITSU, Tomoko[2] ; NASAHARA, Kenlo[2]

[1]Ashoro Research Forest, Kyushu University, [2]Faculty of Life and Environmental Sciences, University of Tsukuba

Land plants exhibit relatively weak absorbance of green light at around 550 nm, for reasons which remain elusive. Most research, however, has assumed that the solar radiation spectrum can be averaged without considering the spectral dynamics. The relations between the spectrum of incident radiation and light-harvesting pigments of organisms are crucial to understanding photosynthesis and light use efficiency. Although several light-harvesting pigments exist, most land plants use specific light harvesting chlorophylls, Chl a and Chl b, and carotenoids. Wavelengths longer than 700 nm or shorter than 400 nm are scarcely absorbed by chlorophylls, and cannot be used for photosynthesis. Radiation within the 400 to 700 nm waveband is defined as photosynthetically active radiation (PAR). However, chlorophylls do not absorb photons in the PAR waveband evenly. Only a few per cent of relative absorbance occurs in the green region (500 to 600 nm), nevertheless the photosynthetic quantum yields are equivalent to those from blue and red light.

Incident PAR comprises two main components, direct PAR (PARdir), which arrives directly from the sun, and diffuse PAR (PARdif), which is sunlight scattered by sky and clouds. These components are characterized by large differences in light quantity, directional characteristics and spectral quality. PARdir is highly directional and its energy can be concentrated and localized on a surface. PARdif is non-directional and its incident energy is well-averaged across a surface, allowing it to penetrate deeper into canopies. Consequently, PARdir and PARdif play different roles in the photosynthetic process both at the scale of individual leaves and of canopies. Most research, however, has assumed that the solar radiation spectrum can be averaged without considering the spectral and directional dynamics.

We had developed a precise solar tracking device for detecting direct and diffuse radiation. Direct and diffuse radiations were measured separately by two grating spectroradiometers (MS700, EKO Instruments Co. Ltd., Tokyo, Japan) fixed to sun trackers (STR-22G-S, EKO Instruments Co. Ltd.) equipped with a collimation tube (angle of view 5 degrees) for measurement of PARdir, and a shadow ball for measurement of PARdif.

Analyzing the relative absorption spectra of chlorophyll, we found that Chl a does not absorb direct solar radiation, while diffuse solar radiation is efficiently up-taken by Chl b. The spectrum of diffuse solar radiation is almost fixed with a peak wavelength (λmax) around 460 nm. However, that of direct solar radiation shifts from a broad peak with λmax around 700 nm towards a narrower peak around 540 nm, as solar zenith angle decreases. The absorption spectrum of Chl a lies outside the strongest energy regions of direct solar radiation. The λmax of the Chl b absorption spectrum matches that of diffuse solar radiation; therefore, Chl b can absorb the most energetic parts of this radiation. The spectral differences between direct and diffuse solar radiation elucidate the meaning of slight spectral differences in pigments for terrestrial organisms.

Strong light is known to enhance accumulation of carotenoids. We found that β-carotene consistently absorbed more energy per photon than other pigments, indicating that it effectively filters (i.e. accepts) the 350-500 nm waveband, independently of PAR class.

Overall, the spectral differences between PARdir and PARdif, as well as the steady λmax of PARdif, exert multiple effects on terrestrial organisms and may be effective drivers of diversification in pigment distribution and function. Further spectral-directional radiation observation at various sites is needed to reveal the effects of the dynamics of incident solar radiation on the terrestrial ecosystem.

Simultaneous Estimation of Hydrologic and Ecologic Parameters in an Eco-Hydrological Model Assimilating Microwave Signal

SAWADA, Yohei[1*] ; KOIKE, Toshio[1]

[1]School of Engineering, the University of Tokyo

To improve the skill of reproducing land-atmosphere interactions in weather, seasonal, and climate prediction systems, it is necessary to simulate correctly and simultaneously the surface soil moisture (SSM) and terrestrial biomass in land surface models. Despite the performance of hydrological and ecosystem models depends highly on parameter calibration, a method for parameter estimation in ungauged areas has yet to be established. We develop an auto-calibration system that can simultaneously estimate both hydrological and ecological parameters by assimilating a microwave signal that is sensitive to both SSM and terrestrial biomass. This system comprises a hydrological model that has a physically based, sophisticated soil hydrology scheme, a dynamic vegetation model that can estimate vegetation growth and senescence, and a radiative transfer model that can convert land surface condition into brightness temperatures in the microwave region. By assimilating microwave signals from the Advanced Microwave Scanning Radiometer for Earth Observing System, the system simultaneously optimizes the parameters of these models. We test this approach at three in situ observation sites under different hydroclimatic conditions. Estimated SSM and leaf area index (LAI) exhibit good agreement with ground in situ observed SSM and satellite observed LAI, respectively. The root mean square error of SSM and LAI at all sites, estimated by the model with optimized parameters, is much less than that estimated by the model with default parameters. Using microwave satellite brightness temperature data sets, this system offers the potential to calibrate parameters of both hydrological and ecosystem models globally. This global-scale and automated parameter optimization system may contribute to many other research activities related to land surface, hydrological, and ecosystem modelling although the global-scale applicability of this approach should be investigated as a future work.

Changes of permafrost environment and the response to the long term climate change

SUEYOSHI, Tetsuo[1*] ; SAITO, Kazuyuki[1] ; ISHIKAWA, Mamoru[2] ; HARADA, Koichiro[3] ; IWAHANA, Go[4]

[1]Japan Agency for Marine-Earth Science and Technology, [2]Hokkaido University, [3]Miyagi University, [4]University of Alaska

Permafrost is soil and sediment that is frozen more than two consecutive years, most of which is located in high latitudes. Ground ice is not always present, as may be in the case of nonporous bedrock, but it frequently occurs and it may be in amounts exceeding the potential hydraulic saturation of the ground material. Permafrost accounts for 0.022% of total water and exists in 24% of exposed land in the Northern Hemisphere.

permafrost contains 1700 billion tons of organic material equaling almost half of all organic material in all soils. This pool was built up over thousands of years and is only slowly degraded under the cold conditions in the Arctic.

Most of the permafrost existing today formed during cold glacial periods, and has persisted through warmer interglacial periods, including the Holocene. The time scale of the thermal process is different depending on the depth (i.e. distance from the ground surface) and the soil thermal properties, while the vegetation processes such as accumulation of organic material have yet different time scales.

In this presentation, we discuss those complex character of permafrost and show the outlook on the future research needs, showing an example study on the relationship between permafrost distribution and long-term climate change.

Impacts of representation of stomatal conductance on vegetation distribution and functions under changing climate

SATO, Hisashi[1*] ; KUMAGAI, Tomo'omi[2] ; KATUL, Gabriel[3]

[1]RIGC, JAMSTEC, [2]HyARC, Nagoya University, [3]Duke University

Stomata reponce is under control of light intensity, CO2 concentration, vapor pressure deficit, leaf water potential. For describing stomatal responses to such environmental factors, several empirical and semi-empirical models have been developed. How these models response to the changing environmental is an important issue, because between 80% and 90% of the total evapotranspiration from the land surface is caused by transpiration, and the process consumes almost half of the solar energy absorbed by the ground (Jasechko et al. 2013).

Here, we examined how representation of stomatal conductance pose impact on the forecast of geographical distribution of vegetation and its functions (i.e. carbon and water fluxes) under the forecasted climatic condition during the 21st century. We studied the African continent, because Africa is a useful target for assessing changes in vegetation due to climate change. The distribution of African vegetation is primarily regulated by soil moisture availability and thus is tightly coupled with climatic variability. For our study, we employed a dynamic vegetation model SEIB-DGVM. Our previous study shows that the model reproduced geographical distributions of the continent's biomes, annual gross primary productivity (GPP), and biomass over the African continent under current climatic conditions (Sato et al. 2012).

1. Introduction

The goals of the modeling group in the terrestrial research project of the GRENE Arctic Climate Change Research Project (GRENE-TEA) are to a) feed to the CGCM research project for the possible improvement of the physical and ecological processes for the Arctic terrestrial modeling (excl. glaciers and ice sheets) in the extant terrestrial schemes in the coupled global climate models (CGCMs), and b) lay the foundations of the future-generation Arctic terrestrial model development. To achieve these goals we are to conduct a model intercomparison project among the participating models, in which we will utilize the GRENE-TEA site observations data (stage 1) and GCM outputs (stage 2) for driving and validating the models. This project (GTMIP) is designated to 1) enhance communications and understanding of the "mind and hands" between the modeling and field scientists, 2) assess the uncertainty and variations stemmed from the model implementation/designation, and the variability due to climatic and historical conditions among the Arctic sites.

2. Data and models for GTMIP

At the stage 1, we will create data for forcing and validating the terrestrial model based on the extant and/or new observation data at GRENE-TEA sites to evaluate the inter-model and inter-site variations. However, the observation data are prone to missing or lack of the necessary variables or parameters to drive the model. Therefore, we create continuous forcing data (Ver. 0) taken from the reanalysis product (i.e. NCEP/NCAR) with the bias correction using the CRU data at the nearest grid to the GRENE-TEA sites. Then, it is merged with the observation data to create site-fit continuous data (Ver. 1) for each GRENE-TEA site (Fairbanks in Alaska, Yakutsk, Tiksi, Tura and Chokurdakh in Russia, Kevo in Finland). These data will be open at Arctic Data Archive System (https://ads.nipr.ac.jp/index.html).

The GTMIP participating models include a land surface model (MATSIRO, 2LM, CHANGE, HAL), a material cycle model (VISIT), a terrestrial ecological model (STEM-NOAHbgc), a dynamic vegetation model (SEIB-DGVM), a regional climate model (WRF), physical snow models (SNOWPACK, SMAP), and a permafrost model (FROST). The models enabled to couple with the CGCMs and regional climate model (RCM) consist of the 70% of the all participating models.

3. Results

The Ver. 0 data was compared with site observations near Fairbanks, Alaska, USA, to evaluate its reliability. The daily mean air temperature was well-reconstructed but the diurnal variation was underestimated. The total annual precipitation was close to the observed, but summer (DOY150-250) rain tended clumpy.

The observed ground temperature (Tg) at near surface showed the zero-curtain, while the simulated Tg failed to produce the zero-curtain except for 2LM. The 2LM reproduced the observed snow depth well while the CHANGE and MATSIRO-r showed later start and end of snow cover with lower snow depth than observed. The sensible heat flux was the dominant component of the energy budget in the simulation by 2LM. The daily net ecosystem exchange (NEE) simulated by CHANGE showed the large carbon uptake in summer. The annual gross primary production (GPP) simulated by CHANGE increased during 1988 to 2011. The simulated GPP by SEIB-DGVM using Tg by MATSIRO-r was similar to the GPP using air temperature. The wood biomass and grass biomass simulated by SEIB-DGVM using air temperature and Tg by MATSIRO-r was similar while it was lower when calculated using Tg by MATSIRO-c. The soil organic matter (SOM) simulated by SEIB-DGVM using MATSIRO-r was largest among the SOM using air temperature and Tg by MATSIRO-c.

The assessments of projection uncertainties of global C budget in ISI-MIP study

NISHINA, Kazuya[1*] ; ITO, Akihiko[1] ; KATO, Etsushi[1] ; YOKOHATA, Tokuta[1] ; ISI-MIP, Team[2]

[1]National Institute for Environmental Studies, [2]ISI-MIP team

Global net primary production (NPP), vegetation biomass carbon (VegC), and soil organic carbon (SOC) changes estimated by six global vegetation models (GVMs) obtained from an Inter-Sectoral Impact Model Intercomparison Project study were examined. Simulation results were obtained using five global climate models (GCMs) forced with four Representative Concentration Pathway (RCP) scenarios. To clarify which component (emission scenarios, climate projections, or global vegetation models) contributes the most to uncertainties in projected global terrestrial C cycling by 2100, we applied analysis of variance (ANOVA) and wavelet clustering to 70 projected simulation sets. ANOVA revealed that the main sources of uncertainty are different among variables and depend on the projection period. We determined that in the global SOC and VegC projections, GVMs dominate uncertainties (90% and 60%, respectively) rather than climate driving scenarios, i.e., RCPs and GCMs. The clustering wavelet spectra of VegC and SOC time series data could identify more specific characterization of simulations in each GVM. Our study suggests that the improvement of GVMs is a priority concern for reduction of total uncertainties in projected C cycling for climate impact assessments.

An aerosol correction algorithm to improve the GOSAT TANSO-CAI NDVI product

KIKUCHI, Nobuhiro[1*] ; YOKOTA, Tatsuya[1]

[1]National Institute for Environmental Studies

The Cloud and Aerosol Imager TANSO-CAI (CAI), onboard the Greenhouse gases Observing SATellite (GOSAT), is equipped with 4 spectral bands of 380, 674, 86,0 and 1600 nanometers (Band 1-4). The main purpose of CAI is to assist the Fourier Transform Spectrometer TANSO-FTS in retrieving accurately the column amount of carbon dioxide and methane by detecting and characterizing clouds and aerosols in FTS footprints. CAI is also designed to monitor the variation of global vegetation indices, and the CAI Normalized Difference Vegetation Index (NDVI) product has already been released.

Since GOSAT is orbiting with a three-day recurrence, CAI observes the same location from the same direction once in every three days. Unlike the MODIS NDVI product, this makes it difficult to correct the effects of Bidirectional Reflection Distribution Function (BRDF) on the CAI NDVI product, but it has a potential capability to detect changes in vegetation with shorter time scale. In the current version, the CAI NDVI is calculated from 30 days composite of the minimum reflectance to minimize contamination of clouds and aerosols, and the effect of aerosols is not explicitly corrected. The goal of this study is to develop an aerosol correction algorithm that can be applied to the CAI NDVI.

Due to the relatively limited number of spectral bands of CAI, we take an approach slightly different from so-called the Kaufmann method or the minimum reflectance method in developing our aerosol correction algorithm. Since the number of observables is four, which are TOA reflectance at bands 1-4, the maximum number of retrieved parameters is also four. We choose optical thickness of fine mode aerosols and coarse mode aerosols, surface reflectance at band 3 and band 4 as retrieved parameters. We assumed that surface reflectance at band 1 and band 2 is expressed as a function of surface reflectance at band 3 and band4. The parameterization of band 1 and band 2 surface reflectance is done by utilizing the CAI minimum reflectance product. We do not expect that this parameterization is rigorously valid in pixel-wise. Therefore, we do not determine aerosol optical thickness for every pixel, but for 10x10 pixels (5x5 km in horizontal scale). Moreover, we do not use all TOA reflectance of 10x10=100 pixels, but select the darkest 10 pixels. Then, the number of observables is 40, and the number of retrieved parameters is 22, which can be determined by least-square fitting.

Left panel of the figure shows optical thickness of fine mode aerosol over souse-east part of Australia on October 20th, 2013. Currently, aerosol optical thickness is not retrieved for pixels with TOA reflectance greater than 0.2 at band 4. Right panel of the figure demonstrates the effect of aerosols on NDVI by comparing NDVI with and without aerosol correction. We can see that the frequency distribution of NDVI is shifted by about 0.1 as a result of aerosol correction, which is consistent with the result of Vermote et al. (2002).

Effects of water stresses due to climate change on production and dynamics of tree community in tropical rain forests

FUJII, Shinjiro[1*] ; SATO, Hisashi[2] ; KUMAGAI, Tomo'omi[1]

[1]Hydrospheric Atmospheric Research Center, Nagoya University, [2]Graduate School of Environmental Studies, Nagoya University

Recently, climate changes caused by the El Nino-Southern Oscillation have been reported to result in the widespread death of trees due to droughts in many parts of the world. Strong reductions in tree growth and litterfall production occurred during the record-hot 1997/98 El Nino. Tropical regions receive strong solar radiation, and tropical vegetation shows a strong feedback effect to carbon sequestration, water circulation, and climate formation. In addition, tropical forests are important ecosystems, and they act as a huge carbon sink because they accumulate 40-50% of land vegetation carbon of the Earth. In a biological community such as a tropical forest that consists of various species, response to changes in the physical environment depends on the operating functional group. A dynamic change in a particular functional group that plays a signi?cant role in the biological community may in?uence the structure and ecosystem functions of the tropical forests. The aim of this study is to predict the impact of drought on matter production and tree community dynamics in tropical rain forests by using a spatially explicit individual-based biogeochemical model developed for predicting vegetation dynamics in response to climate change at the global level, such as global warming (SEIB-DGVM). In the model simulation, applying stochastic rainfall model with the meteorological data, including the 1997/98 El Nino, of the tropical rain forests of Sumatra Island in Malaysia that were measured in 1997-2009, the rainfall experiments were performed by operating some parameters related to daily precipitation and frequency of rainfall events. Based on the experiment results, the turn of production with the amount of tree growth and death, and tree mortality dynamics in the tropical rain forests for 200 years were verified.

Modeling Interactions between Vegetation and Aeolian Processes

BANZRAGCH, Nandintsetseg[1*] ; SHINODA, Masato[1] ; SHAO, Yaping[2]

[1]Arid Land Research Center, Tottori University, [2]Institute for Geophysics and Meteorology

The sustainability of temperate grassland (TGs) ecosystems is determined by the feedbacks between climate, vegetation and human activities, in which Aeolian processes play a key role. Current existing dust models do not have sufficient capability in simulating vegetation growth and decay effects that play a major role in TG aeolian processes. In this study, we purposed to couple the DAYCENT, a vegetation-growth and nutrient-cycle model (the most prominent biogeochemical model), with QF2003, a wind-erosion model. The DAYCENT-QF2003 modeling system enables an examination of the feedbacks between grassland-grazing and aeolian processes. This approach is a completely new approach. First, we assessed the DAYCENT for its capability to provide estimations of vegetation dynamics under different grazing conditions in order to incorporate into the QF2003. DAYCENT was parameterized with the field experiment data (soil physical/chemical properties, vegetation and grazing) at the Bayan-Unjuul (BU) site in 2010-2012. BU is located in north of the most frequent dust outbreak region in Mongolia. Results showed that the DAYCENT could simulate realistically vegetation growth-decay, nutrient-cycle and the effect of grazing on grasslands, which are the factors controlling dust outbreaks in TGs. Then, the DAYCENT model was coupled into the QF2003 wind-erosion scheme. We conducted the numerical test of the coupled DAYCENT-QF2003 model to predict dust flux. With the initial results, we have demonstrated the potential of the DAYCENT-QF2003 coupled model. Therefore, the integrated DAYCENT-QF2003 modeling system will provide a useful tool for an early warning system and the future projection of dust events over dust source areas in TGs region.

Effects of water and dissolved material exchanges between land and ocean on coastal ecosystem and fishery resources

TANIGUCHI, Makoto[1*]

[1]Research Institute for Humanity and Nature

There are two pathways of water and dissolved materials from land to the ocean. The first one is river discharge and another is invisible submarine groundwater discharge (SGD). Many studies show the importance of SGD on coastal ecosystem and fishery resources. SGD is evaluated by using seepage meters and piezometers at local point scale, radon and strontium isotopes as tracers in bay scale to identify the origin of the fresh water, which is river water or groundwater. Another method is resistivity measurement which can tell us the salinity of the pore water in the sea bed near the coastal zone.

SGD observed by seepage meter and Rn concentration of the coastal seawater has a positive relationship over the world with different geology, geomorphology, and hydro-meteorological conditions. All SGD studies show that there are two components in SGD, one is fresh SGD and another is recirculated SGD. It is important for understanding coastal ecosystem and fishery resources to evaluate the ratios and processes of fresh SGD which is driven by hydrological condition in land, and recirculated SGD which is driven by oceanographic conditions in the sea.

In this study, SGD studies by using seepage meter and radon measurements over the world are reviewed to evaluate the physical and chemical factors which drive SGD and material transports by SGD, and the effects of SGD on the distribution of the fishery resources such as shell distributions in the coastal zone. River discharge is a main linkage between land and ocean through water and dissolved material transports, however it has huge temporal changes. On the other hands, the amount of SGD itself is not much but continuous contribution by SGD with constant temperature and nutrient discharges make stable physical, chemical, then biological conditions such as sea grass (Zostera bed).

The effect of freshwater input from rivers on the ecosystem in coastal waters

KASAI, Akihide[1*]

[1]Field Science Education and Research Center, Kyoto University

High production in coastal areas is supposed to be supported by large organic and inorganic inputs from rivers. Therefore, excessive reduction of nutrient loads from rivers would decrease nutrient concentrations in coastal areas. This manifests in poor growth of seaweeds, which has been observed in Seto Inland Sea in recent years. However, primary production in coastal areas is not only supported by terrestrial nutrients, but also external nutrients derived from ocean and regenerated nutrients formed in hypoxic water at the bottom. Evaluation of the contribution of each source of dissolved inorganic nitrogen (DIN) to phytoplankton production in Ise Bay revealed that DIN consumption by phytoplankton exceeds the DIN supply from rivers and ocean. This indicates that a large amount of primary production depends on regenerated DIN within the bay rather than on newly supplied DIN, although the ratio of consumption to external supply differs seasonally. We have to pay more attention to the behavior of each source of nutrients for future managements of coastal waters.

The effect of the freshwater input from rivers on coastal areas is not only the nutrient supply, but also the formation of estuarine circulation, which plays an important role in coastal ecosystems. Since the flux of water by the estuarine circulation is considerably larger than the river discharge, it has large effects on the material transport and biological production in estuaries and bays. For example, larvae of temperate seabass do not distribute in the surface, but in the middle layer, and thus the landward flow effectively transports larvae to coastal areas from the spawning grounds in the offshore. Therefore, the year-to-year variation in the amount of juveniles in the coastal area shows that the survival of juveniles improves in the years when the river discharge increases.

Possible effects of submarine groundwater on biodiversity and fishery production in coastal ecosystems

SHOJI, Jun[1*] ; SUGIMOTO, Ryo[2] ; TOMINAGA, Osamu[2] ; KOBYASHI, Shiho[3] ; YAMADA, Makoto[4] ; TANIGUCHI, Makoto[4]

[1]Hiroshima University, [2]Fukui Prefectural University, [3]Kyoto University, [4]Research Institute for Humanity and Nature

Economic values of the ecosystem services of coastal ecosystems have been evaluated as among the highest of those the world's ecosystems. Recently more attentions have been paid on the mechanisms how the freshwater contribute to the high productivity and species diversity of the coastal ecosystems. In the present paper, previous researches that focused on effects of freshwater input from the land on productivity and species diversity of fishery resources in the coastal ecosystems are reviewed. In addition, results from recent surveys conducted in order to examine the possible effects of river water and submarine groundwater on productivity and species diversity of fishery resources are introduced.

Relationship between river discharge and recruitment of several estuarine-dependent fish species (flatfish, seabass and clupeid) have been reported in the world. Among these fish species, the mechanisms how river discharge promotes survival during the early life stages and recruitment of Morone fishes (striped bass and white perch) have been well studied. Larval survival rate is high and recruitment of 1-year-old fish is successful in years with high precipitation in these species. High freshwater discharge has been reported to increase availability of prey for the larvae, decrease predation through affecting predator species composition and biomass, then increase the growth and survival during the larval stage.

In a previous paper, on the other hand, low salinity zone has been reported to be one of the ecosystems where biodiversity is the lowest among the world's aquatic ecosystems. High fluctuation in salinity and tidal level within a relatively small spatial and temporal scale could be stressful for a variety of animal species. Recently high abundance of juveniles of several flatfish species were observed in low salinity zones nearby an estuary in the coastal waters of Japan. Species diversity of fishes was higher in a seagrass bed where freshwater supply from the land through submarine groundwater was expected compared to the surrounding areas. These observations suggest that low salinity condition does not always decrease diversity of fish species in coastal ecosystems. Future research plan to investigate the mechanism how the freshwater input from the land contributes to the high productivity and species diversity in the coastal ecosystems will be introduced.

Evaluation of nitrogen dynamics in the Yodo River estuary using stable isotopes

SUGIMOTO, Ryo[1*] ; KASAI, Akihide[2]

[1]Faculty of Marine Biosciences, Fukui Prefectural University, [2]Field Science Education and Research Center, Kyoto University

The increase in human population in coastal watersheds has increased the delivery of nitrogen from the land to coastal environments. Accelerated nitrogen cycles in coastal environments have led to an increase in hypoxic waters and instances of harmful algal blooms. Physical and biogeochemical processes within estuaries generally regulate nitrogen fluxes from land to sea. The estuaries of major rivers on the continents are thought to be sites of massive nitrogen losses. However, function of estuaries to nitrogen transfer must vary according to each estuarine hydrology and biogeochemistry. A large amount of terrestrial nitrogen empties into Osaka Bay head from the Yodo River. Although the estuary would have a crucial role in modifying nitrogen fluxes, its function to nitrogen transfer is still unclear. In this presentation, we will report the seasonal difference of nitrogen dynamics along the longitudinal section from the estuary to the head of Osaka Bay.

Factors of the temporal variation of marine phytoplankton at Yodo River estuary

HAYASHI, Mitsuru[1*] ; KOGA, Ryuraro[1] ; FUJII, Tomoyasu[2] ; YAMAMOTO, Keigo[3]

[1]Kobe Univ., [2]Nara University of Education, [3]Marine Fisheries Research Center, Osaka Prefecture

Red tides of *Alexandrium tamarense* have occurred in the estuary of the Yodo River in Japan in 2007, 2011 and 2013. *A. tamarense* is marine phytoplankton and causes shellfish poisoning. We have made in-situ observation in April 2-3 2012, and analyzed the temporal variation of marine phytoplankton by using the numerical ecosystem model. CTD and ADCP observation and water sampling ware carried out linked to the tidal change. Nutrient and chl.a concentration and cell density of *A. tamarense* were analyzed. *A. tamarense* was a few in this year. Typical estuary circulation which seawater run up to upstream in the surface layer and fresh water go down to the sea in the bottom layer. Therefore the estuary which have 2800m length was divided to three layers, 0-0.5m, 0.5-1.5m and 1.5m-bottom. The thickness of the bottom layer is changed with the tidal change. Nutrient, phytoplankton, the dissolved organic matter and the particulate mutter are in each layer, and the bio-chemical process between the forms, photosynthesis, mortality, decomposition and so on, are formulated. Then the temporal variations of each morphology and *A. tamarense*. Diurnal migration, salt limitation and utilization of organic matter for the photosynthesis and mortality by low salinity were considered in the bio-chemical process of *A. tamarense*. The temporal variations of phytoplankton in each layer were almost reproduced. Marine phytoplankton in the Yodo River estuary were not produced hardly and were supplied from the ocen. Phytoplankton which cannot swim by oneself is almost floated by the horizontal advection, it is the estuary circulation. But only 27% of *A. tamarense* transported from the ocean in the bottom layer go through upstream. 36% of it returned to the ocean in the middle and surface layers, and other 36% die in the surface layer. Weak estuary circulation is effective to limit the transport upstream of *A. tamarense* in Yodo River estuary.

Utilization of terrestrial organic matter by marine benthic polychaetes in estuarine eosystem

SATO, Takahisa[1] ; SUGIMOTO, Ryo[2] ; YOKOYAMA, Yoshihiro[2] ; TOMINAGA, Osamu[2*]

[1]Yamagata prefectural fisheries high school, [2]Fukui prefectural university

In semi-enclosed bays, terrestrial plants transported by river have become a major constituent of estuary sediment. Since it is difficult for marine organisms to digest the terrestrial plants which mainly contains the non-living refractory cellulosic matrics, few studies have been taken into account the role played by the terrestrial particulate organic matter(tPOM) in enhancing the productivity of the coastal biotic community. However, the important role of tPOM as the food source for marine benthic organisms has been recognized in estuarine environments. In the present study, we examined the δ^{13}C, δ^{15}N values and cellulase activity of the several species of polychaetes to elucidate the contribution of terrestrial plants to benthic biological production in small semi-enclosed Bay. Polychaete annelids were collected at estuary of the Kita and Minami River in semi-enclosed Obama Bay, the Sea of Japan from August 2007 to June 2010. The carbon and nitrogen stable isotope ratios of polychaetes were analyzed. Cellulase activity analyses were assayed by using carboxymethyl cellulose (CMC) plate assay. The δ^{13}C values of deposit or suspension feeding polychaetes were lower than the δ^{13}C value of POM but higher than the terrestrial plants. The δ^{13}C and δ^{15}N values of carnivores-feeding polychaetes were higher than those polychaetes. Cellulase activities was found in many deposit or suspension feeding polychaetes but also carnivorous feeding polychaetes. On the other hand, the polychaete species with lower isotope signature did not show cellulase activities. The polychaetes which showed cellulase activity were abundant through the four seasons in estuary. These results suggest that many polychaetes can decomposition and assimilation the terrestrial plants.

The origin of submarine groundwater discharge in the coastal zone of Hiji, Oita prefecture

YAMADA, Makoto[1*] ; OHSAWA, Shinji[2] ; MISHIMA, Taketoshi[2] ; ABE, Yutaka[1] ; TANIGUCHI, Makoto[1]

[1]Research Institute for Humanity and Nature, [2]BGRL, Institute for Geothermal Sciences, Kyoto University

It is said that groundwater discharge from the seabed of the coastal zone of Hiji, Oita prefecture. The marbled sole which lives around this submarine groundwater discharge is called a " Shirosita Karei " , and is loved by the local people. From ancient times, the local people have believed that this Shirosita Karei grows because of submarine groundwater discharge. However, regarding the relevance of the ecology of a marbled sole and submarine groundwater discharge, it is not clear that this is the case. Moreover, although it is clear that there is submarine groundwater discharge, there is almost no information about the origin and dissolved component. Kono and Tagawa (1996) conducted an analysis of the major dissolved components of groundwater of this land area, and a vertical distribution investigation of the electric conductivity of the ocean. As a result, it has suggested the possibility that submarine groundwater discharge is the confined groundwater recharged in the mountain area. However, in that report, they said that they were not able to identify a recharge area clearly by this research. Because of that, we sampled the spring water of the land area, the spring water of a salt water mixture discharged in a seashore area, and a sea water sample, in order to conduct hydrological research using the stable isotope of water in this area and to clarify the flow process of submarine groundwater discharge. The recharge elevation of the spring water of this land area was assumed using the recharge-water line (Ohsawa et al., 2009) made using the data of the Beppu area of the southwest part of this research region. As a result, it became clear that the recharge area of most spring water is at an elevation of 200 m or more. Regarding fresh water and salt water mixture, the mixed rate of sea water and fresh water was calculated using electric conductivity, and the isotopic ratio of the original fresh water was computed using the mixed rate. As a result, it became clear that the recharge elevation of the fresh water mixed in sea water is near 300 m. Moreover, as a result of extracting the terrestrial environment of this area, the area with an elevation of 200 m or more is mainly forest, and there was a boundary between the forest area and plains near an elevation of 200 m. It became clear from these results that the origin of the submarine groundwater discharge in the coastal zone of Hiji is the water recharged in the forest area of the mountain slope, and that the water moves under the plain and is discharged at the sea bed.

Location estimation of submarine groundwater discharge from Mt. Fuji in Suruga Bay

MURANAKA, Yasuhide[1*] ; KAMITANI, Takafumi[1] ; WATANABE, Masayuki[1] ; ONO, Masahiko[2] ; MARUI, Atsunao[2]

[1]Shizuoka Institute of Environment and Hygiene, [2]National Institute of Advanced Industrial Science and Technology

Around the foot of Mt. Fuji, the main flow passages of groundwater are thought to be in the Younger Fuji volcano, which consists of the pervious basaltic lavas in new volcanic stage. Especially, the Fujikawa-kako fault zone, which stretches south to north in the southwestern side of Mt. Fuji, has a potentially effect on the local groundwater flow system into Suruga Bay. Therefore, precipitation at Mt. Fuji have been considered to be discharging partly from seabed in Suruga Bay and making a great impact on the biological production at the coastal sea area.

For the purpose of contribution to make sense of the rich coastal ecosystem in Suruga Bay, we conducted a survey for submarine groundwater discharge (SGD) in Oku-Suruga Bay: from the mouth of the Fuji River, at which the fault is found, to Tagonoura, where the lavas of the Younger Fuji volcano are distributed from 100 to 200 m below sea level. We are trying to estimate some locations of SGD from the condition of seabed and geological structure by using the side scan sonar and the sub-bottom profiler. We also use a remotely operated vehicle (ROV) for photographing for the image of the extrapolated spring points. In this presentation, we introduce our works noted above.

Evaluation of submarine groundwater discharge in Suruga Bay by using radon 222

ONO, Masahiko[1*] ; MARUI, Atsunao[1]

[1]National Institute of Advanced Industrial Science and Technology

Submarine groundwater discharge (SGD) in coastal area has been recognized as an important pathway for material transport from land to ocean. SGD has been widely studied throughout the world and it is expected as ubiquitous phenomenon in coastal zone.

Suruga Bay is adjacent to the southern foot of Mt. Fuji where the permeable lava flow deposits and the active groundwater flow system exist. Therefore, large amount of groundwater input is expected at the coastal area in Suruga Bay. It is also expected that SGD has a significant effect for marine products in this area.

To evaluate submarine groundwater discharge in this area, we applied continuous radon measurement and sampled coastal water for chemical analysis. We will introduce these results in this presentation.

Estimating submarine groundwater discharge in Obama Bay, Japan, using 222Rn mass balance model

HONDA, Hisami[1*] ; SUGIMOTO, Ryo[1] ; KOBAYASHI, Shiho[2] ; TAHARA, Daisuke[1] ; TOMINAGA, Osamu[1] ; TANIGUCHI, Makoto[3]

[1]Fukui Prefectural University, [2]Kyoto University, [3]Research Institute for Humanity and Nature

Recently, a number of studies have shown that submarine groundwater discharge (SGD) is even more important than surface runoffs in terms of nutrient transport and can drive primary production in coastal seas. Obama Bay is semi-enclosed bay in central Japan. In spring, phytoplankton blooms in the bottom layer around 2 km offshore from the river mouth. Aquifer distribution in the Obama plain and our previous observation of low salinity water around the bottom layer suggests that unconfined groundwater discharges induce this phytoplankton bloom. However, quantitative contribution of groundwater discharge to the coastal ecosystem has not been well evaluated in Obama Bay. In this study, we estimated the input of freshwater and nutrients via SGD into Obama Bay using mass balance model of radon (^{222}Rn) and salinity. As a result, the volume of SGD into the bay was estimated to be 0.05-0.80$\times 10^6$ m^3 d^{-1} during February 2013 to November 2013. Especially, the fraction of SGD in total freshwater flux in summer reached to 44%, because river water discharge decreased drastically. The nutrient fluxes from SGD were approximately 84%, 210% and 28% of riverine fluxes dissolved inorganic nitrogen (DIN), dissolved inorganic phosphorous (DIP) and dissolved inorganic silicate (DSi), respectively.

A study of primary production in plankton blooms driven by riverine inputs

HOSHIBA, Yasuhiro[1*] ; YAMANAKA, Yasuhiro[1]

[1]Faculty of Env. Earth Science, Hokkaido University

Rivers transport nutrients and suspended sediment matter (SSM) as well as fresh water from land to coastal regions, where the biological productivity is high. In the coastal area, the buoyancy of fresh water leads to the formation of horizontal anticyclonic gyres and vertical circulations, which affect the variation of biological production such as plankton blooms. However, the primary production caused by the three-dimensional dynamics have not been quantitatively discussed, and observations can hardly capture the daily temporal variations of phytoplankton blooms. We developed an ocean general circulation model (OGCM) including a simple ecosystem model, to investigate the three-dimensional and temporal changes in phytoplankton blooms caused by riverine input such as flooding.

We first conducted ideal setting-simulations. The distribution patterns of nutrients and phytoplankton differ significantly from that of fresh water. The phytoplankton maxima shift from the downstream (right-hand side of the river mouth) to the upstream regions (left-hand side of the river mouth). The shift from the downstream to the upstream region (D-U Shift) is categorized by the different nitrate origins: (1) river-originated nitrate (RO-nitrate) is dominant in the downstream region; (2) subsurface-originated nitrate (SO-nitrate) is dominant in the upstream region, and is transported by upwelling associated with vertical circulation and horizontal anticyclonic gyre; and (3) regenerated nitrate (R-nitrate) is dominant in the upstream region. The total primary production in phytoplankton blooms is maintained not only by RO-nitrate but also by SO-nitrate that is larger than the river-originated.

Next, we conducted a realistic simulation and a few ideal setting-simulations. The phytoplankton maxima shift toward the left-hand side of the river mouth during the early time, but the shift does not keep going to the left-hand side all the time. This is because much SO-nitrate does not come from the subsurface to the surface layer after the middle simulated time, due to weak upwelling forced by vertical circulation in the left-hand side. The gentle angle of bottom slope weaken the vertical circulation and SO-nitrate supply from the subsurface, and the NPP is small.

It is natural that D-U Shift of phytoplankton maxima often occurs in the real situation like Ishikari Bay when high riverine input such as flooding. The conclusion that the shift is categorized into three stages by the different nitrate origins, RO-, SO- and R- nitrates in turn depends on the bottom slope angle and the way of inputs and the amounts of fresh water and nutrients. Bottom slope angle and the way of fresh water input change the behaviour of plumes, nutrient supply from the subsurface with the change of vertical circulation, and the rate of regeneration.

Clarification of relationship between nutrient loading and biological productivity in coastal area by ecosystem model

ABE, Masami[1*] ; TATENO, Satoshi[1] ; NAGAO, Kentaro[1] ; HATA, Kyoko[1]

[1]IDEA Consultants, Inc.

Recently, the total volume control of COD loading from continental areas to coastal areas that is generally regarded as a barometer of eutrophication produce an effect for water quality improvement. On the other hands, the reduction in biological productivity caused by concentration reduction of nutrient was pointed out. We face the limit of control policies due to build the suitable interaction between continental areas and coastal areas.

Due to understand the interaction between nutrients loading and biological productivity, the investigation how nutrients provide any biological populations and fish catch is effective. The circulation pathway of nutrients is complex web of interactions, for example, relationship between among biological populations (prey-predator relationship, competitive relationship et. al.) or indirect interaction web (extinction of predator caused by anoxic water, et. al.). The ecosystem response to decrease or increase in nutrient loading is complex.

In this report, we apply ecosystem-model which include fishery product (laver culture, clam) to around Kako-river (*Harima-nada*, *Seto-Inland-Sea*, *Japan*). We quantified responses of material circulation to decrease or increase in continental loading by using this model. The biological productivity is responding to decrease or increase in nutrient loading is varying with the structure of material circulation networks.

Construction of the comprehensive aquatic model of the Ise Bay watershed

ONISHI, Takeo[1*] ; SUGIMOTO, Ryo[2] ; AOKI, Kazuhiro[3] ; SOMURA, Hiroaki[4] ; YOSHINO, Jun[5] ; HIRAMATSU, Ken[1]

[1]Faculty of Applied Biological Sciences, [2]Faculty of Marine Bioscience, Fukui Prefectural University, [3]National Research Institute of Fisheries Science, [4]Faculty of Life and Environmental Science, Shimane University, [5]Faculty of Engineering, Gifu University

Though Integrated Water Resource Management (IWRM) is recognized as an important philosophy for consistent management through terrestrial area to oceans in 1990s', lack of scientific prove and grounds is one of the essential obstacles to implement the philosophy into actual policy making processes. To enhance and enrich scientific basis of IWRM, objective evaluation of change of terrestrial area impacts on oceanic environment is essential. Thus, we are conducting to construct a comprehensive aquatic model which combines water, material, and ecosystem models throughout terrestrial area, rivers, and ocean. The study site is the Ise Bay and its catchment area. Our model is targeting at carbon, nitrogen, and phosphorous for material, and low trophic levels for ecosystems. In addition, model development is based on the philosophy that promotes a model to be opened for public.

The model structure is that combination of hydrological model, river model, oceanic model, and ecosystem model. For about hydrological model, PnET-BGC is used for natural vegetation, SWAT model for agricultural lands, and the tank model for domestic water outflow from urban area. For about river model flow model, one-dimensional open channel model using kinematic wave method is utilized. For ecosystem model, NPZD model was implemented into aquatic systems. And, for ocean model, ROMS was used. In addition, dam operational rules were included to consider the impacts of dams on river discharge regimes. Calibration and validation period was from 2000 to 2010. Simulation time step was 1 day, and spatial resolution of driving force (weather data) of the model was 2km. ASTER-GDEM is utilized for DEM, National Land Numerical Information for vegetation, and Basic Land Classification Survey for soil and geological data. The result showed that while river discharge was relatively good, the level of water quality was not acceptable. One of the possible reasons of this discrepancy was the incomplete implementation of agricultural water use. Moreover, since coupling with ocean model is not yet realized, thus, improvement of terrestrial model, coupling of terrestrial and ocean model, and sensitivity analysis is further required.

Spatiotemporal distribution of organic matter buried in estuarine seagrass meadows

WATANABE, Kenta[1*] ; KUWAE, Tomohiro[1]

[1]Port and Airport Research Institute

Blue Carbon, captured and sequestrated by marine organisms, has attracted attention as one of the major sink of atmospheric carbon dioxide. One of the important process for carbon sequestration is burial of organic carbon into sediments. The burial rate of organic carbon is higher in estuaries and seagrass meadows than open oceans. A large amount of terrestrial carbon flows into shallow coastal systems, consequently being buried in the sediment. Also nutrient inflows elevate autochthonous organic matter production in the systems. Therefore, various organic matter compositions, having different origin and bioavailability, are mixed in shallow waters. In this study, we investigate the quality and quantity of organic matter buried in an estuarine seagrass meadow using elemental and isotopic techniques and ^{14}C dating.

Our study site, the Furen Lagoon, is located at the high latitude in Japan. The Furen lagoon is eutrophic due to riverine inflows. Seagrass meadows occupy 67 % of the total area of the lagoon. We collected core samples (about 2 m) in the lagoon along the salinity gradient. TOC (total organic carbon) and TN (total nitrogen), as well as carbon and nitrogen isotopic signatures were analyzed along the depth. Also Δ ^{14}C was analyzed for dating. In the low salinity zone, δ^{13}C was low and C/N ratio was high, indicating that terrestrial organic matter was dominant. These signatures were relatively stable with sediment depth, showing that terrestrial organic matter would have been buried for thousands years. Within the seagrass meadow, δ^{13}C and δ^{15}N were relatively high, indicating that the contribution of autochthonous organic matter (phytoplankton and seagrass) to TOC would increase in the presence of vegetation. δ^{13}C fluctuated with sediment depth in the seagrass meadow, showing that the contribution of terrestrial organic matter fluctuated temporally. These results suggest that the lagoon can be the long-term sink of carbon due to autochthonous production and deposition of terrestrial organic carbon.

In recent years, a number of studies have shown that submarine groundwater discharge is an alternative nutrient pathway and can drive primary production in coastal seas. However, very little is known about quantitative relationship between input of groundwater and response of primary production, because both processes are temporally variable. Recent technological advances (i.e., automation) have increased our ability to assess submarine groundwater discharge in coastal ecosystems using natural tracers such as radon-222 (^{222}Rn). Simultaneous monitoring of ^{222}Rn with indicators of primary production such as pCO_2 and/or chlorophyll-a would allow us to grasp the nexus of both processes. Therefore, automated radon and CO_2 gas analyzer were connected in series and a closed air loop was established with gas equilibration devices to examine the nexus between submarine groundwater discharge and primary production. In this presentation, we will report the results of simultaneous monitoring of ^{222}Rn and pCO_2 with other parameters in several coastal environments.

Submarine groundwater discharge (SGD) is important as a major pathway for freshwater and nutrients loads from land to ocean. Various natural tracers of SGD have been applied to quantify local to regional SGD fluxes. Radon-222 (^{222}Rn) is a naturally occurring radioactive gas that is typically 2-3 orders of magnitude higher in groundwater than surface waters. Therefore, it is a powerful tracer of groundwater inputs to oceans. We have applied the continuous ^{222}Rn monitoring survey to three local scale coasts (Beppu Bay, Obama Bay and Otsuchi Bay), which have large amounts of groundwater resources in each watershed. As a result, spatial distributions of ^{222}Rn and other parameters displayed not only influence of submarine groundwater discharge but also possibility of submarine hotspring discharge.

Groundwater often discharges from the seabed of the coastal zone. Such groundwater is called " submarine groundwater discharge (SGD) ". Mostly, SGD is the water which not fresh water but sea water and fresh water mixed. Although it is assumed that mixture has occurred under the seabed, there is almost no information about the behavior of water and dissolved component under the seabed such as the mixed process, zone of influence of sea water, and the behavior of the dissolved component from the land area. In order to clarify the behavior of water and dissolved component under the seabed of the coastal zone, we conducted the sampling of the water under the seabed of Obama Bay, Fukui prefecture. The stable carbon isotope ratio of dissolved inorganic carbon (DIC) was lower than that of sea water, and higher than that of groundwater which sampled from well near the seashore. The results show that not only mixture of water but mixture of DIC has occurred under the seabed. In the future, in order to comprehend the extent of the impact of sea water, it is necessary to research vertical distribution of the stable isotope composition under the seabed.

Catastrophic reduction of sea-ice in the Arctic Ocean - its impact on the marine ecosystems in the polar region-

HARADA, Naomi[1*] ; KIMOTO, Katsunori[1] ; ONODERA, Jonaotaro[1] ; WATANABE, Eiji[1] ; HONDA, Makio[1] ; KISHI, Michio[1] ; KIKUCHI, Takashi[1] ; TANAKA, Yuichiro[2] ; SATOH, Manami[3] ; ITOH, Fumihiro[3] ; SHIRAIWA, Yoshihiro[3] ; MATSUNO, Kohei[4] ; YAMAGUCHI, Atsushi[5]

[1]JAMSTEC, [2]AIST, [3]Univ. of Tsukuba, [4]NIPR, [5]Hokkaido Univ.

The sea-ice in the Arctic Ocean has dramatically reduced during the past decade. The drastic sea-ice reduction would cause a complicated and difficulty to understand the perspective on marine ecosystem surrounding the Arctic Ocean, because disadvantage phenomena such as ocean acidification and advantage phenomena such as improving light condition for primary producers, respectively, are simultaneously progressing. We have investigated the response of marine organisms caused by catastrophic sea ice reduction in the Chukchi Sea and Northwind abyssal plain at where the sea ice reduction has progressed most seriously in the Arctic Ocean. The aims of our study are No.1 to understand temporal changes in primary production, No.2 to understand the physiological response of marine phyto and zooplanktons having carbonate tests on warming or freshening associated with sea ice melting, No.3 to develop a new model for marine ecosystems in the Arctic Ocean, to reproduce the primary production by using the model and to understand the response of marine ecosystems on the environmental changes caused by rapid sea-ice reduction. In this presentation, we will show an overview of this project composed of three sub-themes, Observation, Culturing, and Modeling. For the observation, we will show a seasonal change in biogenic components flux obtained at the Northwind abyssal plain by a year round time series sediment trap system and seasonal change in dissolution of pteropod tests due to the seasonal change in the ocean acidification. We will also show the potential mechanism of high biogenic fluxes found in the beginning of the sea-ice season using the original Arctic Ocean ecosystem model. For the culture experiment, the physiological response of Emiliania huxleyi, coccolithophorid strain on the environmental changes caused by sea-ice melting will be presented.

Hindcast simulation of the ice and circulation in the Arctic Ocean for 1978-2012: An application of AO-FVCOM.

CHEN, Changsheng[1*] ; ZHANG, Yu[1] ; PROSHUTINSKY, Andrey[2] ; BEARDSLEY, Robert[2] ; LAI, Zhigang[3] ; GAO, Guoping[4]

[1]School of Marine Science, University of Massachusetts, USA, [2]Department of Physical Oceanography, Woods Hole Oceanographic Institution, USA, [3]School of Marine Sciences, Sun Yet-Sen University, China, [4]International Center for Marine Studies, Shanghai Ocean University, China

A high-resolution, unstructured-grid, finite-volume ice-ocean fully coupled model system, named AO-FVCOM, has been developed for the Arctic Ocean. The governing equations are cast in a generalized terrain-following coordinate system with spatially variable vertical distribution in the vertical and are discretized using flexible non-overlapped triangular grids in the horizontal. This model system includes a) an unstructured grid version of the Los Alamos sea ice model Community Ice CodE (UG-CICE), b) hydrostatic and non-hydrostatic dynamics (NH-FVCOM); c) an unstructured-grid version of the Simulating Wave Nearshore model (SWAN) (named SWAVE), d) 3-D wet/dry point treatment, which can simulate flooding/draining processes in estuaries and wetlands; e) 4-D nudging, OI and Kalman Filters data assimilation algorithms; f) the mass conservative nesting module to integrate multi-domain FVCOM domains; and g) the MPI parallelized visualization tool ViSiT, which allows users to monitor model performance during the simulation and post-process the model output data. An updated version of AO-FVCOM is capable of simulating the ice imbedded in the ocean.

AO-FVCOM is a regional model nested with Global-FVCOM. Two version of AO-FVCOM were configured with a finest horizontal resolution of 300 m and 2 km for the Arctic Ocean, respectively. The 2-km version has run for a period of 1978-2012. Without data assimilation, the model was capable of reproducing the seasonal and interannual variability of the ice coverage area in the Arctic and also significant drops of the ice coverage in 2007 and 2012. The 35-year simulation results for the circulation and water transport are being validated with comparison to field measurement data. The influence of the model resolution on water transport through the Canadian Archipelago has been also examined over seasonal and interannual scales, and an example of the water transport through Nares Strait will be presented.

Changes in the Western Arctic Biogeochemistry over the Last Three Decades: a Modeling Perspective.

SPITZ, Yvette H.[1*]

[1]Oregon State University, CEOAS, Corvallis OR 97331, USA

Over the last three decades, the Western Arctic Ocean (WAO) seasonal and permanent sea ice have experienced significant changes, with the summer sea ice extent still shrinking to record low levels and the permanent ice thickness being greatly reduced. Thus, the WAO circulation (e.g. intensification of the Beaufort Gyre), the oceanic heat content and biogeochemistry are directly impacted. We use the coupled pan-arctic Biology/Ice/Ocean Modeling and Assimilation System (BIOMAS) to investigate changes in the physical system, nutrient fluxes and productivity of the planktonic ecosystem between 1988 and 2011. Model simulations show that an earlier phytoplankton bloom and a slight increase in its biomass in general characterize the WAO. The largest response in the secondary producers is seen as an increase in the magnitude of the microzooplankton biomass as well as in the duration of its growing season. Primary productivity while increasing on average over the WAO shows some decrease in the Beaufort Gyre due to its intensification. Under ice blooms such as the one observed during the ICESCAPE (NASA funded program) in July 2011 are also intensified. This research was done in collaboration with colleagues from University of Washington (Dr M. Steele and Dr. J. Zhang), Woods Hole Oceanographic Institution (Dr. C. Ashjian) and University of Rhode Island (Dr. R. Campbell).

The western Arctic marine ecosystem was addressed using a combination year-round mooring observation and multiple numerical models. Our previous studies have revealed eddy-induced biological pump from the Chukchi shelf region to the southern Canada Basin. Whereas this system caused an early-winter peak of sinking flux of Particulate Organic Nitrogen (PON), we then focused on summertime ecological processes. The sediment trap measurements in the Northwind Abyssal Plain (NAP: 75N, 162W) of the western Arctic Ocean captured a maximum diatom flux with dominance of sea ice species in summer 2011. However, the particle fluxes in summer 2012 were considerably suppressed probably due to extension of oligotrophic Beaufort Gyre water to the NAP area. To examine interannual variability in ocean circulation around the target region, the decadal experiment from 1979 to 2012 was performed using the pan-Arctic ice-ocean model COCO. A virtual passive tracer provided inside the Canada Basin certainly suggested that the Beaufort Gyre direction switched southwestward (toward Station NAP) during the early period of 2012. In addition, the three-box lower-trophic model with sea ice species was applied under physical environments at Station NAP to assess an impact of nutrient deficiency on primary production in 2012. Finally, we plan to discuss how to improve existent problems of Arctic marine ecosystem model.

Estimating potential habitat for chum salmon (Oncorhynchus keta) in the Western Arctic using a bioenergetics model coupl

KISHI, Michio[1*] ; YOON, Seokjin[1] ; WATANABE, Eiji[1]

[1]Hokkaido University

Chum salmon (*Oncorhynchus keta*) are distributed widely in the Northern Pacific and are an important commercial fisheries resource in North Pacific countries. Chum salmon can be divided into North American and Asian groups, and the Asian groups can be divided further into Japanese and Russian groups, which show different migration routes. Japanese and Russian chum salmon stocks are predominant in the Bering Sea during summer and fall. However, recently, several studies reported different tendency. Higher densities of chum salmon were observed within the vicinity of the Bering Strait and the Chukchi Sea than the eastern Bering Sea on September 2007 and alike Japanese chum salmon migrated to northern areas in the Bering Sea on August 2009. Sea surface temperature in the Arctic marginal seas has increased since the mid-1960s, especially since 2000. We speculated that SST increase affect to salmon northing directly. Therefore, we focused on chum salmon migrating northward to the Western Arctic. We estimated the potential habitat for chum salmon in the Western Arctic using a bioenergetics model coupled with a three-dimensional lower trophic ecosystem model (3-D NEMURO). The model domain contained the entire Chukchi Sea and the southern area of the Canada Basin. The horizontal resolution was about 2.5 km, and there were 25 vertical levels (surface to 4000 m). We assumed chum salmon move to a depth where the growth rate is the maximum within 100 m, because chum salmon migrate vertically to below 100 m depth for controlling their body temperature and searching for prey. The model was run for nine months from March to November 2003, thus representing the entire months chum salmon are distributed in the Bering Sea from June to November. In the bioenergetics model, the growth rate of an individual chum salmon was calculated as a function of water temperature, salinity, and prey density, which were obtained from the 3-D NEMURO model results. We calculated the growth rates of chum salmon of 100 gWW to 4000 gWW and defined 'Potential habitat' as 'an area where chum salmon can grow up (i.e., the growth rate is positive)'. The potential habitat reflected the warm and nutrient-rich Pacific water inflowing from the Bering Strait. That was restricted to the southwestern Alaskan coast on June and expanded to the Chukchi Sea and along the Alaskan northwestern coast from July to September and reduced from October. The main limiting factor was the water temperature on June and November and the prey density on July to October. For global warming scenario, we used the modeled monthly water temperature anomaly between 2005 and 2095 under the IPCC SRES-A1B scenario. Under the global warming scenario, the potential habitat for chum salmon increased during early summer and autumn due to the water temperature increase, whereas during summer the potential habitat for smaller chum salmon increased but that for larger chum salmon decreased because the water temperature exceeded the optimal condition, especially in the southern Chukchi Shelf and near the Bering Strait. The water temperature limitation was relaxed with a water temperature increase on June and November, but regionally the water temperature was the main limiting factor during summer.

Seasonal changes in zooplankton swimmer and faecal pellets collected using a sediment trap in the western Arctic Ocean

MATSUNO, Kohei[1*] ; YAMAGUCHI, Atsushi[2] ; FUJIWARA, Amane[1] ; ONODERA, Jonaotaro[3] ; WATANABE, Eiji[3] ; HARADA, Naomi[3] ; KIKUCHI, Takashi[3]

[1]National Institute of Polar Research, [2]Hokkaido University, Graduate School of Fisheries Sciences, [3]Japan Agency for Marine-Earth Science and Technology

Most studies on zooplankton community in the Arctic Ocean have been performed on the basis of net-collected samples. However, seasonal sea ice coverage in this area prevents the accurate evaluation of their seasonal changes. To overcome these challenges, analysis on zooplankton swimmers collected using a moored sediment trap is a powerful tool. In the present study, we analysed the seasonal changes in zooplankton swimmers and faecal pellets collected using a sediment trap moored at the Northwind Abyssal Plain in the western Arctic Ocean.

Samples were collected using a sediment trap moored at 184-260 m at St. NAPt (75N, 162W, bottom depth: 1975 m) in 10-15 day intervals from October 4, 2010 to September 18, 2012. The sample cups were filled with 5% buffered formalin seawater. After the trap was retrieved, a total of 52 samples were gently sieved using a 1-mm mesh, and a fine-size fraction ($<$1 mm) of each sample was filtered using a membrane filter and subsequently weighed. Next, the total mass flux (mg DM m^{-2} day^{-1}) was evaluated. Zooplankton faecal pellets were then quantified in an aliquot of the fine-size fraction, according to four morphological types (oval shape, cylinder shape, spherical shape and brown oval shape). On the basis of both the size fraction samples ($<$1 mm and $\geq$ 1 mm), species identification and enumeration of zooplankton were performed under a dissecting microscope. Furthermore, cluster analysis by Bray-Curtis similarity using the connected unweighted pair group method and the arithmetic mean was performed on the zooplankton flux data (ind. m^{-2} day^{-1}). To identify the species most responsible for the similarity between zooplankton communities, SIMPER analyses were performed on the flux data.

In addition, satellite data were obtained, which revealed the sea ice coverage period (November-June), open water period (August-October), and high chlorophyll a period (August-October). The total mass flux ranged from 0.1-263.3 mg DM m^{-2} day^{-1}, and its peaks occurred in November, which corresponded to the onset of sea ice coverage. In the faecal pellets, oval shaped and spherical shaped morphologies were predominant, and resulted in a total pellet number of 60% and 30%, respectively. With regards to the specific characteristics of the faecal pellets, the brown oval shape occurred only in the open water period (July-August) and their maximum composition during this period reached 80%. The zooplankton flux ranged from 35 to 739 ind. m^{-2} day^{-1} and was significantly higher in September-November compared with other periods (p $<$0.0001, one-way ANOVA). In addition, poecilostomatoid copepods were numerically the most dominant taxa (annual mean$\pm$1sd: 69$\pm$18%). For seasonal dominant taxa, bivalve larvae were found in October-November (53%), and barnacle larvae were abundant in August 2011 (33%) but were not present in 2012. Cluster analysis on the zooplankton flux identified five zooplankton community groups. The occurrence of each group clearly showed seasonality, and alterations in their timings corresponded with the timing of the onset or offset of ice coverage or seasonal changes in daylight hours.

On-board experiments demonstrated that the brown-oval-shaped faecal pellets might be egested by amphipods. Furthermore, the high brown-oval-shaped faecal pellets found during the open water period (July-August) might reflect the massive feeding activity of amphipods. For zooplankton swimmers, seasonal abundant bivalve and barnacle larvae may be transported from a shallower region (e.g., the Chukchi Sea). The annual change in occurrence of barnacle larvae (present in 2011, but not in 2012) may be caused by the annual changes in water mass formation in the upper layer of the St. NAPt.

Volume, heat and freshwater fluxes of Pacific Water through the Barrow Canyon in the Arctic Ocean

ITOH, Motoyo[1*] ; KIKUCHI, Takashi[1] ; NISHINO, Shigeto[1]

[1]JAMSTEC

Interest in Pacific Water flowing from the Bering Strait into the Arctic Ocean has increased markedly in recent years, because of warming and increasing of Pacific Water inflow. Barrow Canyon, in the northeast Chukchi Sea, is a major conduit for Pacific Water to enter the interior Arctic basins. Our study focuses on the quantitative estimate of volume, heat and freshwater fluxes through Barrow Canyon by mooring observations with hydrographic surveys. We conducted year-round mooring observations at one station from 2000 to 2001 and at three stations from 2001 to 2013 in the mouth of Barrow Canyon. The annual mean volume, heat and freshwater fluxes through Barrow Canyon were 0.49 Sv, 2.25 TW and 31 mSv, respectively. Annual averaged volume and freshwater fluxes though Barrow Canyon in recent years from 2010 to 2013 were lower than the 2000-2008 averages, mainly due to strong northerly wind. In contrast, heat flux for the period 2010-2013 was higher than the 2000-2008 average. It tended to be three highest maximum in 2007, 2010 and 2012, when summer sea ice extent extraordinary retreats in the Arctic Ocean, mainly because of the warming of Pacific Summer Water. Heat fluxes observed in these years were 3-4 times larger than that observed in summer 1993. It is sufficient to melt 1-m-thick ice over an area of 360,000 km^2, which is equivalent to the total land area of Japan. The heat possibly contributes to both sea-ice melt in summer and a decrease in sea-ice formation during winter because this water typically subsides just below the surface mixed layer in the Canada Basin.

Water masses transporting process from the Bering Sea to the Arctic Ocean revealed from multiple chemical tracers

JIANG, Kai[1*] ; ZHANG, Jing[2]

[1]Graduate School of Science and Engineering for Education, University of Toyama, [2]Graduate School of Science and Engineering for Research, University of Toyama

The Arctic Ocean is tightly connected to the Pacific Ocean through the only oceanic gateway Bering Strait. Water, heat, nutrients, and other substances inflowing via water masses exchanges affect the marine environment in the Arctic Ocean. In recent decades, the Arctic Ocean has changed dramatically, especially the rapid reduction of sea ice. The changing of water masses through the Bering Strait is thought to be one of the main reasons. Thus, focusing on the process of water masses transporting will contribute to understanding and forecasting the marine environment in the Arctic Ocean. In this research, stable oxygen isotopes, salinity and rare earth elements (REEs) are used to reveal the water masses transporting process from Bering Sea to the Chukchi Sea, which data comes from the Oshoro-Maru C255 cruise during 14June ? 07 August 2013. 182 water samples of δ^{18}O from 31 stations were analyzed by IR-MS (Isotope Ratio Mass Spectrometry). The δ^{18}O composition and salinity are used to separate the different water sources based that river water is highly depleted in δ^{18}O relative to marine waters as well as to sea-ice. Rare earth elements in the sediments from 8 stations were also analyzed by the method of BCR sequential extraction procedure which partitions the elements in sediments among various forms. It aims to trace the material sources, reflecting the water masses transporting process indirectly. The investigations show that in the Bering Sea, δ^{18}O value is around -2 ‰ in the surface increasing to -0.8 ‰ in the bottom water, closed to the δ^{18}O value of Pacific Ocean water, indicating that the up layer water is obviously affected by freshwater. In the Bering Strait, δ^{18}O value is similar in the whole water column, around -1.3 ‰, consistent with salinity, which means that the water is well mixed in the Bering Strait (East side of Bering Strait). In the Chukchi Sea, δ^{18}O value is also affected by sea ice melt water. REEs data shows that different fraction of sediment has different sources, most part of sediments originally come from land, after charged into ocean, they combine with particles or substance under different marine environment.

Influence of the Gulf Stream on the Barents Sea ice retreat and Eurasian coldness

SATO, Kazutoshi[1*] ; INOUE, Jun[2] ; WATANABE, Masahiro[3]

[1]The Graduate University for Advanced Studies, [2]National Institute of Polar Research, [3]Atmosphere and Ocean Research Institute, University of Tokyo

Abnormal winter sea-ice retreat over the Barents Sea has been considered as a leading clue to the recent midlatitude severe winters. Barents Sea is considered as a hot spot for the rapid Arctic climate change due to the intense air-sea interaction induced by the sea-ice decrease; however, the underlying mechanisms remain uncertain, in particular causal relation of sea-ice retreat and atmospheric forcing and response. To understand this causality, we selected typical cases, defined as averaged warm and averaged cold years of December using the NCEP Climate Forecast System Reanalysis (CFSR). The composite analysis, revealed that anticyclonic anomaly is obvious over the northwestern Eurasia. The western Barents Sea and Sbarvard locates at the strong pressure gradient zone, prevailing southerly winds. Over the Barents Sea, the difference in daily mean air temperature between warm and cold winters is more than 10^{o}C, suggesting that warm advection prevails during warm years. Therefore, during warm years, decrease in sea-ice cover is induced by southerly warm advection. The positive anomalies of precipitation from the southeast of Greenland to Barents Sea and negative anomalies of them from Nordic Sea to western Eurasia means the poleward shift of cyclone tracks, suggesting that the moisture transport is also changed poleward. Because the cyclones tend to shift poleward in less sea ice year over the Barents Sea, it is natural that the snow depth over the sea ice near the Fram Strait shows a positive anomaly during warm winters. Here we show that the poleward shift of sea surface temperature over the Gulf Stream, where is situated upstream from the Barents Sea, modifies the horizontal distribution of tropospheric condensational heating resulted from change in convection over the warm current, likely acting as a bridge to the Barents Sea by forcing planetary waves. This remote atmospheric response modifies cyclone tracks poleward, resulting in anomalous warm advection over the Barents Sea sector.

Study of interannual variability of the atmospheric water cycle in the Arctic circumpolar region

ISHIGE, Takaya[1] ; HIYAMA, Tetsuya[2*] ; FUJINAMI, Hatsuki[3]

[1]Graduate School of Environmental Studies, Nagoya University, [2]Research Institute for Humanity and Nature, [3]Hydrospheric Atmospheric Research Center, Nagoya University

The thawing depth (active layer depth) in late summer drastically deepened and the soil moisture increased from 2005 to 2008 in the middle of the Lena River Basin. This was partly due to the high rainfall in late summer, as well as the high snowfall in winter. Subsequently, permafrost-forest degradations and waterlogging has been detected in the region. To clarify whether high precipitation occurred in the past in this region, we investigate the atmospheric water cycle and water budget using archived precipitation (PREC/L) and atmospheric re-analysis data (JRA-25, JRA-55). Previous studies revealed a negative correlation in the summer atmospheric circulation pattern between the Lena and Ob River Basins. However, little is known about the atmospheric water cycles in the Arctic circumpolar region, including the Mackenzie River Basin. Hence we analyzed the interannual variability of the atmospheric water cycle in the Arctic circumpolar region, comparing the three large North Eurasian river basins (Lena, Yenisei, and Ob) and the Mackenzie river basin. The analyzed results are as follows.

1) In the highest five-year summer net precipitation in the Lena River basin during the period 1958 to 2012, significant cyclonic deviation was present from the Barents Sea towards the region across from the Yenisei and Lena. The deviation distribution of the height field and the water vapor flux from the west to the Lena river basin were significantly increased, so as to form a positive deviation of net precipitation.

2) A significant enhancement of cyclonic circulation was detected from 2005 to 2008 on the Eurasian side of the Arctic Ocean. However, anticyclones appeared over Mongolia. These probably increased the atmospheric moisture convergence over the Lena River Basin in this period.

3) A significant positive trend in the summer precipitation and the summer net precipitation appeared after 1995 between the Lena and Yenisei River Basins. On the contrary, the negative trends between the Lena and the Ob River Basins became unclear from 1993.

Evaluation of Large-scale Surface Wetness Variations in Northern High Latitudes During 1980-2010

TAKATA, Kumiko[1*] ; XU, Jianqing[2] ; HARA, Masayuki[2] ; NOZAWA, Toru[3]

[1]NIPR/NIES/JAMSTEC, [2]JAMSTEC, [3]Okayama University

Large-scale surface wetness is evaluated by a wetness index (WI), calculated from GPCC precipitation divided by potential evaporation (Ep) using ERA interim data during 1980-2010. The climatological distribution of annual WI agrees with that of surface soil moisture (SSM) in ERA interim. Annomalies of annual WI also have strong relation with that of SSM in each region; the correlation coefficient between SSM and WI is higher than that between SSM and precipitation. Therefore WI corresponds to SSM for climatology and year-to-year variations.

The linear trends of WI, Ep and precipitation are calculated, with an attempt to decompose the factors of WI trend into those of Ep and precipitations. In high latitudes of Eurasia and eastern Canada, the increasing precipitation trends are canceled by the increasing Ep trends, resulting in little WI trends. In central Asia, western North America and Alaska, the decreasing precipitation trends and the increasing Ep trends lead to the decreasing WI trends. The precipitation variations dominate the WI variations in most regions. For example in Alaska, the decreasing precipitation trend contributes 72% to the decreasing WI trend and the increasing Ep trend does 27%. On the other hand, there are some regions where the Ep trend is important for the WI trend. For example in monsoon Asia, the precipitation trend is small and contributes only 3% to the decreasing WI trend, while the increasing Ep trend does 99%.

Consequently, it is shown that WI corresponds to surface soil moisture and indicates surface wet/dry conditions, and that the contributions of precipitation and Ep to its trends are quantified. Further analyses will be applied to the outputs of global climate models (GCMs) to evaluate reproducibilities of the surface energy-water balances in those GCMs.

To accurately evaluate the spatio-temporal variability of ecosystem functions and service in sub- and Arctic regions under rapid meteorological and climate changes, global, long-term, and comprehensive phenological observations are required. Towards this aim, satellite remote-sensing is useful to detect the spatio-temporal variability of plant phenology such as the timing of start (SGS) and end of growing season (EGS). However, from the in situ ecological research viewpoint, the satellite remote-sensing has not been sufficiently tested and validated by ground-truthing. Here, (1) we performed daily field observations with time-lapse digital cameras in boreal forests in Alaska and Siberia; (2) we examined the relationship between satellite-observed vegetation indices and plant phenology; and (3) we evaluated the spatio-temporal variability of the timing of SGS and EGS in sub- and Arctic regions by using MODIS Terra and Aqua-observed green-red vegetation index (GRVI). We found that (1) satellite-observed vegetation indices (i.e. NDVI, EVI, and GRVI) mainly detected the plant phenology of forest floor in sparse forests; (2) large year-to-year variability of the timing of SGS was detected in eastern Siberia and western Ural Mountains, while that of EGS was not clearly detected; and (3) in contrast, large year-to-year variability of the timing of EGS was detected in western Alaska, which is mainly covered by tundra vegetation, while that of SGS was not clearly detected.

Estimate of permafrost organic carbon balance in Alaskan boreal and tundra ecosystems using natural radiocarbon tracer

KONDO, Miyuki[1*] ; UCHIDA, Masao[1] ; UTSUMI, Motoo[2] ; IWAHANA, Go[3] ; YOSHIKAWA, Kenji[3] ; IWATA, Hiroki[4] ; HARAZONO, Yoshinobu[3] ; NAKAI, Taro[5] ; TANABE, Kiyoshi[1] ; SHIBATA, Yasuyuki[1]

[1]National Institute for Environmental Studies, [2]University of Tsukuba, [3]University of Alaska, Fairbanks, [4]Kyoto University, [5]Nagoya University

The high-latitude regions, where a serious warming is expected, currently store large amounts of soil organic carbon in active-layer soils and permafrost, accounting for nearly half of the global belowground organic carbon pool. Despite the importance of these regions in the present carbon cycle, the soil C fluxes and budget are still only poorly known. Here, we use radiocarbon as the tool for quantifying the C balance of the inputs and decomposition in tundra and boreal soil. We evaluated the C inputs (I) and decomposition rates (k, inverse of turnover time) and net C accumulation (CA), using ^{14}C approaches.

Tundra and boreal soils show different patterns of depth distribution and C storage. Cumulative organic carbon stocks in boreal forest are 5.3 and 19.2 kgCm^{-2}, in surface organic layer (0-25 cm), and deep organic and mineral layers (25-70 cm), respectively. Large annual C input (0.25 kgCm^{-2} yr^{-1}) and relatively slow decomposition (27 years) lead to rapid CA (0.05 kgCm^{-2} yr^{-1}) in surface organic layer in boreal forest. Deep organic and mineral layers including near-surface permafrost show slower rate of input (0.03 kgCm^{-2} yr^{-1}) and turnover (617 years) and CA about 20 times slower (0.003 kgCm^{-2} yr^{-1}) than surface organic layer. Decomposition organic matter (Rh), which in accord with C losses from both surface and subsurface layers, was 0.23 kgCm^{-2}yr^{-1}. This value agreed well with Rh (0.23 kgCm^{-2} yr^{-1}) simulated by process-based models that simulate the biogeochemical and hydrologic cycle, where Rh averaged 45% of ecosystem respiration and 59% of soil respiration.

In contrast, large amount of SOC (36.4 kg m^{-2}) have accumulated over millennia (turnover time: 4540 yrs) below the thin organic layer in tundra. The CA of mineral layer and permafrost is close to zero (0.003 kgCm^{-2} yr^{-1}), and Rh is 0.008 kgCm^{-2} yr^{-1}. Our radiocarbon data show that the most SOC in tundra soil was mode of stabilizing OC by permafrost and steady-state SOC stocks under current C balance.

Large-Scale Forest Fires in Alaska: Weather Conditions in 2004 and 2005

HAYASAKA, Hiroshi[1*]

[1]Graduate School of Hokkaido University

In Alaska, large-scale forest fires mainly occurred in the boreal forest of the Interior (area roughly around 400 x 800 km) in 2004 and 2005. Number of large-scale forest fires (burnt area more than 500km^2) were 17 in 2004 and 12 in 2005. These large-scale forest fires boosted up burnt areas 26,000km^2 in 2004 and 18,800km^2 in 2005. Their areas were largest and third largest among the past 58 years from 1956 to 2013.

In order to evaluate large-scale forest fires in both years, statistical analysis for the fire data in the past 58 years was carried out. As a result, annual average burnt area was 3,480 km^2, and the coefficients of standard deviation (sigma) were +4.25 for 2004 and +2.88 for 2004. In the background of these large standard deviation coefficients, only 11-year could show large burnt area of more than 6,000km^2, and burnt area of other 47-year were less than 5,000km^2. In addition to this trend, the occurrence of fire year with burnt area more than 6,000 km^2 was once per decade from the 1950s to the 1980's. But from the 1990's, fire year tended to occur more frequently. That is, they were 1957 (2nd largest), 1969 (6th), 1977 (7th), 1988 (8th), and these frequencies were once per decade. However, from the 1990s, fire years occurred in 1990 (4th largest), 1997 (9th), and 1991 (11th). From the 2000s, four fire years observed in 2004 (largest), 2005 (3rd largest), 2009 (5th), and 2002 (10th). The frequent occurrence trend of such fire year may be suggesting close relationship with the rapid reduction of sea ice in the Arctic Ocean under a rapid climate change.

From the comprehensive analysis in this paper, largest burnt areas in 2004 happened under the condition made by ridge extended from Canada lasted about three month from June to August. The very severe fires observed in August 2005 occurred along with the movement of the high pressure system from the Gulf of Alaska to the Beaufort Sea.

Detection and attribution of changes in arctic ecosystems and atmospheric CO2

PATRA, Prabir[1*] ; KOBAYASHI, Hideki[1] ; SAEKI, Tazu[1]

[1]RIGC/JAMSTEC

Atmospheric CO_2 responds to terrestrial ecosystem activity widely from sub-hourly to decadal time scales primarily due to photosynthesis, weather and climate variations. The measurements of CO_2 thus consist of source signals from anthropogenic as well as natural ecosystem activities convolved with atmospheric transport. Since the records of CO_2 concentration in ambient air at monthly or finer time resolution began in the late 1950s, the seasonal ecosystem dynamics has enhanced significantly in the recent years (Graven et al., 2013). We further analyse the relative contributions of fossil fuel emissions and atmospheric transport on the CO_2 at a greater number of surface measurement sites since the 1980s using the CCSR/NIES/FRCGC atmospheric general circulation model (AGCM)-based chemistry transport model (ACTM). Our results suggest the trends in fossil fuel emissions and transport have detectable contribution to the CO_2 seasonal cycle chances at the sites in northern tropics to mid-latitudes, and that the seasonal cycle increase in the arctic region is governed mainly by the terrestrial ecosystem.

To attribute causes for the recent changes in carbon cycle dynamics we have chosen the period of 1999-2011, which is covered by high quality process oriented ecosystem parameters from remote sensing and atmospheric CO_2 measurements at the largest network of sites for flux inversion. Our analysis suggests that the early greening by several days in the Alaskan tundra region closely correlated with the amplitude of CO_2 seasonal cycle at Point Barrow, Alaska. But no clear trend in the greening onset is detectable at semi-arid grasslands near Ulaanbaatar, Mongolia, except for the closely coupled interannual variations in greening onset time and CO_2 seasonal cycle amplitude. We estimated CO_2 fluxes from 84-regions of the globe at monthly time intervals using measurements from about 100 sites. The terrestrial CO2 fluxes are estimated after removing the effects of fossil fuel emissions and oceanic fluxes in measured CO_2 concentrations. We find the carbon exchange of the Alaska region of our inversion is increased both for the seasonal cycle amplitude and net annual uptake over the period of 2002-2011.

Our results have large implications for developing the future and validating the present earth system models for studying climate-carbon-biosphere interactions.

Epoch difference of water cycles in eastern and western Siberia

OSHIMA, Kazuhiro[1*] ; OGATA, Koto[2] ; PARK, Hotaek[1] ; TACHIBANA, Yoshihiro[2]

[1]Japan Agency for Marine-Earth Science and Technology, [2]Mie University

Among all the rivers flowing into the Arctic Ocean, the three great Siberian rivers; Lena, Yenisei and Ob, are the three largest in terms of water discharge (R), and they are a large source of freshwater. We examined the relationship of long-term water cycle variability between eastern and western Siberia on the basis of net precipitation (P-E) estimated from an atmospheric reanalysis, and Rs from observations at the river months and from a reconstruction based on tree rings.

The relationship of summer (P-E)s between the Lena and Ob Rivers is different in the first half and the second half of the past three decades. During 1980s to mid-90s, the (P-E)s have a strong negative correlation. These variations were affected by the east-west seesaw pattern of moisture flux. These results are consistent with Fukutomi et al. (2003). The decomposition analysis revealed that the stationary component of moisture flux dominates the seesaw pattern during the period. After mid-1990s, the correlation of the (P-E)s between the Lena and Ob becomes weak. During mid-1990s to 2000s, the P-E over the Lena was affected by cyclonic moisture flux over the basin. In addition to the stationary component, the transient component of moisture flux also affects the P-E variation in this period.

Long-term records revealed that the Rs of the Lena and Ob Rivers have moderate or weak positive correlations and strong negative correlations before the 1980s. Interestingly, the correlations tend to be distributed in the negative side. It implies that the east-west seesaw pattern frequently appear over Siberia. In conclusion, the moisture transport processes over Siberia are different in each era and they result in the different variability of the Rs and (P-E)s of the Lena and Ob Rivers.

A negative phase shift of winter AO/NAO due to the recent Arctic sea ice reduction in late autumn

NAKAMURA, Tetsu[1*] ; YAMAZAKI, Koji[1] ; IWAMOTO, Katsushi[1] ; HONDA, Meiji[2] ; UKITA, Jinro[2] ; MIYOSHI, Yasunobu[3] ; OGAWA, Yasunobu[1]

[1]National Institute of Polar Research, [2]Niigata University, [3]Kyushu University

Attribution of the long-term changes in the wintertime Arctic Oscillation (AO)/North Atlantic Oscillation (NAO) to the recent Arctic sea ice reduction is studied. Observations using ERA interim reanalysis and Merged Hadley/OI-SST show that small (large) sea ice area in summer to autumn leads the negative (positive) phase of AO in early winter and NAO in late winter. Relationship with winter AO/NAO is the strongest with the sea ice variability in November rather than September. To separate influences of sea ice variability and sea surface temperature (SST) anomalies, sensitivity experiments are performed with atmospheric general circulation model (AGCM for Earth Simulator, AFES4.1), in which observed changes (anomalies of 2005-2009 from 1979-1983) of the sea ice and SST are prescribed. The Arctic ice reduction generates the negative AO/NAO pattern that brings cold winter in mid-latitude continental regions. Both SST anomalies in the tropics and mid-/high-latitudes mask the continental cooling. Model-based analysis reveals that stationary Rossby wave response to the ice reduction in Barents Sea induces anomalous meridional circulation corresponding to the negative AO. The ice reduction increases (decreases) a frequency of the large negative (positive) AO occurrence about a twice (half). The anomalous meridional circulation warms the Arctic and cools the mid-latitudes. This provides additional Arctic heating about 25% of heat release due to the ice reduction. As a response to ice reduction, transient eddy activity over northern Eurasia is reduced and the change in the eddy damps the stationary responses.

Cross spectral analysis of the AO index using the AOI equation

TANAKA, Hiroshi[1*]

[1]CCS, University of Tsukuba, [2]Life and Environmental Science, University of Tsukuba

Arctic Oscillation (AO) is explained as an atmospheric dynamical eigenmode. There is an argument, however, that the AO is a statistical illusion by the EOF analysis. Tanaka and Matsueda (2005) showed AO mode as the most unstable standing mode in the barotropic atmosphere. In addition to the zero frequency of the mode, the growth rate becomes also zero for adequate frictional force and interaction with transient eddies. Such a mode can be amplified resonantly by quasi-situational forcing. This idea of the AO is called singular eigenmode theory. For the problem of missing correlation in surface pressure between the Pacific and Atlantic is explained by Suzuki and Tanaka (2007) by analyzing barotropic height instead of the surface pressure. The barotropic height indicates significant correlation between the two regions. The missing correlation is thus explained by the baroclinic component of the atmosphere. We support the singular eigenmode theory, but a further analysis is required by the data analysis of the AO index. In this study we derived an equation called AOI equation from the definition of the AOI differentiated with respect to time, and substituting the primitive equation. According to the analysis result of the NCEP/NCAR reanalysis for 62 years of data, it is found that the AOI time series is proportional to the linear term of the AOI equation. The nonlinear term and external forcing term indicate inverse correlation with the AOI, which tend to damp the AOI to the normal. The fact that the linear term of the primitive equation is proportional to the AO structure, i.e., $L*x = a*x$ implies that the AO is an eigensolution of the dynamical system. The present study supports the singular eigenmode theory from the data analysis using the AOI equation.

GRENE Arctic Climate Research project aims to establish interdisciplinary collaborations of different scientific area. The GRENE project constructed the Arctic Data archive System (ADS) at NIPR to support this researching frame. ADS stores the field data obtained by the project, satellite data by collaboration with JAXA and modelling output from climate models. This presentation introduces activity of data archiving in GRENE Arctic project and ADS for multiple studies.

This study investigates cryospheric change using satellite data stored in the ADS and other satellite programs.

Recent changes of satellite-derived snow grain size and glacial microbial activities in Greenland ice sheet

AOKI, Teruo[1*] ; KUCHIKI, Katsuyuki[1] ; NIWANO, Masashi[1] ; TANIKAWA, Tomonori[2] ; HORI, Masahiro[2] ; SHIMADA, Rigen[3] ; TAKEUCHI, Nozomu[3] ; STAMNES, Knut[4] ; LI, Wei[4]

[1]Meteorological Research Institute, [2]Japan Aerospace Exploration Agency, [3]Chiba University, [4]Steven Institute of Technology

Snow surface albedo strongly depends on snow grain size and mass concentration of light absorbing impurities. These snow parameters are uncertain factors for the recent drastic snow and ice meltings in the Arctic. Particularly, Greenland ice sheet (GrIS) is presently undergoing drastic changes. In 2012 a record melting event of surface snow/ice occurred over the GrIS. When air temperature increases, snow grain size is also increased by accelerating the snow metamorphism and thus the albedo is reduced (positive albedo feedback). This process is mainly dominant in the accumulation areas. On the other hand, the bare ice area is extended by snow melting on ice associate with air temperature raise in ablation areas. It is recently reported that wide bare-ice areas in GrIS are covered with glacial microbes whose albedos are lower than that of blue ice surface. This albedo reduction effect is also another positive albedo feedback effect by glacial microbes. To examin these feedback effects by snow grain growth and glacial microbial activities in conjunction with air temperature increase, we retrieved snow grain size and glacial microbe concentration from Moderate Resolution Imaging Spectroradiometer (MODIS) data. The employed algorithm is based on a look-up table method for bidirectional reflectance distribution function at the top of the atmosphere as functions of snow grain size, snow impurity (soot) concentration, solar and satellite geometry. The employed satellite channels are 0.46, 0.86, 1.24, and 1.64 μm. Since the snow impurity concentrations in accumulation area are the same or lower level of the detection limit of soot concentration in GrIS, we use this retrieval result as an indicator of microbial activities in bear ice areas. The monthly averages of snow grain size and snow impurity concentration from 2000 to 2013 in GrIS derived from Terra/MODIS revealed the following facts. (1) The areas of large grain size changed year by year. (2) There is no constant increasing trend, but the larger values were observed in recent years (2009-2012) and especially for 2012 the remarkable increase in whole Greenland. (3) Larger snow grain size and high impurity concentration, which indicate the areas of high glacial microbial activities, are distributed in coastal regions of GrIS in June (mainly in southern part), July and August. These parameters in colder summer of 2013 than the recent several years, were almost the same as those in 2000.

Acceleration and deceleration of ice thickness variations in Greenland from ICESat laser altimetry (2003-2009)

MATSUO, Koji[1*] ; FUKUDA, Yoichi[1] ; SUZUKI, Kazuyoshi[2]

[1]Graduate school of Science, Kyoto University, [2]JAMSTEC

The laser altimeter mission ICESat, launched by NASA in January 2003, measures the Earth's surface elevation with a precision of several cm. ICESat has performed campaign observation of about 90 days a year between September 2003 and October 2009. The spatial resolution of the measurement in Greenland is about 20 km in average. In this study, we analyze acceleration/deceleration of ice thickness variations in Greenland from ICESat elevation data. We employ Plane fitting method (e.g. Zwally et al., 2011) to correct topographic effect coming from gaps of repeat-track paths, and fit the time-series of surface elevation variations with a linear combination of linear and quadratic terms by least-squares method at every 700m interval. The quadratic trend signal thus extracted represents accelerated/decelerated variations.

The obtained linear variation suggests significant ice thinning trend in southeastern and western Greenland. Their thinning rates attain to about 1.5-2 m/yr. On the other hands, inland area shows ice thickening trend with a rate of 0.3 m/yr. Assuming the firn density as 700 kg/m^3 in ice thinning area and 300 kg/m^3 in ice thickening area, we obtain the total ice loss rate of about -200 Gt/yr, which is equivalent to about 0.55 mm/yr sea level rise. This agrees well with GRACE gravimetric estimate.

Next we focus on the quadratic variation. Western Greenland shows significant negative quadratic variations, suggesting acceleration of ice thinning rate. Such trend is particularly noticeable in Jakobshavn glacier and Qaanaaq area. On the other hands, southern Greenland shows different behaviors: negative quadratic variations (accelerated ice thinning) in Helheim glacier and Kangerdlugssuag glacier, and positive quadratic variations (decelerated ice thinning) in other coastal area. We speculate that accelerated ice thinning in the above outlet glaciers reflects recent global warming, while decelerated ice thinning in other coastal area of southern Greenland does anomalous precipitation of Arctic Oscillation with positive phase during the winter of 2007-2008.

Sensitivity of Response of Greenland Ice Sheet to Global Warming on Surface Mass Balance and Initialization methods

SAITO, Fuyuki[1*] ; ABE-OUCHI, Ayako[2] ; TAKAHASHI, Kunio[1]

[1]JAMSTEC, [2]AORI, Univ. of Tokyo

We present a series of numerical experiments of Greenland ice sheet under global warming condition using Ice sheet model for Integrated Earth system Studies (IcIES).
In this study, influence on the simulation from the difference in the method to compute the surface mass balance is focused.
Typically, ice sheet simulation is driven by a *reference-anomaly* method, in which the surface temperature and/or the accumulation are decomposed into the reference terms (e.g., observation), the anomaly (e.g., climate scenario from climate models).
Then the surface melting is computed using parameterization such as positive degree-day (PDD) method with the temperature.
These decomposed terms have own uncertainties, which may influence the ice-sheet simulation.
In this study, impact of these properties to the present-day control case, as well as the response under uniform warming condition are discussed, which is thought be a useful and basic information of the property/sensitivity of the Greenland ice sheet.

In addition, several initialization methods (free spin-up, fixed-topography spin-up, etc) are applied to IcIES in order to evaluate the influence of the error in the present-day simulated topography to the short-term response of Greenland ice sheet.

Ice discharge from calving glaciers in the Greenland ice sheet (GrIS) has recently increased through the acceleration of glaciers, and this increase plays an important role in the ice volume change of GrIS and sea level rise. Previous studies have used remote-sensing (RS) data to assess surface lowering of calving glaciers in GrIS. However, because of the remoteness of these glaciers, relatively few field data are available on the surface elevation change. Consequently, RS data have been used without calibration with filed data. The accuracy of such studies relies on digital elevation models (DEMs) derived from satellite data.

In this study, surface elevation was measured along longitudinal and three transverse profiles in Bowdoin Gletscher (77^{o}41'18"N, 68^{o}29'47"W) in July 2013. DEMs of Bowdoin Gletscher in August 20, 2007 and September 4, 2010 were generated by Advanced Land Observing Satellite (ALOS) Panchromatic remote-sensing Instrument for Stereo Mapping (PRISM) images with a 50 m grid mesh, and calibrated using field data. Mean surface elevation change along the field survey profiles were -16.3$\pm$4.0 m (5.3 m yr^{-1}) in 2007-2010 and -10.8$\pm$4.0 m (-3.8 m yr^{-1}) in 2007-2013. Surface elevation change along the lower most transverse profile (800 m from the calving front) was more negative than those along the other profiles in the upper reaches. Surface lowering rate at all profiles has decreased from 2007-2010 to 2010-2013.

Estimation of glacier motions at Svalbard, NovayaZemlya with ALOS/PALSAR

KONUMA, Yoshiki[1*] ; FURUYA, Masato[2]

[1]Department of Natural Sciences History, Hokkaido University, [2]Department of Natural Sciences History Hokkaido University

While the Greenland Ice Sheet's mass loss is equivalent to 0.6mm/yr sea level rise, a half of them is attributed to the changes in glacier dynamics (Broeke et al., 2009). Namely, surface velocities of many glaciers in Greenland have increased in the recent decade (Moon et al., 2012). We thus wonder if glacier velocities outside Greenland have also increased or not.

Svalbard and NovayaZemlya are arctic islands located at 78 degrees north and 74 degrees north, respectively, and have many glaciers. Stozzi et al. (2008) estimated glacier motions in these islands with SAR in 1990s. However, there are not any studies with SAR in recent decade.

We examined Duvebreen glacier in Svalbard and Vize Glacier in NovayaZemlya. In this study, we used PALSAR derived by the ALOS satellite launched from Japan. The PALSAR data were acquired 10 times at Duvebreen glacier from July 2007 to October 2010, 13 times at Vize Glacier from February 2007 to December 2010. We compared the result with 1990s velocity in previous study.

Accordingly, two glaciers in Svalbard and NovayaZemlya speeded up from 1990s. This result suggests that velocity of other arctic glaciers increase as Greenland's glaciers.

Snow impurity concentration and snow grain size measured in Ny-Alesund, Svalbard

KUCHIKI, Katsuyuki[1*] ; AOKI, Teruo[1] ; NIWANO, Masashi[1] ; SHIOBARA, Masataka[2] ; GOTO-AZUMA, Kumiko[2]

[1]Meteorological Research Institute, [2]National Institute of Polar Research

Mass concentration of light absorbing impurities in snow and snow grain size are important parameters controlling snow albedo. An increase in light absorbing impurities such as black carbon (BC) reduces the visible albedo and that in snow grain size reduces the near-infrared albedo. To monitor these snow physical parameters and evaluate those effects on snow albedo in the Arctic, we have measured the snow parameters using a ground-based spectral radiometer system for albedo and flux (GSAF) in Ny-Alesund, Svalbard (78^{o}55'N, 11^{o}55'E). The BC concentration in snow and snow grain sizes in the topmost and subsurface layers were retrieved from spectral albedos measured using the GSAF from March to June, 2013. Furthermore, the retrieved snow parameters were validated by comparing with in-situ measurements based on snow pit work and snow sampling in April, 2013. The collected snow samples were filtrated, and then elemental carbon (EC), organic carbon (OC) and dust concentrations in snow were measured by filter weighing and thermal optical analysis.

The snow depth gradually increased up to 40 cm during the polar night from late October to late February. It maintained around 40 cm until the middle of May, and then rapidly decreased to 0 cm in early June. The BC concentrations retrieved from the GSAF varied little during March to June with about 110 and 40 ppbw for external and internal mixture models employed in the retrieval algorithm, respectively. The in-situ measured EC, OC and dust concentrations were 8-35, 32-190 and 570-3180, respectively. The BC-equivalent concentrations estimated from the light absorbing effects of both EC and dust were 18-43 ppbw, which agreed with the GSAF-derived BC concentrations using the internal mixture model. The topmost layer snow grain radius retrieved from the GSAF were varied within the range 30-300 μm until the middle of May, then increased more than 1000 μm with the snow melting. The snow grain sizes in the subsurface layer were generally larger than those in the topmost layer, which was consistent with the in-situ measurement. We estimated the possible albedo reduction by snow impurities using a physically based snow albedo model with the GSAF-derived snow parameters. The albedo reduction was enhanced to -0.038 during snow melting period after the mid-May, compared with -0.027 before the mid-May, mainly due to the increase in snow grain size.

New developments of Arctic Data archive System(ADS)

YABUKI, Hironori[1*] ; SUGIMURA, Takeshi[2]

[1]Japan Agency for Marine-Earth Science and Technology, [2]National Institute of Polar Research

Arctic is the region where the global warming is mostly amplificated, and the atmosphere/ ocean/ cryosphere/ land system is changing. Active promotion of Arctic environmental research, it is large and responsible for observational data. Promotion of Arctic research in Japan, has not been subjected to independent in their respective fields.

In the National Institute of Polar Research, perform the integration and sharing of data across a multi-disciplinary such as atmosphere, ocean, snow and ice, land, ecosystem, model, for the purpose of cooperation and integration across disciplines, we build a Arctic Data archive System (ADS).

Arctic Data archive System (ADS), to promote the mutual use of the data across a multi-disciplinary to collect and share data sets, such as observational data, satellite data, numerical experiment data. Through these data sets, clarify of actual conditions and processes of climate change on the Arctic region, and further contribute to assessment of the impact of global warming in the Arctic environmental change, to improve the future prediction accuracy.

ADS developed the the online visualization system (VISION) of grid data (a satellite and model simulation), which observational researcher was not good. This VISION which can easily visualize special change can become effective for not only the understanding of the phenomenon but also the design of the observation for an observational researcher.

Sea ice and ocean primary production and phenology in the Arctic Ocean

JIN, Meibing[1*]

[1]International Arctic Research Center, University of Alaska Fairbanks

In the Arctic Ocean, both phytoplankton and sea ice algae are important contributors to primary production and the arctic food web. We use a coupled ice algal and pelagic ecosystem model embedded in the global physical model POP-CICE (Parallel Ocean Program- Los Alamos Sea Ice Model) to study the ecosystem response to climate changes. The model results showed a mean seasonal cycle of ice algal production from March to May and subsequent ocean production from May to September in the Arctic. The ice algal production, although smaller than that of the ocean, is of ecological importance as a food source for higher trophic levels during the long arctic winter before ice melt. The simulated mean open-ocean upper 100m primary production within the Arctic Circle was 413 Tg C/yrin the years 1998 to 2006, close to the remote sensing derived estimate of 419 Tg C /yr but with higher interannual variations. The mean sea ice algal production in the Northern Hemisphere from 1998 to 2007 was 21.3 Tg C/yr, which is in the range of multi-observational estimations of 9 to 73 Tg C/yr based on in situ measurements. Arctic organisms are adapted to the strong seasonality of environmental forcing. Climate warming causes shrinking ice coverage and earlier ice retreat in the Arctic, which is likely to change the timing of primary production. Using a synthesis of available satellite observation data and the coupled ice-ocean ecosystem model, we found that, over a large portion of the Arctic marginal seas, the timing variability of ice retreat at a specific location has a strong impact on the timing variability of pelagic phytoplankton peaks but weak or no impact on the timing of ice-algae blooms in those regions. The model predicts latitudinal and regional differences in the timing of ice algae biomass peak (varying from April to May) and the time lags between ice algae and pelagic phytoplankton peaks (varying from 45 to 90 days). The correlation between the time lag and ice retreat is significant in areas where ice retreat has no significant impact on ice-algae peak timing, suggesting that changes in pelagic phytoplankton peak timing control the variability of time lags. Phenological variability of primary production is likely to have consequences for higher trophic levels, particularly for the zooplankton grazers, whose main food source is composed of the dually pulsed algae production of the Arctic.

The effect of meteorological condition on energy and carbon budget on taiga-tundra boundary in North-eastern Siberia

MIYAZAKI, Shin[1*] ; TEI, Shunsuke[1] ; BRAGIN, Ivan[4] ; SUZUKI, Rikie[2] ; TAKANO, Shinya[3] ; SHINGUBARA, Ryo[3] ; MOROZUMI, Tomoki[3] ; SUGIMOTO, Atsuko[3] ; MAXIMOV, Trofim[5]

[1]National Institute of Polar Research,, [2]Japan Agency for Marine-Earth Science and Technology, [3]Hokkaido University, [4]FarEast Geological Institute, FE RAS, [5]nstitute for Biological Problems of Cryolithozone SD RAS

1. Introduction

In Arctic, temperature has increased almost twice the global average rate in the past 100 years. We aim to clarify the land-atmosphere interaction over the boundary between taiga and tundra in northeastern Siberia, where the climate change effect might be remarkable. We have started the energy, water and carbon fluxes observation as well as hydro-meteorological observation in northeastern Siberia, Sakha Republic, Russia in June 2013.

2. Material and methods

Our observation site is located at Kodack site (70.564 N, 148.267E, altitude 7m) about 100km south from East Siberian Sea in Arctic Ocean near Chokurdakh city in the North-Eastern Siberia, Sakha Republic, Russia. The Kodack site is belong to Indigirka river basin (drainage area: 324,244km^2) which flow to the East Siberian Sea. The annual air temperature and precipitation are -13.4 deg. C and 200mm respectively (1979-2008, Baseline Meteorological Data in Siberia (BMDS) Ver.5.0, Yabuki et al., 2011). The surface is covered by snow except July and August and the maximum snow depth is 40cm in April. In this region, the permafrost exits and the active layer depth ranges from 25cm to 40cm (van der Molen et al., 2007). The topography at the site consists of higher mounds and lower wet lands, where the difference of the height are about 50cm. At the higher mound, the shrubs and larches are dominant, while the sphagnum are prevailing at the lower wet land. The meteorological and flux observation has been carried out over the mound area.

The air temperature, relative humidity, wind speed and direction, air pressure, precipitation were observed at 1.5m height. The incoming and outgoing shortwave and longwave radiation were observed by 4-compnent radiometer at 1.37m height. The soil heat flux was observed by heat flux plate at 0.05m depth. The soil temperature was observed by platinum sensor at depths of 0.025, 0.05, 0.225, 0.425, and 0.625 m. The soil moisture was observed by capacitance sensor and frequency domain reflectometry sensor at depths of 0.035, 0.145, 0.335, and 0.535 m. The energy and carbon fluxes were calculated by the eddy covariance method from the observed values of the sonic anemo-thermometer at 2.55m height.

3. Results

The analysis results from 23 June to 27 October 2013 will be shown. The daily mean air temperature and relative humidity varied from 0.5 to 21.9 deg. C and from 53.9 to 90.0%, respectively. The total precipitation was 29.5 mm, and the maximum daily precipitation was 9 mm?day-1. The daily mean wind speed varied from 1.3 to 6.1 m s^{-1}. There was clear relationship between the daily mean air temperature and wind direction. When the wind direction was northerly (southerly), the air temperature was low (high). The soil temperature (Ts) at surface varied from 2.8 to 10.8 deg. C while Ts at deeper than 0.425 m kept below 0 deg. C, which implies the frozen soil. The Ts at depth of 0.225m increased from -0.4 to 1.8 deg. C. The soil water content (SWC) was higher than 50% in surface layer of wet land while SWC at dry mound was lower than 11%. The net radiation varied from 50 to 200 W m^{-2} and soil heat flux varied from 11 to 40 W m^{-2}. The daily mean latent heat flux (average during analysis period: 39 W m^{-2} was little higher than the daily mean sensible heat flux (26 W m^{-2}). The daily mean net ecosystem exchange (NEE) on 24 and 26 June was 0.32 and 0.41 g C m^{-2} day^{-1}, respectively, which implies the carbon was released from the surface to the atmosphere while the NEE of the other days was negative value which implies the carbon was uptaken from the atmosphere. The accumulated NEE during analysis period was about -64 g C m^{-2} day^{-1}, which was smaller uptake than the value observed at tundra (-92g C m^{-2} day^{-1}; van der Molen et al., 2007). As our observation was started about half month after the start of growing season (late May), further analysis using the next year observation is necessary.

Year to year variations in larch growth and their controlling factors in taiga-tundra boundary ecosystem, NE Siberia

LIANG, Maochang[1*] ; TEI, Shunsuke[1] ; SUGIMOTO, Atsuko[2] ; MAXIMOV, Trofim C.[3] ; KIYASHKO, Sergey[4] ; VELIVETSKAYA, Tatiana A.[5] ; IGNATIEV, Alexander V.[5]

[1]Graduate School of Environmental Sci. Hokkaido Univ., [2]Faculty of Environmental Earth Sci. Hokkaido Univ., [3]Inst. Biological Problems of Cryolithozone, SBRAS, Yakutsk, Russia, [4]Far East Inst. of Marine Biology, FEB RAS, Vladivostok, Russia, [5]Far East Inst. of Geological, FEB RAS, Vladivostok, Russia

Eastern Eurasia is covered by permafrost which is the largest and the deepest in the world. In its arctic region of lowland of Indigirka River, taiga-tundra boundary ecosystem covers the area. For better understanding of this boundary ecosystem, it is important to understand controlling factors on the growth of larch trees which is the dominate tree species of taiga. Larch growth can vary spatially and temporally. In spatial variation, we found that high soil moisture influences mortality of the larch trees and N availability explains differences in trees ability of C assimilation among the sites. To know the controlling factors on temporal variation of larch growth, we conducted field measurements on photosynthesis, needle nitrogen (N) content, needle mass and isotopic ratios in larch needle and stem in every summer from 2009 to 2013 at four sites in the Indigirka River Basin, near Chokurdakh (70^{o}37'N,147^{o}53'E), northeastern Siberia.

There was no seasonal variation in needle mass during the growing season after needles were fully open, while needle N content showed seasonality. Needle N content in the year positively correlated with July air temperature and stem δ^{13}C and following year needle δ^{13}C. These results indicates that, in the year with higher July air temperature, more N was allocated to needle and larch trees exhibited higher photosynthetic rate and photosynthetic C used for needle production was one year delayed. Higher air temperature in the year possibly indicates higher solar radiation based on positive correlation between July temperature and sun hours. Therefore, it can be said that larch growth shows strong dependence on solar radiation. In terms of temperature itself, we found higher temperature could limit photosynthetic rate. In addition, wet event, occurred at some sites in 2011 and 2012, caused low photosynthetic rate and low needle N content in 2012, and higher needle δ^{13}C in 2012 and 2013. These results indicate that high soil moisture could limit larch photosynthesis and reduce N uptake and cause stomata closure as well.

Our observational results indicate that solar radiation is one of the most important controlling factors on larch growth, and high soil moisture and high temperature can limit larch growth.

[1]Hokkaido University Graduate School of Environmental Science, [2]National Institute of Polar Research, Arctic Environment Research Center, [3]Hokkaido University Faculity of Environment Earth Science, [4]Japan Agency for Marine-Earth Science and Technology, Research Institute for Global Change, [5]Far East Geological Institute, Far Eastern Branch Russian Academy of Science, [6]North-Eastern Federal University, [7]Institute for Biological Problems of Cryolithozone, Siberian Branch of Russian Academy of Sciences

Vegetation types, species compositions were observed with physical environment such as micro topography and soil moisture at taiga-tundra boundary ecosystem in lowland of Indigirka river in north eastern Siberia near Chokurdahk village(70^oN,148^oE)in July 2012 and 2013. There are 4 types of plant communities: driest Tree mound(*Larix gmelnii* etc.), Shrub(*Betula nana* etc.), Sphagnum(*Sphagnum* sp. etc.), wettest Hollow(*Eriophorum angustifolium* etc.). Large area is also covered by Willow(*Salix udensis* etc.) along the river. Soil moisture is the most important factor controlling vegetation and other biogeochemical cycles, such as methane emission. Thus, it is necessary to make a vegetation map with a classification as a key for estimating methane emission.

The objective of this study is classify land cover vegetation using remote sensing approach on satellite images and photographs. In remote sensing approach we used high resolution satellite multispectral image(GeoEye-1, WorldView-2) and aerial photo by radio-control helicopter. Supervised classification was conducted for spacial distribution of vegetation based on aerial photos. This vegetation map will be used for upscaling of biogeochemical cycle process such as greenhouse gases.

Satellite observation of cryospheric change using Arctic Data archive System (ADS)

ALIMASI, Nuerasimuguli[1*] ; ENOMOTO, Hiroyuki[1] ; YABUKI, Hironori[3] ; SUGIMURA, Takeshi[1] ; KAMEDA, Takao[2]

[1]National Institute of Polar Research, [2]Kitami Institute of Technology, [3]JAMSTEC

Arctic Data archive System (ADS) has been constructed in the GRENE Arctic Climate Research project. ADS is useful for quick look of data and visualizing satellite data in the Arctic. The decline of sea ice area in the Arctic influences on the environment and industrial activities in the coastal region and people's life. Satellite microwave data since 1978 was archived in ADS. They are SMMR, SSM/I, AMSR, AMSR-E and AMSR2. These data sets enable to analyze more than 35-years time series of snow conditions, sea ice conditions in the Arctic.

The data is available for all-weather, even during the polar night season. The data enables climatological analysis for more than 30-years time spanThis study demonstrates ADS capabilities for long-time monitoring and snow and ice conditions.

Age of the Pacific Winter Water in the Canada Basin estimated from SF6

OGIWARA, Yusuke[1*] ; KAWAI, Michiyo[2]

[1]Tokyo University of Marine Science and Technology, [2]Tokyo University of Marine Science and Technology

In the Pacific sector of the Arctic Ocean, Pacific Winter Water (PWW) distributes between 100m and 200m depths. Because the PWW has high nutrient concentrations and low pH, its spreading pathway has implications on primary production and ocean acidification in the Arctic Ocean. In this study, we have observed distribution of SF6, a transient tracer alternative to CFCs, in order to trace newly formed PWW into the Canada Basin.

Sampling was carried out in summer of 2013 on the CCGS Louis S. St-Laurent. Seawater at the core of PWW (salinity = 33.1) were collected in Niskin bottles and then transferred into custom-made glass bottles. Samples were kept at low temperature and brought back to Japan. Concentrations of SF_6 in seawater samples were determined by an ECD-GC following the method described in Bullister and Wisegarver (2008).

Results show that younger PWW distributes at the periphery of the Beaufort Gyre, a major anticyclonic circulation in Canada Basin. The age of PWW estimated from SF_6 was 13∼15 years in the center of the gyre, whereas age was 6∼9 years around the gyre. From the distributions of SF_6 age, dissolved oxygen and nutrients, it is suggested that there is a pathway of PWW from the Siberian shelves or slopes into the northeastern Canada Basin.

Mineralization Rate of Soil Organic Carbon at the Lowland of Indigirka River in Northeastern Siberia

SHINGUBARA, Ryo[1*] ; TANABE, Shinichi[2] ; TAKANO, Shinya[1] ; BRAGIN, Ivan[3] ; MURASE, Jun[4] ; TEI, Shunsuke[5] ; MAXIMOV, Trofim C.[6] ; SUGIMOTO, Atsuko[7]

[1]Grad. School of Env. Sci., Hokkaido Univ., [2]School of Sci., Hokkaido Univ., [3]Far East Geological Inst. FEB RAS, Vladivostok, Russia, [4]Grad. School of Bioagr. Sci., Nagoya Univ., [5]National Inst. of Polar Research, [6]Inst. for Biol. Problems of Cryolithozone SB RAS, Yakutsk, Russia, [7]Faculty of Earth Env. Sci., Hokkaido Univ.

The Arctic has a large amount of organic carbon accumulated in the soil. If the enhanced warming under the Anctic amplification leads to higher soil temperature or deepening of the active layer, emission of greenhouse gases, i.e. CO_2 and CH_4 can increase. The decomposition rate of organic matter, which is an important factor of CO_2 and CH_4 emission, depends not only on the quantity of organic matter, but also on that quality. In this work, surface soils from the lowland of Indigirka river in Northeastern Siberia were incubated at constant temperatures (5, 10 ℃) to evaluate the production rates of CH_4 and CO_2 and to know the degradability of the soil organic matter.

The study site is around Chokurdakh (70.62 N, 147.90 E) located in the continuous permafrost of Eastern Siberia and situated in the boundary of tundra and taiga. Surface soil layers (ca. 10-60 cm deep) were sampled at 7 points of a drier mound with larch trees and of wetter areas with sedges and *Sphagnum spp.*. Besides thawed layers (10, 20, 30 cm deep) sampled in July were incubated at Chokurdakh for 8 days anaerobically, frozen soil layers sampled in the early summer of June (13-62 cm) were incubated in Japan for 34-42 days both anaerobically and aerobically. These soils include the active layer (ca. 20-50 cm) and the top of the permafrost of this region.

CH_4 production was not detected in the mound soils while CO_2 production was, suggesting areas with dry condition have few methanogens and will not produce CH_4 even if they turn into anaerobic condition. On the other hand, soils from wet areas produced CH_4 (0-0.88 μmol (g dry soil)$^{-1}$ day^{-1}) and the production as well as that of CO_2 was more active at the shallower layers, representing larger amount of labile organic matter. The rate of CH_4 production at 10 ℃ were found to be 0.9-1.1 times of that at 5 ℃ in the shallower layers (ca. 10-40 cm), while 1.9-3.3 times in the deeper layers (32-45 cm). It indicates that the temperature dependency of CH_4 production is higher in the middle to the bottom of the active layer than in the top layer.

Accurate snowfall measurement at Yakutsk, Russia

HIRASAWA, Naohiko[1*] ; SUGIURA, Konosuke[2] ; HOSAKA, Masahiro[3] ; MAXIMOV, Trofim[4]

[1]National Institute of Polar Research, [2]Center for Far Eastern Studies, University of Toyama, [3]Meteorological Research Institute, [4]Institute for Biological Problems of Chryolithozone

In association with global warming, the water cycle in the atmosphere also changes for every climatic region on the globe. In polar regions, change in snowfall turns in change in distribution of snow surface and snow cover period, which will drive the ice-albedo feedback process. In order to know the present condition of the water cycle of polar regions and to study the trajectory of the polar climate systems in future, we have to observe not only air property such as temperature but also hydrological property such as snowfall amount, snow depth and so.

In spite of the development in accurate measurements for air temperature, pressure, wind speed and direction, the accuracy of snowfall measurement is not sufficiently high. While heated raingauge is currently generally deployed all over the world, the capture rate of snow particles falls together with wind speed, e.g., around 0.5 of the rate at 5 m/s. It means we measure only a half of the true value of snowfall amount at 5 m/s. This effect has been known for long time as wind loss. Evaporation loss also is more important in the polar regions than the other regions because many snowfall events have the smaller amounts in the total and lower snowfall rates according to the lower-temperature condition in the polar regions. Now, the accurate measurement of snowfall amount is one of the top issues in polar climate science.

The purpose of this study is to measure the accurate snowfall amount in the Arctic region. Moreover, based upon the results, we intend to correct other data which are measured in other region and in past years and also contribute to improve climate model by provideing accurate snowfall data. This study deploys a disdrometer, which measures diameter and fall velocity for each particle and out put the statistics minutely. It is not affected by wind loss and evaporation loss. This presentation shows a snowfall event observed at Yakutsk in early winter of 2013/14.

Continuous measurements of the atmospheric O2/N2 ratio at Ny-Alesund, Svalbard

GOTO, Daisuke[1*] ; MORIMOTO, Shinji[2] ; AOKI, Shuji[2] ; NAKAZAWA, Takakiyo[2] ; MURAYAMA, Shohei[3]

[1]National Institute of Polar Research, [2]Graduate School of Science, Tohoku University, [3]National Institute of Advanced Industrial Science and Technology

Simultaneous observations of atmospheric O_2 (defined as O_2/N_2 ratio) and CO_2 concentrations provide valuable information about the global carbon cycle. For a better understanding of the global carbon cycle, several laboratories have developed precise measurement systems for the O_2/N_2 ratio and carried out systematic observations since the early 1990s. To elucidate the variations of the atmospheric O_2/N_2 ratio in detail and to contribute to a better understanding of the role of Arctic region on the regional and global carbon cycle, we developed a continuous measurement system using a differential fuel-cell O_2 analyzer, and then initiated systematic observation at Ny-Ålesund, Svalbard in November 2012, which is the first continuous observation in the Arctic region. The system is equipped with NDIR analyzer to measure CO_2 concentration simultaneously. The analytical precisions of O_2/N_2 ratio and CO_2 are estimated to be $\pm$1.4 per meg and $\pm$0.03 ppmv, respectively. Here, we will present observational results of the first year.

The O_2/N_2 ratio observed at Ny-Ålesund shows a clear seasonal cycle with peak-to-peak amplitude of about 120 per meg, which reaches a minimum in late March to early April and a maximum in August. On the other hand, the CO_2 concentration varies seasonally in opposite phase with the O_2/N_2 ratio, showing the amplitude of 16 ppm. Short-term variations on time scales of several hours to several days are also clearly seen. In winter, it is often observed that the O_2/N_2 ratio sharply declines in a short time, accompanied by an increase in the CO_2 concentration, and the low values last for several hours or days. The O_2:CO_2 exchange ratio defined as the slope of a linear regression line between the measured values of O_2/N_2 ratio and CO_2 range between -1.6 and -1.5 ppm/ppm, which are close to the average O_2:CO_2 exchange ratio expected from fossil fuel burning in Europe. The results of backward trajectory analysis indicated that the air masses arrived at Ny-Ålesund during the periods when such short-term variations were observed passed near or over Scandinavian Peninsula. Therefore, such a decline in the O_2/N_2 ratio is ascribed to transport of urban air influenced by human activities in Europe. In spring to summer, irregular fluctuations of O_2/N_2 ratio are often observed. The amplitude of such fluctuations reaches 50-60 per meg (corresponding to about 10-13 ppm). Similar fluctuations of CO_2 are also found in opposite phase with O_2/N_2 ratio. However, their amplitudes are 5 ppmv at most. The comparison of backward trajectories of air parcels with the distributions of marine biotic net primary production suggests that such fluctuations of O_2/N_2 ratio are closely related to O_2 emission due to marine biological activity near Norwegian Sea.

Geographical variations in formation process of cryoconite granules on Arctic glaciers

FUJISAWA, Yuta[1*] ; TAKEUCHI, Nozomu[1] ; NAGATSUKA, Naoko[2] ; UETAKE, Jun[2] ; MIYAIRI, Masaya[1]

[1]Graduate School of Science, Chiba University, [2]National Institute of Polar Research

The dark colored impurities deposited on the glacier ice are called cryoconite. Cryoconite is consisted of mineral particles, organic matter and microbes, including snow algae, cyanobacteria and bacteria. They usually form small spherical aggregates known as cryoconite granules. The spherical shape is maintained by filamentous cyanobacteria. The satellite images of Greenland ice sheet revealed that the dark colored bare ice surface has expanded recently and may have a big impact on the melting of ice. The darkening may be due to increase of cryoconite on the surface. Therefore, the understanding of the structure and formation process of the cryoconite granules is important for studies of the influence on the glacier ecosystem and mass balance of glaciers. In this study, we analyzed the structure and characteristics of cryoconite granules on Arctic glaciers and we clarified the differences in the formation process with the glaciers.

We analyzed the cryoconite samples collected on the northwestern part of the Greenland ice sheet, the Longyearbreen glacier of the Svalbard, the Suntar-Khayata glacier of the Siberia, the Gulkana glacier of the Alaska. We observed the cryoconite granules using a microscope in order to clarify the characteristic of the composition, the granule size. Furthermore, to observe inner structures, thin sections of cryoconite granules were made.

Microscopy of cryoconite granules revealed that their size and coloration differed among the glaciers. The size of granules was the largest for Svalbard followed by Siberia, Alaska, and Greenland. The coloration of cryoconite granules was brown for Svalbard, black for Siveria, gray for Alaska, and black to brown for Greenland. Cross section of the granules also showed the disticnct features. The granules from Greenland had mostly subgranules inside. The granules from Svalbard had some concentric layers of dense organic matter. The granules from Siberia had a large mineral particle inside. The granules from Alaska had no specific inner structure. These differences of cryoconite granules may reflect physical and/or chemical conditions of each glacier.

Development of a Palsa along the Denali Highway, Alaska

IWAHANA, Go[1*] ; UCHIDA, Masao[2] ; KONDO, Miyuki[2] ; YOSHIKAWA, Kenji[1] ; LARRY, Hinzman[1]

[1]University of Alaska Fairbanks, [2]National Institute for Environmental Studies

Palsa is a peaty permafrost mound distributing in continuous and discontinuous permafrost zones. Main mechanism of the development the mounds is frost heave by ice segregation of peat or mineral soil material. Upper part of palsa usually consists of peat and lower part of a core of alternating layer of segregated ice and mineral soil material. History of paleo-environment around the period of last glacial retrieve in surrounding area can be inferred from analysis of palsa cores and stratigraphy. Our target palsa was located along the Denali Highway, Alaska, and the mound was truncated during highway construction in 1957. The outcrop of palsa have been eroded away from the highway line about 20m partly exposing the internal structure. This permafrost mound was firstly introduced as palsa by Pewe in 1983, and from dating of basal peat, deglaciation of this area occurred at least about 10500 year BP. History of palsa development and environment change was reconstructed from results of analysis from 6.5m core and ground temperature.

Sr-Nd isotopic ratios of mineral dust in Arctic snow

NAGATSUKA, Naoko[1*] ; OGAWA, Yoshimi[1] ; GOTO-AZUMA, Kumiko[1] ; SUGIURA, Konosuke[2] ; ENOMOTO, Hiroyuki[1] ; YAMADA, Hironobu[1] ; NAKANO, Takanori[3]

[1]NIPR, [2]Toyama University, [3]RIHN

Snow and ice on glaciers contain various atmospheric depositions, such as soot and mineral dusts. These light-absorbing impurities can reduce surface albedo and affect melting of glaciers. Thus, it is important to understand how these impurities were supplied on glaciers.

Stable isotopic ratios of Sr and Nd provide a means of identifying sources of substances and can use for the dusts in snow because it requires low samples for analysis. In this study, we analyzed Sr and Nd isotopic ratio of the mineral dusts collected from snow in several Arctic regions (Mongol, Alaska, and Greenland).

The Sr and Nd isotopic ratios of mineral dusts in Arctic snow showed geographical variations among the sampling sites. The ratios of dust collected from snow in Mongol showed higher Sr and lower Nd values, while those of Greenland were higher Sr and lower Nd values, and were close to the ratios that have been reported in loess, desert sand, soil, or moraine around each region. This result indicates that mineral dusts in snow on the two sampling sites were mainly derived from surrounding regions. On the other hand, the isotopic ratios of dust in snow of Alaska were close to those of deserts in Kazakhstan and Taklamakan Desert, suggesting that the mineral dusts originated from such further deserts were likely to be long-range transported to Alaska.

Intercomparison of Arctic atmospheric reanalysis data: Deriving observation-based forcing data for terrestrial models

MORI, Junko[1*] ; SAITO, Kazuyuki[2] ; MIYAZAKI, Shin[1] ; SUEYOSHI, Tetsuo[2] ; IIJIMA, Yoshihiro[2] ; HAJIMA, Tomohiro[2]

[1]National Institute of Polar Research, [2]Japan Agency for Marine-Earth Science and Technology

The goals of the modeling group in the terrestrial research project of the GRENE Arctic Climate Change Research Project (GRENE-TEA) are to a) feed to the CGCM research project for the possible improvement of the physical and ecological processes for the Arctic terrestrial modeling (excl. glaciers and ice sheets) in the extant terrestrial schemes in the coupled global climate models (CGCMs), and b) lay the foundations of the future-generation Arctic terrestrial model development.

In GTMIP (GRENE-TEA Model Intercomparison Project), we utilize the GRENE-TEA site observations to drive and validate the participating models. However, the observation data are prone to missing or lack of the necessary variables or parameters to drive the model. Therefore, we create continuous forcing data in the following manner: First, we create 30-year hourly time series (version 0; v0) of 7 meteorological components from the closest point data of the reanalysis products (a model-based dataset for the sub-monthly variations, and the observation-based CRU for the monthly). Then, v0 is merged with the observation data to create site-fit continuous data (v1) for each GRENE-TEA site. Use of this v1 expects to reduce the systematic biases in the input data in comparing the model outputs with the site observations, to delineate the variations among the models.

So far several atmospheric reanalysis datasets, for example NCEP-NCAR or JRA-55 are available as model input data. In this study, six atmospheric reanalysis datasets are compared in terms of the climatic reproducibility in the region north of 60^{o}N to select the one to be used for constructing the v0 data. The compared datasets are ERA Interim, JRA-55, MERRA, NCEP/NCAR Reanalysis 1, NCEP-DOE Reanalysis 2, and NCEP-CFSR. The CRU dataset is used as a representative of the ground-level observations. We take air temperature at 2m high and precipitation as the key parameters representing the climate condition.

Automatic measurement of gas emission/uptake of Alaskan permafrost soils

YONEMURA, Seiichiro[1] ; UCHIDA, Masao[2] ; KONDO, Miyuki[2*]

[1]NIAES, [2]NIES

The release of carbon from the decomposition of organic matters in permafrost soils are very important for the acceleration of global watming . We applied our dynamic system to Alaskan soils and measured temperature dependence of gas (CO2, CH4, N2O, NO, H2, CO) emission/uptake. The Four core samples were placed on petri-dishes which were put into chambers where temperature was controlled. CO2 emission from soils showed variations different from sample to sample. Even at -5C, CO2 emissions were observed. From the time series of CO2 emission rates, we estimated Q10 values. Q10 values were similar between 5-15C and 15 and 25C. Some soils also temperature-dependently emit NO, CO and N2O.

Boreal forest and tundra are the major ecosystems in the northern high latitudes and represent one of the largest reservoirs of carbon over terrestrial ecosystems in the world. Most of the carbon is stored in permafrost where frozen organic matter is protected from decomposition due to biotic activity in the underlying soil. The surface humus layers that should work as the protective layers insulate the permafrost soil far away from the effect of climate warming. Hence, the removal of protective layers by natural fire episodes increases the vulnerability of permafrost to thaw, and the carbon stored in permafrost to decomposition under climate warming in the near future. To elucidate effects of fire severity and temperature sensitivity on the soil carbon storage of boreal forest and tundra ecosystems in Alaska, we conducted simulations using the Physical and Biogeochemical Soil organic carbon Dynamics Model (PB-SDM), which consists of meteorologically-relevant land surface model and soil organic carbon dynamics model. The PB-SDM model of fire severity, designed from the analysis of the field observations, describes the effects of fire characteristics in frequency and size on the reduction of the soil organic layer. The simulation captured realistic annual variations in soil organic carbon storage and thickness in boreal forest and tundra ecosystems individually by finding optimal model parameters in terms of the frequency and size of fire events and temperature sensitivity. The result reveals that our model can be used for predicting soil carbon storage in boreal forest and tundra ecosystems at regional scales where fire regimes play a key role in the soil organic carbon storage as affected by climate warming.

Methane Oxidation Potential of Arctic Wetland Soil of a Taiga-Tundra Ecotone in Northeastern Siberia

MURASE, Jun[1*] ; SUGIMOTO, Atsuko[2] ; SHINGUBARA, Ryo[3] ; MAXIMOV, Trofim C.[4]

[1]Grad. Sch. Bioagr. Sci., Nagoya Univ., [2]Fac. Earth Environ. Sci., Hokkaido Univ., [3]Grad. Sch. Environ. Sci., Hokkaido Univ., [4]Inst. Biol. Problems of Cryolithozone

Arctic wetlands are significant sources of atmospheric methane and the observed accelerated warming of the arctic causes increased methane formation in water-saturated tundra soil with deepened permafrost thawing. Methane oxidation is regarded as the key process to regulate methane emission from wetlands. In this study we determined the potential methane oxidation rate of the wetland soils of a Taiga-Tundra transition zone in Northeastern Siberia with special reference of the spatial heterogeneity and response to environmental parameters. The surface peat soil samples (0-10 cm) were collected in the summer of 2012 and 2013 from depressions that were covered with tussocks of sedges and Sphagnum spp. and mounds vegetated with moss and larch trees. The potential methane oxidation rate was estimated by a bottle incubation experiment in which homogenized soil samples were incubated with methane at the initial concentration of 0.5-0.8 %v/v. Soil samples from the mounds showed no detectable methane oxidation, whilst the soils collected from depressions exhibited active methane oxidation with no lag. The potential methane oxidation rates at 15 oC were of 270 and 190 nmol h^{-1} g^{-1} dw in the moss- and sedge-dominated zones, respectively. Methane oxidation was active over the depths including the water-saturated anoxic layers, suggesting the resilience of methane oxidizing bacteria. The maximum methane oxidation rate was recorded in the layer above the water-saturated layer: the surface (0-2cm) layer in the sedge-dominated zone and in the middle (4-6 cm) layer in the moss-dominated zone. Temperature-dependent methane oxidation was observed at the range of temperature from 0 to 15 oC. The estimated threshold temperature of methane oxidation was -4 to -11 oC, which suggested methane oxidation at subzero temperatures. Treatment with inorganic nutrients and black carbon did not affect the potential methane oxidation rate.

Online visualization tool ”VISION” on Arctic Data archive System (ADS)

SUGIMURA, Takeshi[1*] ; YABUKI, Hironori[2]

[1]National Institute of Polar Research, [2]Japan Agency for Marine-Earth Science and Technology

We are constructing an online archive system of data about Arctic research that many researchers and institutes have collected, which is named ADS (Arctic Date archive System). We aim at that the many researchers specializing in the various fields of the Arctic research - such as atmosphere, ocean, land, physical and chemical analysis and computer simulation, etc - can become to mutually use their data across their own fields through our data archive. For this purpose, it is necessary for us not only to manage data systematically, but to build the system where researchers can easily grasp the contents of the data archive.

However, it is difficult to exactly understand contents of the data that others made. The researchers try to understand the contents of the data of their own fields and succeed in many cases. But it is not easy for them even to judge the contents of the data out of their fields. Therefore, we developed GUI-based online data visualization application named “ VISION ”, which all the researchers engaged in the Arctic research can easily operate. It can be expected that “ VISION ” facilitates an understanding the data of the various fields of the Arctic research among the researchers, then the researchers become also use the data out of their own fields.

We will introduce a structure and function of “ VISION ” and demonstrate an operation of this system.

Shrinking glaciers in Suntar Khayata, east Siberia

KADOTA, Tsutomu[1*] ; SHIRAKAWA, Tatsuo[2] ; KUSAKA, Ryo[2] ; TAKAHASHI, Shuhei[2] ; GALANIN, Andrey[3] ; FEDOROV, Alexander[3] ; ENOMOTO, Hiroyuki[4] ; OHATA, Tetsuo[1] ; YABUKI, Hironori[1]

[1]Japan Agency for Marine-Earth Science and Technology, [2]Kitami Institute of Technology, [3]Melnikov Permafrost Institute, [4]National Institute of Polar Research

Introduction

Since Northern Hemisphere high latitude regions are noticeable trend of global warming and climate change, appearance of its impact is interest. Northeastern Eurasia is area of blank of observational research. One of a few regions studied in the past is Suntar Khayata in east Siberia, where Russian scientists carried out wide range of study during IGY (1957-1959).

Study area

Suntar Khayata region, located in the latitudes between 62and 63 degree north and in the longitudes between 140.7 and 142 degree east, forms a divide between the Arctic Sea and the Sea of Okhotsk. Oymyakon depression, known as the cold pole in the Northern Hemisphere, is located to the northeast. Glacier inventory of this region was prepared based on the aerial photographs taken in 1944-1947 (Koreisha, 1963). Total number and area of glaciers were 205 and 206.28 km^2. Three glacierized region are recognized, namely Northern massif, Central massif and Southern massif. The highest elevation of each massif is 2959 m, 2933 m and 2944 m.

Glaciers observed are No. 29 to 33 in Northern massif including No. 31 which was intensively studied during IGY.

Observation

We carried out glaciological observations such as mass balance (stake method), ice thickness measurement (radio-echo soundings), and topographic survey (DGPS) in July/August in 2012 and 2013. Automatic weather stations were also set on/around the glaciers.

Results

Glacier-wide mass balance in 2012/2013 was -1.04 m w.e. for a glacier complex (Glaciers No. 29, 30 and 31). This value shows more negative state than those in 1957-1959.

We generated DEMs of surface and bed of the Glacier No. 31 using ice thicknesses obtained by radio-echo soundings and surface elevations by GPS survey, then we estimated the volume of the glacier to be 0.20 km^3 (area: 3.02 km^2, mean thickness: 62 m). Ice thicknesses in its tongue reduced by 110-60 m (terminus to upstream) since 1957.

Based on multi-temporal aerial and satellite imagery, 18 investigated glaciers reduced in area by approximately 36% from 1945 to 2011.

Concluding remark

Summer (July-August) air temperature observed on the glacier in 2012 and 2013 were higher than those in 1957-1959, which brought about more negative mass balance than those in 1957-1959. Superimposed ice formation was also very limited in 2012/2013. This resulted in disappearance of accumulation area. Reconstruction of long-term mass balance history is present target.

Acknowledgement

This study has been jointly carried out by JAMSTEC (Northern Cryosphere Research Program) and GRENE Arctic Climate Change Research Project (The role of arctic cryosphere in global change).

Effect of snow depth on pan-Arctic permafrost thermal regimes

PARK, Hotaek[1*] ; FEDOROV, Alexander[2] ; WALSH, John[3]

[1]JAMSTEC, [2]Melnikov Permafrost Institute, Yakutsk, Russia, [3]International Arctic Research Center, University of Alaska Fairbanks

This study quantitatively evaluated how insulation by snow depth (SND) affected the soil thermal regime and permafrost degradation in the pan-Arctic area, and more generally defined the characteristics of soil temperature (T_{SOIL}) and SND from 1901-2009. This was achieved through experiments performed with the land surface model CHANGE, to assess sensitivity to winter precipitation as well as air temperature. Simulated T_{SOIL}, active layer thickness (ALT), and SND were generally comparable with in-situ or satellite observations at large scales and over long periods. Northernmost regions had snow that remained relatively stable and in a thicker state during the past four decades, generating greater increases in the T_{SOIL}. Changes in SND have led to changes in the thermal state of the underlying soil, which is strongly dependent on both the magnitude and the timing of changes in snowfall. Simulations of the period 2001-2009 revealed significant differences in the extent of near-surface permafrost, ranging from 15.6 to 18.7 million km^2. This spread was the result of differences in the model$'$s treatment of meteorology. Permafrost loss was greater when SND increased in the autumn rather than in the winter, due to insulation of the soil from the early cooling. Simulations revealed that T_{SOIL} tended to increase over most of the pan-Arctic from 1901-2009, and this increase was significant in northern regions, especially in northeastern Siberia where SND is responsible for 50% or more of the changes in TSOIL at a depth of 3.6 m. In the same region, ALT also increased at a rate of approximately 2.3 cm per decade. The most sensitive response of ALT to changes in SND appeared in the southern boundary regions of permafrost, in contrast to permafrost temperatures within the 60^o-80^oN region, which were more sensitive to changes in the SND. Finally, the modeling performed in this study suggests that snow cover contributes to the warming of permafrost in northern regions and could play a more important role under conditions of future Arctic warming.

Fixed-point observation of diatom biocoenosis and water mass condition in the northern Chukchi Sea during September 2013

ONODERA, Jonaotaro[1*] ; NISHINO, Shigeto[1]

[1]JAMSTEC-RIGC

In order to estimate the relationship between diatom flora and water mass condition in the northern Chukchi Sea, fixed-point ocean observation was conducted at Station 41 (72.45N, 168.24W, 56 m water depth) by R/V Mirai (Cruise MR13-06) in 10-25 September 2013. The optical equipment named ”Multi-wave length excitation fluorescence photometer (Multi-Exciter)” was applied with CTD observation for the estimation of chlorophyll concentration in each major phytoplankton groups (diatom, green algae, and blue algae). Chlorophyll concentration gradually increased with the weakening of summer stratification by intensified sea-surface wind. The Multi-Exciter showed the clear increase of diatom in upper water column, which were also suggested by size-fractionated analysis of chlorophyll concentration and microscopic observation by scanning electron microscope and light microscope. However, the increase of diatom cell abundance was minor compared to the increase of total chlorophyll concentration. The dominance of large diatom genus *Proboscia* and the increased chlorophyll concentration in one diatom cell were the main causes on the increase of total chlorophyll concentration. The 3-6 fold increase of chlorophyll concentration within 6 hours was rarely observed around chlorophyll maximum layer during the middle observation period, which is probably explained by not only improved habitat environment for diatom but also movement of water masses such as lateral input of high chlorophyll waters.

Knowledge on past variability of sedimentary organic carbon in the Arctic Ocean is important to assess natural carbon cycling and transport processes related to global climate changes. However, the late Pleistocene oceanographic history of the Arctic is still poorly understood. In the present study we show sedimentary records of organic carbon(TOC, δ13C), CaCO3, benthic and planktonic foraminiferal δ18O, BIT index for terrestrial organic carbon input, IP25 for sea ice condition, and the coarse grain size fraction. The 8m length sediment core was retrieved in the northern Northwind Ridge in the far western Arctic Ocean, during the MR08-05 cruise by R/V Mirai. An age model based on oxygen isotope stratigraphy, radiocarbon dating and lithological constraints suggests that the core records paleoenvironmental changes of the last 155 kyr. In this conference, we discuss presented millennial scales records of glacial erosion, intermediate water and/or surface water and sea ice variabilities during cold/warm episodes of the last two glacial interglacial cycles in the light of ice sheet and ocean-atmosphere dynamics.

What the recent international field campaign in and around the Indian Ocean has advanced our knowledge of the MJO?

YONEYAMA, Kunio[1*]

[1]JAMSTEC

A coordinated international field experiment with special focus on the convective initiation mechanism study of the Madden-Julian Oscillation (MJO) took place in and around the central equatorial Indian Ocean from October 2011 through January 2012. This campaign consisted of several projects including CINDY2011 (Cooperative Indian Ocean experiment on intraseasonal variability in the Year 2011), DYNAMO (Dynamics of the MJO), AMIE (Atmospheric Radiation Measurement program - MJO Investigating Experiment), and LASP (Littoral Air-Sea Process). More than 70 institutes/universities from 16 countries joined the campaign. During a four-month intensive observing period from October through January, three MJO events were observed. It is worth noting that while it is clear to identify three events (late October, late November, and late December) from the time-longitude cross section of outgoing long-wave radiation data along the equator, the most popular MJO identification method - Real-time multivariate MJO Index introduced by Wheeler and Hendon (2004) - could not capture the December event.

While the vertical stepwise moistening which was trapped around trade inversion and 0degC level were confirmed from the equatorial sounding data as previously reported, it was emphasized that lateral transport of moisture and dry air from the Southern Hemisphere as well as westward-propagating disturbances from the Indonesian Maritime Continent were also keys. Several topics from published works during past 2 years after the campaign will also be introduced to indicate what we expected and what are not.

Mesoscale Convective Complex Activities over Indian Ocean and Their Effects on Convections Over Sumatera Island

-, Trismidianto[1*] ; HADI, Tri wahyu[2] ; KODAMA, Yasu-masa[1]

[1]Meteorological Laboratory, Graduate School of Science and Technology, Hirosaki University, [2]Departement of Earth Sciences, Faculty of Earth Sciences and Technology, Institut Teknologi Bandung

Effects of Mesoscale Convective Complexes (MCC) over Indian Ocean on convections over Sumatera Island have been investigated using Multi-functional Transport SATellite (MTSAT) infrared (IR1) imageries, Tropical Rainfall Measuring Mission (TRMM) rainfall data and Cross-Calibrated Multi-Platform (CCMP) surface wind data of 10-year period (2000-2009). Occurrences of MCC were identified using an algorithm that combines criteria of cloud coverage, eccentricity, and cloud lifetime. This study begins with a case study on 16 to 17 August 2005 and 27 to 28 October 2007 to show the evolution of MCC, we found the development phase of MCC was accompanied by surface wind convergence, while wind divergence was clearly seen below decaying MCC. Following the decay of MCC, convective activities were observed in the surrounding regions by the presence of a new convective cell around the MCC, indicating the role of cold pool mechanism. The new convective cell was generated from cold pool affect convective clouds in the surrounding area and propagate to over Sumatra Island so causing extreme rainfall over Sumatra.

The correlation between MCC and convection over Sumatera was further investigated by performing composite analysis using more samples of MCC events. During the 10-year period, about a number of 553 MCC events have been identified over Indian Ocean. However, it is of interest to that MCC events tend to occur with significantly higher frequency during the monsoon transition season of March- April-May (MAM) period. Available data suggest that the life cycle of MCC over Indian Ocean is about 12 to 15 hours. Results of composite analyses confirmed that the MCC have significant influence on the development of cloud convection over Sumatera Island by means of cold pool propagation mechanism. This seems to imply that weather observations over the western Indian Ocean are crucial for rainfall prediction in Sumatera regions.

Observed moisture variations associated with shallow convection

BELLENGER, Hugo[1*] ; KATSUMATA, Masaki[1] ; YONEYAMA, Kunio[1] ; NISHIZAWA, Tomoaki[2] ; YASUNAGA, Kazuaki[3] ; SHIROOKA, Ryuichi[1]

[1]JAMSTEC, [2]NIES, [3]University of Toyama

The variability of tropospheric moisture is a key feature of tropical climate. In particular, the importance of moisture variations due to convective transport is still to be quantified on a variety of spatial and temporal scales. For instance, there is a debate on the importance of moisture convective transport in preconditioning the atmosphere prior to deep convection development associated with the Madden–Julian Oscillation (MJO). We use here high frequency observations of humidity and convection in the Indian Ocean by lidars and radars on board the R/V Mirai during the CINDY/DYNAMO campaign. Significant moisture variations on the scale of few hours are observed within the first first kilometers of the atmosphere in association with shallow convective and congestus clouds. We then compare these local tendencies with large–scale ones and discuss the potential importance of convective transport by convection in the moisture budget during the transition from convectively suppressed to convectively active periods.

In-situ observed detailed temperature profile in surface 10-meter layer over the tropical western Pacific

KATSUMATA, Masaki[1*] ; BELLENGER, Hugo[1] ; YONEYAMA, Kunio[1]

[1]JAMSTEC

The oceanic thermal stratification in the first meters impacts significantly the energy exchanges between the atmosphere and the ocean by modulating the skin Sea Surface Temperature (SST). A thermistor chain was deployed from a research vessel to continuously measure the temperature profile in the ocean first 10 meters during 17 days in June 2013 in the tropical western Pacific (12N-135E). A clear diurnal cycle was captured with daytime warming in the first meters of the ocean that gradually decrease and deepened during the evening. In addition, a 0.5K-cooling event of the first meter with duration of about 3 hours was also captured during the passage of precipitating cloud system. By utilizing meteorological data from on-board instruments, we asses the relative importance of precipitation and accompanying cold pool in this cooling event.

The cooperative Indian Ocean experiment on intraseasonal variability in the Year 2011 (CINDY2011) was conducted to capture atmospheric and oceanic characteristics of the Madden-Julian Oscillation (MJO) in the central Indian Ocean from late 2011 to early 2012. During CINDY2011, the research vessel (R/V) MIRAI stayed at 8 ^{o} S, 80.5 ^{o} E for two months during the special observing period (SOP). Intraseasonal convection associated with the MJO was organized in the central Indian Ocean in late October and late November during the SOP. In the middle of November, both sea surface temperature (SST) and mixed layer temperature decreased suddenly when cold low salinity water intruded into the upper layer around the R/V MIRAI. This intrusion was accompanied by a surface current change from southwestward to westward/west-northwestward associated with the passage of the annual oceanic downwelling Rossby wave. The mixed layer heat budget analysis shows that horizontal advection plays an important role in the abrupt cooling whereas the net surface heat flux cannot account for the cooling. This is an interesting result because the associated downwelling Rossby wave is usually considered to increase SST through a reduction of entrainment cooling. In addition, for the second MJO event convection was activated around 20 November over the central north and equatorial Indian Ocean but not in the south. It is suggested that the cooler surface waters (as seen at the location of the R/V MIRAI) tended to suppress the initial atmospheric convection, resulting in the lagged convective onset in the end of November over the central south Indian Ocean.

Modulation of Equatorial Turbulence by Tropical Instability Waves

INOUE, Ryuichiro[1*] ; LIEN, Ren-chieh[2] ; MOUM, James[3] ; PEREZ, Renellys[4] ; GREGG, Mike[2]

[1]JAMSTEC, [2]University of Washington, [3]Oregon State University, [4]University of Miami

Strong modulation of turbulent mixing by a westward propagating Tropical Instability Wave (TIW) was observed during October and November 2008 on the equator at 140^{o}W in the stratified shear layer between the equatorial undercurrent (EUC) and the surface mixed layer. At these depths, the unique deep diurnal-cycle mixing in the stratified layer under the equatorial cold tongue was observed with nighttime turbulent mixing a factor of 10 greater than during daytime. The turbulent kinetic energy dissipation rate, ϵ, was O(10^{-6})Wkg^{-1}, and the turbulent heat flux was ˜500 Wm^{-2}, at least 5-10 times greater than previously observed at the central equatorial Pacific. Turbulence mixing varied significantly during the four distinct phases of the meridional flow associated with the TIW: steady northward (˜0.6 ms^{-1}), northward-to-southward transition, steady southward (˜-0.6 ms^{-1}), and southward-to-northward transition. During the northward-to-southward transition, we observed the largest values of reduced shear squared (Sh^2?4N^2), where Sh^2 is the total shear squared and N^2 the buoyancy frequency squared, the thickest nighttime surface mixed layer, the deepest penetration of the deep-cycle turbulence, and the largest turbulent heat flux and largest integrated ϵ in the deep-cycle layer. During steady southward flow, the depth of the bases of the nighttime surface mixed layer and of the deep-cycle layer were shallowest. For the first time, a 50-m-thick layer of strong turbulence was observed immediately above the EUC core during the northward-to-southward and steady southward phases. The average ϵ exceeded 10-^{6} Wkg^{-1}, the eddy diffusivity was ˜10^{-3} m^{2}s^{-1}, and the turbulent heat flux was ˜500 Wm^{-2}. It is likely that to accurately parameterize mixing in the central equatorial Pacific, numerical models must properly simulate not only the enhancement of mixing associated with TIWs but also the variability of mixing within individual TIWs. In this talk, some results from the extensive (from November 2008 to February 2009) mooring data set, comparisons with a general circulation model, and details of mixing events will also be shown.

Why is initialization of heat content anomalies in the tropical Indian Ocean difficult in a CGCM with SST-nudging?

KOHYAMA, Tsubasa[1] ; TOZUKA, Tomoki[2*]

[1]University of Washington, [2]The University of Tokyo

We have evaluated oceanic initial conditions in the tropical Indian and Pacific Oceans prepared by a coupled general circulation model (CGCM) with a sea surface temperature (SST)-nudging scheme. It is shown that the heat content anomalies in the upper 150 m are generated extremely well in the Pacific even though only the SST data is incorporated. In contrast, the upper ocean heat content anomalies produced by the model have negative correlation coefficients over vast areas of the tropical Indian Ocean. We propose that this is due to a difference in the SST-outgoing longwave radiation (OLR) relationship between the Indian and Pacific Oceans; the use of SST-nudging generally assumes that correlation coefficients between SST and OLR are negative, but this is not necessarily true. The correlation coefficients between SST and OLR anomalies are negative in the central to eastern equatorial Pacific, and this feature is well reproduced in the model. As a result, equatorial zonal wind anomalies are well captured by the model, and forced equatorial Kelvin and Rossby waves are accurately reproduced. On the other hand, the model cannot capture the observed positive correlation coefficients in the eastern equatorial Indian Ocean, particularly from January to April. As a result, equatorial zonal wind anomalies tend to have an opposite sign and induce equatorial Kelvin and Rossby waves with a wrong sign. The positive correlation between SST and OLR is an outcome of remote influence, but this is more difficult to simulate in an atmospheric general circulation model (AGCM) and a CGCM with strong SST nudging, in which local air-sea interaction is not explicitly allowed. Since the results presented in this study is based on a single model, it will be interesting to check skills of other models in initializing the upper ocean heat content with an SST-nudging scheme.

Two flavors of the Indian Ocean Dipole

ENDO, Satoru[1*] ; TOZUKA, Tomoki[1]

[1]Graduate School of Science, The University of Tokyo

The Indian Ocean Dipole (IOD) is known as a climate mode in the tropical Indian Ocean accompanied by negative (positive) sea surface temperature (SST) anomalies over the eastern (western) pole and easterly wind anomalies along the equator during its positive phase. However, the western pole of the IOD is not always covered by positive SST anomalies throughout the region. For this reason, the IOD is further classified into two types in this study based on SST anomalies in the western pole. The first type is close to the canonical IOD with negative (positive) SST anomalies in the eastern (central to western) tropical Indian Ocean. The second type, on the other hand, is associated with negative SST anomalies in the eastern and western tropical Indian Ocean and positive SST anomalies in the central tropical Indian Ocean. Based on a composite analysis, it is found that easterly wind anomalies reach the east coast of Africa in the first type, and as a result, positive rainfall anomalies are observed over East Africa. Also, due to the basin-wide easterly wind anomalies, the first type is accompanied by strong sea surface height (SSH) and thermocline depth anomalies. In contrast, zonal wind anomalies converge in the central tropical Indian Ocean in the second type, and no significant precipitation anomalies are found over East Africa. Also, only weak SSH and thermocline depth anomalies are seen during the second type, because equatorial downwelling anomalies induced by westerly wind anomalies in the west are counteracted by equatorial upwelling anomalies caused by easterly wind anomalies in the east. Due to the above difference in oceanic anomalies, the first type is stronger and lasts longer than the second type.

Evolution and mechanism of the positive Indian Ocean Dipole event in 2012

TANIZAKI, Chiho[1*] ; TOZUKA, Tomoki[1]

[1]Graduate School of Science, The University of Tokyo

Evolution and mechanism of a peculiar positive Indian Ocean Dipole (IOD) event that occurred in 2012 are examined. In contrast to the normal IOD event, which starts to develop in late boreal spring, peaks in fall, and decays in winter, the 2012 IOD event was initiated in July, peaked in August, and decayed quickly in fall. Although the normal IOD event is associated with shallower thermocline in the eastern equatorial Indian Ocean, it was deeper than normal in 2012 and this may have delayed the onset of the IOD in this year. For quantitative discussions, mixed layer temperature balance of the eastern pole of the IOD is calculated using outputs from an ocean general circulation model. In agreement with past studies, negative sea surface temperature anomalies in the eastern pole are generated mainly owing to anomalous cooling by the vertical terms (i.e. entrainment and turbulent vertical diffusion) during the normal IOD. However, anomalous cooling by the surface heat flux term played the dominant role in the development of the eastern pole in 2012, and the vertical terms opposed the anomalous cooling. The anomalous cooling by the surface heat flux term is due to stronger cooling by latent heat flux. Also, warming of the surface mixed layer by the climatological shortwave radiation was suppressed owing to deeper mixed layer.

Interannual Variability in SST off Bangladesh

NAGURA, Motoki[1*] ; TERAO, Toru[2] ; HASHIZUME, Masahiro[3]

[1]JAMSTEC, [2]Kagawa University, [3]Nagasaki University

Oceanic variability off Bangladesh is one of the environmental factors which can impact on the local community. For example, Hashizume et al. (2011) pointed out that the number of cholera patients increases in Dhaka, which is populated by 15 million people and the largest city in Bangladesh, when sea surface temperature (SST) off Bangladesh rises. This study examines interannual SST variability in the coastal regions off Bangladesh, which has not attracted much attention in climate sciences so far. We detect a significant interannual SST variability off Bangladesh in two different satellite datasets (NOAA OI SST and TMI SST) and a high-resolution ocean general circulation model driven by a reanalysis dataset. The SST variability is trapped near the coast, amounts to 0.5 to 1.0 degrees Celsius in magnitude, and peaks in the boreal winter. The two observational datasets and the model results show consistency in the spatial and temporal patterns of SST variability, which gives credibility to the detected phenomenon. A statistical analysis shows that SST off Bangladesh tends to be high in the year next to El Nino and in the year of negative Indian Ocean Dipole events, suggesting those climate modes as possible drivers. We are conducting a mixed layer heat budget analysis using the model output, a preliminary result of which shows that a thick barrier layer caused by the freshwater supply from the Ganges plays a role in the generation of the SST variability. Details of the mixed layer heat budget analysis will be reported in the meeting.

A drastic change in predictability of precipitation off the west coast of Australia after late 1990s

DOI, Takeshi[1*] ; BEHERA, Swadhin[1] ; YAMAGATA, Toshio[1]

[1]JAMSTEC APL

Global warming and natural decadal variability after late 1990s strongly warm the coastal ocean off West Australia, which drastically changed climate dynamics there. The warm ocean drives precipitation locally there after the late 1990s, while the local atmospheric variability or the remotely forced atmospheric bridges mainly controlled the local precipitaiton variability before that. By virtue of that, precipitation predictability off West Australia on a seasonal time scale is also drastically changed after late 1990s; austral summer precipitation off West Australia is significantly predictable 5 months ahead after late 1990s, while there is no predictability of that in 1980s and early 1990s. Although the high prediction skill of precipitation off West Australia is useful for its early warning to extreme events and reducing their damages, the extreme event itself might increase due to global warming and decadal climate variability through a local air-sea feedback.

Interdecadal Amplitude Modulation of ENSO and its Impacts on TPDV

OGATA, Tomomichi[1*]

[1]Faculty of Life and Environmental Sciences, University of Tsukuba

ENSO is a major climate mode in the tropical Pacific, and its interdecadal variabilities in ENSO characteristics (e.g. amplitude, propagation, period) are investigated as responses to background mean state change. On the other hand, tropical Pacific decadal variability (TPDV) is known as a major decadal-interdecadal variability, and coupled-GCM has revealed that ENSO also acts to TPDV. This study shows that the GFDL coupled-GCM (GFDL-CM2.1) also captures significant relationship between ENSO amplitude modulation and TPDV in interdecadal timescale. Furthermore, importance of ENSO rectification on TPDV is investigated by OGCM sensitivity experiments.

The role of interaction between the Pacific and the north Atlantic Oceans in the prediction of ENSO

YAMAZAKI, Kuniko[1] ; IMADA, Yukiko[1*] ; WATANABE, Masahiro[1]

[1]Atmosphere and Ocean Research Institute, the University of Tokyo

Observational and climate modelling studies indicate a close link between the north tropical Atlantic (NTA) sea surface temperature anomalies (SSTA) and the El Nino-Southern Oscillation (ENSO). An El Nino peak in boreal winter is followed by a warming of the NTA SSTA in the subsequent spring, which in turn leads to a La Nina in the following autumn/winter. Using the seasonal prediction system based on the atmosphere and ocean general circulation model (AOGCM) MIROC5, we conducted an ensemble of hindcast experiments from 1979 to present, in which the transition from El Nino to La Nina in 1997-1998 was successfully predicted. We also conducted a series of accompanying sensitivity experiments targeted at the transition event in 1997-1998, in which the NTA or equatorial Pacific air-sea interactions were decoupled. We found that NTA SSTA plays an important role in increasing the skill in predicting the following La Nina event. We also found that the preceding particularly-large El Nino SSTA and the associated atmospheric bridge are essential for the generation of NTA SSTA of the observed magnitude.

Important factors for long-term change in ENSO transitivity

OHBA, Masamichi[1*]

[1]CRIEPI

El Nino and La Nina exhibit significant asymmetry in their duration. El Nino tends to turn rapidly into La Nina after the mature, while La Nina tends to persist for up to 2 years. Reconstructed historical sea surface temperatures (SST) show a significantly increase in the intensity of El Nino-Southern Oscillation (ENSO) asymmetry, particularly El Nino transitivity, during the last six decades. Atmospheric observational data have shown that the relationship between El Nino and surface zonal wind anomalies over the equatorial Western Pacific (WP) has strengthened, and anomalous WP easterlies have appeared after the 1970s climate regime shift. To investigate the dependency of ENSO transitivity on its amplitude, a suite of idealized experiments using an atmospheric general circulation model (AGCM) is performed by imposing historical SST and 12 different ENSO-related SST anomalies exhibiting equal spatiotemporal distribution but different amplitude. Our AGCM experiments show strong nonlinearity in the WP zonal wind against the amplitude of the warm phase.

Temporal variations of Mascarene High in austral summer and their causes, and influences on the SST field

OHISHI, Shun[1*] ; SUGIMOTO, Shusaku[1] ; HANAWA, Kimio[1]

[1]Department of Geophysics, Graduate School of Science, Tohoku University

Changes in intensity and longitudinal/latitudinal position of Mascarene High (MH) in austral summer (November-January) from 1951 to 2012 are investigated using NCEP-NCAR reanalysis dataset. We define the MH intensity and longitudinal/latitudinal position as sea level pressure (SLP) maximum within a region of [40E-120E, 50S-10S]. The intensity has an interannual variation on a dominant timescale of 3-4 years. The pressure variations associated with the intensity show annular and equivalent barotropic structures throughout the troposphere, which are similar to Southern Annular Mode (SAM). The intensity time series shows a significant correlation with the SAM index. Therefore, it is suggested that the MH intensity variation results from the SAM. The MH longitudinal position also shows an interannual variation on a dominant timescale of 5-6 years and the time series has no significant correlation with the intensity time series. The SLP anomalies associated with the longitudinal variation represent a dipole pattern, whose centers of action are located off the western Australia (WA) and off the south-eastern Madagascar Island (SEMI). The geopotential height anomalies in these regions have different vertical structures; those off the WA are confined from the sea surface to the middle troposphere, while those off the SEMI are distributed throughout the troposphere. In addition, the SLP anomalies averaged within these regions show no significant correlation. It is indicated that the SLP variations off WA are associated with El Nino Southern Oscillation (ENSO). On the other hand, the SLP changes off the SEMI have no relationship with the large-scale atmospheric variations such as SAM and ENSO.

The MH intensity variation forms southwest-northeast dipole pattern of sea surface temperature (SST) field, which resembles the Indian Ocean Subtropical Dipole (IOSD) pattern. In addition, the MH longitudinal changes also show the dipole pattern, which is shifted westward by 10 degrees in longitude compared to the SST pattern associated with the intensity variation. The correlations between the MH variations and IOSD index show significant values (0.39 for intensity and -0.57 for longitudinal position). Therefore, it is suggested that both the changes in the intensity and the longitudinal position cause the IOSD.

Role of tropical SST variability in the generation of subtropical dipoles

MORIOKA, Yushi[1*] ; MASSON, Sebastien[2] ; TERRAY, Pascal[2] ; PRODHOMME, Chloe[2] ; BEHERA, Swadhin[3] ; MASUMOTO, Yukio[4]

[1]JAMSTEC / RIGC, [2]LOCEAN-IPSL, Universite Pierre et Marie Curie, [3]JAMSTEC / APL, [4]Graduate School of Science, The University of Tokyo

Interannual variations of Sea Surface Temperature (SST) in the midlatitudes of the Southern Hemisphere play an important role in the rainfall variability over the surrounding countries by modulating synoptic-scale atmospheric disturbances. These are frequently associated with a northeast-southwest oriented dipole of positive and negative SST anomalies in each oceanic basin, referred to as a subtropical dipole. This study investigates the role of tropical SST variability on the generation of subtropical dipoles by conducting SST-nudging experiments using a coupled general circulation model. In the experiments where the simulated SST in each tropical basin is nudged to the climatology of the observed SST, the subtropical dipoles tend to occur as frequently as the case in which the simulated SST is allowed to freely interact with the atmosphere. It is found that without the tropical SST variability, the zonally elongated atmospheric mode in the mid-high latitudes, called the Antarctic Oscillation (AAO), becomes dominant and the stationary Rossby waves related to the AAO induce the SLP anomalies in the midlatitudes, which, in turn, generate the subtropical dipoles. These results suggest that the tropical SST variability may not be necessary for generating the subtropical dipoles, and hence provide a useful insight into the important role of the AAO in the midlatitude climate variability.

Mechanism of long-term change in the Indian Ocean subtropical dipole mode

YAMAGAMI, Yoko[1*] ; TOZUKA, Tomoki[1]

[1]Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo

The Indian Ocean subtropical dipole (IOSD) is a climate mode in the Southern Indian Ocean associated with negative sea surface temperature (SST) anomalies in the southeastern tropical Indian Ocean and positive SST anomalies in the southwestern part of the southern Indian Ocean during its positive phase. In this study, the long-term change in the IOSD is investigated for the first time using observational data and outputs from an ocean general circulation model. It is found that the frequency of the IOSD has become higher in the recent decade because of a decreasing trend in the mixed layer depth (MLD) over the southwestern pole in January and February. Positive (Negative) SST anomalies associated with the IOSD are generated when the mixed layer becomes anomalously shallow (deep) and the warming of the mixed layer by the climatological shortwave radiation is enhanced (suppressed). The thinner mixed layer in the recent decade amplifies this effect and even weak atmospheric forcing may trigger the IOSD. Based on a diagnosis of the Monin-Obukhov depth, we show that an increasing trend of surface heat flux is the cause of the decreasing trend in the MLD. On the other hand, it is found that the amplitude of the IOSD has become smaller. This is because the IOSD generally starts to develop in December, but the thicker mixed layer in December in the recent decade is unfavorable for its development. Also, the thinner mixed layer in January and February amplifies the negative feedback processes that damp the SST anomalies, as well as the positive effect on generating the SST anomalies. Since no long-term change in atmospheric forcing corresponding to that in the IOSD is observed, the long-term change in the MLD is essential in that of the IOSD.

Multiscale Interactions In The Genesis Of Tropical Cyclone Observed In PALAU2013

YOSHIOKA, Hiroaki[1*] ; FUDEYASU, Hironori[1] ; KATSUMATA, Masaki[2] ; YOKOI, Satoru[2] ; TSUJINO, Satoki[3] ; MASUDA, Ayumi[1]

[1]Yokohama National University Graduate School, [2]Japan Agency for Marine-Earth Science and Technology, [3]Hydrospheric Atmospheric Research Center, Nagoya University

To understand the formation of a tropical cyclone (TC), has long been a captivating subject at the frontier of science and remains challenging because of the complex multi-scale interactions involved. During the genesis stage, sustained convective activities, which may stem from a variety of processes in a favorable environment, develop into a surface mesoscale or synoptic vortex. The mesoscale processes in the genesis stage have been the least understood aspect of the lifecycle of a TC. Although the climatological large-scale conditions favorable for TC genesis have been well known since Gray (1968, 1979), the interactions between the large-scale conditions and mesoscale processes have been poorly understood. The main purpose of this study is to conduct a detailed analysis on the multiscale interactions involved in the cyclogenesis based on observational data and numerical simulations.

The Japan Agency for Marine-Earth Science and Technology (JAMSTEC) conducted a field project named the Pacific Area Long-Term Atmospheric Observation for Understanding of Climate Change (PALAU2013) over the northwest Pacific Ocean. In this project, a sounding and radar network was deployed over the ocean during the early summer of 2013. During PALAU2013, the four initial disturbances growing tropical depression (TD) or tropical storm (TS) were observed. This study focused on the disturbances, growing TS (T1304) in association with the temporal changes in large-scale environment. We analyzed re-analysis data (JMA-GSM data), observational data during PALAU2013, and simulation results using WRF-ARW. The radiosondes were launched every 3h on the R/V Mirai and every 6h at Koror and Yap. The Doppler radar was installed on this sip, collected volume-scan every 10 and 7.5 min.

Initial disturbances which occurred at (3N, 175W) in 03UTC June 10, 2013, passed through the observation point R/V MIRAI MR13-03 at (12N, 135E), grew T1304 in 00UTC June 18. The disturbance was developing along the convergence region between the trade easterlies and monsoonal westerlies. Results of radiosonde show that potential temperature was higher in the middle and upper troposphere and CAPE increased as disturbances approached. Moreover, the zonal wind component of the lower troposphere changed to the strong easterly, corresponding to the meridional wind component of the troposphere also changed to the south from the north. The temporal variation of the radar-echo area during the convections showed the organization of convective clouds to form the intense cyclones.

Seasonality of boreal winter MJO and its relation to SST variability

SUEMATSU, Tamaki[1*] ; MIURA, Hiroaki[1]

[1]Graduate School of Science University of Tokyo

Madden-Julian Oscillation (MJO) is a prominent intraseasonal variability in the tropics, which is characterized by eastward moving large-scale convective system along the equator. Overall seasonality of MJO paths has been recognized to be eastward during boreal winter and north-eastward during boreal summer. However, analysis of satellite data of NOAA Interpolated Outgoing Longwave Radiation (OLR) from 1982-2012 suggests that there is a notable variability in MJO paths just within boreal winter season. The paths of MJOs were observed to make a notable shift southward from about 10 ^{o} N to 10 ^{o} S from September to April, often with an event passing over the equator during November to December. Structural differences were also recognized between MJOs taking northern paths (northern MJO) and southern paths (southern MJO), with northern MJOs consisting of smaller convective components and being accompanied by more westward propagating components. Using weekly NOAA Optimum Interpolated Sea Surface Temperature (SST) data of the same time period, this shift in the paths of MJOs is further analyzed in relation to variability in SST distribution. Temporal changes in zonal SST gradient of MJO occurring regions, and equatorial asymmetry of SST distribution were evaluated. The result was suggestive of effective influence of positive zonal SST gradient from equatorial Indian Ocean to equatorial Western Pacific on the existence of MJO, and that equatorial asymmetry of SST distribution may be playing a part in the shift of the MJO paths.

Keywords: MJO, SST variability, intraseasonal variability

Seasonal Variations of the Mascarene High and Related Changes in Jetstreams and a Stormtrack

MIYAMOTO, Ayumu[1*] ; NAKAMURA, Hisashi[1] ; MIYASAKA, Takafumi[1]

[1]RCAST, University of Tokyo

The subtropical high in the Southern Indian Ocean, called the Mascarene high, is an integral part of the climate system there, influencing not only weather conditions in the surrounding regions but also the oceanic state. The present study examines the mechanisms for the seasonal variations of the Mascarene high. The high resides over the eastern portion of the basin in summer, while it shifts westward in winter toward the Agulhas storm-track core in strengthening. This large seasonal displacement is a distinct feature of the Mascarene High from other subtropical highs. Our analysis reveals that, while low-level thermal contrasts between the Australian continent and southeastern Indian Ocean is important for the formation of the high in summer, its wintertime formation is owing primarily to eddy-feedback forcing due to the seasonally-enhanced storm-track activity that is maintained in the presence of pronounced SST gradient along the Agulhas Return Current. In winter, the mid-tropospheric subsidence over the surface high is associated with upper-tropospheric convergence of the cross-equatorial divergent flow, indicative of a connection between the high and the Asian summer monsoon. From the viewpoint of vorticity budget, the cyclonic tendency by the upper-level convergence is balanced with the westerly advection of the anti-cyclonic vorticity. While the converging upper-tropospheric flux of Rossby wave activity from lower and higher latitudes acts to reinforce the high in winter, the high itself acts as a source of the climatological-mean planetary waves with the net local divergence of the flux, which is suggestive of the importance of the high even on the hemispheric scale.

Decadal variabilities in the Pacific and Atlantic Oceans and frequency of hot summers over the Northern Hemisphere

KAMAE, Youichi[1*] ; SHIOGAMA, Hideo[1] ; WATANABE, Masahiro[2] ; KIMOTO, Masahide[2]

[1]National Institute for Environmental Studies, [2]Atmosphere and Ocean Research Institute, the University of Tokyo

Mean temperature increase over the Northern Hemisphere (NH) land areas during warm seasons enhances frequency of extreme warm events (e.g. Russian heat wave in 2010; 1). Human influences on Earth's climate have been detected in observational records since the late 20th century. During the past 15 years, the increase in global surface air temperature (SAT) has slowed (called hiatus; 2) whereas observations show a continuous increase in summertime (June-July-August, JJA) land-mean SAT and the frequency of hot summers over the NH land areas. This discrepancy represents that some other factors except global sea surface temperature (SST) can influence on the increasing frequency of hot summers. The recent phase shifts of the decadal and multidecadal SST variabilities in the Pacific and Atlantic Oceans could have influenced the mean SAT and extreme events over the land.

For attributing the recent increase in NH hot summers, we performed three sets of ensemble simulations for 1949-2011 using an atmospheric general circulation model (AGCM). An ensemble driven by prescribed observed SST, sea-ice concentration, and radiative forcing agents, reproduces well the observed SAT time series over the NH land. Simulated anomalies can be decomposed into three components: anthropogenic influence via SST increase (ASST); direct effect of anthropogenic forcing including GHG radiative forcing (ADIR); and natural climate forcing and internal SST variability (NAT). The decomposition is made by conducting two additional ensemble, one with prescribed GHGs at the pre-industrial level and the other similar to the SST run but without human induced components in SST and sea ice have been removed.

The model simulates well 1) the long-term increase of the frequency of hot summers and 2) the recent increase during the hiatus period. Both ASST and ADIR contribute to 1). Particularly, the ADIR effect is the dominant factor for the middle and high latitude land areas, consistent with earlier studies presenting the ADIR effects for increase in mean land SAT during warm seasons (3, 4). In contrast, the NAT effect is essential for 2). The recent SST variabilities in the Pacific and Atlantic Oceans are characterized by the negative phase of PDO and the positive phase of AMO. Atmospheric teleconnection patterns associated with these SST variabilities result in low SAT over the Canada and high SAT over the United State middle latitude. In addition, the warm SST in the North Atlantic Ocean and the Mediterranean Sea contribute to high SAT over the Europe.

The recent decadal and multidecadal variabilities in the Pacific and Atlantic Oceans contribute to the increase in land SAT and frequency of hot summers over the NH middle latitude despite the recent climate hiatus. In the recent future, global and regional frequencies of hot summers can be influenced largely by phase shifts of decadal and multidecadal SST variabilities in the Pacific and Atlantic Oceans.

Zonal Momentum Budget Along the Equator in the Indian Ocean from a High Resolution Ocean General Circulation Model

NAGURA, Motoki[1*] ; MCPHADEN, Michael j[2]

[1]JAMSTEC, [2]NOAA

This study examines the zonal momentum budget along the equator in the Indian Ocean, with emphasis on the Wyrtki Jets in a high-resolution ocean general circulation model. The Wyrtki Jets are wind-driven eastward flows in the upper 100 m of the equatorial Indian Ocean that appear typically twice per year during the monsoon transitions in boreal spring and fall. Our results indicate significant contributions from zonal, meridional and vertical advection of zonal momentum, with the dominant contribution coming from zonal momentum advection. These results contrast with those from previous idealized wind-forced model experiments that emphasized the importance of vertical momentum advection. The extra eastward force caused by zonal momentum advection reinforces eastward wind stress, resulting in swifter jets in the eastern basin than in the western basin. Another consequence of these nonlinearities is that, annually averaged, zonal currents in the upper thermocline flow against the zonal pressure gradient rather than down gradient. Thus, there is no mean subsurface undercurrent flowing against the surface winds in the Indian Ocean as there is in the Pacific and Atlantic Oceans. These results indicate that proper simulation of the mean and the semi-annual zonal flows along the equator in the Indian Ocean, including their climatically relevant impacts on the mass and heat balance of the region, requires accurate representation of nonlinearities that derive from a broad range of interacting time and space scales.

Development of a visualization and download system for dataset of ocean state estimation

FUKUDA, Kazuyo[1*] ; SAITO, Hideaki[1] ; ISHIKAWA, Yoichi[1] ; MASUDA, Shuhei[1] ; SUGIURA, Nozomi[1] ; ISHIGURO, Shun[1] ; SONODA, Akira[1]

[1]JAMSTEC

In order to promote the use of a dataset of ocean state estimation useful for climate research, a data visualization and download system called ”Estimated State of Global Ocean for Climate Research (ESTOC) [1]” has been developed. The dataset contains 3- or 2-dimensional grid data of eight physical parameters such as potential temperature and salinity, and five geochemical parameters such as nitrate and phytoplankton. It covers the 53-year period from 1957 to 2009, and consists of 6996 NetCDF files of 55 gigabytes. We have considered the functions required for the system based on the assumption that the main users of the dataset are researchers not only in climatology but also in ocean ecosystem science and fisheries science.

Quick look of the data can be carried out under the conditions specified by users in the visualization page. Contour lines or vector arrows are drawn on a base map. Users can zoom in an area of the map that they are interested in, and change display color with color tables. Animations of the estimated ocean state can also be played easily. The data at users’specified location on the map can be displayed as a graph of time series, vertical profile, latitude-depth or longitude-depth sections. Furthermore, the displayed map and graph can be downloaded as png or jpeg image files.

Logged-in users are able to download a data file of the map being displayed in the visualization page, and also able to download multiple files in the download page. The following two download methods are available. One is the normal download via web browser. The other is the sending an e-mail describing a download URL to user’s registered e-mail address to use the wget command. The download state of data files is recorded in the log files for the system administrator. It will be used for improvement of data dissemination service in this system in the future.

Development of Wide-area Observation Monitoring System and Data Crawling System for Global Earth Observation

MURATA, Ken T.[1*] ; NAGATSUMA, Tsutomu[1] ; YAMAMOTO, Kazunori[1] ; WATANABE, Hidenobu[1] ; UKAWA, Kentaro[2] ; MURANAGA, Kazuya[2] ; YUTAKA, Suzuki[2]

[1]NICT, [2]Systems Engineering Consultants Co., LTD.

This paper is to propose a cloud system for data-intensive science, which has been developed at NICT (National Institute of Information and Communications Technology), Japan. The NICT science cloud is one of the cloud systems for scientists who are going to carry out their research works.

The science cloud is not for simple uses. Many functions are expected to the science cloud; such as data standardization, data collection and crawling, large and distributed data storage system, security and reliability, database and meta-database, data stewardship, long-term data preservation, data rescue and preservation, data mining, parallel processing, data publication and provision, semantic web, 3D and 4D visualization, out-reach and in-reach, and capacity buildings.

In the present talk, we introduce two types of tools for global data collection (crawling) and data transfer. The former is to collect observation data files from a variety of data server public on the Internet. The latter is to manage observation systems at observatories over the world. Data file transfer, monitoring servers and networks and system recovery are easily carried out using this system.

WCRP/AMY data archive and data release on the DIAS

TAMAGAWA, Katsunori[1*] ; OHTA, Tetsu[1] ; IKOMA, Eiji[1] ; KINUTANI, Hiroko[1] ; OYANAGI, Misa[1] ; MATSUMOTO, Jun[2] ; KITSUREGAWA, Masaru[3] ; KOIKE, Toshio[4]

[1]EDITORIA, The University of Tokyo, [2]Dept. of Geography, Tokyo Metropolitan University, [3]IIS, The University of Tokyo, [4]Dept.Civil Eng., The University of Tokyo

The purpose of this presentation is to introduce World Climate Research Programme (WCRP)/Asian Monsoon Years (AMY) data archiving and opening status along with its data uploading, data quality control, and metadata registration systems on the Data Integration and Analysis System (DIAS).

DIAS was launched in 2006 as a part of the Earth Observation and ocean Exploration System that provides cooperative opportunities for constructing data archives, and developing data integration and analysis functions (http://www.editoria.u-tokyo.ac.jp/projects/dias/).

The goal of WCRP/AMY is to improve Asian monsoon prediction for societal benefits through coordinated efforts and to promote a better understanding on Asian monsoon variability and predictability. Under the framework of the WCRP/AMY the various kinds of in-situ data have been archived among 21 different international projects. (http://www.wcrp-amy.org/). The basic for the WCRP/AMY collaborative framework is the mutual consensus among the participating countries, international organizations, individual participants, and their partner projects. It that defines the data sharing and exchange policies and is responsible for the data management.

VDVGE: Volume Data Visualizer for Google Earth

KAWAHARA, Shintaro[1*] ; SUGIYAMA, Tooru[1] ; ARAKI, Fumiaki[1] ; TAKAHASHI, Keiko[1]

[1]JAMSTEC

Software to visualize volume data that is called VDVGE (Volume Data Visualizer for Google Earth) has been developed. VDVGE visualizes a four-dimensional scalar data, and exports it to KML and COLLADA which are suitable format to Google Earth. Currently, VDVGE are used not only visualization of simulation data, also visualization of observed data, such as meteorological radar and meteorological satellites. In the presentation, the development status of VDVGE is introduced. Application examples of the recent will be also introduced.

Development of a satellite land and cloud data assimilation system coupled with WRF, and its application to Kanto area

SETO, Rie[1*] ; RASMY, Mohamed[1] ; KOIKE, Toshio[1]

[1]Department of Civil Engineering, the University of Tokyo

For flood prediction and optimized dam control, it is crucial to predict whether a rain area will be over the river basin or not after few hours, and this needs very fine prediction of time and space distribution. For system development focusing on the ‘location‘ of rain areas, it is effective to introduce the information of cloud distribution from the observations into the model as initial conditions. Clouds can be observed by microwave remote sensing by satellite. But it is not easy to observe the cloud over the land from the satellite because emissivity of clouds is so week compared to that of land surface.

In order to observe cloud over the land, we at first have to adequately represent the heterogeneity of land state, especially soil moisture distribution, which has large effect on emissivity of the land, and estimate the surface emissivity, then remove it as background information for cloud observation. Therefore, we developed a satellite-based land and cloud data assimilation system coupled with the Weather Research and Forecasting Model (CALDAS-WRF) and applied it to the Kanto area.

The CALDAS-WRF includes Simple Biosphere model version 2 (SiB2) as a land surface driver, radiative transfer models for soil and atmosphere as observation operators, and Ensemble Kalman Filter (EnKF) and 1DVAR as assimilation algorithms for land and cloud, respectively.

The CALDAS-WRF first initializes the whole system, integrates the WRF and the SiB2 repeatedly until observations are available, and then assimilates the soil moisture heterogeneity, using passive microwave brightness temperature (Tb) at lower frequency, which has a high sensitivity to soil moisture. Then the CALDAS-WRF assimilates cloud over the land, using Tb at higher frequency, which is sensitive to cloud, and optimized emissivity of land as a background information.

We applied the CALDAS-WRF to the Kanto area, and the system effectively assimilated information of clouds and largely improved the representation of cloud distribution. Precipitation areas were also reproduced in the correct locations and consistent atmospheric fields were generated around the cloud areas through dynamical and physical processes in the atmospheric model. However the precipitation amount and duration were not enough, which will be the next target of our development.

Keywords: cloud, soil moisture, satellite microwave data assimilation, Kanto area, heavy rain prediction

Atmosphere-Ocean coupled regional modeling for dynamical downscaling of current and future climates

YOSHIMURA, Kei[1*] ; HAM, Suryun[1] ; LI, Haiqin[2]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, [2]Center for Ocean-Atmospheric Prediction Studies, Florida State University

We have developed regional downscaling system of the Regional Spectral Model for the atmosphere and the Regional Ocean Modeling System (RSM-ROMS) to improve the downscaling simulation accuracy of particularly coastal area, and we have achieved a dynamical downscale of the climate model simulation for 20th and 21st century forced by SST and atmospheric state from the global Community Climate System Model version 3.0 (CCSM3) for California area. The results indicate that the surface air temperature rise was decreased over San Francisco Bay area due to the effect of uplifting current at the Pacific coast. The projected change of extreme warm events is quite different between the coupled and uncoupled downscaling experiments, with the former projecting a more moderate change. The projected future change in precipitation is not significantly different between coupled and uncoupled downscaling. Both the coupled and uncoupled downscaling integrations predict increased onshore sea breeze change in summer daytime and reduced offshore land breeze change in summer nighttime along the coast from the Bay area to Point Conception. Compared to the simulation of present climate, the coupled and uncoupled downscaling experiments predict 17.5 % and 27.5 % fewer Catalina eddy hours in future climate respectively. Similar framework was applied for East Asian region, and preliminary results show quite significant change in surface temperature and precipitation field due to having dynamically predicted fine scale ocean currents. Particularly in summer to fall, when Kuroshio Current direction and prevailing surface wind direction are about opposite, coastal subsidence occurs so that it warms the coastal air temperature. This feature is opposite from the California's case, and potentially indicating the possible underestimation of warming. We will further investigate the detail of the influence of regional atmosphere-ocean coupling in the presentation, as well as the impact of fresh water input from the terrestrial runoff.

Climate Change Signal Represented in Reanalyses

KAMAHORI, Hirotaka[1*]

[1]Meteorological Research Institute

Since NOAA/NCEP competed the first atmospheric reanalysis NCEP/NCAR, 20 years are passed. During these 20 years, many reanalyses NCEP/DOE, ERA-15, ERA-40, JRA-25 MERRA, CFSR, and ERA-Interim were released. Last year, JRA-55 was completed as the third generation reanalysis.

Now a day, the atmospheric reanalyses are widely utilized as fundamental database of pseudo observations in meteorology as well as in in various research fields. However, their adaptation to the climate change studies have not been advanced very much, because of less temporal S/N ratio in reanalyses products. That is, present available reanalyses include large artificial variations compared with natural variations in real atmosphere. Since the first reanalysis NCEP/NCAR, all reanalysis assumes the frozen data assimilation system in order to avoid artificial variations accompanying with changes of the system. We expected the homogeneous products with the frozen systems, but there are many artificial changes in the products different from the change of the real atmosphere, due to the change of the observation systems. As the largest artificial change, it should be noted that the large gaps in the products characteristics were introduced due to introduction of geosynchronous satellites around 1979. These artificial variations in the products make difficult to adapt them to climate change studies. On the other hand, continuous efforts have been made to reduce the artificial variation and make the products applicable to the climate change studies. For examples, bias correction techniques for satellite and upper air observations that are input data in the data assimilation system, are developed and adapted in recent reanalyses. As a result, homogeneity of reanalysis products is largely improved, and we become to be able to extract the signals of climate change from the products. Of course, degrees of availability of the climate change signals in the products largely depend on the variables. Here, I introduce specific examples of the application possibilities of the products for the climate change studies.

The data release of Earth observation project data products considering data provider's policies by DIAS

KINUTANI, Hiroko[1*] ; SHIMIZU, Toshiyuki[2] ; LI, Jiyi[2] ; NAKAHARA, Yoko[2] ; YOSHIKAWA, Masatoshi[2] ; KITSUREGAWA, Masaru[3] ; KOIKE, Toshio[1]

[1]The University of Tokyo, [2]Kyoto University, [3]The University of Tokyo, National Institute of Informatics

Our project, DIAS (Data Integration and Analysis System) started in 2006, has a purpose of constructing data infrastructure that can integrate earth observation data, numerical model outputs, and socio-economic data effectively. DIAS also has a purpose to create knowledge enabling us to solve earth environment problems and to generate socio-economic benefits. From October 2010, we have released data of DIAS with Document-metadata, describing about dataset in English and Japanese. Anyone can use the DIAS data discovery system by accessing http://dias-dss.tkl.iis.u-tokyo.ac.jp/ddc/, and can download data files of 195 datasets through the system.

The data in DIAS is classified into 4 categories:

1) Numerical simulation outputs for the purpose of research,
2) Satellite data for the purpose of research,
3) Datasets created by DIAS researchers,
4) Datasets created at related projects supported by DIAS.

Newly released datasets are **NIES CGER Ochiishi Monitoring Station Greenhouse Gases Data**, **NIES CGER Tomakomai Energy, Water, CO2 Flux, Spectral Radiation, Vegetational Index Data**, **Atmosphere and ocean carbon dioxide monitoring using volunteer observing ship (Pyxis) servicing between Japan and West Coast**, **The Japanese 55-year Reanalysis (JRA-55)**, **GRENE-City Tsunami archive**, **AGURAM Ground Information Database** and Asian Monsoon Year projects data products.

Data provider to release datasets from DIAS should create the document metadata (both in English and Japanese) that describes the dataset.Data provider should write a policy concerning the data in order to notify to data user in it. In addition to data policy of data provider, project policy of a project that became the background of the data creation, and DIAS data policy are included in the document metadata. If conflicting terms are written among the data policies, we have determined the priority of data policy; the order is data provider, project and DIAS.

The data policy of DIAS is as follows:

1. With regard to Data policy, if there is any data policy indicated by the data provider, that policy always has priority over this DIAS data policy.
2. DIAS data sets are to be used only for scientific research or educational purposes. Commercial use and exploitation of DIAS data sets are prohibited
3. Any modification or change of the original DIAS data sets is prohibited.
4. Any Re-export or transfer of the original data sets to a third party is prohibited.
5. The origin of DIAS data being used for any publication of scientific results must be acknowledged and referenced in the publication, with the *quotation* given below as an acknowledgement.
6. Whenever DIAS data sets are used for publication of scientific results, the author(s) shall send a copy of the respective publication, preferably in an electronic form or in a separate printed version, to the DIAS CONTACTS as indicated

Data policy of DIAS may use as the basis for data providers to create their own data policy.

In addition, the data download system developed by DIAS has 4 level access controls to the data for users' data downloading.

1) Registered users are able to download.
2) In addition to 1), after agreement of data policy, users are able to download.
3) In addition to 2), after sending a use application through the system to the data provider and approval is obtained, users are able to download.
4) In addition to 2), after users have negotiated individually with the data provider and approval is obtained, users are able to download.

By considering the data policy of data provider in this way, we are trying to improve the reliability of DIAS data repositories and DIAS data release.

Development of a basic common library (SCALE) for future HPC and datasets created by the library

SATO, Yousuke[1*] ; NISHIZAWA, Seiya[1] ; YASHIRO, Hisashi[1] ; MIYAMOTO, Yoshiaki[1] ; TOMITA, Hirofumi[1]

[1]RIKEN Advanced Institute for Computational Science

A basic Common library named Scalable Computing for Advanced library and Environment (SCALE) is now being developed at RIKEN, Advanced Institute for Computational Science (AICS). The library is developed to solve the problems that come from the sophistication of numerical models and the recent trend of high performance computing (HCP). The library is downloadable from the web site of RIKEN, AICS (http://scale.aics.riken.jp/). The license of the SCALE is based on BSD 2 license.

SCALE-Large Eddy Simulation (LES) is now available as a component of the SCALE library. The SCALE-LES is based on fully compressible system, and it uses vertically explicit and horizontally explicit (HE-VE) scheme. Even ordered central differential schemes (2nd ordered central differential scheme for the terms relating to the density, 4th ordered central differential scheme for the other terms) are applied for spatial discretization. The 3rd ordered Runge-Kutta scheme is applied for the temporal discretization. Physical components implemented in the SCALE-LES are turbulent scheme, a radiation scheme, cloud microphysical schemes (1-moment bulk, 2-moment bulk, and spectral bin scheme), and surface flux model. The aerosol model, chemical transport model, urban canopy model will be implemented near future.

In future, the SCALE library will be extended to regional model with nesting system, global model. As well as the atmospheric component, the SCALE will be extended to the entire targets for numerical simulation (e.g. ocean, biosphere, molecular dynamics, or so).

We will introduce some examples of the results obtained from the SCALE-LES and some datasets. We aim to share and discuss about not only the model results but also the problem when we treat the big data (e.g. data handling, visualization or so) with the participants regardless of their background.

Japan mosaic land-cover 0.01 degrees raster dataset

HIGUCHI, Atsushi[1*] ; KAWAKAMI, Satoshi[2] ; MURAKAMI, Akinobu[3] ; MASUTOMI, Yuji[4] ; TAKAMI, Akinori[5]

[1]CEReS, Chiba University, [2]HP Japan, [3]University of Tsukuba, [4]Center for Environmental Science in Saitama, [5]NIES

As one of basic information for numerical weather simulation, land-cover and land-use dataset is essential for initial condition. In Japan, MILT published land-cover information as tile and vector files. We mosaicked tile vector files into one raster (gridded) file dataset over Japan. Such mosaicked raster files are available for 1976, 1987, 1991, 1997 and 2009. We also made convert programs from original land-cover flag (number) into typical land surface model (SiB and SiB2) land-cover flag. We also try to explain how to utilize these dataset for the assessment of urban-green to reduce heat island without use of urban canopy model within the poster session core-time. To make the dataset, SALSA project under RECCA/MEXT supports our activity.

Meteorological observations for the purpose of educational use in Nagata ward, Kobe

FUKUSHIMA, Azusa[1*] ; OTSUKA, Shigeaki[1]

[1]Faculty of Humanities and Sciences, Kobe Gakuin University

Weather and climate are the units in science or geography classes in elementary and junior high school. Recently, many data have archived on the Internet by the individuals or scientific groups other than JMA with the spread of the meteorological instruments. However, if a teacher who is working at a public school hopes to do constructive class with some practical works using the meteorological data, he has to spend for hours and hours preparing. For example, he has to choose a case day to learn the unit in effective way, and he has to prepare the data that it can be used in his students easily. Therefore we considered that if a provider prepares some support measures for using the data, the teacher might be easy to introduce the meteorological dataset into his class as a course material. In this study, we report an approach to the educational use of a meteorological dataset observed at the Nagata center of the Center for Area Research and Development, Kobe Gakuin University from 2011.

The Nagata center of the Center for Area Research and Development was established in 2010. It is located in the former buildings of the Futaba elementary school in Nagata ward, Kobe-shi. The instruments for the observation of the meteorology and seismology were installed on summer of 2011. The elements of meteorological observation are air temperature, wind speed and direction, relative humidity, rainfall, net solar radiation, ultraviolet A and B, and pressure. The elements for the seismology are seismic intensity, seismic wave, groundwater level, and underground water temperature. The observation data is automatically saved as daily reports, monthly reports, and annual reports. The daily reports are available on our website to the registered users. The data can be used only for the educational and research purposes.

Observation site is located in the urban area between Shin-Nagata station (JR line) and the port of Nagata. It is at a distance of about 7km southwest of Kobe Local Meteorological Observatory. JMA Akashi AMeDAS station is in Futami coastal area of Harima-Nada. Nagata is the side of Osaka Bay and is located in the south of Rokko-Awaji fault zone. If the observation data used in conjunction with the data of Kobe Local Meteorological Observatory, it can be carried out a research of urban heat island and sea and land breezes at the regional scale. A practical training of the meteorological observation or the tour of equipment at the Nagata center is also possible.

The data that observed in near at hand can be used to understand local scale weather and climate as a course material in the school. Furthermore, it is possible to feed the geographic and the temporal sense of the weather phenomenon by comparing the data of several weather stations including Nagata.

Study of tropospheric tomography for water vapor distribution with Neural Network

HIROKI, Akimitsu[1*] ; HATTORI, Katsumi[1] ; HIROOKA, Shinji[1]

[1]Graduate School of Science, Chiba University

Many meteorological disasters such as landslides with torrential rain have been reported. Monitoring and a prediction of the precipitation activity are very important to mitigate these disasters. However, in the developing countries such as Indonesia and the Philippines, the observation with the radars is difficult in the present conditions due to the cost and the maintenance. The water vapor tomography using a GPS and/or broadband satellite is considered to be effective for the precipitation monitoring system instead of the radars in the above countries.

When the rain cloud bringing the damage of a heavy rain and the thunderstorm is developing, there is an apparent flow of the water vapor from the neighborhood. It is possible that the GPS can detect the flow and distribution of water vapor. Therefore, in this study, we develop a water vapor tomography from GPS and AMeDAS data using algorithm of residual minimization learning neural network (RMTNN). The numerical simulation demonstrates a capacity of the developed method, that is, the reconstructed image can show the transient changes and the inverse layer in given water vapor distributions. The details will be shown at our presentation.

Influence of existing scenery in an on-site forest environment in terms of Subjective Appraisal, Restorativeness, Affect

TAKAYAMA, Norimasa[1*] ; FUJIWARA, Akio[2] ; SAITO, Haruo[2] ; HORIUCHI, Masahiro[3]

[1]Forestry and Forest Products Research Institute, [2]The University of Tokyo Forests, [3]Yamanashi Institute of Environmental Sciences

INTRODUCTION

Many stressors of urban life are increasingly driving humans to seek some form of stress relief (Frumkin, 2001). Natural environments, including typical urban parks and natural, secondary or artificial man-made forests are generally associated with stronger positive health effects compared with urban environments (Velarde, Fry & Tveit, 2007). For instance, natural scenes bring higher tranquility and a reduced feeling of danger compared to urban scenes (Herzog & Chernick, 2000), while outdoor recreation in a green environment has been shown to relieve stress among urban inhabitants (Li et al., 2008), hence the evidence to date seems to indicate the positive health effect of a natural setting. However, the question of how the existence of scenery as a sight stimulus produces a psychological effect in an on-site forest environment and to what extent remain unclear.

Therefore, during this research conducted in an on-site forest environment (a mixed forest including Larch, Giant dogwood), we set out our research purpose, namely to clarify the psychological healing effect of forest scenery as visual stimuli on respondents.

METHOD

With eleven male and four female adult respondents respectively, we conducted a viewing experiment to investigate the appraisal (Semantic differential method; abbreviated to SDM; 25-paired adjectives), the affect (Positive And Negative Affect Schedule; abbreviated to PANAS; 16-queries), subjective restorative quality (Restorative Outcome Scale; abbreviated to ROS; 6-queries) and degree of attention restoration (Perceived Restorativeness Scale; abbreviated to PRS; 26-queries) using four types of research questionnaires. The viewing experiment was conducted in the forest inside the Forest Therapeutic Research Institute (Fuji Iyashi-no-mori Institute) and managed by the University of Tokyo Forests in early May 2013. The experiments were conducted one-by-one during fine weather throughout the experimental period (four days). Each respondent was given respectively from the opening session (with well-managed forest scenery) to the closing session (forest scenery covered by tarpaulin) or vice versa to eliminate any order effect.

RESULT AND CONSIDERATION

Consequently, in terms of the comparison of appraisal, the opening session saw scores higher than the closing session for many measurement indexes and the degrees of score difference were cleared. Conversely, it became clear that a difference would emerge in both the opening and closing sessions, even if it was a measurement index not corresponding to visual senses but directly to other senses. Finally, based on the result of multiple regression analysis, it emerged that the basic links between them included aspects of difference and commonality for the integrated index appraisal such as likableness, comfort, beauty and sense of security when comparing the opening and closing of the forest landscape respectively, and this was an appraisal of concrete environmental factors which resulted in such differences and commonality. Furthermore, in terms of afect, even though neither a positive nor negative affect could be confirmed from statistical interaction when comparing the opening and closing sessions, there was a statistical decline (reduction) in the before (pre-viewing experiment) compared to after (post-viewing experiment). As for the quality of subjective restorative, the interaction between the opening-closing and before - after sessions was confirmed as well as individual statistical differences when comparing before and after in the opening session and opening and closing sessions in the after session sequentially. Regarding the degree of attention restoration, subsequent results of the opening-closing comparison clarified that the criteria of run away, fascination, scope and compatibility were statistically higher in the opening rather than closing session.

Evaluation of Landscape Conservation at Green Space on Campus Based on the Level of Willingness to Work

TAKASE, Yui[1*] ; FURUYA, Katsunori[1]

[1]Graduate School of Horticulture, Chiba University

1. Introduction

A university campus with a large-scale green space is precious access to green for the residents in the surrounding vicinity. However, very often only a very low budget is granted for management of green space on university campuses in Japan. Volunteer activities among students are expected for management of the landscape and maintenance of those green spaces on campus. In this study, landscape conservation of green space on campus has been evaluated, based on the level of students' willingness to work.

2. Study Methods

Matsudo Campus of Chiba University in Japan has been selected as a subject. The total area of this campus is 15 hectares, and 13.7 of which counts for green space. A survey was conducted in July, 2013, with students who belong to the Faculty of Horticulture at Chiba University. The number of respondents was 77. The following four items were surveyed: 1) Attribute of respondents (gender, participation experience in green space conservation activities, and willingness to participate), 2) future vision of green space on campus from nature experiences, 3) ecosystem services expected from green space on campus, and 4) desired participation hours to spare for green space conservation activities.

3. Results and Considerations

Regarding respondents' attributes, the number of valid responses was 59, with 35 males (59%) and 24 females (41%). The number of people who have participation experience in green space conservation activities counted 27 (46%). The number of those who are willing to participate in those activities was 48 (81%).

With regard to the future vision of green space on campus, an free answer question was provided and 65 valid responses were obtained. The two most common opinions were as following: 1) "Increasing of nature experience events" (19 respondents, 29%), and 2) "Increasing of facilities such as restrooms, benches, gathering area, and lighting" (19 respondents, 29%). The next most significant answer was "Better management of gardens and woods" (15 respondents, 23%).

The next topic about ecosystem services expected from green space on campus was captured from 59 valid responses. Approximately 90% of them had certain expectations from ecological services related to green space on campus: examples, "to create beautiful landscape in the area" and "space where people can enjoy nature".

Finally, as for the number of participation days to spare for conservation activities on Matsudo campus, 59 students provided valid answers. The average number of days that they are willing to participate is 14.2. Since the participation hours per day had been specified and presented as four hours, the average hours figure is 56.8, converted from the number of days. The grand total of days willing to spare among all valid respondents counted 841 days. Next, the number of desired days to spare was computed for each activity location within the campus. "Ohisama Garden", which is a flower garden managed mainly by students' initiatives earned the highest number of days among all the campus locations. Thirty-five respondents (59%) are willing to spare time here with an average of 6.4 days, which totals 225 days. On the other hand, traditional garden is the most popular in terms of the number of respondents who are willing to spare time. Forty respondents (68%) indicated their interest in sparing time in the traditional garden. The average counted 4.8 days, which totals 191 days. While the main reason of the location choice for Ohisama Garden was "interest in the activities" (14 respondents), the one for the traditional garden was "to acquire knowledge and know-how" (12 respondents).

4. Conclusion

In this study, students' willingness to participate in landscape conservation was clarified by gauging their willingness to work. In doing so, the specific number of days and the available labor in scenery maintenance have been drawn.

Keywords: Willingness to Work, Landscape Conservation, Green Space on Campus

Table. Result of the number of participation days to spare for conservation activities on Matsudo campus

Traditional Garden	Ohisama Garden	Bamboo Grove	Around School Grounds	Sloping Forest	Other
					
Average of days 4.7 days	Average of days 6.4 days	Average of days 3.4 days	Average of days 3.2 days	Average of days 4.9 days	Average of days 4.8 days
Number of Respondents 40 (68%)	Number of Respondents 35 (59%)	Number of Respondents 36 (61%)	Number of Respondents 20 (34%)	Number of Respondents 32 (54%)	Number of Respondents 16 (27%)

Landscape Evaluation Method by Visitor-Employed Photography with Usage of Cellphones - Case Study of Mount Gwanak, Korea

MIZUUCHI, Yusuke[1*] ; SON, Yonghoon[2] ; KANG, Moonseok[2] ; FURUYA, Katsunori[1]

[1]Graduate School of Horticulture, Chiba University, [2]Graduate School of Environmental Studies, Seoul National University

1. Introduction

For spatial planning and designing such as natural parks, it is important to understand how users percept and evaluate landscapes. The relationship between viewpoints and a viewing object has been regarded important in the landscape perception model which has been studied in Landscape architecture, Geography and some sciences. One of the study methods to understand such landscape perception uses a camera called Visitor-Employed Photography (VEP), and this method is considered effective in extracting visual images of a space. However, while existing VEP is effective in understanding viewing objects, it still has shortcomings. It requires interviews and descriptions separately in order to extract viewpoints. Therefore, in order to develop a study method of landscape perception to overcome these limitations, we conducted experiments to get viewpoints by using the GPS function of cellphones which visitors to the sites possess for their daily usage.

2. Outline of the experiment

A research was conducted with 60 subjects, and the trail of Mount Gwanak in the suburbs of Seoul, Korea, was selected as a site. This location is designated as Urban Eco-Park. The subjects were instructed to use their own cellphones and take photos of landscapes which subjects evaluate. They were also instructed that Geotag must be attached to the photos. In addition, geographic information of the subject's action was simultaneously collected by GPS logging application of their cellphones. Following this activity, a questionnaire survey about subject's profile was conducted. From the collected photos and spatial characteristics of Mount Gwanak, we analyzed landscape objects which are appreciated by the visitors.

3. Results

1,119 photos were collected from 60 respondents. Among these, the redundant photos of the same composition taken by the same subject (121 photos) were eliminated. In addition, geographic information were not available from 6 subjects, hence theirs (99 photos) were also eliminated. Further eliminated were the other photos with geographic information errors (45 photos), and the remaining 842 photos were used for analysis. These photos were categorized based on the viewing objects and viewing distance. As a result, based on the trail as a viewpoint, the photos of landscapes within the woods counted most with 120 photos. Panoramic views (105 photos) and closer shots of the space with a river as a main subject were also common. We analyzed the collected geographic information with the Kernel density estimation, and identified the viewpoints of visitor's preference (Fig. 1). This result was combined with the categorized viewing subjects for further analysis, and it was found that photo shooting density tends to be high at the following locations: 1) panoramic view, and the rock and the building at the mountain top in the surrounding area of the mountain top (Fig. 1.1), 2) the touching points of the trail and the river (Fig. 1.2 and 1.3), and 3) locations with a temple (Fig. 1.4)

4. Conclusion

In this research, landscapes within the woods, panoramic views, and river views from the trail are highly appreciated at Mount Gwanak. While panoramic views and river landscapes were concentrated in certain locations, there was no spatial tendency detected with the landscapes within the woods. From the questionnaire survey, 42 respondents (70%) responded comfortable. Eighteen (30%) responded not comfortable; and among those, two (3.3%) were about GPS and others were about the course. Thus, the load of study method itself can be considered light. As described above, this study method can be useful as a future development of a landscape perception research method. It enables visual extraction of viewpoints and viewing objects as shown in this research. Furthermore, this method can be applicable to international comparative studies to identify cultural differences in landscape recognition.

Comparison of natural landscape appreciation between Russia and Japan: landscape exoticism evaluation

PETROVA, Elena[1*] ; MIRONOV, Yury[2] ; AOKI, Yoji[3] ; MATSUSHIMA, Hajime[4] ; EBINE, Satoshi[4] ; FURUYA, Katsunori[5] ; PETROVA, Anastasia[6] ; TAKAYAMA, Norimasa[7] ; UEDA, Hirofumi[8]

[1]Lomonosov Moscow State University, Faculty of Geography, [2]Vernadsky State Geological Museum of the Russian Academy of Sciences, [3]Haiku International Association, [4]Research Faculty of Agriculture, Hokkaido University, [5]Graduate School of Horticulture, [6]Institute for Oriental Studies of the Russian Academy of Sciences, [7]Forestry and Forest Products Research Institute in Japan, [8]School of Design, Sapporo City University

People belonging to different cultures differ by their landscape preferences due to a number of ethno-cultural features as well as historical, social, and environmental factors. It is very important to reveal and consider these differences. The purpose of this study is to compare perception, visual and emotional evaluation of natural landscapes in Russia and Japan, that are situated so close to each other and share a common border, but differ so greatly in cultural aspects, while both have deep-rooted traditions of landscape appreciation. We have interviewed respondents in university centres of Russia (Moscow in Central Russia, Irkutsk in East Siberia, and Petropavlovsk-Kamchatsky in Far East) and Japan (Sapporo, Chiba, and Miyazaki); metropolitan areas of both countries and two outermost areas, which differ most strongly in their natural environment, were represented. Young respondents (17 to 30 years old men and women) have taken part in the survey. During the interview, each respondent received the same set of 70 photos of natural landscape. For evaluating the exoticism, we asked respondents to use the 3-point scale, on which exotic landscape got a mark ”+1” and usual landscape - ”-1”. When respondents could not decide between these categories, they were suggested to use an average value ”0”. Data obtained were analyzed using elementary and multivariate statistical methods.

Exoticism is very important parameter in landscape appreciation and evaluation. As we have learned during the interview, respondents consider attractive landscape as beautiful and comfortable not only for a long-term stay, but for living in. Exotic landscape is ”unfamiliar” to respondents; even if it were unsightly, it would be interesting to look at, at least once. Therefore, when assessing attractiveness of landscape, respondents focus primarily on their aesthetic feelings, but in the evaluation of exoticism dominates their educational interest to an unknown. As we revealed, practically no correlation exists between Russian and Japanese respondents to evaluate exotic landscapes (R = 0.26). The majority of Russian respondents evaluate mountain landscapes, waterfalls, and see coasts as the most exotic, but forests, rivers, and treeless plains as the most usual. At the same time, coastal areas are usual and treeless plains are exotic for the Japanese. All the other types of landscapes vary considerably in their exoticism degree for Japanese respondents. All groups of Japanese respondents assess the exoticism of landscapes virtually identical (the correlation coefficients between their scores are: R = 0.90-0.96), while the groups of Russian respondents show some differences.

To discover the ethno-cultural aspect, we compare the survey data from Kamchatka to that from Hokkaido, which are similar in terms of natural conditions. In their assessments of the exotic landscapes residents of Kamchatka are closer to the representatives of their culture, living in fundamentally different environmental conditions, than to the representatives of the Japanese culture, living in a similar environment. At the same time, Kamchatka respondents evaluate some of exotic landscapes virtually identical to the estimates of Japanese respondents and very different to those of Russian respondents from other regions. This applies to seacoasts and mountain landscapes that are both the most remarkable and most similar elements of natural environment of Kamchatka and Japan. Thus, if all respondents evaluate the attractiveness of landscapes almost equally, which may indicate the existence of universal human concepts of their aesthetics, then when assessing the exoticism, important role play both ethno-cultural differences and features of natural environment where the respondents live or that they have experience to communicate with. For Russian respondents the most exotic landscapes are also the most attractive, although we cannot see such a tendency for Japanese respondents.

Exploring reasons for residents use and appreciation of informal urban greenspace in Sapporo and Brisbane

RUPPRECHT, Christoph[1*]

[1]Environmental Futures Research Institute, [2]School of Environment, Griffith Univ.

Informal urban greenspaces (IGS), such as vacant lots, street verges and river banks are an important new topic in urban recreation and landscape studies. At last year's JpGU 2013 I showed that residents in Sapporo (Japan) and Brisbane (Australia) use and appreciated IGS as adults and during their childhood. But two important questions remained: (1) What role does IGS play for residents in comparison to formal green space, such as parks?, and (2) Why do residents in Brisbane evaluate IGS more positively than in Sapporo? This presentation reports preliminary answers to these questions.

To examine the first question, I used a GIS analysis to compare the amount of formal greenspace within 500m of the sites where the questionnaire on IGS use and perception was distributed to Sapporo and Brisbane residents. A negative correlation between formal greenspace area and IGS use would imply residents indeed use IGS as a substitute for parks. But the results showed no correlation. This suggests residents deliberately choose to use IGS. IGS therefore plays a unique role in residents' recreation - different from formal greenspace.

But why did residents in Sapporo feel IGS made their daily life both better and worse, while residents in Brisbane felt IGS had a mostly positive impact on their daily life? Looking for potential reasons for this difference in IGS appreciation, I measured IGS quantity, accessibility and vegetation structure in both cities. The type of IGS (e.g. lot, street verge, brownfield, railway, gap space, powerline, waterside etc.) was determined using a IGS typology. Accessibility of IGS was categorized in three levels: accessible, partially accessible and not accessible. Vegetation structure was recorded by measuring coverage of four strata: tree, bush, herb and ground cover.

The results show IGS makes up a surprisingly large percentage of city land use in both cities (˜5% of total surveyed land use), but there were differences in the amount of IGS types and vegetation structure. We analysed the questionnaire data and field survey data, and found these different IGS types and vegetation structure could explain why residents evaluate IGS differently. Understanding how residents appreciate IGS may in turn help us to unlock the potential of IGS for recreation.

A review of English papers on psychological evaluation of landscape from 2009 to 2013

AOKI, Yoji[1*]

[1]Open University of Japan

This paper reviews interesting studies on landscape evaluation in terms of psychological tests referred in Landscape and Urban Planning, Landscape Research, J. of Environmental Psychology, Environment and Behavior, J. of Environmental Management and some other scientific journal from 2009 to 2013. Until 2005, I reviewed various experiments of landscape evaluation in the papers of Review Articles (Aoki 1999, Aoki 2006, and Aoki 2007). During recent 5 years, more works were published compared to the decade of last report. So I tried to summaries them according to the key subjects of the former papers, i.e. (1) clarifications of landscape phenomena, (2) respondents' attributes, (3) landscape appreciation, (4) sampling of landscapes and presentation, and (5) predictive models of psychological response and applications in physical planning.

(1) Clarifications of landscape phenomena (Table1)

The first proposal of the explanation of the landscape appreciation was proposed by J. Appleton (1975). The detail mechanisms of the appreciations were not explained because of the complicated reaction system of human brain (Thiel 1997). This hard situation was discussed by the advanced brain system endowed to human being (Bourassa 1991). We already got the tool to measure the activities in the brain, but the clarification of the landscape phenomena will take more time because of the complicity of the landscape appreciation (Aoki 2008).

In recent 5 years, the childhood and adolescence to feel at home was examined (Adevi and Grahn 2012).

(2) Respondents' attributes (Table 2, 3)

Two kinds of attributes e.g. identities of human group and personality were reported.

For the former, mountain tribe Sherpa (Beza 2010) and Nigeria children (Falk and Balling 2010) were investigated.

For the latter, the attribute of tourists was increased and sibling was newly investigated (Howley et al. 2012).

The meaning of sampling through internet was yet under consideration.

(3) Landscape appreciation (Table 4)

Preference has popularly used in recent years. Willingness to pay became popular in this field. SD method was yet used in the appreciation.

Other appraisals, e.g. feeling at home (Adevi and Grahn 2012), familiarity (Dobbe 2013) and photo location (Sugimoto 2013) were used.

(4) Landscape sampling and presentation (Table 5, 6)

In the landscape sampled, new ideas; transportation (Bernasconi et al. 2009), Mt Everest (Beza 2010), fire prone (Islas and Vergara 2012), seasonal change (Eroglu et al. 2012) were tried.

As for the presentation method, on-site visits was increasing and use of GPS (Sugimoto 2013) became popular by the development of mobile phone.

(5) Predictive model and planning (Table 7, 8)

As for the predictive model, biodiversity (Jungels et al. 2013) and flow of stream (Pflueger et al. 2010) were tried.

Proposal for planning were offered in terms of mapping (Ribeiro et al 2013, Schirpke et al. 2013).

Comparison of Races in Terms of Images of Landscapes in Fiji Using Image Sketches

KOSUGE, Takashi[1*] ; FURUYA, Katsunori[1] ; VERMA, Mukesh[2]

[1]Graduate School of Horticulture, Chiba University, [2]Hard, Social Sciences, Fiji National

Methods

This research was intended to clarify the difference in imaging of forests between Fijian and Indian residents based on the SKETCH SURVEY. We administered the sketch survey to Fijian residents during our stay in the Republic of Fiji from August to December, 2013. The survey was carried out through interviews, and 158 respondents gave their answers. In the survey, the respondents were asked to describe forests in keywords, sentences or sketches. 1) Firstly, the respondents entered several keywords related to FORESTS in Fiji based on their own idea. 2) Secondly, they described the image of FORESTS in sentences consisting of about 100 words. 3) Lastly, they drew simple sketches of the image of FORESTS. In the process of analysis, the number of elements depicted in the sketches was counted in order to review their imaging of forests. Furthermore, the space structures of the sketches drawn by the respondents were divided into four categories in total: the near view, intermediate view and distant view based on the distance between the landscapes and the drawers, and the downward view depicted from high view points. For analysis of the differences in the races, Mann Whitney U test was used.

Considerations and Research results

1,504 elements were sampled from the sketches drawn by all the 158 respondents, and that is to say 9.5 elements were sampled from one sketch on an average. These 1,504 elements were classified into 73 categories. When the appearance rate of the elements in the 158 respondents sketches was calculated, the appearance rate of mountains was highest (82%), followed by trees (69%), the sun (63%), palm trees(58%), houses (51%), oceans (47%), rivers (44%), woods (42%), birds (35%), villages (34%) and clouds (32%). In many of their sketches, not only nature elements such as mountains, trees and the sun but also familiar elements such as palm trees, houses and oceans were depicted. In some of the Fijian residents sketches, palm trees extending in the tropical zone with a background of mountains were depicted. Furthermore, houses, villages and other elements were simultaneously depicted in the natural landscapes, and it seems that nature is closely linked to their daily lives. Concerning space structures of the sketches, the rate of the distant view was highest (59%), followed by the downward view (18%), near view (13%) and intermediate view (8%).

Regarding the differences in the percentage of the answers between the races, 76% of Fijian respondents and 54% of Indian respondents associated forests with nature, and here a significant difference was found ($p<.05$). Furthermore, 24% of Fijians and 44% of Indians associated forests with farming villages, and here a significant difference was also found ($p<.05$). It may be possible that Fijians regard forests as a factor of nature, while on the other hand Indians consider forests as a factor of not only nature but also farming villages.

Differences between the races were checked in each of the 73 categories, and significant differences were detected with only six categories of them. The categories in which significant differences in the percentage of the answers between the races were detected were palm trees (50%, 74%), the sun with expression (19%, 34%), grass fields (34%, 12%), sugar canes (7%, 20%), plains (1% of Fijians, 10% of Indians) and hotels (0%, 8%). The analysis of the depictions in the sketches showed that Fijians tend to depict nature-related objects elaborately and Indians tend to depict plants and other similar objects more elaborately than Fijians.

Concerning space structures of the sketches, 55% of Fijians 55% of Fijians and 68% of Indians drew distant-view sketches, and there was a tendency that both races preferred the distant view. In some of the sketches, there was a range of mountains from which waterfalls and rivers flew into the sea, and in some of the sketches trees, tropical palm trees and artifacts such as houses and villages were depicted.

A Comparative Study on Landscape Cognition Between Japanese who have been in New Zealand(NZ) and who have not been to NZ

HORIUCHI, Kana[1*] ; FURUYA, Katsunori[1]

[1]Graduate School of Horticulture, Chiba University

Introduction

NZ is almost same size and has same climate, temperate zone and subtropical zone, with Japan. Though a lot of Japanese have immigrated to or lived on long term in NZ, few Japanese knows NZ well because the long distance between both countries might be bottleneck for flow of people. Thus, the objective of this study is to clarify differences of landscape recognition of Japanese who have been in NZ and Japanese who have never been to NZ.

Methods

69 landscape photos taken in both countries (35photos from Japan, 34photos from NZ) were categorized to the group of coast, waterfall, river, forest, wetland, mountain, and lake. Respondents were asked to select three photos each for characteristic landscape image of NZ and Japan. Then, they were asked to write down the three keywords each about the landscape image of both countries. Respondents were the group of 25 Japanese people who have been in NZ (NJG), the group of 42 Japanese people who have never been to NZ (JPG), and the group of 12 New Zealander people (NZG).

Result

Firstly, the most selected photo as the characteristic landscape image of Japan among all groups was the photo of Mt.Fuji with Ashinoko lake and shrine gate (NJG76.0%, JPG74.0%, NZG50.0%). Also, second top photo was Mt.Fuji's one. The different result was shown on third top photo. NJG chose the photo of Mt.Fuji with forest (32.0%), JPG chose the photo of creek (28.7%), NZG chose the photo of waterfall with autumn leaves (16.7%), and the photo of forest with lingering snow (16.7%).The creek's photo selected by JPG was recognized as Japanese landscape though taken in NZ.

For the characteristic landscape image of NZ, there was not the photo selected intensively such as Mt. Fuji one. However, the most selected photo was common among all groups. That was the photo of lighthouse on cape surrounded by ocean (NJG36.0%, JPG40.5%, NZG16.7%). As Second top photo, NJG chose the lake on volcano with volcanic steam (24.0%). JPG selected the solid magma in volcanic crater (23.8%) and the lake (23.8%). These two photos might be chosen as the characteristic landscape image of NZ because those are unfamiliar sceneries in Japan. In NZG, it was hard to find out the characteristic scenery because the groups of selected photos were decentral.

For keywords about the landscape image (KLI), noun showing plants and landscape, noun showing animals, noun showing color, adjective indicating impression, and proper noun were answered. As KLI of NZ, FOREST, MOUNTAIN or HILL was answered 29.6% as total. And GREEN, DYNAMIC or BROAD was answered 22.2 % for each in NJG. People would have the image of landscape that broad and dynamic mountain and hill are spread in NZ. On the other hand, JPG answered BROAD(35.0%), MEADOW and GRASSLAND(27.5%), SKY(25.0%), WILD(25.0%) as KLI. Though it also shows broad image, JPG would have the image of broad glass land instead of mountain or hill.

It revealed the difference of landscape cognition between NJG and JPG. There was not obvious difference on the photo selecting exercise. However, JPG recognized the photo taken at NZ as Japanese landscape photo. For KLI, JPG indicated broad glass land, and NJG shown the landscape consisted of broad forest and mountain.

Analysis of Scenery Transition and Residents' Opinion in Dalai Lake Nature Reserve

HAN, Guorong[1*] ; FURUYA, Katsunori[1]

[1]Graduate School of Horticulture, Chiba University

Introduction

Grassland scenery has been diminishing in Inner Mongolia in People's Republic of China. It is said that increase in farmland and desertification of grasslands are the cause of diminishing grasslands. This is a serious issue for the Mongolians who make a living from pasturing. In this research, Dalai Lake Nature Reserve, which is located in the Hulunbuir Grasslands has been selected as a study subject. The objective is to clarify the transition of the scenery in the nature reserve by extracting scenery factors in relation to usual lives of the residents in the area.

Study Methods

An opinion research was conducted between the end of December, 2013 and the middle of January, 2014. The survey subjects were the residents who are nomadic in the grasslands of Dalai Lake Nature Reserve. Interviews were conducted and 409 responses were obtained. In this research, demographics of the respondents and the composition factors of grassland scenery in Dalai Lake Nature Reserve were confirmed. The composition factors of grassland scenery were studied in three different time frames: 10 years ago, present, and future vision (for example, 10 years later). For this research of scenery composition factors, 25 factors had been obtained from the initial literature research, and typical factors had been pre-selected among those for multiple choice questions. Multiple answers were accepted for this question, and an open answer section was also provided. Responses to the grasslands management which local residents would expect were also obtained. A chi-square test was applied to statistical analysis.

Results

Scenery factors of Dalai Lake Nature Reserve obtained from literature research included; 1) natural scenery such as lake, river, swamp, wild animals, and wild vegetation, 2) cultural landscape like Mongolian gels, and 3) factors which developed along with economic development, including electricity, mining and building.

The demographics of respondents showed that residents within the nature reserve counted 236; therefore, the number of the effective responses has been determined as 236. The average age of the respondents was 41.1 years old. These respondents include 170 Mongolians (72%), the Hans (23%), and the Evenk (5%).The following factors are the ones that all effective respondents selected as typical scenery composition factors of 10 years ago: wild animals, wild vegetation, grasslands, and river, whereas 99%selected lake, sandy soil, and livestock. Only1%selected railroad, ger camp, signboard, tourism facilities, and camping car. Next, the following factors are the ones that all effective respondents selected as current factors: village, railroad, sandy soil, and livestock, while 232(98%) selected roads and electric lines. Following these, 229(97%) selected mining field. The factor mentioned by the least respondents was wild animal with 54respondents (23%).Lastly, in the question of future scenery composition factors, the following ones are those that all respondents selected: wild vegetation, grasslands, livestock, and river. Road was selected by 233 respondents (98%), and lake by 227 (96%). A small number of respondents selected mining field (41 respondents, 17%) and electric wire (50 respondents, 21%).Comparing the scenery composition factors of 10 years ago and those of current, natural scenery factors decreased from 93% to 60%. On the other hand, future natural scenery factors counted 87%.

In terms of grasslands management which residents would expect, major responses were as following: 1) maintain status-quo (103 respondents, 44%), unplanned succession(79 respondents, 34%), and reinforce management (51 respondents, 22%).

Conclusion

This study clarified the scenery which residents in the nature reserve area have in mind and specified it in three different time frames: 10 years ago, present, and future vision (approximately 10 years later). Grasslands management which residents would expect has been also captured.

Research on Comparison of Races in Terms of Evaluation of Natural Landscapes in the Republic of Fiji

KOSUGE, Takashi[1*] ; FURUYA, Katsunori[1] ; VERMA, Mukesh[2]

[1]Graduate School of Horticulture, Chiba University, [2]Hard, Social Sciences, Fiji National

Methods

1) after collecting Natural landscape photos of Japan and Fiji national countries, Fiji 33 photos and Japan 39 phots of WATERFALL, FOREST, SEASHORE, RIVER, FARMLAND, SWAMP, MOUNTAIN, and LAKE were selected from each country, which sum up to a total of 72 photos, 2) these photos were categorized in groups by 141 a citizens and each group was labeled with a name, 3) the same students evaluated these photos according to preference (5-scale) and exoticism (3-scale), and 4) they were asked to select three photos which they believe to represent the unique characteristics of the Fiji, so that landscape that exhibit the unique characteristics of each ethnic can be extracted. I stayed in Fiji August-December 2013. And A research was run among the Fiji residents during stay. I used a investigation by interview. Then answers were collected from 141 respondents. Cluster analysis (Ward's method, squared Euclidean distance, 3) was applied for the analysis of photo categories, and Mann-Whitney U Test was applied for the analysis between ethnic groups.

Considerations and Research results

Firstly, the difference in classification of the pictures of SWANP was observed between the two races. Fijians classified SWANP and FOREST into different groups, and they included SWANP in the category of RIVER. On the other hand, some Indians included SWANP in the category of FOREST and some included SWANP in the group of RIVER.

Secondly, regarding classification of LAKE, both Fijians and Indians classified LAKE into the same group as SEASHORE. In Fiji, where the percentage of water area in the land is extremely low, there is a possibility that LAKE are not recognized as such. Regarding classification of SEASHORE, both races divide BEACHE into two broad categories: landscapes of sandy BEACHE where there are only a few rocks and trees, and rocky BEACHE where rocks and reefs are common.

In the analysis of preference, significant differences were detected with the six pictures. Five of the six pictures were landscapes of Fiji, and one of them was a landscape of Japan. Furthermore, in the analysis of exoticism, significant differences were seen with the four pictures. Three of the four pictures were landscapes of Fiji, and one of them was a landscape of Japan. Concerning preference of the pictures of the landscapes of Fiji, the value of Fijians is 4.06 higher than that of Indians. Regarding selection of the pictures typical of Fiji, there was a variance between Fijian and Indian residents. Fijians selected the pictures of FARMLAND (21 %), MOUNTAIN (17 %) and SEASHORE (17 %), while on the other hand Indians chose the pictures of SEASHORE (44 %), RIVER (14 %) and SWANP (12 %). The reason for Fijians' choice may be that they think fields of taro, which is the staple food in Fiji, and mountains extending into villages as traditional landscapes of Fiji. On the other hand, the reason for Indians' selection may be that they associate landscapes of BEACHE with a scattering of resort spots in Fiji.

Fijians' preference was in the order of WATERFALL (4.43), LAKE (4.41), RIVER (4.14) and SEASHORE (4.09), and Indians' preference was in the order of WATERFALL (4.41), LAKE (4.33), SEASHORE (4.08) and RIVER (4.02). That is to say, both races preferred the pictures of waterfront landscapes. Particularly, the pictures of SEASHORE may be considered as familiar landscapes of Fiji. Most of the pictures of WATERFALL and LAKE were from Japan, and they are unfamiliar sights in Fiji and considered as exotic landscapes (the pictures of Japanese landscapes). However, the pictures of SWANP were not very much preferred compared to other pictures of waterfronts. There was not much big difference in preference between Fijians and Indians excluding the six pictures with which significant differences were detected. However, there was a difference in that Fijians preferred traditional landscapes whereas Indians preferred landscapes of seashores.

Study on natural amenities in off-limits area: imagination of virtual activities received from landscape

MIZUKAMI, Shogo[1*]

[1]Department of Public Policy, School of Sociology, Bukkyo University

Introduction

In urban areas, there is little space that has been kept natural although it is now recognized that natural elements such as green space, water features or wildlife habitat, etc. increase the value of an environment. However, human influences on natural habitats interfere with restoring natural spaces to their original condition.

It is difficult to maintain such green space and limit its availability to people. In fact, it is often the case that areas with a high level of undisturbed natural habitats are off-limits areas.

For example, storm-water reservoirs for flood control in urban areas are off-limits, concrete-covered, fenced-in spaces. However, a variety of wild fauna and flora manage to make their habitats in some reservoirs. In other words, reservoirs are an example of artificial yet informal urban green spaces, where spontaneous wild vegetation grows. However, clearly reservoirs were not planned as natural spaces.

Although these spaces are off limits, people can enjoy a view of natural growth from the wall of the reservoirs. On the other hand, due to the physical boundary, people cannot get in touch with natural elements due to perceptual constraints.

Viewing such restricted areas has a beneficial effect as a solution for symbiosis with nature because human development and natural preservation are opposed to each other.

This study clarifies people's impressions of the spontaneous and wild vegetation in reservoirs. Moreover, this study considers the affordance research for environment afford prevision of behavior to perceiver as seen in the case of flying stone. Flying stone is a concrete block put into a river bed. This paper presents a new way for people to virtually take part in nature-friendly activities. This study explains how imaginary contact with nature by viewing spontaneous vegetation in off-limits, informal urban green space creates satisfaction.

Methods

Research Questionnaire 1

In a Tokyo suburb, 108 reservoirs were selected for this study. We surveyed shapes, size, location, and surrounding environment and explored possibilities of whether the space was a beautiful landscape and from what perspective.

We conducted an awareness survey regarding environment and landscape with 88 residents living around three reservoirs. Correlative relationship was applied to analyze the relationship between question items.

Research Questionnaire 2

Another study was conducted in Kyoto with 175 university students who responded to questions about the image of flying stones on the Kamogawa River. Responses were given as free descriptions. A text mining approach was applied to analyze symbolic representations for water-friendly activities.

Results and Considerations

The results show that most of the reservoirs were concaved and had good views of open space. Therefore, reservoirs have a high potentiality to be urban green space, where people can view spontaneous natural habitats. Reservoirs are artificially made. The results also showed vegetation succession has possibilities for creating transient esthetic appraisal. However, questionnaire results showed that residents who lived around reservoirs feel that the naturally occurring vegetation is not beautiful.

The results of affordance research were as follows. Flying stones provide an image of physical behavior. for getting across a river or playing in the water. The image is a trigger for the imagination of virtual water-friendly activities. Symbolic representation of environmental signatures is a device that affords imaginary familiarity with environmental elements.

Keeping a view of nature in off-limit green spaces leads to an imaginary sense of familiarity with nature.

Symbiosis with nature increases the value of an environment in urban. Image of nature-friendly activities have a commonality of body. Therefore, symbolic representations for nature-friendly activities have a functional role as a landscape appraisal standard.

The questionnaire was consisted with two main part, survey about figure of the coastal mindscape and individual backgrou

MATSUSHIMA, Hajime[1*]

[1]Research Faculty of Agriculture, Hokkaido University

In this study, the image of coastal landscape as the mindscape were compared between Japanese university students and Russian university students by the questionnaire survey.

The questionnaire survey were conducted to 24 university students of Irkutsk city as Russian university students and 73 university students in Sapporo city as Japanese university students.

Furthermore, 12 Russian students who studied in the university in Sapporo city were added as Russian students in Japan.

The questionnaire was consisted with two main part, survey about figure of the coastal mindscape and individual background of respondents. As a result, the sandy beach and sea were the major component of mindscape. Because most respondents enjoyed sea bathing as recreational use, it was guessed that the viewpoint from the beach were dominated and inland area, like coastal dune, was not described.

On the other hand, Russian university students described more emotional words as beautiful, calm, bright, etc. in addition to major components.

There was no difference in a drawn composition type, but Russian university students described more natural components, mainly coastal plants, than Japanese. About the shore protection, the Russian student did not image in particular it at all.

Landscape Appreciation on Green Passages with Waterway in Edogawa Ward, Tokyo

SADO, Susumu[1*] ; FURUYA, Katsunori[1]

[1]Graduate School of Horticulture, Chiba University

Introduction

Edogawa Ward equipped itself with the first water nature park in Japan in 1974, and sterilized purified water has been utilized in this park. By 1996, water nature parks with natural water had been also established with considerations for ecosystem. The focus of this study is inhabitation of living creatures and human usage in relation to differences between purified water and natural water. The objective of this study was determined to clarify the following three points at two green passages in Edogawa Ward: 1) impressions among the users, 2) behavior of users, and 3) inhabitation of living creatures. Comparing the aquatic life, more variety of living creatures was identified in natural water, and fewer in purified water.

Study Methods

First, an opinion survey about impressions of green passages was conducted among the green passage users. A survey questionnaire was directly handed out to 288 users on the 24th and the 28th of July and the 4th of August, 2013. The following four items were tested in this study: 1) if they like it, 2) if they feel good, 3) if the water is clean, and 4) if there are many living creatures. Following this questionnaire, a behavioral study was executed in order to compare the results of the opinion survey and the actual usage of green passages. This behavioral study was administered between 10:00 and 14:00 on the 25th and the 31st of July, 2013. The subjects of this research were fish, crustacean, reptiles (turtles), and amphibians (frogs). This research was conducted between 9:00 and 17:00 on the 17th, the 18th, and the 31st of July, 2013. The research area of the green passage was segmented into 27 sections.

Results

The impression survey concluded that over 98% of the users had favorable impressions of both green passages from the results of two questions: *if they like it* and *if they feel good*. As for the question *if there are many living creatures*, 74.5% responded *very many* or *many* in the green passage with many natural water streams. Although the difference is small, relatively smaller figure of 65.6% responded *very many* or *many* in the one with purified water streams.

The behavioral study result showed that the most popular usage among the eight categories was *playing with water* with over 25% of usage. The result was same with both green passages. Similar tendencies were detected with both passages with other activities which followed the most popular *playing with water*: *resting*, *walking*, and *exercising*, in order of popularity.

The inhabitation research confirmed 14 kinds of aquatic habitat on the green passage with natural water, and nine kinds on the one with purified water. Among the confirmed aquatic habitat, reptiles and amphibians such as the Chinese three-keeled pond turtles, Mississippi common sliders, and Japanese toads were observed on the green passage with natural water; however, they were not found on the green passage with purified water. In addition, the average number of creatures per 100 meters counted 14.7 on the green passage with natural water, but the figure on the green passage with purified water counted only 7.0. More than double the difference was detected between the two.

Considerations

Based on the research results of the two green passages, the difference in the inhabitation situation has been clarified. However, there were no significant differences detected in users impressions of the scenery and in their behavior. From these results, it can be inferred that the differences in aquatic habitat on the green passage does not have a significant influence on users impressions with the scenery or on their behavior. Futures researches on other factors such as vegetation and surrounding environment of a green passage, including grass and woods, shall further clarify favorability of sceneries and user behaviors.

The Development of Large-scale Upland Farming and Farmland Use in Hokkaido : A Case Study of Otofuke Town

SASAKI, Toru[1*]

[1]Sapporo Gakuin University

Japanese agriculture falls into a decline. Especially, farmland resources very important as a factor of production are decreasing. From 1961 to 2010, farmlands decreased by 25% in Japan. On the other hand, in Hokkaido, farmland is not decreasing so much.

This presentation tries to explain the characteristics of large-scale upland farming and condition of farmland use in Otofuke town.

Change of forest use and current state of coppice forest in Nenoshiroishi near Sendai

MATSUBAYASHI, Takeshi[1*] ; KANO, Arika[2] ; UCHIGASAKI, Aya[3]

[1]Tohoku Fukushi University, [2]Resarch Student, Miyagi University of Education, [3]East Japan Railway Company

Coppice forest had been repeatedly felled in an interval of about 15 to 30 years in order to produce and provide fuel wood and charcoal. A charcoal production worker produced 1,500kg of the charcoal in the winter of 2009-2010 in Nenoshiroishi near Sendai. The felled area is approximately 800 square meters. The amount of production of charcoal was approximately 3,000,000kg per year in Nenoshiroishi in the 1930s, therefore the felled area is calculated approximately 1.6 square kilometers per year at that time. After the fuel revolution in the late 1950s and the early 1960s, felled area rapidly decreases, and trees have grown to large sized. In recent years, mass mortality of oak trees has been expanding rapidly in Nenoshiroishi. Growth of the tree is considered to one of the causes of mass mortality of oak trees.

Utilization of local resources in agricultural cooperatives in Inner Mongolia,China

SEKINE, Ryohei[1*] ; SASAKI, Toru[2] ; SUDE, Siqin[3]

[1]Tohoku University, [2]Sapporo Gakuin University, [3]Inner Mongolia University

This study considers about the regional action mainly on the sales of dried beef established with agricultural cooperative modality in Xilingol League, Inner Mongolia Autonomous Region, China that it lived by mainly in live stock farming before 1990s. Agricultural cooperative in China is a new co-operative association institutionalized from 2007 as a position improving local economy. Dried beef is winter excellent products in this area. The agricultural cooperative targeted in this study produces dried beef by oneself, and sells it by oneself at the store established in Xilinhot City that is local metropolis of Xilingol League.It is administered by 25 households live in Bulgan County.They got an adjunct to 300,000 yuan from the government in 2009 to establish this cooperative. This study discusse about the business processes after the establishment of this cooperative and the relations with local resources.

Placing sediment budgets in the socio-economic context for management of sedimentation in Lake Inle, Myanmar

FURUICHI, Takahisa[1*] ; WASSON, Robert[2]

[1]Department of Science, IT, Innovation and Arts, Queensland Government, Australia, [2]National University of Singapore, Singapore

In soil erosion and sedimentation research in developing countries, scientists are expected to be better involved in quantifying mechanisms and rates of sediment movement and objectively demonstrating their impacts. Soil erosion and sedimentation in the ca. 3,800km^2 Lake Inle catchment, Myanmar have been of both local and national concern given the significance of the lake to the economy, environment, and culture. Sediment budgets that include a focus on different sedimentation rates in various sink environments around and in the lake were constructed for this lake catchment. The sediment budgets showed that deltas stored more than half of the sediment transported to the lake area, and that, despite the relatively smaller storage mass, the highest specific storage was found at river mouths. Socio-economic assessment identified diverse perspectives on impacts of sedimentation. Of those perspectives, increasing difficulty in water transportation was recognized as a common, significant problem among stakeholders. Proposals for management of sedimentation therefore emphasize that a priority should be given to controlling sedimentation at river mouths.

Regional Governance of Forest and its Fringe - case of South India -

KIMOTO, Koichi[1*] ; S., Arun das[2]

[1]Hiroshima Jogakuin University, [2]University of Mysore

In recent years, on a global scale, forest issues are being ”organized”. The ”facts” of a serious deforestation and ”needs” of appropriate protection, as the international public opinion, becomes the general framework of forest policy in each country and region, and under the framework various policies have been implemented. In the late of the 1980s, it may be said that the short turn from the timber-oriented forest government to the community based forest management and governance is a beginning of such a trend. Since the 1990s, many of research such as various case studies of the present situation of forest, a critique of forest policies and foreign aids, and theoretical studies including the commons theory, have been accumulated.

In India, Joint Forest Management (JFM) which was launched at the beginning of 1990s has been showing a certain ”recovery” in the forest rate. However, since the late 1990s, various problems such as land acquisition and competition and the human ? wildlife conflict spout out. Indeed, under the JFM program, we might be able to recognize the results of certain ”improvement” in both the macro level of forest rate recovery and micro level of participatory activities in village. On the other hand, it has been overlooked the issues related with the forest ”region” including the forest and its fringe areas. The success of forest policy, so to speak, has dug out the forest ”region” issues.

Even if the community based forest management will be developed continuously, the problem of the forest ”region” must be considered with a peculiar frame of its own. As the forest ”purification” by the setting of ”National Park” and an enclosing of legal and/or physical, the doughnut-shaped chaotic area around the forest appears like sprawling phenomenon in the sub-urban area.

In this study, we are trying to overview of the problems in the forest ”region” based on our field survey in Karnataka, India.

Borehole use and management in agro-silvo-fishery settlements around Lake Victoria, Kenya: water use rules

UEDA, Gen[1*] ; OTSUKI, Yoshinori[2]

[1]Graduate School of Environmental Studies, Tohoku University, [2]Graduate School of Science, Tohoku University

This study is an interim report on the use and management of boreholes, whose importance as a domestic water source becomes greater as one goes far from Lake Victoria, in the sub-area (former Suba District) of Homa Bay County, Nyanza Province, Kenya. As for one of the boreholes outlined in 2013, the water level rose during the rainy season, the daily change in the water level corresponded to control by the water users' association, and not all member households could fetch water within the daily stipulated time table. Water use of this particular borehole was on the "first come, first served" basis, and it alternated between one queue for those who transported water with a donkey and the other queue for those carrying by human power. Individual boreholes scattered in the research area had a variety of "queueing system" rules reflecting different geographical and other conditions. The water use rule of each borehole can be seen as a historical product of people's attempt to level off inequality in water use in each settlement. It is indispensable for a better understanding of sustainable water use and livelihood security to investigate such rules.

Pig raising frontiers in Tropical Africa: Changing small and medium sized piggeries and their regional system in Kenya

UEDA, Gen[1*]

[1]Graduate School of Environmental Studies, Tohoku University

Although Eastern and Southern African regions have experienced dramatic growth in the pig raising industry since the early 1990s, its enterprise reality has not yet been well researched. This study takes Nyeri County, Central Province and Homa Bay County, Nyanza Province, both in Kenya, as examples of ”pig raising frontiers” in Tropical Africa where pigs are introduced as new livestock. It examines changing entrepreneurial activities that small- and medium-sized pig raisers have performed since their beginning, particularly between 2009 and 2012. Zero-grazing is affected by increasing feed prices, and free ranging/scavenging in urban and peri-urban areas causes crop damages and hygienic problems. These are pointed out as the main reasons which stimulate shift among breeding, fattening and integrated production in an enterprise, and which even trigger withdrawal from pig husbandry. The study also illuminates locational conditions and the regional system of rural and urban pig raising, all of which influence the change in the economic sector. Since the frontier experiences constitute a variety of trial and error, and changes, in achieving a success, their cases suggest potential factors that may promote distribution and sustainability of pig husbandry in Tropical Africa as a quick means to supply food and alleviate poverty.

The value of coral and its change in Kushimoto, southern Kii Peninsula

SAKITA, Seishiro[1*]

[1]Graduate School of Environmental Studies, Nagoya University

In the tropical and subtropical regions, coral is given the status important as one of the symbolic living things of the marine environment. Especially, in the consideration of resource use, coral is generally treated as a physiographic factor which provides a coral reef ecosystem and is often related to local fishing. Meanwhile, the use of coral itself has been seldom brought up for discussion.

Kushimoto is one of the regions in Wakayama Prefecture, and is located in the southernmost end in Kii Peninsula. Owing to the influence of the Kuroshio Current, the subtropical marine biota, typified by coral assemblages, has been produced in the western coastal waters of Kushimoto, and some local residents who lived in the area have collected and used coral as resources. In Kushimoto, coral was usually collected by gathering the casted corpses on the littoral zone, and sometimes by skin diving. Mainly, people has used coral as a material of slaked lime to make mortar, or for processing as a souvenir thing. The scale of these productions was not much extensive, but the use of coral in Kushimoto has been practiced and continued in relation to other local resource uses. For instance, to make mortar, other materials which were collected or produced in the region, such as seaweed and whale oil, were also used with slaked lime made from coral. And when making slaked lime, old timber and thinnings were used as fuel at the sequence of calcination.

Such collection and use of coral in Kushimoto were at least continued until 1970s, and then, these activities have been completely abandoned now. Instead, since the designation of some parts of the coastal area in Kushiomoto as a national park in 1970, the coral and coastal environments have become an object of conservation. Therefore, a collection and use of the coral which inhabits the coastal waters of Kushimoto have been forbidden. And also, following such a increasing of the evaluation to the coral as an important factor of the marine environment, it brings an expectation of the value of coral as tourist attractions.

Besides, in recent years, the temperature of the nearshore waters in Kushimoto tends to rise notably, and it brings about the increase of a number of species and cover degree of coral which inhabits the coastal waters of Kushimoto. Given this situation, the increase in coral has a negative effect on regional fishery. On the other hand, large amounts of corallivorous organisms such as *Acanthaster planci* and *Drupella* spp. have been caused a problem for the conservation of coral since 2000s. Thus, the conditions of natural and social environments which surround the coral inhabits the coastal waters of Kushimoto have been constantly changing.

In this presentation, I would like to show the structure of resource use focusing on coral once formed in Kushimoto, and examine how the value of coral has been changed up to the present to consider the relationship between coral and people.

PALEO-ENVIRONMENTAL HISTORY AND KOSA (DUST AND SAND STORM) FLUCTUATION AT ARID - SEMI-ARID REGIONS IN EAST ASIA

KASHIMA, Kaoru[1*]

[1]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

There are two methods to monitor environmental changes and desertification at arid and semiarid regions. The first one is the short-term monitoring, and examined the changes during several years or decades by meteorological, hydrological, geophysical and geochemical observations. The second one is the long-term monitoring, and presumed changes of environment during hundreds or thousands years using geologic and geographical methods. Although a lot of expeditions have reported short-term changes, the reports for long-term environmental changes have been limited because it takes a lot of efforts to take efficient samples to presume in detail environmental histories.

Department of Earth and Planetary Sciences, Kyushu University has started international research project to make long-term monitoring of desertification in East Asia to correspond with the East Asian Environmental Problems Project of Kyushu University. In cooperation with Mongolian Academy of Sciences, National University of Mongolia, Xinjiang University in China, the filed surveys have been done to obtain samples for long-term monitoring at lakes, ponds and marshes in Mongolia and north western China using geological and geographical methods. Our researches presumed long-range (about hundreds or thousands years) changes of the lowering of lake levels and under grand water levels, the reducing of forest areas and the expanding of deserts in those regions. The desertification has been accelerated in these two hundred years in both regions.

Visualization of liquefied layers using GPR in Watarase flood plain, central Kanto

SETO, Masayuki[1*] ; ICHIKAWA, Minami[2] ; KITAZAWA, Toshiyuki[2] ; NAKAMURA, Yosuke[1] ; TAMURA, Toshikazu[2]

[1]Fukushima University, [2]Rissho University

At the Watarase flood plain, central Kanto, there were many cracks and sand mounds caused by liquefaction in 11, Mar 2011. Various liquefaction models have been proposed based on a profile observation of the old liquefaction and experiment. This study tried visualization of liquefied underground layers. We carried out boring investigations and GPR explorations in Watarase flood plain. Core samples show typical lower river deposits. There was loosely-deposited sandy layer near the groundwater level which was 2m deep. We traced liquefied layers using GPR (Ground Penetrating Rader) which can display the reflection profile about 5m deep with frequency of 250 MHz. By the comparison of core records with GPR images, we confirmed that GPR image is applicable to the distinction of sand, sandy clay and clay layers. Moreover, we found sharply shaped reflection patterns in sandy layers near 200cm deep. Width and height of the pattern is 0.5-2.5m and 0.2-0.95m respectively. Interval of sharp-shaped reflection patterns are 1-20m. The interval is related between the GPR survey line and the location of deformed layer. We considered that these sharp shaped reflection patterns were shown liquefied sandy layers. GPR is thus available for the visualization of the invisible liquefied layers.

Coastal geomorphology as a proxy of large paleothrust earthquakes along the Andaman Trench

ANDRADE, Vanessa[1*] ; RAJENDRAN, Kusala[1] ; RAJENDRAN, C. P.[2]

[1]Indian Institute of Science, Bangalore., [2]JNCASR, Bangalore.

Estimating hazards from earthquakes and tsunamis along subduction zones is of significance to coastal communities. Here, we discuss the coastal geomorphology of selected sites in the Andaman Islands, which lie within the rupture zone of the 2004 Sumatra-Andaman earthquake. As part of the near-source region, these islands witnessed considerable geomorphic changes, both before and after the 2004 earthquake, which may be related to the maturity of a megathrust subduction zone earthquake cycle. Assuming that these geomorphic landforms are properly preserved and attributed to the right sources, it is possible to build the history of large paleothrust earthquakes for the Andaman Islands. Given that these landforms are a result of similar processes through time, our sites are broadly divided as regions that subsided or were uplifted in 2004.

At Hut Bay and Interview Island, uplifted coralline terraces were mapped, as were stream inlets that cut through the newly-formed as well as older terraces. Samples collected from these locations include wood pieces from trees embedded in the stream bank, shells from pebble-rich layers along the exposed bank as well as coral fragments from the terraces themselves. At Port Blair, large stretches of land subsided in 2004. While several farmlands remain inundated beneath the present-day tidal-line, several mangroves trees died in situ, their roots being preserved in the shallow subsurface. Along a steam bank, a similar root horizon was identified 1m below the present day surface which was sampled at multiple locations. Additionally, a shell sample was collected from within the paleo root-zone.

The ages of these samples were estimated using AMS radiocarbon dating, and they cluster at AD 1100, AD 1500, and AD 1900. Though these geomorphic landforms may be the result of other coastal processes, either regional or global, we believe that these ages, with corroborating evidence from several studies in the Andaman Islands and from coastlines in Sri Lanka, mainland India, Sumatra, and Thailand are representative of large earthquakes in recent history, some of may have been tsunamigenic.

Volumetric changes of various rocks during weathering and their geologic significance

CHIGIRA, Masahiro[1*] ; NAKATA, Eiji[2] ; OOYAMA, Takahiro[2]

[1]Disaster Prevention Research Institute, Kyoto University, [2]Central Research Institute of Electric Power Industry

A rock volume may change during weathering, which would have various importance in earth surface processes. However, little is known on the volumetric change. We summarize our research results of various rock types and refer to it's geomorphological importance. Basic idea is so-called isocon concept, which assumes immobile chemical elements during weathering and calculate a volume change from density and chemistry of rock before and after weathering (Grant, 1986). We assume TiO2 is the immobile element.

Granitic rocks:

Volumetric change may be different between granite and granodiorite/quartz diorite. White et al. (2002) reported that granodiorite and quartz diorite are isovolumetric during weathering. Chigira (2002) reported that granite expands 50% during weathering, which is consistent with Folk and Patton (1982) who estimated the volume change from the inflection of a pegmatite vein in a weathering zone. These expansions lead to spheroidal weathering or micro-sheeting.

Sandstone:

Matsuzawa (2008) studied the weathering of sandstone of the Cretaceous Izumi Formation in Ehime and estimated 20-30% expansion during weathering, which closed joint openings.

Mudstone:

Calculation from the data of Chigira (1988) for the Quaternary Haizume Formation in Niigata suggested that mudstone expanded 10-30% during weathering in the upper part of the dissolved zone. Such expansion may facilitate downslope soil creep.

Vapor-phase crystallized tuff:

Calculation from the data of Chigira et al. (2002) for vapor-phase crystallized tuff of the Shirakawa ignimbrite in Fukushima suggested it's weathering was isovolumetric except for the topmost part, in which fabric collapsed and the rock shrank.

Tuff breccia:

We studied the weathering of tuff breccia of the Miocene Tomari Formation in Aomori, which suggested that it occurred with 20-50% expansion. So-called active faults in the Higashidori nuclear power plant site are apparent active faults made by rock expansion during weathering.

Use of rock properties in classification of weathering grades: A Sri Lankan case study

UDAGEDARA, Dashan T.[1*] ; OGUCHI, Chiaki T.[2]

[1]Graduate School of Science and Engineering, Saitama University, [2]GRIS, Saitama University

Rocks utilised for the Samanalawewa project, have undergone severe weathering after they were excavated late 90's. The rate of weathering is incomparably high with respect to the normal soil formation processes. Different weathering grades of rocks that were used as construction materials, foundation materials and road aggregates are found in the project area. Consequently, they have been threatening to the sustainability of the project. The access adit and rip-rap zone of the dam are vulnerable to damage owing to the rapid weathering. Even though charnockite, marble, biotite and garnet granulitic gneisses were utilized for the project, only pyrite-sillimanite-garnet gneiss has shown extensive weathering. The rapid weathering of this rock is being observed since the commissioning of the project. Rocks were subjected to a petrographic study under the optical microscope. Point load strength, slake durability, loss on ignition and water content tests were employed to distinguish weathering grades. Water-rock interaction was experimented to study the pyrite oxidation. Comparatively to charnockite and marble, pyrite-sillimanite-garnet gneiss is weaker according to point load strength and slake durability indices. Rock strength and chemical properties illustrates that the weathering process takes place at a rapid and a normal stages. It is mainly observed on set of weathering. Corroded grains boundaries and decayed minerals in the rock are consequences of weathering induced by the acidic water generated by pyrite oxidation. The abundance of pyrite in pyrite-sillimanite-garnet gneiss is uneven. Thus, different weathering grades of the rock can be seen over the study area. Extensive fractures, which might be generated during tectonic activities or during excavations, facilitate better interaction with the atmosphere. It also effectively reduces the strength of the rock. It is another reason for differential weathering.

Experimental Study on Deterioration and Durability of Bicks due to Salts

NGUYEN, Thi hai duong[1] ; OGUCHI, Chiaki T.[2*]

[1]Graduate School of Science and Engineering, [2]GRIS. Saitama University

In Vietnam, heavy construction materials such as bricks are often used because there are many floods. However, the deterioration due to weathering has been found at general houses and historic brick buildings. To investigate deterioration of bricks used in these buildings, the present study performed salt weathering experiments using 6 bricks produced in Vietnam, Japan and China; red brick (RD), beige brick (BG), Vietnam brick (VN), amber brick (AB), brown brick (BR) and refractory brick (RF). These bricks were cut into cylindrical with a size of 3.5 cm in diameter and 7.0 cm in height. After examined rock properties such as physical, mechanical chemical and mineralogical characteristics, two types of salt weathering experiments were performed under 15-35 ℃ and 20 ℃ atmosphere. The saline solutions used in this study are 4%-Na_2SO_4, 8%-Na_2SO_4, 10%?Na2CO3. Results of the experiments show that the deterioration mechanism of bricks is explained that 1) when the salt is absorbed and crystallizes inside brick, micropores of brick are extended by crystal expansion pressure and make cracks, 2) strength of the brick increases slightly by salt crystallization, but decreases gradually by salt deliquescence, and 3) with repeating of 1) and 2), bricks will be damaged. Even chemical and the mineralogical characteristics are almost equal except for BG, physical and mechanical characteristics are deferent, which controls durabilities of these bricks.

Channel migration processes observed in 2013 in the upper reaches of the Azusa River, central Japan

SHIMAZU, Hiroshi[1*]

[1]Rissho University

The upper reaches of the River Azusa in central Japan is a braided gravel-bed river running down Japan Alps. They are characterized by frequent landform changes occurring in the riverbed. This area is located in the high conservation area in the Chubu-Sangaku national park and thus physical processes of river are preserved. This study is the first step to clarify the fluvial processes of a braided gravel-bed river during a flood event.

The geomorphological maps of the observation site were made by the Research Group for Natural History in Kamikochi in every summer from 1994. These maps recorded annual landform changes of the riverbed. Sediment transport and/or major landform changes, such as channel migration, occurred once or twice in several years in severe heavy rain events more than 120 millimeters per day during the snowmelt flooding season in late May and/or the rainy season in June and July.

Interval shooting cameras were set up in 2011. These have taken the images of the riverbed and recorded the condition in every 15 or 20 minutes since 3 July 2011, only in the daylight and twilight. Channel migration in the observation area during the flood event was recorded on 19 June 2013, 166 millimeters of daily rainfall. The rain event began at night of 18 June. Water level began to rise early in the morning of 19 June. The heavy rainfall more than 13 millimeters per hour was recorded from 3 a.m. to 5 a.m. and from 7 a.m. to 9 a.m. The river was above bank-full stage at 12:00 a.m. and this condition continued until night. Highest water level was recorded at 16:15. Although water overflowed on gravel bars and shallow branching channels were formed before the bank-full stage, the landform of the main channel was still in the same condition. Changes of patterns of the water surface and movement of woody debris flowing downstream show that during the bank-full stage the channel landform changed and the main channel was migrated. The channel migration was not caused by lateral shifting with lateral erosion. Channels were buried and new channels were excavated tracing the shallow branching channels.

Risk evaluation of steep slope failure using a slope angle and mean curvature

NISHI, Hayata[1] ; OGUCHI, Chiaki T.[2*]

[1]Civil and Engineering Department, [2]GRIS. Saitama University

According to the previous techniques for the evaluation of slope failures, only steep slopes are taken into account. However, the influence of earthquakes on slope failures has not been considered on the hazard map delivered by local government. After the Great East Japan Earthquake occurred in 2011, Necessity for considering earthquakes on to slope failure evaluation is increasing. Therefore, the present study focused on risk evaluation of steep slope failures caused by earthquakes. Within various techniques, a technique proposed by National Institute for Land and Infrastructure Management, was adopted in this study. With comparing manual and GIS calculations to obtain the parameters of slope angle and mean curvature, the degree of the risk was evaluated. The target slope is Mt. Shinobu, in Fukushima Prefecture. After examination , it is resulted in that the evaluation using GIS is useful as well.

Limit of mountain growth in the development of experimental landforms

OUCHI, Shunji[1*]

[1]Faculty of Science and Engineering, Chuo University

A series of experiments with rainfall-erosion and uplift of various rates, in which a square (60×60 cm) mound of a mixture of fine sand and kaolinite is uplifted at a constant rate under the artificial mist-type rainfall, suggests the existence of threshold uplift rates. In the run with the uplift rate below the lower threshold, drainage networks develop as the surface is slowly uplifted. The erosion is exclusively fluvial and no high slope develops. When the uplift rate becomes higher than this lower threshold, uplift exceeds erosion on the divides of drainage basins, which developed with fluvial erosion, and hills grow and slope processes start working. The divides grow into low mountain ridges with the uplift and slope failures become dominant. When the relief grows high enough, large landslides occur concentratedly. The average height and relief lower with the landslides, but the ridges soon grow again with the uplift till the next concentration of large landslides, and this process proceeds repeatedly. Uplift and erosion seems to become balanced to keep average height and relief roughly constant and landscapes similar. Assuming the existence of the critical slope controlled by the strength of mound-forming material and the rainfall intensity, the experimental landform is considered to reach a dynamic equilibrium condition at a certain relief regardless of the uplift rate. However, when the uplift rate is in the range between the lower and the upper thresholds, both relief and average height become higher with the uplift at higher rate. A simple equilibrium or steady state seems difficult to be expected with the critical slope. Although the maximum slope in a 1 cm grid becomes higher than 80 degree in all runs, considering that the angle of repose of dried mound-forming material is about 34 degree, it is rather difficult to take this maximum slope as the critical slope. The observation of the experiment suggests that large landslides require triggering events to occur, and without triggering events slopes can grow higher. Large landslides often occur when the rainfall is resumed after halting the rainfall for the measurement. This resumption of rainfall can be the major triggering event in the experiment. The interval of measurement is not exactly constant but does not vary so much among runs. As far as the resumption of rainfall after the measurement is the major triggering event, hills can grow higher with the uplift at higher rate. Moreover, fluvial processes can work more with the uplift at lower rate to widen valleys and therefore increase the area of lower slope. Average slope, relief, maximum height, and average height all become lower. In this way experimental landforms can have average height and relief corresponding to the uplift rate. This condition may be called quasi steady state. When the uplift rate is higher than the upper threshold, on the other hand, relief grows to the limit determined by the width of deposition area. In this case further increase in uplift rate cannot increase the height or relief any more, and this condition apparently does not agree with the condition of equilibrium.

Erosion rate is considered to increase with average slope, and some people pointed out that the relation is nonlinear. In the experiments the average value of the highest slope in a 1 cm grid shows similar linear increase with relief regardless of the uplift rate, but they become to show no clear relationship after relief reaches about 60 mm when landslides become dominated in the landform change process. Erosion rate also increase linearly with average slope first, but it becomes almost constant after the dominance of large landslides in the process of landform development. The relation between erosion rate and average slope seems necessary to be reconsidered with taking uplift rate into account.

Evolution of river profile of experimental mountain building

OGAMI, Takashi[1*] ; OUCHI, Shunji[1]

[1]College of Science and Engineering, Chuo University

River profiles and their evolution during mountain building are investigated and the characteristics of river profile under mountain steady-states are examined by rainfall-erosion experiments under various uplift rate. Miniature landforms are developed with constant uplifting of sand-block (mixture of fine sand and kaolinite) and artificial rainfall. Four experiments are operated under the uplift rate of 0.2 mm/h, 0.5mm/h, 1.2 mm/h and 5.0 mm/h. Based on landform measurement, 1 cm grid elevation models are constructed. Streams are generated by basin analysis with the elevation models.

Relationship between the slope of channel (S) and the catchment area (A) are examined. Plots of log S and log A (S-A plots) show convex, linear and slightly concave forms as mountain building progress. In the mountain steady-states, the S-A plots show slightly concave forms, and the forms are stable until end of uplifting. It is deduced that S-A plots become linear forms if they are at steady-state by stream-power incision model. But our result shows that S-A plots under steady-state shows slightly concave forms, expressing that channel slopes at downstream becomes relatively steep than those deduced by the model. This situation should be result of downstream increasing sediment flux, which is important factor of graded river but neglected by the traditional stream-power incision models.

Experimental study of the effect of partial uplift on river channels

NAKAUCHI, Takuya[1] ; ENDO, Noritaka[1*]

[1]Kanazawa Univ.

Flume experiments were conducted to examine the effects of uplift on river channels in which the uplift area was restricted to the middle reaches. Experimental landform was evolved by exerting fine water mist on the slope consisting of a mixture of fine sand and clay, and the uplift was realized by jacking up the partial area of the flume bottom. The conventional idea that the occurrence of water gaps was determined by the balance between rates of uplift and downward erosion is true locally. The rate of down erosion is, however, variable due to the change of channel paths in the meso-scale. The avoidance of flowing in the uplift area tends to cause a new confluence and higher stream power producing larger erosion rate. A confluence makes the possibility of forming water gap high. The avoidance of the uplift area, however, does not always induce a confluence, in which the water gap is not generated.

Current status and issues of grain-size analysis using a digital image method and a laser diffraction method for sedimen

NANAYAMA, Futoshi[1*] ; FURUKAWA, Ryuta[1]

[1]Geological Survey of Japan, AIST

Grain size measurement is the most fundamental physical information in evaluating the characteristics of various materials, the analytical technology. These are JIS standardized clearly by the association of powder process industry and engineering, Japan. In geomorphological field, we are carried out the grain size analysis of volcanic ash, mud, sand, and gravel using in combination of settling tube method, laser diffraction scattering method (LD), sieve classification method and the precipitation method in generally. According to currently technology, it is possible that the LD of each company to measure the particles of a wide range of 10nm to 3mm in a short period. However, we believe that a technical problem for analyzing nature sediments still now because these are not a powder of industrial products with same physical properties.

For example, we know a large scattered light intensity can be achieved in the shorter wavelength of the incident light because it is confirmed by measurement of the fine particles of submicron order, strength is not enough laser light. Moreover backscatter increases depending on the shape of non-spherical particles, tend to shift the fine particle side is confirmed grain size. Further, when using an algorithm for determining the particle size by inverse calculation using the Mie theory, it is necessary to set the user side of the value of the absorption coefficient and the particle refractive index.

This assumption is a very annoying problem for the user.

Recently, the particle size measurement in the field of powder technology, the development of new analytical instruments using digital image analysis method has been increasing. In this method, it is acquired the two-dimensional image of the particle is first digitally imaged by pixel division using the CCD camera and divided into two sub-methods, static (JIS Z 8827-1:2008; ISO 13322-1) and dynamic (JIS Z 8827-2:2010; ISO 13322-2). The methods may be used either, a process that takes as a digital image the particles, the statistical processing on a personal computer is the same.

Analysis method using a digital image of a single particle is clear, it is easy to be trusted from the user side. In addition, the use of the digital image, various particle shape parameter as well as information about the particle size distribution and the particle size of each definition different, for example, can be analyzed at the same time the value aspect ratio, elongation, circularity, HS circularity, convexity, solidity, etc.. Further, it is possible to obtain also the physical properties such as transmittance and intensity. We believe that it is analyzed in conjunction with the particle size measurement result data on physical properties and particle shape these, and becoming a new standard for particle size analysis in the future.

The present study includes the result of ”Research and Development of Margin Assessment Methodology of Decay Heat Removal Function against External Hazards” entrusted to Japan Atomic Energy Agency by the Ministry of Education, Culture, Sports, Science and Technology of Japan (MEXT).

Causes of gravel-sand distribution in upstream part of the river revealed from changes in lithology and form of detritus

UTSUGAWA, Takako[1*] ; SHIRAI, Masaaki[1]

[1]Department of Geography, Tokyo Metropolitan University

Downstream fining of fluvial clastic sediments has been generally attributed to two processes, ”hydraulic sorting” and ”sand grains production”, the former is that finer grains are transported farther than coarser grains, while the latter implies crushing and abrasion of gravels. In this study, we investigated that how the two processes operate on this tendency along the tributary of Watarase River, the major branch of the Tone River on the basis of field survey and measurement of finer grains (4 to 0.5 mm in diameter). Lithological composition of each grain size fraction from cobble to coarse-grained sand (128-0.5 mm in diameter) with 1 ϕ (phi scale) intervals and roundness were obtained with digital microscope.

Changes in lithological composition of cobble – pebble, granule and very coarse sand fractions are not explained only with ”hydraulic sorting” of clastic grains. It implies that crushing and abrasion of gravel – very coarse sand fractions and consequent ”sand grains production” occur at the studied area.

Whereas, coarse sand fraction (1-0.5 mm) shows remarkable features that (i) change in lithological composition along the tributary was not recognized and (ii) grains become rounded in downstream direction. These facts suggest that abrasion of the grains occur dominantly than crushing in coarse sand fraction and ”sand grain production” may not be efficient to grains smaller than coarse sand. Therefore, it will be important to research the distribution of coarse sand and finer grains in bed material along the river in order to reveal the transition from ”producing process” to ”sorting process”, erosion – transport processes of clastic sediments and a development of sedimentological geomorphology along the river.

Earth-surface processes on the basis of instrumental observations in Takidani-ike lake-catchment system, central Japan

ITONO, Taeko[1*] ; KASHIWAYA, Kenji[1] ; OCHIAI, Shinya[1]

[1]Kanazawa University

Lacustrine sediments contain both high-resolution regional environmental records and global information in lake-catchment systems. They are also of great use for reconstructing short-term environmental changes (precipitation, water discharge, etc.) and understanding earth-surface processes (erosion, transportation, sedimentation) in the lake-catchment system.

Process understanding is essential for clarifying causal relations in earth surface phenomena and proper interpretation of sediment information. Instrumental observation (monitoring) is of great use for the process understanding. This study deals with the instrumental observation for a small pond-catchment system (Takidani-ike) near Kanazawa University. The pond is storage reservoir. It is used for agricultural irrigation in summer. Therefore the water level shows highly fluctuation. Our observation consists of sediment sampling with trap, water level measurement, temperature measurement, and precipitation measurement. Observation in Takidani-ike using sediment trap has continued since June 2000.

Observational and analytical results for Takidani-ike show that; the sedimentation rate (both monthly and seasonal sedimentation) is expressed as a function of two factors; precipitation intensity (external factor) and water level change (system factor, closely related to size of erosible area). The correlation for the seasonal relationship is better than one for the monthly relationship, suggesting that reservoir effect in the catchment should be considered. The results also show that mineral grain size may be used as proxies for sedimentation rate.

Characteristics and production processes of coastal huge blocks in the Miyako Island

SHIMAZU, Hiroshi[1*] ; SETO, Masayuki[2]

[1]Rissho University, [2]Fukushima University

There are many coastal huge blocks in the Miyako Island. Some were brought from the sea bottom by tsunamis. Most of others were made by landslides of the coastal cliffs. Previous studies showed the dynamics of the production of such huge blocks from the coastal cliffs of Ryukyu limestone. Development of notches formed near the sea level and vertical cracks on the surface of the marine terraces near the cliffs caused the instability of the rock mass and finally it were torn into coastal huge blocks. This process indicates that the height of the cliff relates the block form and size. However there are large variety of form and size of coastal blocks in Miyako Island. Although smaller blocks are distributed in front of the higher cliff in the Boraga beach, huge blocks with vegetated top are distributed in front of the 20 meters high cliff in Higashi-hennazaki. This Study aims to describe the characteristics and distribution of coastal blocs and discuss production processes of the blocks.

In the Miyako Island the Ryukyu limestone covers the semi-consolidated sandstone or mudstone called the Shimajiri formations. These are unconformable. The Ryukyu limestone is hard and permeable rock and the Shimajiri formations are soft and impermeable rocks. These two layers outcrop on the cliffs and their boundary usually occurs high above the sea level. Groundwater springs or seeps from the boundary on the cliff. The water erodes the Shimajiri formations along the boundary. This process causes the notch-like form at the boundary. At the Braga beach the height of the cliff is more than 40 meters and the boundary of the layers, where groundwater springs, locates 14-20 meters high above the sea level. Development of the notch-like form caused instability of the limestone layer. And then the layer collapsed and produced limestone blocks. They rolled down to the beach breaking into smaller blocks. At the Aragusuku and Urasoko fishing port coasts the blocks were produced by same process. At the Higashi-hennazaki the boundary locates several meters above the sea level. Groundwater sapping forms notch-like form at the boundary. At the Shimajiri coast the Ryukyu limestone appears on all the cliff. A notch was formed at the sea level by the wave process. On these type of coasts the limestone cliffs were torn into huge blocks. The blocks with vegetation on the top of them were deposited along the coast.

Late Quarternary tectonic development at the northeastern margin of Tibet revealed by 10Be and 26Al

SHIRAHAMA, Yoshiki[1*] ; MIYAIRI, Yosuke[2] ; HE, Honglin[3] ; FU, Bihong[4] ; KANO, Ken-ichi[5] ; ECHIGO, Tomoo[6] ; YOKOYAMA, Yusuke[2] ; IKEDA, Yasutaka[1]

[1]Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, [2]Atmosphere and Ocean Research Institute, The University of Tokyo, [3]Institute of Geology, China Earthquake Administration, [4]Institute of Geology and Geophysics, Chinese Academy of Sciences (IGGCAS), [5]Faculty of Science, Shizuoka University, [6]Geo-Research Institute

Tibetan Plateau has been growing up due to collision between the Indian and Eurasian plates and expanding its area laterally by invading marginal forelands and making them involved into deformation. The mechanism of expansion at the northeastern margin of the plateau is still a subject of much debate due to the scarcity of tectonic researches. In the Kumkol Basin at the northeastern margin of the plateau we made detailed geomorphological mapping using satellite images, and revealed that there is a huge anticlinorium that consists of many thrusts and folds covered with significantly deformed fluvial or fluvio-glacial fans or terraces along the Pitileke River. The development and deformation rate of the anticlinorium would give an important clue to understanding the growth mechanism of the plateau. In order to estimate the deformation rate, we dated depositional surfaces by surface exposure dating by using cosmogenic radionuclides (CRNs), such as ^{10}Be or ^{26}Al. Field investigations were conducted in 2011 and 2013, and mainly pebbles of vein quartz were collected at 22 points on the surface of fans and terraces. Depth-profile samples were collected also from 3-m deep sections at two points; each depth profile of ^{10}Be and ^{26}Al concentrations were analyzed for the exposure age, erosion rate, and inheritance by the Monte Calro simulation. In addition, grain-by-grain CRN concentrations were measured for surface samples from two points to estimate the origin of sediments. Following three inferences were obtained: (1) the sediments of the lower part of terraces and the present river contain reworked sediments; (2) depositional processes and erosion processes are strengthened in the glacial and interglacial period, respectively; (3) the upper-most two steps of terraces were formed before the MIS6 and in the transition period from MIS6 to MIS5, respectively.

Longitudinal distribution of incision rates in the Oshika Gorge, Tottori prefecture using terrestrial cosmogenic 10Be:

WATAKABE, Takuma[1*] ; KODAMA, Yoshinori[2] ; MATSUSHI, Yuki[3] ; MATSUZAKI, Hiroyuki[4]

[1]Graduate School of Regional Sciences, Tottori University, [2]Faculty of Regional Sciences, Tottori University, [3]Disaster Prevention Research Institute, Kyoto University, [4]School of Engineering The University of Tokyo

We determined longitudinal changes of incision rates in the 3 km long Oshika Gorge, Tottori prefecture, Western Japan, by exposure dating of a series of granitic strath terraces using terrestrial cosmogenic 10Be. Thereby we discuss development of a waterfall sequence zone and an incised meander zone. The bedrock of the gorge consists of granite. We collected 24 granite samples from surface of erosional terraces. The oldest exposure age of a strath terrace was 50.2 kyr (relative height from river-bed is 11.0 m) and the youngest exposure age was 1.2 kyr (relative height is 1.2 m). Incision rates in the Oshika Gorge varied from 0.24 mm/yr to 1.40 mm/yr. Those of step-pool sequence zones and large boulder scatter zones were about 0.64˜1.40 mm/yr, which showed increasing tendency toward downstream. Those of the waterfall-pool sequence zone were 0.24˜0.57 mm/yr, which showed rapid increase toward downstream. This means that gradient of the waterfall-pool sequence zone has been under increasing conditions in these c.a.50 kyr, resulting from river-bed roughness increase according to waterfall-pool growth. The incised meander zone is located just upstream adjacent to the waterfall-pool sequence zone. Incision rate of the incised meander zone was 0.36 mm/yr, which was slower than that of step-pool sequence zones and faster than that of the waterfall-pool sequence zone. In this reach, alternate gravel bars were developed because of lower gradient and as a result, lateral migration of the river occurred and the incised meander zone was developed.

Basin-averaged erosion rates of Yakushima using cosmogenic 10Be in river sediments

SHIROYA, Kazuyo[1*] ; MATSUSHI, Yuki[2] ; MATSUZAKI, Hiroyuki[3]

[1]Geological Survey of Japan, AIST, [2]Disaster Prevention Research Institute, Kyoto University, [3]Department of Nuclear Engineering and Management, School of Engineering, The University of Tokyo

Quantitative understanding of erosion rates under several geomorphic and geological settings is important to discuss the process of erosion. We investigated basin-averaged erosion rates from cosmogenic ^{10}Be in quartz grains from river sediments in Yakushima. Erosion rates in Yakushima are relatively low within a similar range to those in regions of several times lower rainfall than Yakushima. This finding suggests that rainfall is not necessarily a causal factor of landform evolution. In this presentation, we focus on a pattern of hillslope erosion and a process of landform evolution in Yakushima.

This research project has been conductedas the regulatory supporting research funded by the Secretariat of Nuclear Regulation Authority (Secretariat of NRA), Japan.

Temporal variation of Kurobe River Sediments revealed by TL and ESR signals in quartz

YOSHIDA, Msanori[1*] ; TOYODA, Shin[1] ; NINAGAWA, Kiyotaka[1] ; TAKADA, Masashi[2] ; SHIMADA, Aiko[3]

[1]Department of Applied Physics, Faculty of Science, Okayama University of Science, [2]Department of Geography, Nara Women's University, [3]Application Support Team, JEOL RESONANCE Inc

While the ESR signals of the E1' center in quartz was used to investigate the origin of the loess in MIS 1 and 2 (Toyoda and Naruse, 2002) and of the sediments in the Sea of Japan (Nagashima et al., 2007). Shimada (2008) showed that TLCI (thermoluminescence color image) may be useful for similar qualitative study on river sediments. In the present study, the wavelength-temperature two dimensional thermoluminescence measurement was employed, together with the ESR measurements, to investigate the temporal change of these characteristics observed in fluvial sediments of the Kurobe river.

Eight sediment samples were collected from the present river bed along the Kurobe River in 2012 and 14 samples in 2013. They were sieved into two grain size fractions of 500-250μm, 250-75μm. Quartz grains were extracted using chemicals, heavy liquid, and an isodynamic magnetic separator. The obtained quartz grains were heated at 300 degree Celsius for 1 hour to erase the inherited signals. Each sample was then separated into 9 subsample aliquots for gamma ray irradiation up to 2640 Gy, which are for ESR measurements. Other aliquots for TL measurement were given a dose of 809 or 857 Gy with wrapping the tubes with Al foil in order to keep the samples in the dark.

TL measurements were performed by using the two dimensional TL apparatus. We measure the TL emission spectra during heating up to 450 degree Celsius. Red emission (538 to 658 nm) was observed between 140 and 250 degree Celsius (Low Red) and 290 and 370 degree Celsius (High Red) and Blue emission (379 to 538 nm) was between 103 and 211 degree Celsius (Blue). The integrated counts were taken as the intensities of the red and blue emissions. The results of ESR measurements will be given in the presentation together with the TL results.

Distribution pattern and formation processes of potholes in Oshika, Tottori: role of pothole on river incision processes

KODAMA, Yoshinori[1*] ; INOUE, Yuuki[2]

[1]Fac.of Regional Sciences, Tottori-Univ., [2]Under Graduate, Fac.of Regional Sciences, Tottori-Univ.

Potholes on the Oshika River bed near Takaganma, Misasa-Town, Tottori, Western Japan were surveyed. Surrounding terrace development revealed that there potholes were formed within 3,600 years. Plan view survey illustrated a line distribution pattern of potholes, resulting from longitudinal vortices generated in flood flows. Longitudinal profiles (Fig.) showed that bottom levels of potholes were close to or towards to those of the present river bed. In general, potholes have a role of effective drilling erosion on a hard bedrock elinimation with few sediment loads in the river incision processes.

Accumulation patterns of in-channel modern deposits in the lower Stung Sen River

NAGUMO, Naoko[1*] ; SUGAI, Toshihiko[2] ; KUBO, Sumiko[3] ; OKAZUMI, Toshio[1]

[1]ICHARM, PWRI, [2]Graduate School of Frontier Sciences, University of Tokyo, [3]School of Education, Waseda University

The Stung Sen River flows down the central region of Cambodia, is the main tributary in the Tonle Sap drainage basin. It develops fluvial lowland in its downstream and the longitudinal profile is very flat, with the slope of less than 0.1 ‰. Monsoonal precipitation provides seasonal flood every year in the fluvial lowland and cyclic water level changes of the Tonle Sap Lake about 8 m in the river mouth, therefore the river seems to change sediment transportation processes in each season. While meander scrolls formed by channel migration and back marsh are found in the floodplain throughout the year (Nagumo et al., 2013), four types of channel bars are recognized within the river channel about 10 m lower than back marsh during dry season. Outcrop observations at concave type channel bars revealed the alternate layers of reverse-graded sand and mud layers, and inserted plastic pieces with date stamps indicated that the deposits are quite new and have been partly replaced to reflect flow regime changes of the river. Such sedimentary structures suggest that minute fluctuations of water level and discharge control bar construction, and would be important source to understand recent flood history and patterns.

Controlling factor on evolution of late Pleistocene to Holocene sequences in Nara Basin

HORI, Kazuaki[1*] ; ITO, Nobuaki[1] ; TAKADA, Masashi[2]

[1]Department of Geography, Graduate School of Environmental Studies, Nagoya University, [2]Department of History, Sociology and Geography, Faculty of Letters, Nara Women's University

Many researches on late Pleistocene to Holocene sequences (Chuseki-so) have been carried out in coastal lowlands. In contrast, stratigraphy and evolution of alluvial plain located above the coastal lowlands is less well known. We focus on Nara Basin to clarify stratigraphy and evolution of alluvial plain.

Two borehole cores (MK1, MK2) were taken at Matsukasa, Yamatokoriyama city located in the middle part of the basin. Sedimentary facies analysis and AMS radiocarbon dating were performed. Stratigraphy of late Pleistocene and Holocene deposits was built by analyzing existing borehole columns and radiocarbon ages. Additionally, an incised valley formed beneath the Kawachi Plain located near the Old Yamato river mouth during the sea-level lowstand was reconstructed by analyzing existing borehole logs. Sediment accumulation rate of the basin mainly during the last two millennia was estimated from depth of remains shown in archaeological reports published by Archaeological Institute of Kashihara, Nara prefecture.

Radiocarbon ages obtained from the cores suggest that thickness of Holocene deposits is less than approximately 3 m and they have mainly accumulated after 2,000 cal BP. The timing is not related to sea-level change of Osaka Bay. Sea-level change would affect change of river-bed gradient at Kawachi Plain near the river mouth. However, Kamenose narrow segment in Ikoma Mountain is located between Kawachi Plain and Nara Basin and is composed of Cretaoeous and Neogene igneous rock. Rock hardness may have resulted in small incision rate of the river bed at the segment, and influence of the sea-level change above the segment was little.

Geological section of Nara Basin shows thickness of Holocene deposits on south area is larger than that of north area. Discharge and drainage area of south district are ca. 2.3 times larger than those of north district. This may be related to the difference in thickness of Holocene deposits.

Depth of remains during the era of Yayoi to Kamakura suggests that increase in sedimentation rate occurred after Asuka era. Existing pollen analysis results indicate that second growth forest probably influenced by human activity had already occurred in and around the basin at Kofun era. Therefore, it is possible that artificial effects in the basin caused increase in sediment production and influenced formation of late Pleistocene to Holocene sequences in Nara Basin.

Quantitave Evaluation of Microtopography in the Riverside Land of the Mizunashigawa River, Japan

OGURA, Takuro[1*] ; AOKI, Tatsuto[2]

[1]School of Humanities, Kanazawa University., [2]School of Regional Development Studies, Kanazawa University.

This research did the quantitative assessment of how the amount of encroachment changed and microtopography change in the outside area of the new dike, which modify the land, of Mizunashi River. The origin of this river is the mount Unzen which is well known of its eruption in 1990. This area is unique because of the artificial preparation of the soil; its base-level of erosion was reset. Thus, this area cannot be discussed by the usual landform evolution, but quantitative assessment.

The result of the research showed that the effect of the change can be divided into 4 periods. There was no large-scale debris flows and erosion of the lateral had progressed with the formation of the micro watercourse network in the 7 years since the 1998.

vdebris flows in the riverside land stabilized as the result of the terrain became stable in 2005.

There were debris flows that occurred intensively in a short period while 2005 to 2008. They were large enough to cause the outflow of the vegetation of the surface layer. As a result of these debris flows, the lateral erosion changed to the downward erosion. After those debris flows, the passage was fixed.

There was a rapid recover of the flora in 2011. This increased the stability of the outside area of the bank.

Overview of the area

It has been more than 20 years since the Heisei eruption; however, a light rain amount of about 20 ˜30mm rainfall time can cause debris flows in the Mizunashi River. To minimize the damage of the volcanic disaster, constructions for the erosion control are still continuing.

Results and the research method

Calculation of bare land ratio by GIS

Putting the base-level of the erosion to the 1998, as the time lapses the ratio of the bare land decrease. For instance the bare land area was 91.62[%] in 2003, but in 2005 it became 50.32[%]. However, the ratio of the 2008 was 58.66[%] and after 2008 the ratio is repeating a micro increase and decrease.

Calculation of the flow path extending ratio

The calculation is about the the ratio of the flow path extending of the same waterway since 2008. The result of the calculation shows the quantitative assessment of the immobilization of the channel. This is shown by the result of the 2008, 2011 and 2013, in these three years the ratios are 1.11 and 1.10.

Measure of the erosional cross section and local observation

The survey date show the width of gully is 8.27[m]. This is approximately equal to the size of the width and gully erosion in the upper reaches. This date can be seen in the report of 2011 by the Unzen reconstruction office. Calculating the average erosion speed (v) from the base level of erosion and the maximum deepening speed (Mv) from the maximum depth of erosion, the results are v=4.66[cm/year] and Mv=20.6[cm/year]. These results show two things. First, the lateral erosion has the bigger scale than that of lower erosion. Second, the direction of the erosion changed recently from horizontal to down.

Timing of sediment discharge events on a welded tuff slope in Chugoku Mountains, Japan

WAKATSUKI, Tsuyoshi[1*] ; YAMADA, Ryuji[1]

[1]National Research Institute for Earth Science and Disaster Prevention

Many slope disasters were occurred by a heavy rain on July 28, 2013 in Yamaguchi and Shimane Prefectures. In particular, a number of shallow slope failures and debris flows occurred on mountain slopes underlain by rhyolite-dacite welded tuff in the Tsuwano Town, Shimane Prefecture and the adjacent Ato District, Yamaguchi City. The debris flows eroded the sidewalls and the riverbed of the flow channel, and outcrops of deposits accumulated by sediment discharge events older than 2013 appeared intermittently. From five outcrops along two channels, we collected 11 chip samples of the woods that may have buried and died at the time of the sedimentation. We performed 14C dating of them, and the calendar-calibrated radiocarbon ages showed a 0.6 - 52 Ka BP. Sedimentary structures suggest that these ages correspond to the occurrence time of debris flows and slope failures in the past.

The characteristic of roots distribution on the slopes in Izu-Oshima where landslides were occurred by Typhoon No.26

MURAKAMI, Wataru[1*] ; OGAWA, Akiho[1] ; OGAWA, Yasuhiro[1] ; DAIMRU, Hiromu[1]

[1]FFPRI

Large-scale landslides were occurred in Izu-Oshima by Typhoon No.26 on October 16, 2013. By the urgent investigation after the disaster, it is reported that the landslides were occurred in the part within about 1m from the slope surface and the few rhizomes were on the slip surface. We surveyed the distribution of the fallen trees (species, height, the root depth, and the extensions (widths) of the roots) on the slope near the landslide. The surveyed fallen trees were a lot of *Eurya japonica*, and were the order of *Ilex crenata var.hachijoensis*, *Prunus lannesiana var. speciosa*, and *Camellia japonica*. Most of the surveyed fallen trees were about 5-7m in height, and the high one was 10m or less. The root depth of most fallen trees was 60-80cm; however, the root depth had the difference by the tree species. The Camellia japonica and the Prunus lannesiana var. speciosa had comparatively deep roots. On the other hand, the Eurya japonica and the Ilex crenata var.hachijoensis tended to be distributed shallowly the root systems. As a factor to which the root systems are not deeply distributed, a peculiar properties of soil situation of the volcano is pointed out. In this survey, the difference of characteristics of the tree species on the surveyed slopes was guessed as a cause, too.

Verification of incision rate estimation baseed on the geomorphological history of river terraces in Kaligandaki, Nepal

YOSHIDA, Takahiro[1*] ; SUGANUMA, Yusuke[2] ; MAEMOKU, Hideaki[3]

[1]The Guraduate University for Advanced Studies, [2]National Institute of polar rearch, [3]Housei unversity

The Himalaya is the highest mountains of the world. To estimate long-term (1 ˜100 kyers) uplift history of the Himalaya, erosion rates of the incised river have been used with presuppose of dynamic equilibrium between tectonics and aggradations. This estimation is based on the correlations of the river terraces, however, depositional processes of the terraces usually have not been described in detail.

The Kaligandaki is the one of the longest river across the Nepal Himalaya. The long-term uplift history of the Himaraya has been estimated from the distribution of Holocene and Pleistocene terraces along the Kaligandaki river. In this study, we carried out the detailed geomorphological and sedimentological survey at the upper and middle part of the Kaligandaki River to verify the correlations of the river terraces. The fluvial terraces at the upper part of the Kaligandaki river is thought to be originated to the local sediment supply from three phases of the glacial events, although the middle part of the terraces are fluvial sediment. This indicates that correlations of the river terraces along the Kaligandaki river is not suitable for the estimations of incision rate and uplift history of the Himalaya.

Keywords: Himaraya, Geomorphology, Kaligandaki, Fuluvial terrace

Field measurements on the reduction of wave height on a fringing reef: A study from the Miibaru coast, Okinawa Island

TAKEISHI, Yu[1*] ; AOKI, Hisashi[2] ; MAEKADO, Akira[3] ; HIROSE, Takashi[3]

[1]Graduate School of Humanities and Social Sciences, University of the Ryukyus, [2]Faculty of Business Administration, Daito Bunka University, [3]Faculty of Law and Letters, University of the Ryukyus

To investigate the relationship between reduction of wave height on a fringing reef and the water depth at the reef edge, field measurements were carried out on Miibaru coast with a fringing reef in Okinawa Island, Japan. The ratio of the shore break height (the height of final breaking waves near the shoreline) to the wave height at the reef edge, H_b/H', which denotes the degree of the reduction of wave height on a reef, was found to decrease with decreasing water depth at the reef edge. This result indicates that the reduction of wave height on a reef is greatly controlled by water depth on a fringing reef.

Experiments on Salt Weathering in Cold Environments : Effects of Dissolved Salts on Frost Shattering

SATO, Masato[1*] ; HATTANJI, Tsuyoshi[2]

[1]Graduate School of Life and Environmental Sciences, University of Tsukuba, [2]Faculty of Life and Environmental Sciences, University of Tsukuba

Weathering experiment was carried out to investigate the effects of dissolved salts on frost shattering using four types of rocks (two tuffs, one sandstone and one andesite) and three types of salt solutions (sodium chloride, sodium sulphate and magnesium sulphate). Cubic specimens with a side of 5 cm in length were immersed in saturated salt solution of NaCl, Na_2SO_4, $MgSO_4$ or distilled water for 72h. After immersion, the specimens were covered with foil and subjected to up to 80 freeze-thaw cycles in a cold chamber where the temperature ranges from -30 ℃ to 10 ℃ within twenty four hours.

Freezing points of salt solutions were decreased by dissolved salts. In particular, the saturated solution of NaCl did not freeze under -25 ℃. The liner strain on the surface of specimens was measured with strain gauge during freeze-thaw cycle. The specimens immersed in salt solutions showed greater freezing strain than those immersed in distilled water. Specimens with $MgSO_4$ solution produced the large strain. In most cases, the strain strongly correlated with Weathering Susceptibility Index (WSI). The decreasing rates of the longitudinal wave velocity and the Equotip hardness value during freeze-thaw cycles also correlated with WSI.

The volume expansion of pyroclastic rocks by the crystal growth of Halloysite at the Higashidoori

NAKATA, Eiji[1*] ; OOYAMA, Takahiro[1] ; TORIGOE, Yuji[2] ; MIWA, Tadashi[2] ; CHIGIRA, Masahiro[3]

[1]Central Research Institute of Electric Power Industry, [2]Tohoku Electric Power Co., Inc., [3]Disaster Prevention Research Institute Kyoto University

We find the ground deformation by volume expansion of pyroclastic rocks at the Higashidoori Nuclear power station site. The Tomari formation is strongly altered by light brown colored weathering with halloysite crystallization. The Tomari formation mainly consists of lappili tuff including andesitic lava. The Gamanosawa formation is laid on the Tomari formation consists of alternated sandstone, mudstone, conglomerate and tuff layers. These stratum are covered by the middle terraces deposit including the Toya tephra: 110 ka and Towada red tephra: 80 ka. Towada red tephra in the middle terrace deposit is not deformed on this site.

The convex deformation is formed absorbing the water of montmollironite in fault zone (clay rich zone). Strongly weathered surface rocks of the Tomari and Gamanosawa formation are also deformed toward upper parts around fault zone. This deformation is also formed regardless of fault zone.

Montmollironite distributes at the deeper area (the Tomari formation) which consists of weakly weathered rocks. Halloysite crystallized from montmollironite at shallow area. Plagioclase disappers with the crystallization of halloysite by XRD results. Halloysite which formed tube shapes covered the all over the materials are changed the shape to aggregation of fan shapes by SEM observation. Halloysite crystals increases a distance of the space between minerals under the micro scopic observation.

To assume that Ti is immobile elements with weathering in the rock, the volume of weathered rocks (lapilli tuff: the Tomari formation) increases in 1.3 to 1.5 times to compare with fresh rocks.

Montmollironite crystallizes the surface of minerals at first. After crystallization of montmollironite, halloysite crystallizes on the montoollironite to be affected by weathering at shallow depth.

Crystal growth of halloysite causes the volume expansion of rock and the deformation of ground surface.The old faults plane and joints slip as the appearance reverse faults by crystal growth at this site.

Characteristics and Development Processes of Wetlands on Landslide Masses in Hachimantai Volcanic Group, NE Japan

SASAKI, Natsuki[1*] ; SUGAI, Toshihiko[1]

[1]the University of Tokyo

Wetlands are widely distributed in the mountainous regions in Japan, and are subject to protection and conservation because of their beautiful landscapes and their peculiar biota. Considering not only their climate and hydrological conditions but also their geomorphological conditions is necessary to characterize development processes and environmental responses of wetlands. In tectonically active and warm humid regions like Japan, landslides are one of the most important factors for mountain development. Recently the role of landslides creating biodiversity and landscape diversity has been much attracted attention in the field of ecology and geomorphology(Geertsema *et al*., 2007). This study focuses on wetlands as one of the representative landform units composing landslides and presents their characteristics and development processes in Hachimantai volcanic groups which have been deformed by many landslides. 'Wetlands' generally includes various types of water-rich conditions. In this study, as their primary components we focuses on 'bogs' and 'ponds', and define 'bogs' as grasslands in moisture conditions.

Hachimantai volcanic group stands in Ohu backbone range and is composed of some Quaternary complex basaltic or andesitic stratovolcanoes. Their bodies are being collapsed by landslides characterized by a variety of body size and structures: some have deformed into several numbers of sliding blocks. Wetlands occur in almost all large scale landslide bodies. Its climate is categorized in Japan Sea side climate pattern as heavy-snow.

We investigated the characteristics of wetlands using remote sensing images and digital elevation models and analyzed the relationship with landforms by GIS. Then we reconstructed the development process of typical wetlands located both in and out of the landslide masses by the analyses of the sediment including ^{14}C dating, tephra identification, carbon content measuring and grain size analysis.

On landslide masses 33.2 % (185 of the 599 in total) wetlands stood and area rate was 63.7 %. Most wetlands out of landslides stood on the volcanic original surface along the ridge line of Ohu mountain range or some were in the craters of Hachimantai volcano. The formers are the small bogs formed by meteoric-water (snow) cultivation in the nivation hollows. On the other hand, those on the landslide masses scattered widely. Large landslide masses frequently had ponds cultivated by ground water in the large and deep depressions along the scarps and in the small ones among pressure ridges.

In Oyachi, a wetland in a landslide, black mud and organic sand and silt (representing for bog and forest), sand and gravel (disturbance), clay and silt (pond) and peat (bog) deposited from their bottoms. Wetlands typically develop under the stable circumstance from ponds to bogs, and finally to forests. In the case of Oyachi, at BC 4000-3500 the bog changed to the pond, the former developmental stage, probably because the landslide activity formed the dam, and then it developed to the bog with stabilization of the slopes and the water discharge. On the other hand, the development process of Okuno-maki, a wetland out of landslides, were probably directly affected by climate changes. Diminishing erosion along with decreasing snow accumulation in the nivation hollow and warming of melt season climate toward the Medieval Warm Period enabled to be the bog. In contrast, landslide activities and denudation of landslide masses control the developmental stages of wetlands. Consequently, various ages and types of wetlands are presumed to coexist in humid mountains with large landslide masses.

Comparison between two chronological methods - in situ TCN and WRT applied to periglacial landforms in Kiso Mountains

ENDO, Ryo[1*] ; SUGAI, Toshihiko[1] ; EZURE, Yasuhide[1] ; MATSUZAKI, Hiroyuki[1] ; MATSUSHI, Yuki[2]

[1]The University of Tokyo, [2]Kyoto University

A lot of types of chronological methods have been suggested in the field of earth science. Chronological methods are classified into absolute dating methods and relative dating methods. Absolute dating methods contain isotopic age or tree-ring chronology for example, and they provide the age as numerical values. Otherwise, relative dating methods are the methods which detect the time series of the formation of geomorphology or deposition. However, they cannot fix the age without the absolute age data (Watanabe, 1990).

Two chronological methods - in situ Terrestrial Cosmogenic Nuclides (TCN) and weathering-rind thickness (WRT) -are subjected. These two methods are especially effective in high mountain areas as it is difficult to find radiocarbon samples or key tephra layers (Aoki, 1994). These two methods were compared using terminal moraines in the cirques (Aoki, 2000). However, this comparison is not made in other mountainous terrains, and it is made in Kiso Mountain Range in this study.

In order to compare these two methods, samples were taken from multiple ridges in the eastern part of Mt Kisokomagatake, and Shirabidaira. Six samples were taken from 3 ridges and 2 depressions of triple ridges, and one sample from Shirabidaira. In order to obtain the exact formation age, we selected the bedrock or the oldest boulder filling the depression and collected their surface layer of 4 cm or less in thickness

Each sample is divided in two, one for TCN and the other for WRT.

10Be exposure dating method is subjected as TCN. The samples are chemically preprocessed and at MALT (Micro Analysis Laboratory, Tandem Accelerator), University of Tokyo. The exposure age is calculated by means of the formula as follows(∗)

$T=-1/\lambda \ln\{(1-\lambda N/P)\}$ (∗)

T: Exposure Age [yr] λ:Decay constant [1/yr] N: Number of isotopes [atoms/g] P: Production rate of isotopes [atoms/(g • yr)]

Weathering-rind is a discolored part of rocks. It is formed due to oxidation or hydration. Though the age is nearly in portion to WRT, its correlation depends on the rock type, sampling point and so on. In this study, samples were cut so that the weathering-rind can be observed as clearly as possible.

In 7 samples, radioactive ages are in either late Pleistocene or Holocene. Weathering-rind was observed and detected for 5 samples. There is a positive correlation between WRT and the exposure age. The primary regression equation is as follows : WRT [mm] = 0.367 × (Exposure age [kyr]) + 1.16. The correlation coefficient is about 0.85. This suggests that in order to get the exposure age of multiple ridges, WRT is also an effective method to a certain extent. Therefore, mean weathering rate (= 0.367 mm/kyr) can be gained by calculating a primary regression line that shows the relationship of the WRT and the exposure age. This weathering rate is the same in the order of magnitude as that (= 0.283 mm/kyr) estimated from Seki and Koizumi (1992).

Tree-line change since the Last Glacial from the pollen profile at the Hiroppara peat bog, central Japan

YOSHIDA, Akihiro[1*]

[1]Center for Obsidian and Lithic Studies, Meiji University

To better understand the interaction between the human and environment in past period, this study reconstructed vegetation history and climate change since the late Pleistocene at the Hirropara peat bog (1,400m a.s.l.), central Japan, from the pollen and micro-charcoal profiles at HB-1A cores. Arboreal pollen assemblages and influx of the cores indicated the vegetation history and climate change since the Last Glacial Maximum as follows; 1) ca. 30,000˜19,000 cal BP, grassland and wasteland distributed due to decreasing the tree-line; 2) ca. 19,000 cal BP, around the site was covered with a mixed forest of boreal conifers and cool-temperate deciduous, because the tree-line passed the altitude of site; 3) ca. 16,000 cal BP, Betula forest expanded; 4) ca. 12,000 cal BP, a cool temperate deciduous broad-leaved forest consisting of *Quercus* subgen. *Lepidobalanus* and *Carpinus* was distributed; 5) ca. 4,000 cal BP, temperate conifer such as Taxaceae-Cupressaseae, Tsuga, and Abies increased; 6) secondary forest of *Pinus densiflora* and *Larix kaempferi* plantation increased in ca. 500 and 100 cal BP, respectively. It is highly possible that the tree-line change impacted strongly the human activities since the Last Glacial Maximum.

Vertical crustal movements along the Japanese coastlines inferred from the Quaternary and recent sea-level changes

OKUNO, Jun'ichi[1*] ; NAKADA, Masao[2] ; ISHII, Masayoshi[3] ; MIURA, Hideki[1]

[1]NIPR, [2]Faculty of Sciences, Kyushu University, [3]MRI

Observed relative sea-level (RSL) changes during the past 130 kyr are mainly caused by change of ocean volume, tectonic crustal movement and glacio-hydro isostatic adjustment (GIA) of the Earth in response to the redistribution of ice and water loads. Here we examine the tectonic crustal movements along the Japanese coastlines on three typical timescales (50 yr, 6 kyr and 125 kyr) based on several sea-level observations and their predictions due to GIA process and recent melting of mountain glaciers and both polar ice sheets. We use the observations of RSL based on tide gauge and Holocene RSL observations and the altitudes of marine terraces formed at the last interglacial (LIG) phase at about 125 kyr. The rates on a timescale of 50 yr are derived from tide gauge data, thermosteric sea-level changes due to thermal expansion of the oceans and predictions due to the GIA for the last deglaciation and also recent melting of the mountain glaciers and both polar ice sheets. Those for 6 kyr and 125 kyr are based on the RSL observations and the predictions by GIA modeling, considering uncertainties for temporal changes in eustatic sea-level for the mid- to late-Holocene and LIG phase. The inferred rates for 50 yr are significantly different from those for 125 kyr in most sites, particularly for sites along the coastline from eastern Hokkaido to northeastern Japan, Shikoku and south Kyushu facing the Pacific Ocean. In these regions, the rates for 125 kyr and 50 yr are positive (uplift) and negative (subsidence), respectively. Also, the observed RSL changes at 6 kyr BP are consistent with the inferred RSL changes using the rates for 125 kyr and GIA-predictions in many sites, but inconsistent with those for 50 yr in most sites except for a few sites. These results suggest that the rates on a timescale of 50 yr are not representative of the tectonic crustal movements for timescales longer than 6 kyr in most sites along the Japanese coastlines. The inferred rates on these timescales may be useful in discussing the recurrence of megathrust earthquake with its interval of about 1 kyr like the 2011 off the Pacific coast of Tohoku Earthquake.

Prehistoric human activity around the Hiroppara wetland, central Japan: a case study in and around the obsidian sources

HASHIZUME, Jun[1*] ; SHIMADA, Kazutaka[2] ; SUDA, Yoshimitsu[1] ; ONO, Akira[1]

[1]Center for Obsidian and Lithic Studies, Meiji University, [2]Meiji University Museum

The Hiroppara wetland is located about 1.5 km to the north of Wada-toge, a well known obsidian source 1,400 m above sea level. Many prehistoric sites and geological obsidian sources are scattered around this area.

Through general surveys and small-scale excavations conducted by the former Wada Board of Education between 1989 and 1991, several prehistoric sites were identified around the wetland. In 2011, the Center for Obsidian and Lithic Studies (COLS), Meiji University began a new research project on this wetland and the prehistoric sites around it. Our research goal is to reveal the relationship between human activities in and around the obsidian sources and paleoenvironmental changes during the late Late Pleistocene (Upper Palaeolithic) to the Early Holocene (Incipient to Early Jomon period). This presentation is a preliminary report of our research, with a particular focus on the results of our archaeological excavations.

On the basis of results of previous surveys and our observations of the topographical features around the wetland, we distinguished the archaeological landscape around the wetland into seven sites, which we numbered from I to VII. The COLS has set up an excavation area 1 (EA-1) at site I and excavation area 2 (EA-2) at site II.

Excavations at EA-1, the Hiroppara I site, and EA-2, the Hiroppara II site, have revealed the following:

1. EA-1

1) This site yields evidence of an Early Upper Palaeolithic lithic industry from layer 6 (under the Aira-Tn tephra).

2) The latter part of the Late Upper Palaeolithic industry, represented in layers 2b and 3, primarily features bifacial points with a blade core.

3) Incipient to Early Jomon period assemblages are found in layers 2a and 2b.

2. EA-2

1) The early part of the Early Upper Palaeolithic industry, from layers 4a and 4b, yields an ”obsidian concentration” characterized by a dense lithic concentration in a small area mainly composed of large lithics. Layers 4a and 4b contain the Aira-Tn tephra and a ground-edge stone ax made from tremolite rock.

2) The latter part of the Late Upper Palaeolithic industry, from layer 3, appears to be a knife-shaped tool industry using a developed blade technique.

3) Jomon pottery of the early part of the Initial Jomon with pebble concentrations and a pit, arrowheads, and cobble tools.

These new findings expand the scope of information about multilayered prehistoric occupations at the Hiroppara I and II sites. In addition, it has allowed us to extract a significant amount of information on prehistoric human behavior with specific regard to exploitation, transportation and consumption of obsidian during the late Late Pleistocene to the Early Holocene. However, these issues require further study.

Prehistoric obsidian exploitation in the Central Highlands obsidian sources and excavations of the Hiroppara site group

SHIMADA, Kazutaka[1*]

[1]Meiji University Museum

The Center for Obsidian and Lithic Studies, Meiji University (COLS) has conducted archaeological and palaeoenvironmental excavations at the Hiroppara wetland and prehistoric site group (sites I and II) located 1,400m of the Kirigamine mountains in Nagawa Town, Nagano Prefecture, Japan. This paper presents a review of the Central Highlands obsidian source area where Hiroppara is located and its circumstances of prehistory, and preliminary results of Hiroppara excavations. Many sites assigned to the Upper Palaeolithic and the Jomon periods have been discovered in and around the Central Highlands. The site distribution of both periods shows distinctive patterns. The Upper Palaeolithic sites concentrate in relatively high-altitudinal zone over 1,000m close to the obsidian sources, while the Jomon sites shows dense-distribution on the hill slopes in low-altitudinal zone below 1,000m. This ebb and flow pattern reflects historical changes between the Upper Palaeolithic and the Jomon periods in the technology of obsidian acquisition, the way of land-use in the source area, the group organization, and the obsidian circulation system. The emergence of an obsidian mining site in the initial Jomon is one of representatives of those changes in the relationship between humans and obsidian. Data for archaeological chronology and changes in palaeoenvironment in the Central Highlands, however, are less accumulated than other areas, resulting in insufficient explanation for changes in human activities in and around obsidian sources. Multidisciplinary research on the Hiroppara wetland and site group provide us with a useful set of data concerning archaeological and palaeoenvironmental changes that represents a limited narrow area. The excavations of Hiroppara by COLS have been conducted three times in 2011, 2012, and 2013. The excavations at sites I and II have unearthed several cultural layers ranging from the Early and Late Upper Palaeolithic to the earliest Jomon. Palaeoenvironmental data during the late MIS 3 and the early Holocene have been obtained from microfossil analyses on the peat cores from the Hiroppara wetland. Though further analyses and integration on obtained data are still required, the Hiroppra wetland and site group will allow us to make an explanatory model for relationships between prehistoric humans and palaeoenvironmemt in and around obsidian sources of the Central Highlands.

Discovery of fresh water diatom from aeolian sediments in the conical pit structure in the Arsanjan area, south Iran

HISADA, Ken-ichiro[1*] ; TSUNEKI, Akira[2] ; CHIBA, Takashi[1]

[1]Graduate School of Life and Envionmental Sciences, University of Tsukuba, [2]Graduate School of Humanities and Social Sciences, University of Tsukuba

It is well known that the life of ancient people was greatly influenced by various natural conditions, such as climate, topography, and geology. In particular, geology is not only important as a source of raw material for stone tools and residence construction material, but also as a provider of groundwater and mineral resources. Furthermore, soil is generated from weathered bedrocks, and soil is a key influence on vegetation. Thus, when ancient people considered the natural conditions for first settlement locations, geology would have been a crucial factor in these conditions. The present paper offers a preliminary examination of interaction of the humankind - Iranian Zagros Mountains.

One of the most important discoveries among the humankind studies was the existence of many Middle Paleolithic and Epi-Paleolithic cave sites in the Arsanjan area, south Iran. One of the caves, named A5-3 (Qar-e Tang Sikan), produced a large amount of Middle to Epi-Paleolithic stone implements. Thus the Arsanjan area is one of the most suitable areas for the study of human evolution and cultural transition from the Middle/Late Paleolithic to the Epi-Paleolithic/Neolithic periods. This means that the investigation of this area can possibly provide opportunity for the better understanding of the evolution of modern Homo sapiens and of the interface of geology-archaeology.

We accomplished the trench survey recently. The results of B3 trench survey (4 X 4 m square) at A5-3 (Qar-e Tang Sikan) are as follows (Hisada and Tsuneki, 2013). The culture layers are divided into ten layers. Layers 1 to 3 correspond with Late Paleolithic to Proto Neolithic. Six samples from layers 2 and 3 indicate approximate 36,000 BP. Layers 4 to 10 are included into Middle Paleolithic culture layers. It is noteworthy that structure 3 was discovered from layer 7. Structure 3 presents a circular from on plan, 1 m in long axis and 0.7 m in short axis. In profile, it is conical and depth is about 50 m. Cave limestone bedrock is used as a bottom wall of the conical shape, and concrete-like harden wall with pebbles and clays is used as the other one. The concrete-like wall might be built after cutting soil surface. The filling of the conical shape structure is light orange color clay, 50 cm in thickness. This clay presents a bimodal pattern, 5 phi and 11 phi in grain size analysis, and consists of quarts, muscovite and hydroxylapatite. The color of the clay is characteristics (10YR7/6, 6/6 etc) and conspicuous from other soil. Based on the color and clay-seized sediments, it can be concluded that they are aeolian sediments. This conical structure may be intended to be a water-reserved place keeping water oozed from the limestone wall (Hisada and Tsuneki, 2013). Thus, the clay might be deposited in this conical pit, 50 cm deep. This laying down at the pit seems to be prevented from erosion and transportation because the pit was full of water. Very recently, it is clarified that clay bed yields diatom, Pinnularia spp.. This genus indicates a living in fresh water (Watanabe et al., 2005). The ages for layer 7 are inferred before 51,000 BP, because layer 5 is dated as 50±2Ka and the ages for the boundary between layers 6 and 7 are 51±2Ka based on the photoluminescence measurement (Ito, in pers. comm.).

Quantitative detection of event deposits in the piston core of Beppu Bay, central Kyushu, Japan

YAMADA, Keitaro[1*] ; TAKEMURA, Keiji[2] ; KUWAE, Michinobu[3] ; IKEHARA, Ken[4] ; YAMAMOTO, Masanobu[5]

[1]Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, [2]Beppu Geothermal Research laboratory Institute for Geothermal Science, Kyoto University, [3]Center for Marine Enviromental Studies, Ehime University, [4]Institute of Geology and Geoinformation, AIST, [5]Faculty of Enviromental Earth Science, Hokkaido University

Particle transportation and deposition is repeated by various phenomena to be caused by constant cycle of water and atmosphere (non-event) and sudden phenomenon (event) such as earthquake, volcanic eruption, flood, and a stratum is formed. Therefore we can know paleo-disaster or climate change from the stratum. In addition, because the deposit caused by event (event deposits; Shiki, 1998) supplied a lot at a time, it is very important for solving formation process of the stratum. In recent years, due to analysis technique development high resolution/precision study in sedimentology is increasing (Katsuta *et al*., 2007). For this reason, details of the sedimentation mechanism and the environmental change are more clearly, but on the other hand influence of development on age models and various analyses is actualized. Therefore clear distinction of event and non-event is one of the important problems.

In Beppu Bay, the detailed age model to omit major events was constructed by Kuwae *et al*.(2012). Event deposits were identified by sighting based on facies, CT images, magnetic susceptibility and wet bulk density. This method can identify event deposits seamlessly, but it is a problem to depend on the personal experience and to have difficult to quantitative detection. Therefore we tried quantitative detection of event deposits by the statistical method and compared the detection result and the sighting result in Kuwae *et al*.(2012). The BP09-3 core (about 9.3 m long) using this study which was used in Kuwae *et al*.(2012) was obtained at the deepest place in the head of Beppu Bay.

Generally, because the source and sedimentation process of event deposits are greatly different from non-event deposits, chemical composition, particle composition or other profiles have difference. Therefore, in this study, we defined event deposits as " the sediment which has significantly different composition or physical properties ", we tied the quantitative detection of the event sediment using test for outliers. Analysis data are particle composition of very fine sand which sampled every 2 cm from the core, and we used MSD method (Wada, 2010) which is the robust and multivariate method for test. As a result, 47 events were detected. The detected event in this study and the sighing event in Kuwae *et al*.(2012) are relatively congruent, so it is thought that detective method using this study is useful for quantitative detection of event deposits. However, there are problems that 1) one is not to be able to detect minute event sediments enough and 2) the other is difficult to recognize the border of event deposit and non-event deposit. Because the event layer which was not able to detect is thin relative to sampling interval, it is thought that event layer was diluted by non-event deposits. Because there is no a meaningful difference in composition of the neighborhood of border, clear border detection using only test for outliers is difficult. It is necessary to evaluate and reflect event attenuation (vertical change) and preservation potential to solve these problems.

Sakitari-do archeological site is located in Gyokusen-do cave system in Nanjyo City, Okinawa Prefecture. Since 2009, this site has yielded important remains including a 12.4-ka-old human canine (Yamasaki et al., 2012). One of the noticeable animal remains is Eriocheir crub. Large and uniform size of the forceps indicates individuals of autumn season when this crub grows into an adult. Paleolithic people may have stayed in this cave during autumn and eaten Eriocheir crub.

In order to examine this hypothesis, this study focuses on Semisulcospira shell that was excavated together with Eriocheir. Semisulcospira is a freshwater gastropod that grows spiral shell. It is known that change in the water temperature was recorded in oxygen isotope of a series of samples collected along the spiral growth axis (Kano et al., 2008). If the Paleolithic people ate the gastropod, the oxygen isotopic value of the outermost sample indicates when it was taken. We analyzed the gastropod shell from two Paleolithic layers (19 ka and 12.4 ka) of the Sakitari-do site, as well as modern Semisulcospira collected a stream 5 km east from the site in late November 2013.

Paleolithic specimens from the Sakitari-do often exhibit a sign-shaped oxygen isotopic curve. Amplitude of the change is ˜2 permil that corresponds to ˜8 degree temperature change under stable water isotopic composition. More importantly, the outermost value locates on an autumn position in many specimens, which support the hypothesis based on Eriocheir remains. In contrast, the modern Semisulcospira specimens that lack the sign-shaped pattern were young individuals that born in early summer. They recorded temperature change from summer to November. Comparing the summer oxygen values, the modern specimens are 1-1.5 permil lower than the Paleolithic specimens. If the oxygen isotopic value has been constant, it can be evaluated that the Paleolithic summer water was 4-6 degree cooler than the modern summer water.

Kano, A., Suzuki, S., Hori, M. (2008) Information recorded in oxygen isotopic profiles of freshwater gastropod Semisulcospira livertina. Ann. Bull Hiroshima Univ. Taishaku-do site Research Center. 22, 47-61.

Environmental changes of prehistoric culture of the Ryukyu, reconstructed by sedimentological studies of Haneji-naikai.

GOTANDA, Katsuya[1*] ; YAMADA, Kazuyoshi[2] ; HARAGUCHI, Tsuyoshi[3] ; SETO, Koji[4] ; HAYASHIDA, Akira[5] ; YONENOBU, Hitoshi[6]

[1]Faculty of Policy Informatics, Chiba Univeristy of Commerce, [2]School of Human Sciences, Waseda University, [3]Department of Geosciences, Graduate School of Science, Osaka City University, [4]Research Center for Coastal Lagoon Environments, Shimane Univeristy, [5]Department of Environmental Systems Science, Doshisha University, [6]Graduate School of Education, Naruto University of Education

The beginning of agriculture in Ryukyu Islands goes back to the 10th-12th century (Takamiya and Itoh, 2011). Land clearing for farm lands accelerated soil discharge into water systems in Ryukyu Islands due to heavy rain in summer. In a closed bay, finer-grained clastics can remain sub-merged for long periods, causing adverse effects in fishery.

In this study we will report on the analytical results for sediment cores recovered from Haneji-naikai. Haneji-naikai is a bay closed by the Yagachi and Okubu Islands. Its maximum water depth is 10 m with the area is 10km^2. The Nasata river flows into the Haneji-naikai. In 2010 and 2012, 3-m and 24-m long sediment cores were recovered from the center of the bay. These were used to reconstruct the past environmental changes and human activities. The latter longer cores consisted of clay and silt with shell fragments from the surface up to the 16-m depth, while he lower part was composed of gravels. The radiocarbon dates of terrestrial plant flagments were 2880+/-40, 4210+/-30 6150+/-40 and 31680+/-220 at the depths of 7.42 m, 10.78 m, 14.84 m and 23.90 m, respectively. The cores were subsampled at an interval of 2.3 cm to analyze carbon, nitrogen and sulfur (CNS) contents, magnetic susceptibility and visible color reflectance. It is considered that the Haneji-naikai was dried up around 30000 yr BP probably due to marine regression. The changes in TOC, TN and TS were recognized from 4m in depth, showing drastic decreased from 4m in depth. This suggests that the deforestation induced by agricultural activities have begun since 1000 yr BP in this region.

Paleoenvironments analysis for the past 50 ka based on TOC and TN of the sediment cores INW2012-1 and -2,Lake Inawashiro

WATANABE, Kei[1*] ; NAGAHASHI, Yoshitaka[2] ; HIROSE, Kotaro[3] ; KUMON, Fujio[4]

[1]Graduate School of Science, Shinshu University, [2]Faculty of Symbiotic Systems Science, Fukushima University, [3]Graduate School of Systems and Technology, Fukushima University, [4]Department of Environmental Sciences, Faculty of Science, Shinshu University

The total organic carbon (TOC) and total nitrogen (TN) were measured at 2 cm interval for the long sediment cores (INW2012-1, INW2012-2) taken from a central site of 90 m depth in Lake Inawashiro in Fukushima Prefecture. Depth-age relationship has been established based on six 14C data, and the bottom of the drilled core, about 28 m, is estimated as old as 48 ka. Sampleinterval is 50 to100 years.

The compilation of information on lithology, TOC and TN concentrations, C/N ratio and water contents of INW2012-1 and -2 enable us to reveal the paleoenvironments of Lake Inawashiro from the early stage to the present with high temporal resolution. Deep condition of Lake Inawashiro started 42,000 years ago and then the lake has been constantly deep until now.Temporal change of TOC concentration of Lake Inawashiro shows the quasi-periodical fluctuation similar to the marine isotope curve known as LR04, and corresponds well to that of TOC concentration of Lake Nojiri in Nagano Prefecture. Vegetation change revealed at theYanohara, moor in Fukushima Prefecture corresponds with the TOC fluctuation of TOC in the lake. Therefore, Temporal change of the TOC concentration in Lake Inawashiro seems to be controlled mainly by climate, probably temperature, and can be one of the useful paleoclimate records in the Tohoku region, Japan.

Environmental Changes based on the variations of the grain size distributions of MD179 cores, off Joetsu, Sea of Japan

TAKIZAWA, Michiru[1*] ; SUGAI, Toshihiko[2] ; MATSUMOTO, Ryo[3]

[1]Graduate School of Frontier Sciences, University of Tokyo (current PASCO Corporation), [2]Graduate School of Frontier Sciences, University of Tokyo, [3]Gas Hydrate Research Laboratory, Organization for the strategic Coordination ,Meiji University

1.Introduction

Climate change during the Quaternary period experienced a 10,000year?glacial?interglacial cycle. This cycle has an influence on land formation. In Japan, the sea level changes, in coastal areas, and the variations of precipitations, at up stream and middle stream areas, change the riverbeds. Thus the marks from climate changes are expected to be archived around the rivers. However, the long term and continuous records hardly remain on the land, due to weathering and erosion. On the other hand, owing to the more stable environment, the continuous records are expected to remain on the seafloor(Tada et al., 1999). In this study, to reconstruct the correlation between the land formations and climate changes, the variations of the grain size distributions during past 130 ka on the East marginal area of Sea of Japan was revealed.

2.Study Area and Methods

There are a lot of Paleoenvironmental records concerning the Sea of Japan. In this study, 3 cores, which were sampled during the MD179 cruise in the Umitaka Spur and the Unnamed ridge off Joetsu, are used and the variations of grain size distributions of these cores were revealed. The Umitaka Spur is located in the continental slope. Moreover the sedimentation rate off Joetsu is very rapid (Nakamura et al., 2013; Ishihama, et al., in press) and the supply from the island arc is active (Freie et al., 2009). The supply from the Tateyama Mountains has the highest amount in Japan. So the of these supply are speculated to contribute to the sediment off Joetsu.

In this study the age models of these cores are constructed by using tephrochronology, radiocarbon dating, oxygen isotope ratio of foraminifer (Ishihama et al., in press) and additional data from tephra and radiocarbon dating. The organic matters in 485 samples from the 3 cores were removed by 10%H2O2. Then the grain size distributions of these are analyzed by using SALD3000S (Laser diffraction particle size analyzer).

3.Result

The sediments off Joetsu are composed mainly of suspended load. The coarser sediments that contain little fine sand existed during the interglacial age. The variations of the median grain sizes off Joetsu have a similar pattern to the glacial cycles.

In general, it is assumed that the grain sizes of seafloor sediments become smaller as it gets farther from the land. Nevertheless, in this area, the variations in the size of the sediment supplied from land driven by the glacial cycles, have a large influence on the grain sizes of sediments in the study area, because of (1) the active supply from the rivers and (2) the narrow continental shelf.

However, in the case of the rapid rise in sea level, for example after LGM, the formation of alluviums in coastal zone is speculated to have an influence on the size of the sediment in study area.

Developing process of the erosional landform and the developmental mechanism of slope failure in Shirasu area

IGARASHI, Ryusuke[1*] ; SUGAI, Toshihiko[1] ; IMURA, Ryusuke[2]

[1]Graduate School of Frontier Sciences, The University of Tokyo, [2]Graduate School of Science and Engineering, Kagoshima University

Pyroclastic flow deposits are distributed throughout Japan, dotting the country's landscape. In Kagoshima Prefecture, in particular, the cliff overlain by " Shirasu " deposits has undergone repeated slope failures during a period of several decades, which is an extremely short timeframe for such activity (Tsukamoto, 1993). Ito pyroclastic flow deposits are part of a huge pyroclastic flow that occurred approximately 29,000 years ago (Machida and Arai, 2003); these deposits span an area of approximately 90 km from Aira Caldera, which was the source of Shirasu deposits (Yokoyama, 2000). Although the stratigraphic relationship between the erosional landform and the Shirasu deposits of volcanic ash and gravel layers is important, little research has been conducted on this topic. Among the current and the former incised valleys engraving Shirasu plateau, an ancient fossil valley has been identified; however, the factors contributing to the ceasing of its growth remain unknown (Yokoyama, 2000). This study examined the relationship between the developmental mechanism of slope failure and the long-term development process of the erosional landform in the Shirasu distribution area to clarify the region's geomorphological evolution. In this presentation, we focus on the Satsuma Peninsula, which includes a part of the Shirasu plateau in northern area. In the peninsula, ancient shallowly incised valleys remain on the plateau, while the current deeply incised valleys have been dissecting the plateau. A landform classification map was made by interpretation of color aerial photograph in 1975 and by analysis of samples obtained from the plateau cliff that developed through erosion-denudation processes such as slope failure and erosion of Shirasu by running water; strength measurements were performed with a Schmidt hammer.

The valley width decreases rapidly from the main stream valley to the tributary valley and in the current incised valley, from downstream to upstream corresponding to the high-density distribution of failures in this site. The failure substance can be easily transported downstream because the " Shirasu " rapidly changes fine sand and silt after the failure. The failure at the valley wall slope has likely been continued by the valley width expansion of the current incised valley. Incision can be estimated from the beginning edge of the downstream side of the original Shirasu located in the place that is near to the East China Sea of the Satsuma Peninsula west, and has progressed in the upstream side gradually. This is probably because that the attitude of the Shirasu deposition surface is low, and the incised valley bottom is close to the base level of erosion, which has been almost stable during the last 7ka.

It is considered that lateral erosion of current incised valleys has continued during the time whereby failure has occurred in the vicinity of the lower end of the incised valley wall. From a long-term perspective, it can be said that the failure potential is high for current incised valleys dominated by width enlargement processes.

Total organic carbon fluctuation from the lake sediments in central Japan during the past 200 ka

KIGOSHI, Tomohiko[1*] ; KUMON, Fujio[2] ; TAWARA, Takaharu[3]

[1]Interdisciplinary Graduate School of Science and Technology, Shinshu University, [2]Faculty of Science, Shinshu University, [3]Wakayama Prefectural Government

Lake sediment is a useful recorder of paleoclimate in the mid-latitude regions. However, the life span of a lake is shorter than that of the marine sediments or polar ice sheets in the most cases. Furthermore, a general condition of a lake may be disturbed by an accidental event. Then, we try to combine a climate proxy of total organic carbon (TOC) records from several lake sediments central Japan, and have compiled an average TOC in the past 200 ka which may correspond to the regional climate change.

Used data include Lake Biwa (BIW07-5, 6 core: 0-50 ka, BIW08-B core: 0-200 ka), Lake Nojiri (NJ88+NJ95 core: 0-72 ka), Takano Formation (TKN-2004: 38-160 ka). The time resolutions in those data are between 20-100 years. TOC data of the six sediment cores were normalized as dividing a data by standard deviation. Their fluctuation curves of the normalized TOC were matched by the method of Lisiecki and Lisiecki (2002). Then the matched normalized data were interpolated at 100-year interval by polynomial interpolation method.

The compiled TOC fluctuation in central Japan is well correspond to the D18O curves of the marine sediments (LR04) and the Greenland ice core (NGRIP) respectively both in the orbital and millennial time scales. In late MIS (marine isotope stage) 7 and MIS 1, the compiled TOC values are generally high. In MIS 6, 4 and 2, the TOC values are generally low, and their temporal fluctuation is not so large. The compiled TOC in MIS 5 is characterized by large fluctuation in orbital scale. In contrast, the compiled TOC in MIS 3 shows many peaks which correspond with the repetition of cold stadials and warm interstadials, known as D-O cycle.

This result suggests that the normalized TOC may be a useful proxy of paleoclimate for the past 200 ka, which can be correlated with other sediments or climate records by the many marker tephra beds in central Japan.

Morphosis of the Oyster shell bed and Diatom assemblage in Tokyo bay

NOGUCHI, Marie[1*] ; ENDO, Kunihiko[2] ; KASHIMA, Kaoru[1]

[1]Kyushu University, [2]Nihon University

Recently, oyster shell beds and reefs have been found in various places in Tokyo bay. Six shell bed types can be recognized on the basis of their lithology (YOKOYAMA et.al., 2004). Topographic and paleogeographic changes closely related to the Holocene Jomon Transgression, have been investigated by reconstructing the migration of oyster shell beds, which are good markers of paleoshorelines, throughout the wide inner bay during the rising stage of sea-level. However, ecology of benthos and diatom assemblages is not clear about oyster shell bed types(Endo et.al.,2013). This study describes taphonomic processes of the oyster reefs well exposed in Tokyo bay, Sanbanze. The oyster reefs of Sanbanze have grown up during about 5 years. The growth of oyster reefs was rapid but nowadays it is reduced due to change of oyster environment as consequences of Torrential rain and Typhoon. We started to do research 5 years ago in Sanbanze. We are making a report on oyster shell bed types and ecology of diatom assemblage in this area.

A possibility of influence of deposition in dam-lake to deep marine environments around the Japanese Islands

SHIRAI, Masaaki[1*] ; OMURA, Akiko[2] ; HAYASHIZAKI, Ryo[1] ; UTSUGAWA, Takako[1]

[1]Tokyo Metropolitan University, [2]University of Tokyo

It is well known that dams construction on river caused decrease in sediment supply and serious coastal erosion. While, taking into account similarity of grain size, deposition in dam-lake may also cause decrease in deep marine hemi-pelagic depositional rate. Mass accumulation rate (MAR) during ca. 100 years around the Japanese Islands were estimated with Pb-210 radioactivity concentration.

Core samples were obtained with multiple corer (core length <60 cm) on the R/V Tansei-maru from off the Enshu, Kumano and Niigata regions in the central Japan. Subsamples sliced with 1 or 2 cm thick were dried, crushed and measured by an ORTEC High Purity Ge gamma spectrometer housed in the Department of Geography, Tokyo Metropolitan University with a 48 hour counting. MAR was estimated from Pb-210 radioactivity concentration and dry bulk density of other subsamples measured with the Shimadzu Accupyc 130 gas pycnometer housed in Atmosphere and Ocean Research Institute, the University of Tokyo.

In the off Enshu area, MAR of two core samples obtained from small basin on the outer ridge-Nankai Trough slope (ca. 2500 m water depth) were estimated for this study. Although one core did not show change in MAR, the other core showed decrease in MAR around 1930-1940. In the off Kumano area, MAR of two core samples obtained from bottom of the Kumano Trough (ca. 2100 m water depth) were estimated. Both core showed decrease in MAR around 1940-1960. In the off Niigata area, MAR of a core sample obtained from bottom of submarine canyon on the SE slope to the Mogami Trough (ca. 400 m water depth) was estimated. The core showed decrease in MAR around 1960-1970.

Although estimated ages of decrease in MAR have considerable error, it is remarkable that decrease in MAR was estimated from all the studied areas. Contemporaneity of decrease in MAR and dams construction and similarity of the grain size between hemipelagic sediment and dam sediment suggest that deposition in dam-lake may influence sediment supply to deep marine hemipelagic environment.

Seismic history of the last 5500 years reconstructed from the topographic development of the Furen-ko barrier system

NANAYAMA, Futoshi[1*] ; SHIGENO, Kiyoyuki[2] ; HASEGAWA, Takeshi[3] ; WATANABE, Kazuaki[1] ; ISHIWATA, Kazuto[5] ; IKEDA, Yasuo[4] ; UCHIDA, Yasuhito[6]

[1]Geological Survey of Japan, AIST, [2]Meiji Consultants Ltd., [3]Ibaraki University, [4]Kushiro Branch, Hokkaido University of Education, [5]Betsukai Museum, [6]Geological Survey of Hokkaido, HRO

There are some active barrier (island) systems in eastern Hokkaido. Since 2011, we have been investigating the Hashirikotan barrier spits in the northern part of Furenko barrier system facing the Sea of Okhotsk/ Nemuro Strait because five branches of spits (BR1-BR5) are clearly observed. According to GPS topographic survey, GPR exploration, hand drilling survey, grain size analysis, AMS 14C dating and tephra chronology, we already got some important geomorphological results as bellows.

As a first point, the Furenko barrier system has been established since 5.5 ka, and there were two lagoon-expanding stages at 5.2 and 4.0 ka estimated by volcanic ashes, Ma-e and Ma-d from Mashu volcano. As a second point, the youngest BR5 has occurred after the 17th century and BR4 caused by the last seismic up rifting in the 17th century because it was covered with two historical volcanic ash layers, Ta-a and Ko-c2 from Tarumai and Komagatake volcanoes. BR2 caused by the seismic up rifting in the 9th century because it was covered with B-Tm from Baitoushan volcano in AD 929. BR3 and BR1 were undated clearly, but we are able to assume that BR3 rifted in the 12-13th century and BR2 rifted at 4.0 ka. These two BRs were covered with large eolian dune layers just after emerging each BR.

Since 2003, it was clearly that the great earthquakes (Mw8.5˜) have been occurred at an interval of 500 years along the southern Kuril subduction zone. Especially coastal area raised almost 1 or 2m just after the great earthquakes due to the post-seismic displacements. But conversely land subsidence has been continuing at a rate 8.5mm/year since the 17th century until now. We express that geomorphological evolution of the Furenko barrier system has been controlled by the seismotectonics along the southern Kuril subduction zone.

This work was supported by JSPS KAKENHI Grant Number 23540539.

Late Quaternary tephras and basin fill sediments under Ukinuman, Murayama city in the north part of Yamagata basin, Nort

SUZUKI, Takehiko[1*] ; KASAHARA, Amao[1] ; YAGI, Hiroshi[2] ; IMAIZUMI, Toshifumi[3] ; YOSHIDA, Akihiro[4]

[1]Tokyo Metropolitan University, [2]Yamagata University, [3]Tohoku University, [4]Meiji University

Yamagata basin, one of the tectonic basins aligning along the west part of Ou Backbone Range, Northeast Japan Arc, exists between hills and mountains. Active faults concentrate along the west margin of the Yamagata basin. In the north part of the basin where more active faults were recognized than the south part of the basin, not only marginal faults bordering hills and mountains but also isolated faults in central part of the basin were recognized by Yagi et al. (2001). In order to establish the history of fault activity and landform development in the basin, chronological and sedimentological studies on the basin fill sediments beneath the ground surface is necessary. In this study, an all-core boring (MR-13-1) with a depth of 101.00 m was carried out at Ukinuma (81.40 m a.s.l.), Murayama City, Yamagata Prefecture in October to November, 2013. Preliminary results are as follows.

Stratigraphy

Fine sediments dominate less than 64.60 m in depth, composing of silt to organic silt except three sand and gravel layers with thickness of $<$1.65 m. Sediments between 64.60 and 101.00 m in depth consist of an alternation of silt, sands, and gravels. Depths of tephras already identified are 3.34-3.47 m, 35.34 m, and 75.86-76.24 m.

Tephra

A gray to white ash-fall deposit with a depth of 3.34-3.47 m contains hornblende (n_2=1.670-1.673) and orthopyroxene (gamma=1.709-1.714). Refractive indices of glass shards is n=1.499-1.500. These characteristic properties show that this ash is correlative to Hijiori-Obanazawa Tephra (Hj-O, 11-12 ka; Machida & Arai 2003).

A thin white vitric tephra (4 mm in thickness) at 35.34 m in depth characterized by bubble-wall to stripe types of glass shards (n=1.496-1.500; SiO_2: 78.44 wt.%, Al_2O_3: 12.05 wt.%, CaO: 1.08 wt.%, FeO: 1.12 wt.%, K_2O: 3.21 wt.%, Na_2O: 3.40 wt.%) (containing a small mount of quartz) is correlated to Kikai-Tozurahara Tephra (K-Tz, 95 ka; Machida & Arai 2003).

An ash-fall deposit with a depth of 74.86-75.17 m was detected. This tephra contains orthopyroxene (gamma=1.724-1.730), quartz, and sponge to fiber types of glass shards (n=1.498-1.502), and is possibly originated from volcano in the vicinity.

In presentation, chemical compositions of glass shards in tephras mentioned above and ages by carbon 14 dating will be reported.

Late Quaternary tephras and basin fill sediments under northeast part of Yonezawa basin, Northeast Japan

KASAHARA, Amao[1*] ; SUZUKI, Takehiko[2] ; KITAMURA, Akihisa[2] ; KATO, Shinji[4]

[1]Graduate student, Tokyo Metropolitan University, [2]Tokyo Metropolitan University, [3]Shizuoka University, [4]NEXCO East

We report tephras distributed under the northeastern part of the Yonezawa Basin, in the southern part of the Northeast Japan Arc.The Yonezawa Basin is the one of the inland tectonic basins along the backarc side of the Ou Backbone Mountains. There is a wetland which delimited by the small fans in the southern and western margins and by the mountains in the northern and eastern margins around the Lake Hakuryu in the northeastern part of the Yonezawa Basin, which called Oyachi (Yoshida, 1955). We observed two cores, B7-1-2 and B7-1-14, both drilled at Fukanuma , Takahata Town at the southern margin of the wetland. Both core obtained at distance of about 200 m, and about 90 m long.

Both B7-1-2 and B7-1-14 cores have well developed peat deposit. Silt and peat deposit contains about 1-20 cm thick thin sand layers repeatedly. Well sorted granule thin layers and pebble thin layers which contains max 4 cm in diameter are observed at the middle and lower part of the sediments, but poorly lateral continuities. In addition, both cores are not drilled through the Quaternary deposit under the Yonezawa Basin.

In the B7-1-2 core, Numazawa-Kanayama tephra (Nm-KN; 62-65 ka: Suzuki and Soda, 1994) is in 31.59-31.655 m depth, Aso-4 tephra (Aso-4; *ca.* 87 ka: Aoki et al. 2008) is in 44.16-44.23 m depth as a blocky form, and two-pyroxene crystalline ash (B7-1-2L) is in 79.14-79.16 m depth, are observed.

In the B7-1-14 core, Nm-KN is in 27.33-27.34 m depth, two-pyroxene crystalline ash (B7-1-14E) is in 75.47-75.485 m depth, and glassy ash contains babble-wall type of glass shards (B7-1-14G) is in 83.97-84.07 m depth, are observed. Furthermore, a beige ash patch observed in 39.385-39.39 m depth would correlate to Ontake-Nagawa tephra (On-NG; 85.1 ka: Nagahashi et al., 2007).

We could not observed a AT bed in the both cores, however, we detected babble-wall type of glass shards from correlate to AT in the gray silt bed in 21.62-21.63 m depth between a peaty silt bed in the B7-1-2B core (not sequential sampled). In addition, B7-1-2L and B7-1-14E are correlate to each other because of its height above sea level and petrographic features.

It is concluded that height above sea level of Nm-KN and B7-1-2L/B7-1-14E indicate sediments in the both cores deposited almost horizontal form. Deposition rate simply calculated and estimated from age and depth of Aso-4 in the B7-1-2 core is about 0.5 m/kyr, which shows slightly larger value than 0.22-0.35 m/kyr (Suzuki et al., 2013) based on tephrochronology obtained in the Aizu Basin to the south of the Yonezawa Basin recently. This deposition rate is generally reconciling rate if it is assumed that deposition rate of the Yonezawa Basin floor depends on the activity of the Yonezawa Basin Western Margin Fault which slip rate is 0.4-0.5 m/kyr.

The age of the Inubou Group in the Choshi district, Chiba Prefecture, Japan, based on tephra correlation

TAMURA, Itoko[1*] ; YAMAZAKI, Haruo[1] ; MIZUNO, Kiyohide[2]

[1]Dep. Geography, Tokyo Metropolitan Univ., [2]AIST, GSJ

Numerous widespread tephra layers of late Pleistocene and Holocene age have been known since the early 1970s and greatly contribute to paleoenvironmental reconstruction in the Japan islands and adjacent seas. This study has identified a new widespread tephra using the trace element composition of volcanic glass determined by ICP-AES analysis and the stratigraphy.

In1 tephra is found at lowest part of the Naarai Formation in the Inubou Group, Choshi district, Chiba Prefecture, accumulated during Pliocene to Early Pleistocene. Ikg1 tephra is found in upper Ikego Formation in the Miura Group, Kanagawa Prefecture, accumulated during Pliocene. B25 tephra is found at Horinouchi Formation in the Kakegawa Group, Shizuoka Prefecture, accumulated during Pliocene to Early Pleistocene.

In1, Ikg1 and B25 tephras are white and fine grain. The thickness of these deposits range from cm(Ikg1) to 22cm(B25). These tephras mainly consist of glass shards of bubble-wall type. The glass shards of these are poor in K_2O ($<$2 %) and La ($<$15 ppm) and rich in Y($>$40 ppm), which give low La/Y (about 0.3) and high Ba/La (about 30). These characteristic chemical compositions of glass in tephras erupted from the Tohoku area (Mizuno, 2001).

The age of In1 tephra is estimated at about older than 3 Ma based tephrochronology in Choshi area (Tamura et al.,2007). The age of Ikg1 is estimated at about older 3.1Ma based biostratigraphy and magnetostratigraphy (Utsunomiya et al, 2012 and Utsunomiya, 2013). The B25 tephra is estimated at about older 2.9Ma based on tephrochronology (Tomita and Kurokawa, 1999 and Kurokawa and Tomita, 2000).

This tephra correlation indicates that the age at lowest part of the Inubou Group is estimated older than 3.1 Ma.

Underground electrical resistivity and soil water content on the surface around former river channel of Tone River

NAKANO, Takayuki[1*] ; KOARAI, Mamoru[1]

[1]GSI of Japan

Land liquefaction occurred in a land reclaimed water area such as former river channel induced by the 2011 off the Pacific coast of Tohoku Earthquake. The land liquefaction was a biased distribution even in former river channel. We assumed that groundwater level and/or shape of former river bed (depth of former river) have a significant influence though the factor of this phenomenon is various. Therefore, we conducted electrical prospecting (2-D electrical resistivity prospecting) on former river channel of Tone River around Kozaki Town, Chiba Prefecture, to estimate a distribution of groundwater level and/or shape of former river bed from underground distribution of electrical resistivity. In addition, we considered a relationship between underground distribution of electrical resistivity and soil water content on the surface by measuring soil water content on the surface along the electrical prospecting line. In this survey area, there are data of layer profiles (trench survey profiles) and boring core stratigraphes by the National Institute of Advanced Industrial Science and Technology (AIST) and the Chiba Prefectural Environmental Research Center (CERC) (Mizuno et al., 2013; Miyaji et al., 2013).

Electrical prospecting was performed by the pole-pole array in 280m length, electrode intervals of 1m and until 15m deep. Measurement of soil water content was performed by volumetric soil water content sensor (by the method of responding to changes in the apparent dielectric constant) and weight water content sensor (by alternating current two electrode method). These measurements of soil water content were performed intervals of 10m on the electrical prospecting line, and three times in each measurement points and each sensors. We used these average values.

Electrical resistivity profile indicated clearly difference between reclaimed soil in the former river channel with relative high electrical resistivity (more than 20-30 ohm-m) zone and a ground out of former river channel with relative low electrical resistivity (less than 20-30 ohm-m) zone. The position where the boundary of these zones reaches near the surface was correspondent with a boundary of land liquefaction (sand volcano) area by the 2011 off the Pacific coast of Tohoku Earthquake. It is possible that the underground distribution of electrical resistivity is affected by a soil property more than soil water content. Distribution of groundwater level was unclear though it was estimated to be 1.5m in depth from that usual electrical resistivity of saturated sand is 80-100 ohm-m (The Japanese Geotechnical Society, 2003). As a groundwater level near this survey area by the boring survey (Mizuno et al., 2013) was 0.7m in depth, it is possible that electrical resistivity near the groundwater level is higher than 80-100 ohm-m.

As a result of compared the soil water content on the surface with the electrical resistivity beneath the surface, there was a correlation that weight water content is low in a high electrical resistivity. However, there was not a correlation between volumetric soil water content and electrical resistivity. Also, it was not able to confirm the relationship between soil water content and groundwater level because of the groundwater level was not able to estimate from the distribution of electrical resistivity.

This result indicated a detection of the shape of former river bed and a correlation between the soil water content on the surface and the electrical resistivity beneath the surface. We would like to find out an index with land liquefaction in former river channel due to perform a ground penetrating radar survey in the same field.

2011 off the Pacific coast of Tohoku Earthquake and the aftershock brought heavy damage in the various places in East Japan. At a public high school in Mihama ward, Chiba city, remarkable liquefaction - fluidization phenomena occurred in a part of the bicycle place. Sand spouted out the surface of the ground and the ground level sank partially 30 - 40cm height.

In the part that the level of the ground surface changed, we investigated portable dynamic cone penetration test every 1.5 - 2m densely horizontally.

As a result of investigation by portable dynamic cone penetration test, the situation of the subsidence of the ground surface and relations with geological structure became clear.

We can grasp the hardness of the layer in exact depth by portable dynamic cone penetration test, but it is only hardness. We cannot confirm a particle size and the sedimentation structure of the stratum by portable dynamic cone penetration test.

It becomes the high investigation into precision more by comparing geological survey with portable dynamic cone penetration test. Because stratum sample may expand and contract when we pull up stratum in geological survey, this is because it can correct depth by comparing it with the result of portable dynamic cone penetration test.

Thinking about origin by collecting the stratum in the alluvial lowland that is the main living surface of us is very important. Liquidizing-fluidizing phenomenon occurs mainly in man-made strata distribution area in Chiba Prefecture, surface subsidence local area of more than 50cm occurs in the Tohoku-Pacific Ocean Earthquake in 2011. As one of the causes liquidizing-fluidizing, greater potential impact of geological structure of the deep alluvium and man-made strata of shallow has become high (Kazaoka et al., 2012). This improved ACE liner ((Japanese patent application No.3669495) in order to clarify the mechanism and certification of liquidizing-fluidizing point in the layer , and man-made strata deeper and man-made strata that has been soil filled with the dredged sand in shallow underground in this study because it was able to taken the state of the oriented and non-disturbing, observe various structures of the layer, and reports a research method.

Survey results, as well Geoslicer (Nakata et al., 1997) and, without having to be re-liquefaction during drilling the sand hard cohesive soil soft to subsurface 8m, new ACE liner became recoverable in undisturbed sample. Survey results, as well Geoslicer (Nakata et al., 1997) and, without having to be re-liquefaction during drilling the sand hard cohesive soil soft to subsurface 8m, new ACE liner became recoverable in undisturbed sample. On the other hand, there is the core shrinks during drilling and fall of the sand layer at the bottom device to prevent falling of the sample does not operate, loose sand layer is dehydrated deformation during press-fitting part. I believe you require improved by updating technology and experience accumulated in the future.

Terrible liquefaction-fluidization phenomena happened partially with subsidence, 10-50 m width and 20-100 m length, less than 1m height in northern Tokyo bay reclaimed land on the 3011 off the Pacific coast of Tohoku Earthquake. Large amount of sand and groundwater spouted out in the terrible subsided parts. But there are little subsidence and jetted sand outside of the terrible subsided part (RIEGC, 2011).

Continuous box core samples from surface to 5-7 m depth could be taken at the each 3-5 m length from little subsided part to terrible subsided part in Chiba city. Detailed litho-stratigraphy and liquefaction-fluidization parts were studied on the continuous box core samples and large relief peel on the core samples. These data indicate as follows.

1. The thickness of man-made strata is 5-7 m. The thickness increases to subsided part.

2. Man-made strata is composed of Dumped Association, Upper Filling Association and Lower Filling Association. Two Filling Associations were made by sand pump method from bottom sediments in the Tokyo bay. Upper Filling Association consists of lowermost, lower, upper and uppermost bandle.

3. Litho-facies of each man-made strata is as follows.

Dumped Association: This association is composed of 1.5-2.2 m thick sandy silt to silty fine sand layers with siltstone brocks and rock gravels. Sand dike with yellowish brown sand and gray sand distribute rarely

Uppermost Bandle of Upper Filling Association: this bandle is composed of 0.2-0.8 m thick yellowish brown laminated fine-medium sand layers. Upper part of this bandle lost primary sedimentary structures and loose. The base of this bandle consists of laminated coarse-very coarse sandy shell fragment layers.

Upper Bandle of Upper Filling Association: This bandle is composed of 0.4-1.8 m thick gray medium sand layers. Shell fragment layers often interbeded in this sand layers. The sand layers lost primary sedimentary structures and very loose.

Lower Bandle of Upper Filling Association: This bandle is composed of 0-1.8 m thick gray silt layers. Lower part of the silt layer sometimes show slump structures.

Lowermost Bandle of Upper Filling Association: This bandle is composed of 0.7-1.8 m thick gray shelly medium sand layers. Shell fragment layers often interbedded in the shelly sand laters. Top of this bandle consists of loose medium sand without primary sedimentary structures. The medium sand injected in the upper silt layers.

Lower Filling Association: This association is composed of 0.5-3.5 m thick yellowish gray laminated relatively dence matrix free good sorted fine-medium sand layers. This association may deposited removed filling sand by wave action on shoreface.

4. Liquefaction-fluidization parts are in man-made strata, top of the lowermost bandle, upper bandle and uppermost bandle of the Upper Filling Association.

5. Subsidence part distribute in thin part of lower bandle and thick part of upper bandle of the Upper Filling Association. The aboves show that subsidence concern with the liquefaction-fluidization part of the upper bandle of Upper Filling Association.

Revised stratigraphy of the upper Quaternary in Yufutsu Plain and Shikotsu Pyroclastic flow upland, central Hokkaido

KOMATSUBARA, Junko[1*] ; KOMATSUBARA, Taku[1] ; TANABE, Susumu[1] ; HONGO, Misao[2] ; UEKI, Takeyuki[3] ; NAKASHIMA, Rei[1] ; ISHIHARA, Takeshi[1]

[1]AIST, [2]Alps Technical Research laboratory Co. Ltd., [3]Chiba Institute of Science

Upper Quaternary stratigraphy in Yufutsu Plain and Shikotsu Pyroclastic Flow Upland, southern Hokkaido is revised based on review of previous studies and three boring core analysis, which includes sedimentary facies, pollen, diatom, shell assemblages and paleomagnetic analysis.

Active folds have been assumed beneath Yufutsu Plain and Shikotsu Pyroclastic Flow Upland because they are located south-west of the active faults along the eastern margin of the Ishikari Lowland, but neither displacement rare nor continuity of the folds has been specified. The detailed stratigraphy of the Shikotsu Pyroclastic Flow Upland is unknown due to lack of boring surveys for stratigraphic research. To establish subsurface stratigraphy in Yufutsu Plain and Shikotsu Pyroclastic Flow Upland to specify the fold activity, we take three boring cores (BT1, YF1 and CT1). BT1 and YF1 are 4.25 km apart along the coastline, the former is on the Yufutsu anticline axis and the latter is on the west side of the axis. CT1 is in the center of the upland.

In BT1 core we found two characteristic units: First unit is estimated as MIS11 for its abundant *Fagus* pollen, and second unit is estimated as MIS7 for its marine strata which yields cool temperature pollen assemblages. CT1 core is composed MIS7 marine deposits, MIS6 conglomerate, and MIS5 marine deposits. Two unidentified tephra layers found in MIS7 marine deposits in CT1 core may be traceable upto the north of the Shikotsu Pyroclastic Flow Upland.

Geological overview of the Mobara District: Quadrangle Series, 1:50000, GSJ/AIST

NANAYAMA, Futoshi[1*] ; NAKAZATO, Hiroomi[2] ; OOI, Shinzou[3] ; NAKASHIMA, Rei[1]

[1]Geological Survey of Japan, AIST, [2]NARO, [3]GSI

Between 2010 and 2014, geological and geomorphological research for the Quadrangle Series, 1:50000 of the Mobara district was performed by Geological Survey of Japan, AIST. In this poster presentation, we presents the proto version of geological map due to have opinions from everyone.

The Mobara district is located in the northeastern part of Boso Peninsula of the Kanto region. The district partly includes the Pacific Ocean in the eastern district. The land area is geomorphological divided into hills, diluvia uplands, river terraces, alluvial lowlands and Kujyukuri strand plane. The hills and uplands occupy the southwestern to western and northwestern part of the district, respectively. The hills constitute parts of the Kazusa Hills and the uplands are parts of the Shimosa Uplands. River terraces and alluvial lowlands are distributed along Ichinomiya River, Isumi River and Murata River. The Murata River runs through the northwestern district flows into the Tokyo Bay. On the other hand, the Ichinomiya River runs through the central district eastward into the Pacific Ocean. Also the Isumi River runs through the southern district eastward into the Pacific Ocean.

In the Mobara district, there are mainly two stratigraphic units, the lower to middle Pleistocene Kazusa Group and the middle to upper Pleistocene Shimosa Group, trending northeast to southwest and gently dipping northwest. Furthermore Upper Pleistocene terrace deposits with Kanto Loam, Holocene terrace deposits and alluvial deposits arc mostly distributed along the Ichinomi, Isumi and Murata Rivers.

The Kazusa Group is divided into seven formations, Otadai, Umegase, Kokumoto, Kakinokidai, Chonan, Kasamori and Kongochi Formations. These were conformably deposited upward the continuous change of the sedimentary environments from the lower bathyal through upper bathyal to inner shelf.

Subsurface geology of the Shimizu Loland and the Miho Peninsula along the northern Suruga Bay, central Japan

ISHIHARA, Takeshi[1*] ; MIZUNO, Kiyohide[1]

[1]Geological Survey of Japan, AIST

We conducted the drilling survey, core analysis, and boring data analysis to clarify the subsurface geologic structure of the the Shimizu Loland and the Miho Peninsula, the Shizuoka Prefecture, central Japan. GS-MMB-1 was drilled in the northern Miho Peninsula. GS-MMB-1 is composed of the gravely layer, sandy and muddy layer with burrows and shell fragments, and gravely layer in ascending order.

In the Shimizu Lowland, a buried incised valley is along the right bank of the Tomoe River. The basal altitude of the incised valley appears to be decrease upstream, suggesting that coastal area of the Shimizu Lowland has been relatively uplifting.

Reconstruction of tectonic movements using ravinement surfaces: A case study for the subsurface geology of the Osaka

SAKURAI, Minao[1*] ; MASUDA, Fujio[2]

[1]Graduate School of Science and Engineering, Doshisha University, [2]Facluty of the Science and Engineering, Doshisha University

Ravinement surfaces are produced when the sea floor is eroded into a flat surface by the action of waves or tides during a marine transgression. They are preserved in the transgressive deposits as a sharp erosion surface. In a geological cross section across the ancient shoreline, primary ravinement surfaces appear as a subhorizontal line slightly dipping toward the sea. In a cross section, comparing successive ravinement surfaces deformed by tectonic movement allows for the reconstruction of relative tectonic movement. For example, when successive ravinement surfaces are parallel, the entire region has subsided or uplifted uniformly. However, when the lower ravinement surface dips more steeply than the upper ravinement surface, this indicates differential subsidence. With sufficient data, ravinement surfaces can be used to reconstruct the deformation history of an area in three dimensions. Furthermore, because many ravinement surfaces in Quaternary sediments are associated with transgressions related to glacio-eustatic sea level changes, the age of the surfaces can determined and used to estimate the rate of the tectonism.We used the reconstruction of tectonic movement derived from ravinement surfaces to reconstruct the shallow subsurface geologic structures of the Osaka Plain, an intra-arc basin in the Japan island arc. For this study, we constructed cross sections from drill hole data extracted from a civil engineering drilling database. Our study revealed that, in different areas of the Osaka Plain, the land had been uplifted and differentially subsided toward the sea; a relatively large uplift occurred near a flexure zone, and the rate of the tilting of an anticline was constant.

Effects of the offshore barrier against the 2011 Tohoku Earthquake Tsunami and related Recovery Process

MORI, Nobuhito[1*] ; WILLIAM, Pringle[1] ; YONEYAMA, Nozomu[1]

[1]Disaster Prevention Research Institute, Kyoto University

In this study, the effectiveness of an offshore breakwater for the 2011 off the Pacific Coast of Tohoku Earthquake Tsunami was examined by two-dimensional (2D), quasi three-dimensional (quasi-3D) and three-dimensional (3D) numerical models. First, both 3D numerical models were applied to the behavior of tsunami inundation for Kamaishi Bay in Iwate Prefecture where an offshore deep-water breakwater was installed against an assumed tsunami before 2011. The numerical results indicate 20% error of maximum inundation height compared with the post-event tsunami survey on the land. It is found that the offshore breakwater significantly reduced the tsunami height on the land. The reduction of tsunami height on the land gave about 30% tax revenue in comparison with similar locations with or without breakwater. Based on the results the construction and or rebuilding of damaged offshore breakwaters can be considered as a viable option against tsunami particularly in vulnerable areas

The Agri-Reconstruction Project and Rapeseed Project for Restoring Tsunami-Salt-Damaged Farmland after the GEJE

NAKAI, Yutaka[1*] ; NISHIO, Takeshi[1] ; KITASHIBA, Hiroyasu[1] ; NANJO, Masami[1] ; SAITO, Masanori[1] ; ITO, Toyoaki[1] ; OMURA, Michiaki[1] ; ABE, Miyuki[1] ; OGUSHI, Yukie[1]

[1]Tohoku Univ, Grad School Agricultural Sci.

The Graduate School of Agricultural Science, Tohoku University, launched an Agri-Reconstruction Project in 2011 immediately after the March 11 Great East Japan Earthquake disaster, and this continues to date. The project's objective is to support the agricultural, forestry and fisheries reconstruction process in the tsunami disaster area. The activities have been implemented through more than 40 research projects along the Tohoku region including the Rapeseed Project for Restoring Tsunami-Salt-Damaged Farmland.

Immediately after the disaster, damaged farmlands were surveyed and salt-tolerant rapeseed varieties from Brassicaceae and related species were used to restore the soil. The plants came from the gene bank developed at the Graduate School of Agricultural Science, and were planted on damaged farmland in Sendai, Iwanuma and Higashi Matsushima cities. The varieties used to restore the soil depended on the specific damage.

As part of the project, the production and sale of edible as well as fuel oil obtained from rapeseed plants was organized in coordination with the Miyagi Prefecture Sendai City government, a number of private companies and other partners. This enterprise continues to date.

Besides using the salt-tolerant varieties of Brassicaceae plants in tsunami-damaged fields they are also used overseas in the rehabilitation of salt-damaged farmlands.

Evacuation response of fishermen during the 2011 Great East Japan Tsunami and present recovery status

SUPPASRI, Anawat[1*] ; YASUDA, Mari[1] ; ABE, Yoshi[1] ; FUKUTANI, Yo[1] ; IMAMURA, Fumihiko[1]

[1]International Research Institute of Disaster Science (IRIDeS), Tohoku University

The 2011 Great East Japan tsunami severely damaged or destroyed most of the fishing ports and facilities along the Sanriku coast. Fishing boats can be considered as the most important thing for fishermen as their activities are mostly depending on their boats. By getting out offshore to protect their boats from tsunamis is a custom in Japan but this is considered as a risky action. Interviews with fishermen were conducted to investigate their evacuation response, experience and opinion of the recovery status after the 2011 tsunami. We found that most of fishermen who did not decide to get out offshore but evacuated to high ground was although felt deploring in losing their boats but in all cases, they believed that their own lives are the most important. Knowing about tsunami characteristic of fishing port is also important. Tsunami generally arrives the Sanriku areas as fast as 30 min because of the deep sea and short distance from the earthquake epicenter. By this reason, boats can reach to the safety zone of 50 m sea depth very soon as well. However, boats in Sendai Plain will need about one hour to the deep sea. For the recovery, all of the villages are still facing problems resulting from land subsidence when the ports are partly submerged during high tide. In addition, land ownership is another issue that delays any recovery process as local governments need their permissions before doing any kind of construction. Although there are some small differences in detail, they have decided to move the entire community to high ground. Local residents feel that constructing high seawalls are unnecessary because there will be no more houses on the low part of the land and the local governments are trying to solve these problems neutrally.

A method to determine the area of tsunami inundation level 1 and level 2 for pre- and post-disaster situation

MUHARI, Abdul[1*] ; IMAI, Kentaro[1] ; SUGAWARA, Daisuke[1] ; IMAMURA, Fumihiko[1]

[1]IRIDeS, Tohoku University

After the 2011 tsunami, a new approach in the land use planning is introduced and starting to be applied in some areas in Japan. An area that is likely to be affected by the high frequency, but low impact tsunamis -calling as Level 1. It will be used in a separated function in an area that is likely to be affected by low frequency but high impact tsunamis -calling as Level 2. The countermeasures adopted in both areas are different as well. The physical structures will be improved to minimize the effects of the medium-to-low tsunamis to human as well as prosperies in the area of tsunami Level 1. In the area of tsunami Level 2, the coverage of flooded area is much wider. Thus, evacuation facilities and education are the major efforts to save lives. This study aims to address the process on how we can distinguish the boundary between area Level 1 and Level 2. We firstly exercise the use of numerical simulations to establish the framework in assigning area Level 1 and Level 2 at a post-disaster area. Next, we examine the possibility to apply similar techniques in a pre-disaster area. We demonstrate that distinguishing areas of tsunami inundation Level 1 and Level 2 is not only important for the reconstruction in the post-disaster areas, but also necessary to mitigate the future tsunamis in pre-disaster areas.

Based on lessons learned from the 2011 East Japan Earthquake/Tsunami, we recognized the importance of real time monitoring of these natural hazards. As a real time monitoring system, DONET1 was already deployed and DONET2 is being developed constructing the dense ocean floor networks around the Nankai trough Southwestern Japan. DONET observatories detected offshore tsunamis 15 minutes earlier than onshore stations at the 2011 East Japan Earthquake, and provided the significant information of the tsunami amplification process between off shore and on shore. Using these systems, we can detect not only early earthquakes and tsunamis but also low frequency tremors, slow earthquakes and micro earthquakes in the inter-seismic or pre-seismic stage, which provide useful information for the estimation of seismic stage. As the conclusion, the integration of the real time monitoring data and advanced simulations such as the recurrence cycle of mega thrust earthquakes, tsunami inundation, seismic response on buildings/cities and evacuation, is the very important methodology towards future disaster mitigation programs and related measures. We will explain disaster mitigation researches on earthquakes and tsunamis around the Nankai trough.

Sociocultural and Economic Aspects in Restoration after Tsunami Hit: Minamisanriku, Miyagi, Japan

KIMURA, Naoko[1*]

[1]GSGES, Kyoto University

This research discusses sociocultural and economic aspects through description of initiatives taken by local people and organizations in Utatsu area, Minamisanriku, Miyagi Prefecture, for reconstruction after the Great East Japan Earthquake and huge tsunami hit in March 2011. Utatsu is located on the coast of Isatomae-Bay, the Pacific Ocean. The key industry of town is fishery, however, the number of people involved in fishery has decreased since 1990, and the town also has issue related to aging of population year by year. Like any afflicted people by huge tsunami induced by the earthquake, Utatsu residents had to move to another area located higher hillside and start to rebuild their life. This research focuses on two initiatives: a painting-art project and *miso* factory (*miso* is fermented soybean paste, a traditional preservative food in Japan) managed by local housewives. Interviews were conducted to some key stakeholders of those initiatives, and its results were qualitatively analyzed. The interview revealed some positive changes in mind among participants, especially young generation, as well as problems and obstacles long-deep rooted in the local socio-economic structure of the area, for example, mental conflicts between communities, concerns to influence of radionuclides from Nuclear Power Plant accident in Fukushima. The research concludes with a view regarding a possible way forward to their sound rebuilding and reconstruction.

Living with Natural Hazards; Tsunami

SANTIAGO-FANDINO, Vicente[1*]

[1]Independent Environmental Advisor

Tsunamis are a common natural hazard originated by earthquakes, landslides, volcanic eruptions and even meteorological conditions. These events have hit coastal areas particularly along the Pacific Ocean (Rim of Fire), Eastern Mediterranean Sea and the northern part of the Indian Ocean resulting in large impacts to the environment and coastal settlements.

Adaptation by organisms and ecosystems after being hit by tsunamis follow nature's processes for adaptation to the new realities, which also applies in the case of mankind but in this case intelligence, reasoning and complex social structures makes the process more complex reflecting in turn in how the restoration and reconstruction process may develop and its success.

Efforts made to reconstruct and restore impacted areas have proven to be very complicated and controversial oftentimes, this mainly due to differences of opinion on the approaches to be taken and decision-making processes added to the societal aspects. Moreover, lack of direct and effective participation of impacted communities, sectorial and top dawn decision-making further exacerbates the debate resulting in reducing trust by the locals, diminished resilience and increases emigration amongst other aspects.

Tsunamis are complex natural events requiring the integration of sound research and knowledge, the same is required to understand local communities where traditions, customs and societal components are crucial before decision making. Living in Tsunami exposed areas call for building trust with authorities as well as developing early warning and disaster prevention policies, appropriate defence systems and mechanisms, provision of education and awareness raising as well as the understanding of the affected communities needs, capabilities as well as their customs and traditions together with their living environment. Proactive and integrative policies rather than sectorial and reactive top dawn ones bring all these elements together whereby strengthening local communities, increasing resilience and allowing the reconstruction and restoration process to be effective and successful.

Local community and Tsunami-lesson from 2011 eastern Japan mega earthquake

HARUYAMA, Shigeko[1*]

[1]Mie University

The coastal plain facing Pacific Ocean in north-eastern Japan was suffered by Tsunami and mega-earthquake at 2011 Easter Japan Mega-Earthquake. Still now, the regional planners are preparing for appropriate resuscitation or reconstruction for mitigation in the disaster-stricken areas. In this study, the authors tried to clarify local community activity for disaster prevention at the moment of Mega-earthquake occurrence and Tsunami intrusion. The lower Abukuma river basin and coastal and fluvial landforms comparing with former Tsunami intrusion referred to historical records on this site and local communities based on different landform units of the lower Abukuma river basin were selected for analysis to avoid disaster risk level using questionnaire survey. The local community activities were designed by strong leadership of community, former experience of disaster, preparedness of evacuation drill, work sheering experience of community building up social capital in each region. The land use pattern and recent land use change processes in this study area are analyzed and the rapid land use change dealing with urbanization is another trigger of disaster risk level enlargement under the disaster. The future disaster prevention work and disaster mitigation planning should be argued with local community social capital.

Fluvial Environmental Changes of the Ayeyarwady Delta: Case Study for Nyaungdon Borecore Area

KAY THWE, Hlaing[1*] ; SHIGEKO, Haruyama[2] ; AYE, Maung maung[3]

[1]Researcher, Graduate School of Bioresources, Mie University, [2]Professor, Graduate School of Bioresources, Mie University, [3]Professor, Department of Geography, University of Yangon

The Ayeyarwady River is one of the largest rivers in Myanmar and drains an area of 85,534 km2. The study area is mainly located in the central part of deltaic of the Ayeyarwady River belonging to Nyaungdon Township, Ayeyarwady Region.The main purpose of this study is to clarify geomorphologic land classification mapping and fluvial features of the Ayeyarwady River Delta derived from aerial photos, Landsat +ETM7 Global Digital Elevation Model Version 2 with GIS and RS linkage and to check long term natural environmental restoration of the lower Ayeyarwady River at Nyaungdon drilling point in Ayeyarwady Region. The volume of sediment deposited rate and discharge rate should be accumulated rapidly before Holocene period because we could clarify with the results of 14C dating of the organic materials including each layer and all core drilling samples, concept of paleo-geography and geomorphologic evolution, landform development of the study area.

The Impact of Joint Forest Management on Household Income and Forest Condition: The Case of Madhya Pradesh, India

SAKURAI, Takeshi[1*] ; ISAKA, Masashi[2]

[1]Institute of Economic Research, Hitotsubashi University, [2]Graduate School of Economics, Hitotsubashi University

Joint Forest Management (JFM) is a benefit-sharing scheme between rural households and the state government. Rural households are the user of forest resources for their livelihood, such as grazing, fuel woods, wild foods, etc., while the state government is the owner of the forest land and trees in the forest and makes revenue from the sales of forest resource such as timber, medicinal plants, etc. In the past, the state government used to protect the state forest from rural households, but the protection had been becoming more costly due to the increasing population and as a result forest resources had been depleted. JFM scheme was formally introduced by the central government in 1988 to provide rural households with incentive for forest management by benefit sharing, and each state government adopted JFM since then. Under JFM scheme, rural households have to regulate their use of forest resources for their livelihood and they are promised to will a significant share (e.g. 50%) of timber sales revenue.

Although JFM has been implemented for almost 20 years in most states in India, its impact on the welfare of rural households and forest condition has rarely investigated quantitatively. Thus, the objective of this paper is to tackle this remaining question. This paper utilizes a two-year panel data of 360 households and the satellite images of forest around their residential places. The panel data were collected in 1998 and 2008 in 60 villages spread over 6 districts in Madhya Pradesh.

Our analyses show that JFM neither increased nor decreased household income per capita although household income per capita increased significantly during the 10 year period investigated. It implies that the restriction of forest use did not have any negative effect on the welfare of rural households, but that the benefit sharing was not realized or did not increase household income. The latter is consistent with the fact that most timber trees are still immature to harvest. On the other hand, forest condition was improved during the 10 year period in villages where JFM was implemented. The improvement of forest resources is considered to be caused by forest protection from grazing and tree plantation as part of JFM activities. In conclusion, the state government has benefited from JFM, while rural households have not benefited from JFM although they have not decreased their welfare at least in the short-run.

Forming the Inter-mediate Region between Urban and Rural in India - a case of Mysore city, Karnataka -

SUNDERRAJ, Arun das[1] ; KIMOTO, Koichi[2] ; R., Umakanth[1] ; HR, Vishwanatha[1*]

[1]University of Mysore, [2]Hiroshima Jogakuin University

The fragmentation of agricultural land due to inheritance and partial selling has put the farming community into marginal farmers. A marginal farmer owning less than one acre of land, losses complete livelihood from his land. He becomes a partial non agriculture worker along with his farming occupation. Ultimately, leading to permanent change in occupation. In the later period he disowns the farming activity and migrates to the fringe of the nearby city. The CBD pressure on fringe begins as ripples from the city towards fringe. Consequence of this the fringe pressure ripples towards the farming and forest land. This has vice versa effect from Rural to Urban Fringe. The rural pressure which emanates from outer country land towards city mounts up its pressure on Fringe.

This paper discusses about the process of expanding cities, its pressure on fringe, the rural farming land, shifting occupation and bouncing effect towards city. A fast growing city like Mysore city bounded by farming land of Mysore and Chamaraja districts is a good example to explain the situation of many cities of India which are experiencing similar process and bouncing effect.

Time-serial trend of built-up area of China - A preliminary consideration of statistical data

DOI, Haruhiro[1*]

[1]Faculty of Education and Welfare Sciences, Oita University

The research group of SLUAS (Research project of ”Towards Sustainable Land Use in Asia” Grant-in-Aid for Scientific Research(S) 2009-2013, Yukio Himiyama) has executed several research field trips in various regions of China. The author fortunately has chance to join the field trips and to observe several land-use conditions and land-use changes on the way. As a result of those research field trips, the author confirmed that the built-up area remarkably expanded by fast growing economy of big cities in the coastal area such as Beijing and in those cities not only the industrial development but also the housing development and shopping malls are developed actively in the suburban area. On the other hand, the author also felt that the cities in the inland area, however, it is late comparatively its economic growth from the coastal region, a built-up area growth is generated recently by the industrial and housing developments in the high rise apartment building etc. The present study intends to confirm such a personal impression about recent built-up area growth of China by using statistical material.

The objectives of the research are as follows. First object is to confirm time serial feature of the built-up area expansion. Second is to analyse the relation between the built-up area expansion and population scale. Third is to confirm regional difference of built-up area expansion by using regional division in China. And forth is to consider factors or the background of the built-up area expansion. So the author analyses the relations among built-up area expansion, a population increase, and GDP indexes. Findings concerning obtaining by these objectives are beneficial to estimate how a spatial expansion of the China city will become in the future.

The author set up hypothesis obtaining by the research are as follows. One is that built-up area expands according to a population increase and economic growth of a city. Second is that structural change of an economic condition of a city such as secondary industry and tertiary industry is reflecting its expansion of built-up area of a city. Third is that the growth wave of a city spreads from the coastal region to the inland area.

Study on the relationship between human activities. natural environment of food production in Xinjiang

XIAOKAITI, Aji[1*] ; KONDOH, Akihiko[2]

[1]Graduate School of Sciences, Chiba University, [2]CEReS, Chiba University

Maintaining the food production force is a basic condition for ensuring the food security in Xinjiang Uygur Autonomous Region. In this study, We have carried out the factors analysis from both sides of the natural and social factors on food production in Xinjiang, using the unit area production volume as the main indicator of food production. In order to understand the temporal change of the unit area production volume in Xinjiang at first, We extracted the unit area production volume data from the Statistical yearbook in Xinjiang, and analyzed the secular change of food production in Xinjiang. The result shows that the unit area production volume had been growing steadily over the 1990-2003, but shows an unstable state since 2004, and has been reduced in 2008; In order to understand the spatial variation of the unit area production volume, We have created a difference image using GIS technique, between 2008 when the unit area production volume reduced, and 2003 when the unit area production volume had been continued growth to analysis the regional changes of food production. It shows that the regions which the unit area production volume decreased are distributed more in the area of the north and east of Xinjiang in 2008 comparison to 2003.

In order to understand the change factor of food production, the analysis has been done on the causes of changes in food production in Xinjiang, by extracting the data of the chemical fertilizer that was used for the food production, irrigation area, agricultural machinery and the rural electricity from the statistical yearbook, The result shows that the effective irrigation rate in Xinjiang after 2005 was reduced by the loss of irrigation facilities and equipments, and it is confirmed that these area are substantially matches to the region in which the unit area production volume decreasing. The data of the agricultural production material price, commodity retail price, agricultural products purchase price are also used for the same analysis, It was estimated that the rise of agricultural production material prices, has become a factor in reduction of food production indirectly through reduced production cost in 2008 that unit area production volume was reduced.

On its outer, using the TRMMB343 precipitation data and CRU TS3.21 temperature data, analyzed the natural factors of food production change. It shows that the trend of precipitation in decline, and the reduction position matches well with the area of unit area production volume are decreased. However, it is suspected that both of human activities and natural factors have been the impact jointly to the changes in food production in Xinjiang.

Framing Land Use Sustainability Research in Future Earth Context

HIMIYAMA, Yukio[1*]

[1]Hokkaido University of Education

The Future Earth Initial Design issued late in 2013 emphasizes the importance of land use research related with sustainability. What are written about land use are not particularly new to land-use specialists, but what is significant is that land use is considered as a priority concern of Future Earth. The paper discusses how to frame land use sustainability research in Future Earth Context based on the achievements and experiences of IGU-LUCC (International Geographical Union Commission on Land Use/Cover Change), GLP (Global Land Project), SLUAS (Towards Sustainable Land Use in Asia Project) and others.

RIHN Archives - for transdisciplinary research on global environmental studies

YASUTOMI, Natsuko[1*] ; SEKINO, Tatsuki[1]

[1]Research Institute for Humanity and Nature

Research Institute for Humanity and Nature (RIHN) solicits, develops, hosts, and funds fixed-term research projects on pressing areas of interaction between humanity and nature. RIHN promotes coordinated, problem-centered, context-specific, and multi-dimensional science. RIHN projects can last from three to five years; they are always multidisciplinary and employ multiple methodologies, and they are supposed to offer solutions to the problems under study.

RIHN undertake an important task to accumulate their research products on transdisciplinary global environmental studies and resources for successors since almost all researchers leave RIHN after the end of their project.

”RIHN Archives” was developed in 2008 in order to accumulate and charge research products of RIHN research projects. It contains metadata of publications, reports, posters, handsouts and movies of seminars, evaluations, obtained data, maps, and so on. RIHN Archives database is open to public.

”RIHN Archives” itself is the record of transdisciplinary studies held in RIHN. Moreover, RIHN research projects have been conducted on objectives which should contribute to Future Earth. RIHN Archives must play an important role on planning new feasible studies to design futurable earth.

Application of Information on Seasonal Landscapes for Landcover Classification by Satellite Data

KUROKI, Takahito[1*]

[1]Fukuoka Univ. of Edu.

We cannot ignore the influence of seasonal landscapes in landcover classification by Satellite data. Therefore in the analysis, we always have to select the data acquired in the best season for available landcover classification. The seasonal landscape change is also caused by human activities as well as natural conditions. The higher the resolution of the data used for classification, the influence on the landscape by human activity increases in the results. Considering human activity on the classification, it seems that we cannot obtain the realistic image for natural conditions. We do not have much interest in the influence of classification of natural conditions induced by landcover classification based on human activity and the countermeasure. In this study, seasonal landcover classifications based on human activity are analyzed in Aso volcano with remarkable seasonal change of landscape every year. Then, the accuracy is confirmed by such as sign of human activity that can be identified in the classified images. Finally, I discuss on the influence of the classification to that of natural conditions in the volcano and show a countermeasure for the problem in the classification. We used four ALOS data acquired in spring 2010, summer 2006, autumn 2007 and winter 2007 for the classification. The study area was classified into 6 items such as green grass, withered grass, forest, arable land, urban area, open burning area by the supervised maximum likelihood classification.

On the landcover classified maps of all seasons, similar distribution patterns were observed on forest of caldera wall and piedmont of central cone, and on arable land and urban area of caldera floor. On the other hand, distribution of different items was shown in crater rim and mountainside of central cone every season. They are green grass in September, green grass, arable land and withered grass in November, withered grass in February, green grass, withered grass and open burning area in April. On the classified maps, the large seasonal landscape changes at the grassland in crater rim and mountainside of central cone can be understood. From the interpretation of these changes, signs of human activity of boundary of management association for grassland, such as firebreak of open burning were identified clearly. However, this classification work could not induce appropriate classified images that represent the natural conditions in the volcano at the summit area and crater lake area of central cone, dissected valley of lava dome and past slope failure area in caldera wall. At the summit area of central cone, I selected the seasonal image that is easy to represent the distribution for each class of natural conditions. The items in the image were reclassified into the classes of natural conditions and the values of the power of 10 were given to them. Finally, I obtained the realistic landcover classification image at the volcanic area from the overlay analysis by using the reclassified images. Consequently, I clarified in this study that landcover classification representing the characteristics of natural conditions can be performed with high accuracy by using the information of seasonal landscapes based on human activities.

Disaster information gathering depend on the geographic characteristics zone using geospatial information

KOARAI, Mamoru[1*]

[1]GSI of Japan

In order to build a national land equipped with resilience, it is important to advance environmental preservation, land conservation and development which performed geographic division summarized the area where the geographic characteristics is similar. The author tried to classify into the about one hundred geographic characteristics zones of Central Japan for disaster prevention.

Geographic characteristics classification from the viewpoint of the disaster prevention was carried out by the following method. First, it classified into mountain, hill, volcano, plateau and lowland by landform classification. Next, about mountain, hill and volcano, it subdivided according to geology. About plain, it subdivided according to the ratio of plateau and lowland. High-risk areas, such as slope collapse, landslide, liquefaction and collapse of volcanic bodies, were extracted from the analysis of geospatial information, including DEMs, geological maps, landslide distribution maps, landform classification maps, etc.

In this presentation, the author will discuss how to use the geographic characteristics zone for emergency assistance at early stage. It is necessary to consider the disaster information gathering according to the difference of disaster characteristics on each geographic characteristics zone. The most important issue in mountain area is grasping of an isolated colony, and detection of an isolated colony is possible by overlay of slope collapse expected area and road network information. In the viewpoint of a catastrophic secondary disaster, extraction of the flooding area by a landslide dam is very important. Satellite SAR and airborne SAR ware effective method in the case of deep collapses by the typhoon heavy rain of Kii Peninsula in 2011. In the disaster information gathering in early stages of a plain area, tsunami damage is very important. Satellite SAR was effective method for the detection and monitoring of the tsunami flooding area in the case of the Great East Japan Earthquake. From the viewpoint which carries out emergency assistance at early stage, the extraction of the heavy damaged area is required. The development of automatic classification technology about spill zone, failure zone and flood zone using polarization SAR is required.

Keywords: geoigraphic characteristics zone, geospatial information, disaster information gathering, emergency assistance at early stage, synthetic aperture radar

Towards detailed tsunami hazard assessment for specific regions

HIRATA, Kenji[1*] ; FUJIWARA, Hiroyuki[1] ; NAKAMURA, Hiromitsu[1] ; OSADA, Masaki[1] ; OHSUMI, Tsuneo[1] ; MORIKAWA, Nobuyuki[1] ; KAWAI, Shin'ichi[1] ; AOI, Shin[1] ; YAMAMOTO, Naotaka[1] ; MURASHIMA, Yoichi[2] ; MURATA, Yasuhiro[2] ; INOUE, Takuya[2] ; SAITO, Ryu[2] ; MATSUYAMA, Hisanori[3] ; TOYAMA, Nobuhiko[3] ; KITOH, Tadashi[3] ; AKIYAMA, Shi'ichi[4] ; KORENAGA, Mariko[4] ; ABE, Yuta[4] ; HASHIMOTO, Norihiko[4]

[1]NIED, [2]KKC, [3]OYO, [4]CTC

NIED began research projects regarding tsunami hazard assessment (THA) in Japan to support various kind of measures against possible tsunami attacks in future by sectors such as local governments, life-line companies, etc after the national tragedy caused by the 11st March 2011 Tohoku earthquake (Mw9.0) (Fujiwara et al., 2013, JpGU). One of the research projects is a research of probabilistic tsunami hazard assessments (PTHA) in which we consider all of possible tsunamis that may affect coastal regions in future. The research of PTHA consists of two subjects; (1) nation-wide probabilistic tsunami hazard assessment (NWPTHA) (Hirata et al., 2014, JpGU) and (2) detailed probabilistic tsunami hazard assessment for specific regions (DPTHASR). We briefly show outlines of (2) here.

The objective of DPTHASR is to bridge the gap between probabilistic tsunami hazard assessment and local measures for disaster prevention in city-scale. In the research and development process of DPTHASR, we are planning to conduct several kinds of tsunami inundation assessment for specific regions by using tsunami propagation and inundation simulations based on a non-linear long wave equation with staggered leap-flog, finite difference method (FDM) over a nesting grid system with the minimum grid size of 10 meters. As for presentation tools of DPTHASR, we are planning to present (a) inundation flow depth hazard curve (excess probability) at specified point and (b) probabilistic spatial distribution of inundation flow depth as well as we are also planning to investigate development of (c) probabilistic inundation flow velocity assessment that is closely related to tsunami destructive force against buildings, etc. and that can be directly applied to risk assessments. As the first attempt in researches regarding DPTHASR, we are investigating a probabilistic method of depth flow assessment in which both of probabilistic assessment for inundation flow depth distribution and inundation flow hazard curves (excess probability) are presented (Saito et al. 2014, JpGU).

For a high-precision forecast of inundation phenomena based on tsunami run-up calculation in DPTHASR, it is the most important to use fine and precise topographic data with detailed information on breakwaters and seawalls in coastal region and riversides. We make effort to collect these information and will have to investigate relationship between inundation flow assessment and destruction conditions of coastal infrastructures in near future. The Ministry of Land, Infrastructure, Transport and Tourism (MLIT) of Japanese Government recommends users for tsunami runup calculation to basically use high-precision topographic data acquired with airborne laser scanning (MLIT, 2012, Guideline for tsunami inundation forecasting). The Geospatial Information Authority of Japan (GSI) is progressively releasing the precise coastal topographic data acquired with airborne laser scanning. DPTHASR will be advanced using processed data, converted for tsunami simulation, created from high-precision topographic data acquired with airborne laser scanning by GSI.

The Significance of Partnership and Participatory Sharing of Geospatial Information through crisis mapping in Izu-Oshima

SETO, Toshikazu[1*]

[1]Center for Spatial Information Science, the University of Tokyo

1. Introduction

Various platforms enable online-based plotting of disaster information map using reviews and other social networking services (SNS). Examples Ushahidi has been noted since the Great East Japan Earthquake for its usefulness in promoting rapid situational awareness in disaster areas. This platform also is used OpenStreetMap (OSM), a free mapping project used to generate background maps. Indeed, as regards natural disasters that occurred in Japan after year of the Great East Japan Earthquake, simplified versions of information sharing sites have been established by volunteers, such as Crowdmap. Meanwhile, during the onslaught of Typhoon Wipha last October 2013, information sharing by volunteers progressed smoothly using the rapid launch of Crowdmap.

However, the method of geospatial information gathering in the event of a crisis as a means of quickly relaying information in and out of disaster areas, as typified by crisis mapping using Ushahidi, is not fully and properly utilized in Japan.This study examines the role of information sharing and the development of geospatial information on the Web related to disaster response.

2. Sharing of geospatial information by participatory mapping in Izu-Oshima

To promote Izu-Oshima tourism around the Geopark with the aid of information technology, Izu-Oshima Tourist Association and other groups held the Hackathon and Mapping Party in January 2013. In this event, a detailed map created or developed smartphone applications for leisure by about 30 cooperating participants composed of OSM developers and mappers, as well as local residents involved in geopark's tour guide.

3. Cooperation with other organizations and launch of crisis mapping during the occurrence of Typhoon Wipha

After the event in January 2013, participants continue to engage in exchanges through a Facebook group, including participants of the island nature tour guide. For instance, users in Tokyo, who tuned in to the news regarding the occurrence of heavy rain and landslides brought by typhoon Wipha last October 16, intensified their information collection and uploaded data on the Web site very quickly. Twitter accounts with high reliability, such as that of "Izu-Oshima's disaster prevention", published information picked up by disaster prevention radio stations.

In another case, the Red Relief Image Map made by Asia Air Survey and slant ortho-photo data gathered by emergency shooting by some survey companies provided as a possible WMS layer through "e-com map" of the Research Institute for Earth Science and Disaster Prevention and Geoserver of the Code for Japan community. Such geospatial information can serve as the basic data for the estimation of location information, in which Crowdmap helps screen information via SNS features. As such, the number of page views of Crowdmap reached 12,000, and 248 reports are posted on Crowdmap in about a month after the disaster. In addition, as information transfer throughout and mapping of the disaster area had become a major issue, it was reported in local as well as analog information of paper maps, such as the large-format guide to the Great East Japan Earthquake by the Nature and Tourism Association staff.

4. Conclusions

In Japan, crisis mapping that fully utilizes the Web, such as online maps, has come to be carried out quickly and serve as a source of understanding and cooperation between volunteers and various organizations. In this context, the need for information gathering and sharing at a high public degree in the initial disaster stage is recognized, triggered by the events of the Great East Japan Earthquake. In addition, even in areas where information technology and geospatial information have not been as highly developed compared with Izu-Oshima, the cases covered in this study revealed that stakeholders could work together through workshops to build a relationship aimed at advancing information sharing development.

Study of natural disasters and terrain of Izu Oshima with Red Relief Image Map

CHIBA, Tatsuro[1*]

[1]Asia Air Survey Co., Ltd.

Introduction

In recent years , advances in LiDAR technology , detailed topographic data with high accuracy by eliminating the influence of the tree is now obtained. The contour by aerial photogrammetry so far , terrain under the trees is due to the estimation of operator that assumes the tree height , the difference of the laser measurement was evident . However, it is to express in scale in which it is easy to utilization of the whole picture microtopography measurement such results is difficult. Also shaded contour plot also altitude tints Figures it was not appropriate. I ivented red relief image map method at the time of terrain reconnaissance of Aokigahara-Jukai of Mount Fuji in 2002. After that I've been used to field survey and interpretation of volcanic terrain around the country .

red relief image map

The more red than at steep slope , as bright as ridge , expressed the darker the valley , red relief image map is a some false color image of certain ortho . Since the state overlapping the topographic map , without the use of specialized equipment , it is possible to obtain a natural three-dimensional feeling in one piece , a combination of a red relief image map and LiDAR DEM and revolutionized the field survey.

terrain of Izu-Oshima

Also in Izu-Oshima , LiDAR DEM were detected, H24 by Tokyo,H25 by Tokyo ,H18 by GSI has been carried out . In addition , as the foundation map information 5mDEM, measurement results of H24 have been published from the GSI.

This section shows a red relief image map of Izu-Oshima , we describe the features of the volcanic terrain that can be read from there .

Izu-Oshima , there is a caldera in the center , Mt central cone is located in the center . Mt shows the terrain of tuff cone crater is large in proportion to size , but I'm repeating the activity in which the bottom of the crater of the central vertical hole moves up and down , to overflow the lava . The eruption occurred at 1950-51 and 1986 in recent years . In addition, in the Izu-Oshima , fissure eruption many distribution on the outside of the caldera , C fissure eruption in 1986 . It has been estimated that there is a fissure of Y5 drained the lava flow the steep slopes on the east side of Motomachi , but the exact location has not been clearly covered in trees . The red relief image map by the laser measurement of H18, Y5 fissure is visible clear , although confirmation has been difficult by many trees . After that , the field survey of the collapse can be accomplished by the typhoon disaster of October 2013 , it was confirmed to be Y5 fissure .

Features of the terrain of the surface slope collapse

The typhoon of October 16, 2013 , a large debris flow disaster occurs at the Motomachi Kandachi area of Izu-Oshima . Wake of this disaster was the collapse of the surface layer of volcanic ash on the slopes , and this slope are crossed by Y5 fissure, debris flow was flowing down over the Motomachi lava flowed from there . For the valley of this lava flow is very shallow , became the disaster spill debris flow can not swallow . In addition, I describe the characteristics of the micro-topography in the poster .

Role of the cloud based GIS for disaster management system at Emergency Operation Center

GOTO, Shintaro[1*] ; SAWANO, Nobuhiro[2] ; SAKAI, Toshikazu[1]

[1]Department of Environmental Systems Faculty of GEO-Environmental Science Rissho University, [2]Kanazawa Seiryo University

The cloud-based GIS center with the assumption that on the basis of the lessons learned in disaster information logistic support of the Great East Japan Earthquake 2011, ICS is introduced at the provincial level, to function under ICS concepts in the field Saitama Prefecture. The object of the invention is to organize the features and to operate by implementing it.

For this purpose, the contents of this study are as follows;

1. Study of cloud-based GIS data management perspective for the basic system

2. Application to the COP(Common Operational Picture) and the study of the utilization by the cloud of electronic results

3. Demonstration and calibration in collaborative disaster drill applying the ICS

Micro - Landform Mapping and Applications in Hilly Area Using LIDAR Data

BORJIGIN, Habura[1*] ; GOTO, Shintaro[2]

[1]National Institute for Environmental Studies Center for Regional Environmental Research, [2]Rissho University Department of Environmental Systems Faculty of GEO-Environmental Science

The objective of this study is to develop the information to be provided for natural regeneration by investigating the relationship between Micro-Landform and vegetation in hilly area of Higashi-matsuyama City in Saitama Pref. The Micro-Landform was classified based on the conversion line of the slope angle derived from DEM (digital elevation model) generated from LIDAR (Laser Imaging Detection And Ranging). Furthermore, we summarized the classification situation of each Micro-Landform by every tree measurement. Finally, the relationship between vegetation and Micro-Landform in the study area was detected by analyzing the relationship between the summarized situation of Micro-Landform and the woody life type corresponding to the Micro-Landform classification using TWINSPAN.

An influence of roadway on occurrence of slope failure and debris flow of the Izu-Oshima Typhoon Wipha (1326) disaster

SHIRAI, Masaaki[1*] ; WATANABE, Makiko[1]

[1]Tokyo Metropolitan University

Vast slope collapse took place and debris flows struck the Motomachi-town foot of western slope of the Izu-Oshima Island on early morning 16, Oct. 2013. Field survey on the collapsed slope by *TMU Group for Izu-Oshima Typhoon Wipha (1326) Disaster Survey* was carried out 4 to 6, Dec. 2013.

One of the major concerns of the authors was an influence of roadway built after 1986 eruption on occurrence of 2013 slope collapse. Results of the survey are summarized as follows, (a) Collapse points originated from downslope side of the roadway (type-A collapse) were located on ridges and adjacent to collapse points originated from upslope side of the roadway (type-B collapse). (b) A large amount of debris of fallen tree which would have been transported by mud flow on the road was observed around the type-A collapse points. (c) A 1-0.5 m thick surface soil mass with tree and its dense roots was peeled from base of the retaining wall at the other small collapse. An appearance of the base of the retaining wall at the small collapse is similar with base of the retaining wall at type-A collapse.

Taking account into these results (a) to (c), it is inferred that type-A collapse would have occurred according to the following scenario, (1) rainwater and mud flow from type-B collapse flowed on the roadway, (2) around the curve on the ridge, rainwater/muddy water fell down from road surface to retaining wall and (3) surface soil mass (1-0.5 m thick) with dense tree roots and trunks was saturated by water and peeled from base of the retaining wall. Consequently, we conclude that the roadway was not a primary factor but secondary factor of the slope collapse, which expanded collapse area in this case.

Utilization of the natural hazard database by NIED - a case of utilization at Typhoon Wipha (2013) on Izu Oshima island

SUZUKI, Hinako[1*] ; UCHIYAMA, Shoichiro[1] ; USUDA, Yuichiro[1]

[1]National Research Institute for Earth Science and Disaster Prevention (NIED)

This study introduces a case study on utilization of natural hazard database by NIED for extracting historical hazard events on Izu Oshima island suffering Typhoon Wipha in 2013. This powerful typhoon attacked on Motomachi area, and caused large-scale landslides. We searched the historical hazard events in this place from the natural hazard database to investigate relation between hazard this time and old events. Keywords for searching the database were ”typhoon”, ”heavy rain” and ”landslide”. As a result, seven events were found between 1925 and present, and typhoon Ida in 1958 was a particularly massive scale. The typhoon Ida that caused large landslide in Motomachi area, which was devastated again by Typhoon Wipha, was named ”Kanogawa typhoon” in Japan. Through these unification processes, we found two problems in our database:

1) No records about typhoon, heavy rain, and landslide before 1925 in this area
2) Little information about the date and time of occurrence and the extent

We will enrich these event records and information.

A new methodology to assess the impacts of precipitation change on flood risk in Tokyo 23 ward Area

HIRANO, Junpei[1*] ; DAIRAKU, Koji[1]

[1]National Research Institute for Earth Science and Disaster Prevention

n this study, we attempted to develop a new methodology for flood risk assessment in the Tokyo metropolitan area by considering the effect of precipitation change. By comparing the statistical distribution of the daily precipitation frequency for the whole study period, and those for flood occurrence days, we found that the distributions of the precipitation frequency for the flood occurrence days are corresponding to those for the whole study period. These results indicate that we can estimate flood damage based on frequency of daily precipitation. Based on these results, we estimated the flood damage for Tokyo based on distribution of daily precipitation frequency. We then created a flood-risk curve that represents the relationship between damage and exceeding probability of a flood. By comparing the newly developed flood-risk curve, based on the precipitation frequency, with those in the previous studies, we indicated that a newly developed flood-risk curve could evaluate the potential flood risk in Tokyo with high accuracy.

Map Drilling of Disaster Prevention by Voluntary Group - An Example at Nasu Volcanic Area

FUKUSHIMA, Tamio[1] ; TAKAMORI, Shouji[3] ; INABA, Shigeru[4] ; NAKAMURA, Yoichi[2*] ; NASU, Local governmnet[5]

[1]National Association For Diaster Prevention, [2]Utusunomiya University, [3]Promotion Council of Distric Continuity Management, [4]Disaster Prevention Qualiged Counselor in Tochigi, [5]Manucipal Governmnet of Nasu Town

A map drilling of volcanic disaster prevention by voluntary groups: An Example at Nasu volcanic area was hold in the area of Nasu active volcano. This evacuation drilling at Nasu municipal government for voluntary groups of town people was supported by National Association for Disaster Prevention, Promotion Council of District Continuity Management, and Disaster Prevention Quailed Counselor in Tochigi. This project was managed financially to perform for last two fiscal years between 2012 and 2013. As a result, present drilling was very effective, especially for community people living near active Nasu volcano, in order to learn evacuation managements at the future volcanic emergency.

Disaster risk reduction workshop utilizing GIS and Saba-meshi: A practice of the Department of Geography, Oita Univ.

KOYAMA, Takushi[1*] ; DOI, Haruhiro[1] ; MORIMATSU, Maya[2] ; UCHIYAMA, Shoichiro[3]

[1]Department of Geography, Oita University, [2]Nihon Suido Consultants Co. Ltd., [3]NIED

The Department of Geography at Oita University held a disaster risk reduction workshop on November 3, 2013, for schoolchildren and their parents (A total number of participant was fifty one). The purpose of the event was to motivate the schoolchildren and their parents to aware of a disaster prevention and reduction in their daily life. The event consisted of the following two experiences: drawing a map using a geographic information system (GIS), and cooking rice using two 350ml aluminum cans and three 1L milk cartons (Survival *Meshitaki*). Survival *Meshitaki* is called *Saba-meshi* for short, and it is material for teaching about disaster prevention through practical experience.

After the event, the participants were requested to respond the questionnaires in order to evaluate the event. The results of the questionnaire showed that we received high evaluations from many participants on the experiences offered at the event. Therefore, we were able to raise the participants' awareness of disaster prevention and disaster reduction.

Furthermore, thirteen university students, who intend to become schoolteachers, participated the event as assistant staffs. They acquired in advance the fundamental skills of GIS and *Saba-meshi* by a preliminary training workshop. These are useful skills in the field of school education. The event, in conclusion, has given the participants and the students intending to be schoolteachers' very effective experiences and practical knowledge respectively and the experience-based event such as this workshop is worth to be held repeatedly.

Liquefaction occurrence ratio and geomorphic conditions in the inland area caused by the Great East Japan Earthquake

AOYAMA, Masafumi[1*]

[1]Japan Map Center

The area ratio of liquefied sites in the inland area caused by the 2011 off the Pacific coast of Tohoku Earthquake was estimated from the field survey and Google Earth images interpretation. In the Tone River lowland, the occurrence of liquefaction concentrated in the former river channel and pond, and the area ratio of liquefied sites is about 23%. The ground consisting of younger landfill age is more susceptible to liquefaction than that created by the older ones. Area ratio of Liquefied sites in the Tone River lowland is larger than the Osaki plain, Miyagi Prefecture. In the Osaki plain, the area of former river channels and ponds buried by loose sandy soils is less than the Tone River lowland.

Tsunami hazard inventory survey of utilize for municipalities

OHSUMI, Tsuneo[1*] ; NAKAMURA, Hiromitsu[1] ; HIRATA, Kenji[1] ; OSADA, Masaki[1] ; FUJIWARA, Hiroyuki[1]

[1]National Research Institute for Earth Science and Disaster Prevention

A tsunami hazard inventory is important for tsunami disaster mitigation due to earthquakes, and also for a Tsunami hazard assessments. The tsunami hazard assessments project for Japan was started since 2012 by NIED (Fujiwara, *et al.,* 2013, Hirata, *et al.,* 2014). We performed inventory survey on utilization of the tsunami hazard assessments to Ibaraki and Chiba prefectures, which damaged municipalities of the tsunami during the 2011 off the Pacific Coast of Tohoku Earthquake. First stage, we surveyed the crisis management departments of the Ibaraki and Chiba Prefectures. Second stage, we surveyed 10 municipalities of Ibaraki prefecture and 18 municipalities of Chiba prefecture. Tsunami hazard inventory was carried out with a description of the Tsunami hazard assessments as the introduction. To discuss the possibility of the use of the municipality of tsunami hazard assessments current status and Issues of tsunami measures, organize the opinion and negative opinion aggressive to report the problem extraction.

Reconstruction of paleo earthquake intensity

INOUCHI, Yoshio[1*] ; OKUMURA, Yuka[2] ; NAMEKI, Katsuhiko[3]

[1]Faculty of Human Sciences, Waseda University, [2]School of fHuman Sciences, Waseda university, [3]Graduate School of Human Sciences, Waseda University

Many drastic earthquakes have been occurred historically in Japan. In order to reduce damages caused by those earthquakes, data concerning frequency, magnitude and influenced areas of each earthquake are inevitable. Here, we report measuring method of paleo intensity of historic earthquakes at arbitrary selected stations based on empirical formulas. Based on data regarding position of epicenter and magnitude of each paleo earthquake, intensity of paleo earthquake at arbitrary site is estimated. At the beginning, these data were used to recognize earthquake triggered turbidites at several lakes. The results show that lower threshold of triggering turbidites are 45gal in Lake Biwa and 79gal in Lake Inawashiro, respectively. Usage of this kind of method will enable us to reconstruct paleo earthquake data which have no written record.

An overview on current status of public disclosure for tsunami hazard information in and around Japan

OSADA, Masaki[1*] ; NAKAMURA, Hiromitsu[1] ; HIRATA, Kenji[1] ; OHSUMI, Tsuneo[1] ; FUJIWARA, Hiroyuki[1]

[1]National Research Institute for Earth Science and Disaster Prevention

A probabilistic tsunami hazard assessment research work is currently conducting by the National Research Institute for Earth Science and Disaster Prevention (NIED) (Fujiwara et al, 2013, Hirata et al., 2014). It is well recognized that output from such assessment should be transferred to the public as understandable and utilizable informations in various stages on hazard prevention works. From this point of view, as part of this project, we make a brief survey on how and what sort of hazard informations local residents are receiving from administrative authorities or agencies in and around Japan. Survey is focused on hazard map which is reachable through internet. In this paper, results are summarized in two categories, 1) type of maps and 2) distribution methods. Category 1 is able to divide into four subgroup; 1a is due to tsunami height map at shore (ex. Australia), 1b is tsunami inundation depth map which are based on the simulations on worst, most probable case, or probabilistic case (ex. most of Japanese prefectures, Indonesia, Oregon and Washington, USA), 1c is tsunami evacuation map in which zones to be quit are shown according to the warning level (Wellington, NZ, Oregon and Hawaii, USA), and 1d tsunami regulation map which prohibits (Oregon, USA). These maps are based on probabilistic or deterministic assessment outputs. Tsunami hazard informations are available mainly in style of the poster (downloadable in PDF format) although Web mapping (ex. Hawaii, USA) or GIS format (ex. Australia) can be found. Later seem to urge a user to secondary or further utilization. This survey suggests that it should be to provide tsunami hazard assessment results in various ways of presentations which meet user’s purposes.

Pore water pressure in slopes composed of multi-layer geological structure

IMAIZUMI, Fumitoshi[1*] ; MIYAMOTO, Kuniaki[2]

[1]Graduate School of Agriculture, Shizuoka University, [2]Faculty of Life and Environmental Sciences, University of Tsukuba

Increasing in pore water pressure in the slopes during heavy rainfall events is considered as an important factor induceing landslides. Sliding surface of many of these landslides locates on the boundary between different rock/soil strata. We need to know spatial distribution of the pore water pressure in slopes composed of multi-layer geological structure in order to explain occurrence mechanism of these landslides. Many of prior studies generally analyzed slope stability under condition that the pore water pressure is same as the hydrostatic pressure. These studies ignored influence of depth profile of hydraulic parameters on magnitude of the pore water pressure. We, therefore, tried to understand spatial distribution of the pore water pressure on the basis of the continuity equation and equation of motion for seepage flow in two-dimensional slopes with multi-layer soil structure. Our study clarified that the water velocity as well as the depth profile of the pore water pressure are affected by depth profile of the hydraulic conductivity in the saturated zone. Pore water pressure agrees with hydrostatic pressure in case that the saturated zone develops on the impermeable soil layer. Meanwhile, pore water pressure is smaller than hydrostatic pressure in case that bottom of the saturated zone contacts with unsaturated zone. In this case, magnitude of the pore water pressure depends on the difference in the hydraulic conductivity between upper and lower layers. In addition, pore water pressure is highest at a layer boundary. Our analysis results agree with the general landslide characteristic that the sliding surface locates on a layer boundary.

Landsliding phenomenon under abnormal weather conditions: a case study

WANG, Gonghui[1*] ; SUEMINE, Akira[1] ; MATSUURA, Sumio[1] ; ARAIBA, Kiminori[2]

[1]Disaster Prevention Research Institute, Kyoto University, [2]National Research Institute of Fire and Disaster

To examine the initiation and movement mechanisms of landslides occurring during abnormal weather conditions, we have been monitoring a landslide on Nisenotani area in Miyazaki Prefecture, Japan. The monitoring items include the weather conditions (rainfall and air pressure), moisture content of surficial soil layers, groundwater table, and displacements (by means of borehole wire extensometer, surficial extensometer, and total station). Cracks appeared on the slope after a heavy rainfall and borehole investigation revealed that this landslide is a large compound one, consisted of several sub-blocks. Our dense monitoring is performed on a small block of the toe part, and our results showed that: (1) landsliding was initiated by a heavy rainfall, but was not less affected by small rainfall; (2) landsliding varies with air-tide; (3) lower part of the sliding sub-block had been continuously compressed; (4) the sliding surface and the compressed soil layer had been effectively identified by means of a surface-wave technique.

Extreme Rainfall Effect on Slope Hazards along Mountain Roadway

WANG, Chao-wen[1*] ; YOSHIMI, Kazuhiro[1] ; YAMADA, Tadashi[1]

[1]Graduated School of Science and Engineering, Chuo University

Due to the global climate changes, the scale and frequency of natural disasters are more difficult to predict and measure. Extreme rainfall often brings astonishing amount of water and causes very serious damage in the mountain areas. And for different environment conditions, the slope hazards induced by rainfall would be different like geology, topography or location. Therefore in this research, the authors considered the elevations, slope aspect, slope gradient and geology to compare and analysis the rainfall effect on slope hazards by using the historic landslides records. And the major method of rainfall analysis is the snake line model that is using dual-indexes of rainfall- short term rainfall intensities and accumulated rainfall data. Short term rainfall intensities mean hourly rainfall, 3 hourly rolling rainfall, 6 hourly rainfall and so on. The most important of these rainfall analyses are trying to find some regulars in occurrence of slope hazards. Furthermore, the authors also collected different hazard types in order to try to get the rainfall characteristics of different disasters. In this research, the authors used the Da-Jia River upstream region (Taiwan) as the case study. In this region, over than half area the slope gradient is larger than 55%. Through the results of the analyses, the authors get some important conclusions. Firstly, in the environment conditions, the effects of slope gradient, elevation, and geology are obvious. Secondly, the effect of slope aspect is according to the rainfall events. Finally, in extreme rainfall events, the trend of occurrence time in different hazards can be observed. According to the above conclusions, it can be effective to make decisions to prevent disasters and reduce lost.

Shallow Landslide Susceptibility Mapping for Selected Areas in the Philippines Severely Affected by Super Typhoon Haiyan

RABONZA, Maricar[2*] ; FELIX, Raquel[1] ; ORTIZ, Iris jill[1] ; ALEJANDRINO, Ian kaye[2] ; AQUINO, Dakila[2] ; ECO, Rodrigo narod[1] ; LAGMAY, Alfredo mahar francisco[2]

[1]University of the Philippines Diliman, [2]Nationwide Operational Assessment of Hazards, Department of Science and Technology

Super Typhoon Haiyan, considered as one of the most powerful storms recorded in 2013, devastated the central Philippines region on 8 November 2013. In its wake, Haiyan left 6,190 fatalities, 28,626 injured and 1,785 missing, as well as damage amounting to more than USD 823 million. To mitigate damage from similar events in the future, it is imperative to characterize hazards associated with tropical cyclones such as those brought by Haiyan, with detailed studies of storm surges, landslides and floods. Although strong winds and powerful storm surges up 15-17 feet were the primary causes of damage, landslides studies are also vital in the rehabilitation of typhoon damaged areas. Cities and municipalities of Leyte (7,246.7 sq. km) and Samar (13,121 sq. km) provinces, the heaviest cities area during the onslaught of Haiyan, require detailed and up-to-date hazard maps for their rebuilding and disaster mitigation programs. In order to delineate areas susceptible to rainfall-induced shallow landslides and generate a worst-case scenario hazard map of the two provinces, Stability INdex MAPping (SINMAP) software was used over a 5-meter-resolution Interferometric Synthetic Aperture Radar (IFSAR)-derived digital elevation model (DEM) grid. SINMAP has as its theoretical basis in the infinite plane slope stability model. Topographic, soil-strength and hydrologic parameters (cohesion, angle of friction, bulk density and hydraulic conductivity) were used for each pixel of a given DEM grid to compute for the corresponding factor of safety. The landslide maps generated using SINMAP are found to be highly consistent with the landslide inventory derived from high-resolution satellite imagery dated 2003 to 2013. The landslide susceptibility classification found in the landslide hazard maps are useful to identify no-build, areas that can be built upon but with slope intervention and monitoring as well as places that are safe from shallow landslides. These maps complement the debris flow and structurally-controlled landslide hazard maps that are also being prepared for rebuilding Haiyan‘s devastated areas.

Calculation of Shallow-Landslide Rainfall Threshold for Libon, Albay, Philippines Using TRIGRS

ALEJANDRINO, Ian kaye[1*] ; ALEMANIA, Maneka kristia[1] ; AQUINO, Dakila[1] ; ECO, Rodrigo narod[1]

[1]DOST Project NOAH

In a rainfall event caused by a cold front and a low pressure area during the 14th until the 21st of February 2008, the Albay province experienced several landslides with $4.6 million in damages to infrastructure alone. Aside from delineating areas that are highly susceptible to landslide, it is important to determine shallow-rainfall threshold aid in the development of an early warning system. The study area was carried out on an area in Libon town in Albay with approximately 1000 residents living near the high hazard area. Using TRIGRS software (Transient Rainfall Infiltration and Grid-based Regional Slope-stability analysis), 6 different sustained rainfall intensities with the duration of 24 hours were simulated to a 5-meter resolution IFSAR (Interferometric Synthetic Aperture Radar)-derived DEM (Digital Elevation Model). Topographic, soil strength, and hydrologic parameters were assigned to each pixel of the given DEM grid to compute for the factor of safety using the theory on Infinite Plane Slope Stability to produce a shallow-landslide susceptibility map. The values of the different rainfall intensities were selected to represent different rainfall events equal (1.26mm/hr), less than (.5 and 1mm/hr) and greater than (1.5, 2.73, 7.5 mm/hr) the infiltration rate of the soil. After comparison, there were no observed differences in the hourly variation of the Factor of Safety Maps for 1.26 mm/hr and greater intensities. The rainfall threshold determined to be 4.5 to 5mm of effective accumulated rainfall on which the pixels that failed (FS$<$1) matched the landslide inventory from 2003-2014 and the shallow-landslide hazard map. This study shows that in determining rainfall thresholds for shallow landslides the effective infiltration rate and hydraulic diffusivity of the soil serves as factors on how fast the slope reaches instability during a rainfall event. The results of this study may be treated as the worst case possible due to the sustained intensities and may be further improved through simulations using data of actual rainfall events, considering varying rainfall intensities and durations.

Sensitivity of the initiation of debris flow to initial soil moisture

HU, Wei[1*] ; XU, Qiang[1] ; WANG, Gonghui[2] ; VAN ASCH, T.w.j.[3] ; HICHER, Pierre-yves[4]

[1]State Key Laboratory of Geo-Hazard Prevention and Geo-Environment Protection, Chengdu University of, [2]Disaster Prevention Research Institute, Kyoto University, Japan, [3]Faculty of Geosciences, Utrecht University, Heidelberglaan 2, 3584 CS, The Netherlands, [4]LUNAM University, Ecole Centrale de Nantes, CNRS UMR 6183, France

The initiation of debris flows is commonly attributed either to fluidization as a result of rainfall induced landslides or to gully erosion induced by concentrated run-offs. A series of flume tests have been performed to show how the initial soil moisture influences the initiation of debris flows. At the start of each experiment, surface run-off was generated over loose granular deposits, triggering debris flows. These experimental debris flows enacted different scenarios according to the small variations among the initial soil moistures. In the loose granular deposits with initial soil moistures ranging from 1% to 5%, most run off water could infiltrate and trigger a landslide, which accelerated within one second to speed over 1 ms-1 and then transformed into a debris flow. In the same soil deposits with initial moistures >5% or <1%, the debris flow was initiated by slow gully erosion with episodic events of damming and breaching due to small-scale landslides occurring on the side-slopes of the erosion valley. The slope failures were not triggered by positive pore pressure but by a decrease in suction due to the wetting of the soil. This suction decrease in initially unsaturated slopes explains why the transformation of these slope failures into debris flows are due not only to an increase of pore pressure leading to soil liquefaction, which is one of the expected triggering mechanisms, but also to a loss of the cohesive strength of the soil.

Gully development on flows and deep-seated slides in the Mangaoporo catchment, North Island, New Zealand

PARKNER, Thomas[1*]

[1]College of Geoscience, University of Tsukuba

Mass movements and gully erosion are widespread phenomena in many steep, erosion prone catchments. Understanding gully erosion on unstable slopes is important for the management of slopes as well as for management of river systems, as large quantities of sediment are supplied by gully erosion directly into river systems causing off-site damage.

The development of gullies on unstable slopes is not well understood. In this study gully development on slopes affected by mass movements was analysed in 14 headwater catchments of the Mangaoporo catchment, North Island, New Zealand. Bedrock consists of Cretaceous-aged, highly crushed and sheared mudstones and sandstones. Deforestation by European settlers at the beginning of the 20th century for pastoral farming was followed by reforestation for wood production from the 1980s. Sequential aerial photographs from 1939 to 2005 were interpreted to map mass movements and the development of gullies. Digital elevation models were extracted from aerial photography using ERDAS to assess the applicability of the commonly applied topographic threshold approach for gully incision.

Flows of varying depth occurred in all catchments underlain by mudstone, while the catchment consisting of alternations of mudstone and sandstone were affected by deep seated sliding and secondary shallow sliding. Deep (few meters to 15m) gullies were located at the toe of mass movement bodies. Such gullies developed oversteepened sidewalls, which in turn initiate extensive mass movements at the gully walls. Shallow (about 1 -2m deep), hundreds meter long gully arms extended upslope. Topographical changes by active flows and slides caused stream capture or gully destruction. Cracks and scraps functioned as incision pathways.

The topographic threshold approach is not appropriate for unstable slopes, as the mass movement topography exhibits irregular drainage pattern and gully incision depends on the morphology of mass movements. New approaches need to be developed for gully incision on unstable slopes to understand the spatial and temporal variability of incision dynamics on unstable slopes.

Quantifying the seismic response of slopes: observed and modelled amplification from the Port Hills of Christchurch

MASSEY, Chris[1*] ; KAISER, Anna[1] ; HOLDEN, Caroline[1]

[1]GNS Science

ABSTRACT: Before the Christchurch 2010/11 earthquake sequence the influence of site effects on landslide triggering during earthquakes was reported in many studies, but evaluating these effects has been difficult through lack of high-resolution data, especially the lack of local ground motion instrumental observations. As a result of the Christchurch 2010/11 earthquake sequence we now have high temporal and spatial resolution data, including subsurface geotechnical and geophysical information that allows quantification of the amplification relationships between the near surface geology, topography and seismic inputs.

This paper presents preliminary results on site effects in the Port Hills of Christchurch caused by near surface material impedance contrasts and slope morphology. Results from small scale temporary arrays installed on several of the large rock slopes that failed repeatedly during the earthquakes suggest amplification factors of up to 300% of peak ground acceleration when compared to free field rock outcrop peak ground accelerations. These are corroborated not only by two dimensional seismic site response analyses using synthetic earthquake motions as inputs to the models but also by comparing recorded ground motions from borehole and surface seismometers.

Based on these findings it is apparent that particular slope shapes and material contrasts can significantly amplify peak ground accelerations during earthquakes. At present in New Zealand such amplification effects are not routinely taken into account when designing earthworks or structures on slopes or in landslide risk assessments.

Distribution loess landslides triggered by the 1920 Haiyuan earthquake and their formation mechanisms

HUANG, Runqiu[1*] ; PEI, Xiangjun[1] ; HAN, Xiangsen[1] ; ZHANG, Xiaochao[1]

[1]Chengdu University of Technology

The 1920 Haiyuan Earthquake (M=8.5) is one of the strongest earthquakes in Chinese modern history, and directly resulted in more than 200,000 people dead. The Earthquake induced a large number of landslides. Among them, we investigated 544 landslides in the meizoseismal area, and found that the distributions of the landslides are mainly concentrated in the southeastern part of the seismogenic fault, but the relationship with the NW-trending seismogenic fault is not noticeable. Further investigation indicated that such distribution is mainly controlled by two types of factors. One is the nearly SN-trending secondary faults concealed under the loess cover. The other one is the thickness of the loess. The landslide is more intensive in those areas with thicker loess and the density of the landslides decreases with the decreasing in the loess thickness, while landslides occurring in the bedrocks are very rare.

Investigation shows that the sliding surface of a large number of loess landslides is extremely gentle with the apparent friction angle ranging between 8 -11 degrees. Liquefaction phenomenon was found on a large number of areas in loess tableland along both sides of the river in the meizoseismal area. This is likely one main reason for the occurrence of landslides with very gentle sliding surface angle. Laboratory testing of undisturbed loess of these regions indicated that the sand content ranges from 3% to 15%, silt content is about 65% - 85%, clay content between 10% - 20%, and thus this kind of soil belongs to silt. But the sand content showed uneven distribution and high sand content occurred in local area. Dynamic triaxial tests showed the saturated loess could suffer from liquefaction failure.

However, there existed a large number of low angle slip surface, large runout and high mobility loess landslides in the slope zone with low underground water level. Loess is characterized by large pores with high compressibility and low strength. Scanning electron microscopy revealed that cement of loess particles were dispersed particulate, distributed discontinuously attached to the particle surface or accumulated at the point of the contact in the skeleton, the adhesive strength is very low. The earthquake occurred in December of that year’s winter. Due to very low water content of loess, relatively dry shallow loess easily shattered and collapsed under strong shaking of extreme earthquake. Therefore this caused occurrence of the high-speed and long runout landslide.

Finally, we conclude that because of the special geological characteristics of loess, there are more than two types of landslide mechanism: one is the liquefaction occurring on the loess layer affected by the groundwater level; the other one is the collapse of loess structure under strong earthquake.

Geomorphological and Geological Features of The Collapsing Landslides Induced by The 2009 Padang Earthquake.

NAKANO, Maho[1*] ; CHIGIRA, Masahiro[2]

[1]CTI Engineering Co., Ltd., [2]Disaster Prevention Research Institute, Kyoto University

The Mw7.6 Padang earthquake in 2009 attacked the northwest of Sumatra, Indonesia, and triggered many landslides, which killed at least 130 people at one village. We made satellite image interpretations, field investigations, and laboratory tests to identify the geomorphological and geological features of these landslides. As a result, we found that the number of landslides was 159, materials that slid were pumice fall deposits, and their sliding surface was made within the base of the pumice layer where pumice grains were mixed with underlying lahar and heavily weathered. These landslides had the following characteristics: 1) they occurred in the areas with pumice beds with $>$3 m thickness, which was controlled by the distance from their source; 2) the pumice fall deposits had a slope-parallel layering, which had been cut at the foots of slopes; and 3) the mixed layer at the base of the pumice beds was heavily weathered to be clayey materials with abundant halloysite.

We made an isopach map of the pumice fall deposits, which is so-called Qhpt and believed to be from Maninjau Caldera. The isopach contours, however, showed that Qhpt is from Tandikat Volcano, and that landslides occurred in clusters in the areas with pumice beds thicker than 3.5 m.

Qhpt beds had slope-parallel bedding, but they were undercut by subsequent river incision. Interpretations of stereoscopic satellite images and field surveys showed that there are four terraces along the Magung River, and Qhpt covers widely distributed higher terraces (Lh) of lahar younger than 80 ka and middle terraces (Lm) but are cut by lower terraces (Ll1 and Ll2) as well as small nearby tributary gullies. This undercutting likely reduced the support of Qhpt beds from downslope.

The mixed layers, in which sliding surfaces were formed, were heavily weathered and very weak; weaker than the main Qhpt above and the lahar below. XRD analyses showed that pumice grains of the main part of Qhpt scarcely had halloysite but pumice grains and weathered lahar in the mixed layers were rich in halloysite. The formation of halloysite could be attributed to the interaction between the materials of the mixed layers and the water coming through Qhpt beds; water, which gets Si and other chemical components from the volcanic glass of pumice, may become stagnant in the mixed layers because they are much less permeable than the Qhpt beds above. This would be a preferable condition of halloysite formation.

Infinite slope stability analysis using geotechnical parameters, pumice bed thickness, and slope angles, which we obtained, suggested that landslides with sliding surfaces within the mixed layers could be triggered by the shaking of the 2009 Padang earthquake. The natural water contents of the materials of the mixed layers exceeded their liquid limits, which suggests that they would behave like a liquid after remolding.

The geological history, which is volcanic eruption, weathering, and undercutting by river incision as stated above, is typical in tropical volcanic areas. That means we can make a hazard map of such a catastrophic landslide induced by earthquakes on the basis of geological development.

The seismic signals from the model slope failure and erosion tests

FENG, Zheng-yi[1*] ; YU, Chia-cheng[1]

[1]National Chung Hsing University, Taiwan, ROC

High intensity rainfalls in mountainous areas often induce floods. The floods could erode riverbank slopes and cause them to landslide. This study selected Landao Creek of Huisun Experimental Forest (Nantou, Taiwan) as the in-situ test site for the model slope failure and erosion tests. We built a large size model soil slope and an artificial landslide dam in Landao Creek for the tests. The Nengau agricultural channel at the upstream of Landao Creek was setup to control the inflow to Landao Creek. Therefore, the artificial landslide dam were overtopped when the retention space were full by the inflow water. Consequently, the dam breached and caused the model soil slope to be eroded by the flooding water. The model soil slope failed partially due to the erosion and generated seismic signals during the slope materials sliding down. We installed of several accelerometers sensor on the model soil slope to collect seismic signals generated. We present two test results in this study. The seismic signals were analyzed using the Hilbert-Huang Transform for time-frequency spectrograms. We explored the characteristics of seismic signals due to the model soil slope sliding and the flooding. In addition, we can use the time-frequency spectrograms to identify the timings when the model slope slid repeatedly.

Characteristics of the slope failures in Izu-Oshima Island on Oct. 16, 2013, inferred from seismic waveform records

DOI, Issei[1*] ; KAMAI, Toshitaka[1] ; WANG, Gonghui[1] ; MORITA, Yuichi[2]

[1]DPRI, Kyoto Univ., [2]ERI, Univ. of Tokyo

On Oct. 16, 2013, large-scale slope failure took place due to extreme rainfall in Izu-Oshima Island in Japan. The precipitation reached over 90 mm per hour from 1:00 to 5:00 before and during the period when the failures took place. Through geological surveys by us and Natural Disaster Research Council, piping holes were observed on the collapsed slopes, which suggested that the ground water spouted due to high water pressure. It is important to grasp the detailed behaviors of water and sediment movement in order to reduce the slope disaster in the volcanic regions.

Signals of failures and their related sediment movements were recorded many times by several seismometers installed around by Oshima Volcano Observatory of ERI, Univ. of Tokyo. The seismic signals were observed almost at the same time at several stations. Four major signals were detected from 2:00-3:00, while at least a few tens were observed from 3:00-5:00. These signals had unclear initial phases and long (several minutes) durations. The amplitudes increased almost at the same time at the beginning among the stations, while the times when they attained the maximum values were earlier at the stations located in the upper side of the slope. These facts indicate that the vibrations were firstly generated in the upper side of the slope, then moving toward the downside.

Acknowledgments: We used meteorological data recorded by JMA.

Friction law of gouges from monotonic and cyclic shear tests - implications for rockslide triggered by earthquakes

DONG, Jia-jyun[1*] ; TETSUHIRO, Togo[2] ; LAI, Jun-rong[1] ; YANG, Che-ming[1] ; LEE, Chyi-tyi[1] ; SHIMAMOTO, Toshihiko[2]

[1]Graduate Institute of Applied Geology, National Central University, Taiwan, [2]State Key Laboratory of Earthquake Dynamics, Institute of geology, China Earthquake Administration

The differences of soil strength under static and dynamic loading have been well recognized. This study utilized rotary shear apparatus to elucidate the friction coefficient of gouge materials under monotonic and cyclic shearing conditions. A rigid block model incorporating the velocity/displacement dependent friction law from monotonic tests was adopted to simulate the dynamic shearing behavior. Basically, the friction coefficient under maximum shearing velocity was well depicted. However, the friction coefficient under zero velocity for dynamic shearing tests was overestimated. A frequency factor, which taking the healing effect into account, was successfully incorporated into the friction law to simulate the variation of the friction coefficient under dynamic loading condition. The modify friction law with consideration of the cyclic shearing frequency was used to evaluate the triggering of a dip slope rockslide during earthquake. It is illustrated that the cyclic shear induced from the earthquake is critical for the initiation of large scale rockslide. The influence of seismic loading on earthquake-triggered rockslide can thus be evaluated quantitatively.

Fast Shear Behaviour of Granular Material and Rapid Landsliding Phenomena

JIANG, Yao[1*] ; WANG, Gonghui[2] ; KAMAI, Toshitaka[2]

[1]Graudate School of Science, Kyoto University, [2]Disaster Prevention Research Institute, Kyoto University

Many rapid landsliding events are normally catastrophic in which granular masses flow with extremely low friction. In order to prevent and mitigate the disaster, it is essential to better understand their mechanisms of initiation, motion and deposition. Although a great deal of research and attention has been focused on the unusual physical features for rapid landsliding events, the dependence of frictional properties on particle characteristics and test conditions has not yet been clearly understood. In the present research, we performed a set of experimental studies to examine the grain-scale frictional properties. We used two kinds of glass beads to examine how particle size affected the strength and stability of granular materials by employing a large ring-shear, and sheared the samples by changing the shear rate from 0.1 to 100 mm/s under different normal stresses (50, 100, 200, 400 kPa). It was found that the influence of shear rate on the residual shear strength for glass beads was negligible, while the stress fluctuation was observed for different particle sizes. Three distinct spectral peaks were identified in the frequency spectra for the two glass beads by utilizing Discrete Fourier Transform (DFT) method. According to the frequency spectra, we found that the stress fluctuation of glass beads was closely related to the particle size. Then we analyzed the role of particle size in the fast shear behaviour of granular materials and their relationship to the rapid landsliding behavior of rock avalanche.

Changes in particle size distribution of clayey material at a catastrophic landslide base

TSOU, Ching-ying[1*] ; CHIGIRA, Masahiro[1] ; FENG, Zhengyi[2] ; HIGUCHI, Kohei[3]

[1]Disaster Prevention Research Institute, Kyoto University, Uji, Japan, [2]Department of Soil and Water Conservation, National Chung Hsing University, [3]Department of Civil Engineering, National Cheng Kung University

In August 2009, a catastrophic rockslide avalanche was initiated by a cumulative rainfall of 1676.5 mm by Typhoon Morakot in the southern mountainous region of Taiwan. The landslide occurred on slopes extending from head scarp to the opposite riverside with a fall height of 830 m and generated the runout distance of 3.2 km long. The mobility of the landslide was high, indicating by its low apparent friction angle of 14 degrees and velocity of 70 to 120 km hr^{-1} in 95 s. The landslide claimed more than 400 people dead and missing when the village of Shiaolin was destroyed directly in the path of the landslide. We found clayey material in many locations at the base of the landslide deposits. Two samples S1 and S2 and one sample D1 of clayey material were respectively collected from the base of the remaining debris in the lower part of source area and the base of the deposits in the depositional area. Their mineralogy and particle size distribution were analyzed using an X-ray diffractometer (Rigaku Gaigerflex RAD IIB) and a laser diffraction particle size analyzer (Shimadzu, SALD-3100), respectively. The X-ray analysis indicates that the samples are the same material, in terms of texture and mineralogy, consisting of illite, chlorite, quartz, feldspar, and calcite. Besides, particle size analysis shows that samples S1 and S2 of the source area had two particle size modes at 15 μm and 50 – 100 μm, and sample D1 of the depositional area had one mode at 15 μm. This difference between the samples may reflect pulverization during movement of the material from the source area to the depositional area. The overall particle size distribution is narrower in sample D1, and the mean grain size (D_{50}) decreased from 11.03 μm in sample S2 to around 8.96 μm in sample D1. Sample S1 has larger amounts of finer fractions than do samples S2 and D1, and its distribution curve has a flattened top in comparison with the other two samples, which could be attributed to intense shearing between bedrock and debris. The results suggest that the clayey material at the landslide base and the increasing fine-grained content of the clayey material during shearing are assumed to have a significant impact on its long, rapid movement.

Application of TCP-InSAR technique for the Deep-Seated landslides detection and monitoring at Cingjing village, Taiwan

LIU, Shouheng[1] ; LIN, Chingweei[1] ; CHEN, Roufei[2*] ; ZHANG, Lei[3]

[1]Department of Earth Sciences, National Cheng Kung University, Taiwan, [2]Department of Geology, Chinese Culture University, Taiwan, [3]Department of Land surveying and Geo-informatics, Hong-Kong polytechnic university, Hong-Kong

Taiwan located at an active mountain belt and subtropical climate environment, severe gigantic landslide that have caused considerable damages commonly occurred in mountainous areas. After the 2009 Hsiaolin landslide that caused 450 casualties, how to identify potential sites of Deep-Seated landslides, evaluate their activity and susceptibility become an important issue. In the past few years, our research team has processed many slope failures that have caused considerable damages by using airborne LiDAR Digital Elevation Model (DEM), and implemented related analyses for the goal of deep-seated landslide. Cingjing village located at Centre Taiwan is well known as one of the three high altitude agriculture area in mountainous regions. In this study, we using TCP-InSAR interfermotry from ALOS/PALSAR images to detect and monitoring the landslide activity and its susceptibility of deep-seated deformation over a large area. The method obtains more ground deformation information than other InSAR approaches, providing more comprehensive analytical results for the slope related hazard studies. Our TCP-InSAR result shows a significant subsidence pattern around the Cingjing area. Comparing the surface deformation data and the field investigation records, several imperceptible deep-seated landslide locations are found and the boundaries can be identified as well as the spatial distribution of instability to them. The deposition pattern also implies different landslide development types on the slopes. This case study shows the great potential of TCP-InSAR evaluating the slope activities and deformation in the vegetated mountain area. Combined with topography signatures from high resolution digital elevation model data, it will be an effective way to determine the stability of slopes and potential hazard locations over a large area.

Preceding topographic features of catastrophic landslides in an accretion complex in the Kii Mountains

CHIGIRA, Masahiro[1*] ; MATSUSHI, Yuki[1] ; TSOU, Ching-ying[1] ; HIRAISHI, Narumi[2]

[1]Disaster Prevention Research Institute, Kyoto University, [2]previously Fukada Geological Institute

Slope movements is one of the major processes of denudation as well as erosion and transportation by rivers or glaciers, and many slope movements themselves are induced by river or glacier erosion. We investigated the linkage of river erosion, deep-seated gravitational slope deformation, and catastrophic landslides in the Kii Mountains Japan, where occurred tens of catastrophic large landslides during 1889 Totsukawa typhoon and 2011 typhoon Talas. The consequent fatalities were 168 and 56, respectively. The Kii Mountains is underlain by the Cretaceous to Neogene Shimanto accretional complex in large areas and has paleosurface remnants in higher elevations. The paleosurfaces have been newly incised by rivers, of which the Kumano River catchment occupies the central part of the Kii Mountains. The new incision of the Kumano River proceeded with the upstream propagation of knickpoints, which developed well-defined convex slope breaks on interfluve slopes. High-resolution DEMs clearly delineated deep-seated gravitational slope deformations, which are characterized by scarps, linear depressions, and bulges, aligned along the convex slope breaks, suggesting that they were induced by gravitational instability induced by the erosion undercutting. The catastrophic landslides during the 1889 Totsukawa typhoon and 2011 typhoon Talas occurred had been preceded by deep-seated gravitational slope deformation on newly incised inner valley slopes. Most of the landslides had sliding surfaces along undulating minor faults, probably thrusts, which might have made rock bridges when shearing along preferably oriented parts of the faults occurred. Catastrophic slop failure may occur when those rock bridges are finally fractured.

Recognition of large scaled deep-seated landslides using high resolution topography and case studies in Taiwan

HO, Dia jie[1*] ; LIN, Ching-weei[2]

[1](1)Disaster Prevention Research Center National Cheng Kung University, [2](2)Department of Earth Sciences National Cheng Kung University Tainan Taiwan

High resolution topography and topographic characteristics of large scale deep-seated landslides (landslide area >10 ha) are used to interpret large scale deep-seated landslides in an area of 4980.8 km2 and a total number of 1607 potential large scale deep-seated landslides are recognized. The results show that main distribution of potential large scale deep-seated landslides in Kao-Ping River watershed is near structural lineaments and both sides of the river.

Two cases discussed in the study are on the right bank of Baolai River in Baolai, Kaohsiung City and on the left bank of Luliao River in Yanping Township, Taitung County. Typhoon Trami (08/20˜08/22), Typhoon Kong-Rey (08/27˜08/29) and Typhoon Usagi (09/19˜09/22) are main typhoon events of 2013.

Potential landslide area, average slope angle and main lithology of case I is 96.6 ha, 31.1? and argillite. GPS data show a maximum horizontal displacement of 27.6 cm to southwest and a maximum subsidence of 20.5 cm after Typhoon Trami and Typhoon Komg-Rey. Surface extensometer data show the extension amount of 8 cm and 5 cm after three typhoon events. Potential landslide area, average slope angle and main lithology of case II is 6.4 ha, 32.5? and slate. A landslide with an area of 2 ha happened in the range of case II after Typhoon Usagi. These two cases indicate that rainfall and riverbank erosion are important factors on triggering large scale landslides.

The Assessment of Landslide Displacements Using Digital Photogrammetry and Numerical Analysis

CHANG, Kuang-tsung[1] ; LIN, Chun-te[1*] ; SU, Miau-bin[2] ; CHENG, Min-chieh[1]

[1]Department of Soil and Water Conservation, National Chung Hsing University, Taichung 402, Taiwan., [2]Department of Civil Engineering , National Chung Hsing University, Taichung 402, Taiwan

Instead of comparing remote sensing images between before and after a landslide event, this study compares aerial photographs over the years with the velocities of surface movements of landslide to evaluate the feasibility of aerial photographs as a monitoring tool. Before the total collapse of the slope of Freeway No.3, there were signs showing sliding of the slope, but no equipment was set up for monitoring. We use GIS to discriminate aerial photographs of different years to evaluate the displacements of specific objects or marks. From 2002 to 2004, the average displacement was 49.5cm, and the average displacement rate was 23.7cm/yr; from 2004 to 2007, the average displacement was 22.5cm, and the average displacement rate was 7.3cm/yr.

According to time-dependent creep behavior, the primary creep might have occurred from the beginning of the excavation in 1998 to 2004. And the secondary creep was from 2004 to 2007, so the velocity was comparatively lower than the previous stage. As for the tertiary creep, the displacement rate might rise since 2007 till the total collapse in 2010. The software Plaxis 2D based on the finite element method will be used to analyze the displacement process of the slope. The numerical model is set up according to the digital terrain model (DTM) of the slope. The numerical results will be calibrated with the results of the digital photogrammetry. We expect to obtain the creep behavior of the slope such as the slope strength reduction with time and the changes of surface displacement rate with time.

Deformation Analysis of the Pliocene-Pleistocene Sedimentary Rocks Mountain using Lidar Data

ASAHINA, Toshihiro[1*]

[1]PASCO CORPORATION

1.Introduction

Be a topic for the deformation of the Shimanto Supergroup in the Oigawa River basin and in the Kii Peninsula in many cases. How deformation of sedimentary rocks of the Pliocene to Pleistocene age strata earlier age and lower strength than the Shimanto Supergroup is in progress, I report on the basis of the analysis result of airborne Lidar data. The study area is the mountain in Tsunan of Niigata Prefecture around located on the border between Nagano and Niigata Prefecture. Geologically, the study area is located in the south side of the Matsunoyama dome and the Uonuma formation of Pliocene to Pleistocene age is widely distributed.

2.Mountain block geology and geomorphology

The northwestern part of Tsunan is a steep mountain of 1100m altitude from 200m, where the Uonuma formation, being of sand, silt, alternating beds of silt and sand, massive silt and volcanic rocks, is distributed. The investigation mountain has a monoclinic structure facing the Shinanogawa River on geological structure, which the Uonuma formation dips 40 degrees from 15 degrees SE generally and shows a monotonic spread to the whole.

In this area, a number of landslides have occurred, but at the time of the earthquake in northern Nagano Prefecture (March 12 2011, M6.7, depth: 8km, epicenter: Sakae village in Nagano Prefecture), the large plane slip presumed to be caused by this earthquake has occurred.

3.Lidar data

An airborne Lidar survey was conducted on May 14, 2013 for the morphological analysis of the northwest mountain of Tunan. Lidar measurement was carried out in the range of about 30km2 by ALS60 system. The Lidar point data were interpolated using a natural neighbor method on a grid with 1.0m spacing.

In order to understand the characteristics of the mountain deformation, I analyzed the mountain terrain in the following procedure.

1)Analysis 1

a.Classification of slope gradient (a grid with 5.0m spacing),b.Extraction of the cells of 40 degrees from 15 degrees slope gradient,c.Analysis of surface structure,d.Extraction of bedding surface slopes that is likely to cause a slip

2)Analysis 2

a.Image analysis,b.Extraction of linear deformation terrain , such as a lineation or an edge,c.Extraction of deformation terrain surface, such as a depression zone,d.Integrated analysis of analysis 1 and 2

4.Discussion

The GIS analysis of the cells obtained by the process of Lidar data and GIS processing has revealed that the slopes which are considered to bedding plane are found very widely in the mountain. Furthermore, based on the morphological features obtained, the two mountain blocks with a trace of a slip plane as the bedding planes were extracted. These mountain slopes have a characteristic of both showing a bedding plane sliding surface morphology on the terrain surface and the irregular linear trough. The largest linear trough is running diagonally across the hillside slope, and its extension reaches 600m from 550m. The thickness of the terrain block forming a linear trough is about 10m from 6m maximum. These morphological features suggest that the bedding surface played a major role in events that may have caused the extensive deformation and collapse of the edifice. The above is a morphological characteristic that is not found in such the Shimanto Supergroup.

These are important key points in extracting mountain deformation due to the bedding slip.

5.Conclusions

By the analysis of Lidar data, it has been confirmed the distribution of distinctive slopes to suggest that the edifice extensive deformation has occurred in the past in this area.

Interaction between river bed condition and debris flow in Ichino-sawa subwatershed of Ohya-kuzure landslide, Japan

TSUNETAKA, Haruka[1*] ; HOTTA, Norifumi[1] ; IMAIZUMI, Fumitoshi[2] ; HAYAKAWA, Yuichi S.[3]

[1]Life and Environmental Sciences, University of Tsukuba, [2]Graduate School of Agriculture, Shizuoka University, [3]Center for Spatial Information Science, The University of Tokyo

In recent years, there has been significant concern about large-scale sediment movements, such as deep-seated landslides, that are expected to occur more intensively due to changes in rainfall patterns. These landslides not only induce immediate sediment disasters downstream but also produce a large amount of unstable sediment that is transported gradually following the landslide. Most of the unstable sediment residing in a deep-seated landslide area is first discharged as debris-flow forms. Thus, after the occurrence of landslides, debris flows have a long-term affect on the watershed regime through their impact power, riverbed aggradation, and the production of turbid water, among other effects.

To facilitate better prediction of debris flows from landslide areas, this study investigated the interactions among topographic conditions, bed-material conditions, and debris flow events in a headwater catchment where a deep-seated landslide had occurred.

The study site was the Ichino-sawa subwatershed in the Ohya-kuzure basin, Shizuoka Prefecture, Japan. The basin experienced a deep-seated landslide about 300 years ago and is currently actively yielding sediment with a clear annual cycle. During the winter season, sediment moves from the hillslope to the channel bed because of freeze?thaw activity and weathering. In the summer season, the deposited sediment is discharged incrementally by debris flows related to storm events.

Topographical surveying and grain-size analysis were carried out several times between November 2011 and November 2013. Point cloud data were acquired during the topographical surveying, using a ground-based laser scanner, and used to create a high-resolution digital elevation model. Grain-size analysis was conducted in the upper, middle, and lower parts of the study site. A line-grid method was employed for the in situ analysis, and the fine particle fraction was determined by sieving the sampled materials. Debris flow occurrences were also being monitored in the same period by a sensor-triggered video camera. Rainfall was observed during the summer season for comparison with debris flow occurrence and magnitude.

Several debris flows with different magnitudes were observed during the study period. Although rainfall events in the early spring season altered bed inclination, the thickness of deposited sediment, and the grain-size distribution of the bed material, more significant changes were detected after the debris flows. While the initial grain-size distribution in early spring was roughly identical over the study site, the subsequent grain-size distribution changed differently, according to location. The source, transport, and deposition areas of the debris flows were different among different rainfall events, resulting in different transitions in geomorphic conditions at different locations. The lower part of the study site changed from a source area to a deposition area through the summer season.

A comparison of the topographic conditions, bed-material conditions, and debris flow events indicated that, in addition to the conditions of the triggering rainfall, topographic and bed-material conditions affected debris flow occurrence and magnitude. These interactions could be observed in the deep-seated landslide area, where a substantial and continuous supply of sediment prevents stabilization of the channel bed through exposure of bedrock or by armoring of bed materials.

Thus, to predict the long-term impact of large landslides, it is necessary to assess the subsequent debris-flow discharge considering the sediment dynamics and changes in topographic and bed-material conditions in the landslide area.

Deep seated landslides along the geological structure in Chishan River Watershed,southern Taiwan

LIAO, Chi-yueh[1*] ; LIN, Ching-weei[2]

[1]) Disaster Prevention Research Center National Cheng Kung University, [2]Department of Earth Sciences National Cheng Kung University Tainan Taiwan

Landslide is the common nature hazard in Taiwan. The Typhoon Morakot in 2009 brought huge precipitation and induced severe hazards in south-central and eastern Taiwan. Except the landslides, debris flow and flooding hazards induced by Typhoon Morakot, the large scaled deep seated landslides deserve more attention because they may cause the destructive disaster.

The Chishan River watershed which covered 750 km2 is selected as study area. The study area is mainly compose of meta-morphic and sedimentary rocks. Within the study area, 313 sites greater than 10 ha with sliding topographic features of deep seated landslide such as crown main escarpment, down slope scarp ,and lateral cracks are recognized from LiDAR derived 1 m resolution DEM, and we noticed the distribution of these sites is close to the structure in our study area. In order to know the influence of structure in the development of deep seated landslides, landslide density are calculated. The landslide density decreases with increasing distance and there are 79% of. deep seated landslides developed along the structure with a 1km buffer zone. The Result indicates that deformation zone associated structure is crucial in the development of deep seated landslides in the study area.

Natural-technological disasters of recent years in Japan and Russia: social and economic consequences

PETROVA, Elena[1*]

[1]Lomonosov Moscow State University

During the last decade, natural hazards impacts on people, the environment, urban and industrial areas, infrastructure and other technological systems were increasing, causing large social, environmental and economic damages in many countries. The number and severity of natural-technological accidents and disasters were also increasing all over the world, because of these impacts. The term ”natural-technological” applies to an accident (disaster) in the technosphere (including industrial plants, power stations, transport, infrastructure facilities, communication lines, etc.) triggered by any natural process or phenomenon. Their growth is accounted for: 1) by observed increasing in frequency and intensity of various natural hazardous events; 2) by much more complicated structure and complexity of modern technological systems and facilities exposed to natural hazards, and 3) by increasing advancement of economic activities and population into the regions at natural risk. The most severe consequences for people and the environment have the so-called Natech-accidents, which are accompanying by release of dangerous substances (like chemicals or oil), and accidents at nuclear power stations.

One of the most large-scaled natural-technological disasters having enormous social, environmental and economic consequences occurred on March 11, 2011 in Japan due to a massive 9.0-magnitude earthquake off the northeast coast of Honshu Island, which triggered a more than 30-meter tsunami. The disaster not only caused a large direct and indirect damage to the people (about 20 thousand fatalities) and economy of the country (more than $500 billion), but also influenced on regional, national and international development reaching a truly global scale. It clearly demonstrated high vulnerability of a human society and modern technosphere to natural disasters; even in a country like Japan that is highly developed and well-prepared to natural risks. A distinctive feature of events, such as of the 2011 Tohoku earthquake, is their multihazard and synergistic nature, as a disaster spawns a secondary disaster that increases the impact on people and technosphere, resulting in simultaneous occurrences of numerous technospherical accidents. The secondary effects of natural-technological accidents can be even much more serious, such as at ”Fukushima-1” nuclear power plant. These impacts are the more severe the higher are the population density and concentration of industrial facilities and infrastructure (especially hazardous and vulnerable objects) in disaster-affected areas. In addition, all rapid reaction forces and resources tend to be primarily fighting natural disaster; it limits the capability to eliminate secondary technological impacts, especially in those situations when transport facilities and required infrastructure are destroyed, and economic communications are broken.

The lessons of the Tohoku disaster should be taken into consideration while placing, constructing and operating nuclear power plants and other high-risk facilities. It is necessary to consider carefully possible intensity and frequency of all potential impacts, including natural hazards.

In Russia, natural-technological disasters with catastrophic consequences occur not so often. However, their possibility should be taken into account, especially in the economic development of areas at high natural risk, which is, for example, the Far Eastern region exposed to earthquakes, tsunamis, volcanic eruptions, floods, strong winds, storms, heavy rain- and snowfalls and other natural hazards. The most severe damages caused the Sakhalin earthquake in 1995, which was the most destructive in the Russian history. Severe social and economic consequences cause floods, for example, the flood in the autumn 2013. Natural-technological risk to the regions of Russia was evaluated using a database that was created by the author.

The Egyptian Tempest Stele: an Example of Ancient Natural Disaster

PETROVA, Anastasia[1*]

[1]Institute of Oriental Studies, Russian Academy of Sciences

Some Ancient Egyptian texts tell us about violent storms and rains. One of the most impressive ancient accounts of natural disasters is the so-called Tempest stele (1550 BC), which describes a very destructive storm happened under Ahmose I, the king of Egypt's 18 dynasty. The upper portion of the stele describes the catastrophe. Many essential details are given, such as the specific noise, overall darkness etc. Numerous houses were washed into the river; temples, tombs and pyramids were badly damaged. The main features of the storm can be highlighted: torrential rain; darkness; and loud noise, probably caused by a thunder or a wind, or both. It evidently occasioned large-scale flooding, property damage, and loss of life. After describing the events, the stele gives account of the restoration works made by the king to repair the damages made by this great disaster. There are Egyptologists who believe the stele to be propaganda put out by the pharaoh, the "tempest" being the depredations of officials of the embattled seventeenth dynasty of Egypt drawing upon the financial resources of the temples during the escalating conflict with the Hyksos. To my opinion, we don't have sufficient grounds to deny that the storm took place in reality. Nevertheless, the Tempest Stele actually is a political propaganda, because the main purpose of the erection of the stele was to draw attention to the role of the king in coping with the disaster. Traditionally, the king was responsible for maintaining maat (a cosmic order as opposed to chaos), and this responsibility included protection from natural disasters. The main point of the specific political context of the Ahmose I's times was the struggle of what would become the 18th Dynasty to establish its rule in opposition to the Hyksos. This effort required success on two levels: the human and the divine, which meant what would be classified as the natural world today. To simply liberate the land from Hyksos rule was a necessary but not sufficient step to legitimate one's rule. The king also needed to demonstrate divine blessing meaning that the cosmic order of the natural world had been restored as well as the political world had been. The storm commemorated by the Tempest stele is not the only example of heavy storms in Egypt. It seems that hazards of that kind were more common than we now believe. What makes the Ahmose stele unique is the description of the details of such a severe catastrophe, which go beyond what is usually experienced by a regular storm and therefore might be the oldest description of a natural hazard. The catastrophe described in the Ahmose I's Tempest Stele can be considered one of the most ancient examples of natural disasters, which caused a huge impact on the society. This is also a significant example of a political propaganda, reflecting the situation when government uses a catastrophe and its consequences to its own benefit.

Relationship between social and natural disasters

VIKULINA, Marina[1*] ; VIKULIN, Alexander[2] ; SEMENETS, Nikolai[3]

[1]Research scintist, Faculty of Geography, Lomonosov Moscow State University, Russia, [2]Senior Research Fellow, Institute of Volcanology and Seismology, Russia, [3]Acting general director, Research and Production Company " EKOS ", Moscow, Russia

The problem of reducing the damage caused by geodynamic and social disasters is a high priority and urgent task facing the humanity. The vivid examples of the earthquake in Japan in March 2011 that generated a new kind of threat ? the radiation pollution, and the events in the Arabic world that began in the same year, are dramatic evidences. By the middle of this century, the damage from such disastrous events is supposed to exceed the combined GDP of all countries of the world. The authors have developed the first database to include the largest geodynamic and social phenomena that occurred on Earth before 2005. We suggest the following phenomenological model based on the database (uniform with respect to the quantitative classification). All disasters are classified by size using a single logarithmic scale suggested by Rodkin and Shebalin in 1993. The base consists of 2000 disasters. The following phenomenological model is proposed: 1. The scale of disasters does not decrease with time. (Earthquakes in China in 1556 and 1976; the tsunami after the Sumatra earthquake in 2004, which can be compared in regards to the level of consequences only with the World Flood or a series of floods that occurred approximately 13000 years BP). 2. There were a minimal number of disasters in the 15th century; during which there were not a single disaster with J = I and II; from that time the number of such disasters gradually increases; in the 20th century there were 20. 3.The number of disasters is characterized by cycles, which are a few thousand years long; the available longterm measurements confirm this (for example, the overflow of the Nile observed over more than 5000 years or deformations of the Earth surface in the last few thousand years based on the geodynamic, seismotectonic, and paleoseismic data). 4. Natural and social disasters together are distributed uniformly in time, while only natural and only social disasters are distributed nonuniformly, i.e. disasters group.

5. The proportion of the social disasters has a tendency to increase in time, which confirms the viewpoint of V.I. Vernadskii about the constantly increasing role of humans and society in the noosphere. It was shown that natural and social disasters are interrelated. The Earth from the point of view of the disaster theory evolves according to the definite laws of the unique bio-socio-geodynamics. The investigation and understanding of the nature of this mechanism that "mixes the disasters" will allow us in the future to formulate a scientific hypothesis and/or a law on the basis of the phenomenological model that we suggest in this work and use it in the system of expert global process management. In the aspects of modern methods of studying of the global disasters, the authors suggest an approach to understanding global disasters based on modern data. The global disaster is an event damage from which cannot be liquidated by the joint resource. Irreversible process of death of a modern civilization can become a consequence of a global disaster.

The numerical model of natural hazards development in the environment stressed by opposing forces

KUDIN, Valery[1*]

[1]Lomonosov Moscow State University, Faculty of Geography

Natural hazards include earthquakes, tsunami, volcanic eruptions, floods, etc. The time of appearance of such significant events within hundreds of years can be considered as random. In most cases, the dangers' amplitudes are not amenable to prediction, i.e. their size is also random. From the mathematical point of view, the deposition of natural hazards is described by exponential dependence, which is connected with the involvement of the own "mass" of danger. In the presence of opposing forces in a first approximation, these processes are described by the Verhulst equation. It is a particular variant ($Q<0$, $A=L$) of the total autonomous differential equations of the 2nd order for the function x(t) on time t, i.e. $dx/dt=N+L*x+Q*x*x$, where N,L,Q are constants of equation with initial conditions t(n) and x(n).

The complete solution of this equation with arbitrary initial conditions has bulky appearance, although the logistic curve reflects it qualitatively quite well. However, these solutions allow us to reveal a violation of the principle of stability of numerical solutions of the logistic equation $x(n+1)=x(n)*(1+a*(1-x(n)))$, where $a=A*(t(n+1)-t(n))$, when the derivative dx/dt is replaced by the value for $(x(n+1)-x(n))/(t(n+1)-t(n))$.

It is shown that the instability of the processes with the opposing factors invoked by jumps of initial conditions on consecutive segments. For certain values of the parameters of the differential equation associated with capacity of the stressed environment, both volatile and deterministic modes of development of the variable x(t), normalized to unit, can be formed. An example of the Verhulst model with parameter A shows the dependence of the solutions x(t) at time intervals t(n+1)-t(n) and tabular values of x(n) and different a jumps of initial conditions. Negative inclinations of dependency associated with the tabular values x(n) are shown. Thus, there appears a situation, which leads to the release of the variable x from the corridor, normalized per unit, of sustainable values. For each a-case, the changes in the structure of x(t) in time look diverse and complex.

Therefore, the numerical logistic equation can be taken as a numerical model for the development of natural hazards in the geographical environment, characterized by capacity (option a) of a tension of opposing factors.

Studies on the understanding of haiku composed by earthquake disaster of East Japan on 11. 3. 2011

AOKI, Yoji[1*]

[1]Student of Open University of Japan, [2]Member of Kuramae Hiku Club, [3]Translator of Haiku International Association, [4]Professor of Aomori University

Studies on the understanding of haiku composed by earthquake disaster of East Japan on 11. 3. 2011

Aoki, Yoji (student of Open University of Japan), Chida Sosuke (Kurame Haiku Club), Jambor Kinuko (translator of Haiku International Association) and Hitoshi Fujita (Professor of Aomori University)

The damage of the Fukushima nuclear power plant and the East Japan big earthquake, the east part of Japan received big impact on the March 11, 2011. Many haiku poet composed haiku poems to the impact of the nuclear power plant accident and the earthquake disasters. Of these haiku what was published in the magazine, 234 haiku on the home page were to be used in the data. Copies of haiku were shown to 19 people of the general public and the poet, and we asked whether they can understand them, or they are impressed by them. 2354 haiku was chosen in total. 124 haiku was chosen average.

10.1 average people, understand of haiku and the distribution of the two-peaked mountain with 8 and 13 people was observed. Haiku understood by more than half of people were relatively large and 132 (56.4%), so it was found that haiku is yet the useful means of communication of mind for the Japanese today. As for the impressive haiku, it has the maximum value in 0 and at 1.4 person average, and decreases the distribution of people. 91 (38.8%) haiku were impressed by more than two people. To convey the emotion equally to many people, it showed difficulties. Taking the correlation of the number of people impressed with the number of people evaluated, it showed weak association of 0.515. The results suggested that haiku could be understood by a lot of people, but could give the impression variously.

According to the evaluation method in the Haiku Society, one point in haiku which was able to understand, to give two points to haiku that was impressed, we calculated the total score. Correlation of the number of people understood and the people impressed indicates 0.731, the stronger association was obtained. This is a result of the score added points. As it was not a very strong connection, so the individual differences affect the evaluation of haiku.

By the principal component analysis in the factors respondents, six-axis was obtained with eigen value greater than 1.0. This indicates that there are many different preferences in the evaluation by the respondents. The axis with maximum eigen value has the largest explanatory power, and showed the severity of the evaluation. We estimate 5-axis remaining as the evaluator's preferences for haiku.

The highest scored Haiku observed 2 haiku of 20 points.

(1) Mud certification of graduation, mud portrait digging under the debris by Tsunami (Sinogo SONE)

(2) Finding my mother in turning disaster's debris, light snow falling (Minu KASHIWABARA)

(3) Children crying bright hopes for their future a graduation ceremony (Nagahiko KAMIGORI)

(1) described the scenery that the photographs of deceased persons and the certification of diploma by deceased became muddy by the tsunami, people are digging them after the disaster in the damaged areas.

(2) described the scenery that light snow was falling, while people are removing the disaster debris of earthquake to find their mother of missing, at the neighborhood home.

(3) was praying for the pupil who were singing the graduation song with full of tears to be lighten

We thought that both of them were touched deeply by sadness.

Hazard Mapping of Structurally Controlled Landslides in Leyte, Philippines Using High Resolution Digital Elevation Model

MONTALBO, Kristina rochelle[1*] ; LUZON, Paul kenneth[1] ; LAGMAY, Alfredo mahar francisco[1]

[1]Nationwide Operational Assessment of Hazards, Department of Science and Technology, Philippines, [2]National Institute of Geological Sciences, University of the Philippines, Diliman, Quezon City, Ph

Structurally controlled landslides are one of the most destructive natural hazards that have occurred in the Philippines. The 2006 Guinsaugon Landslide, which was produced by the displacement of the Philippine fault, is a classic example of such hazard that took more than 1,000 lives and displaced more than 19,000 residents in the municipality of St. Bernard, Southern Leyte. Frequent monitoring and assessment should be done across the Philippine archipelago. The purpose of this study is to locate structurally controlled landslide prone areas with the aid of Coltop3D, Matterocking and Conefall using a high resolution digital elevation model (5 m resolution Interferometric Synthetic Aperture Radar images). The study area is set in the municipality of Ormoc, Leyte where the Philippine fault also cuts through and trending northwest. Discontinuity sets were identified using Coltop3D software that simulates a 3D model of the digital elevation model showing the dip and dip direction of different discontinuities. Lineation analysis and rose diagrams were made to verify the discontinuity sets in the area. Matterocking computes and estimates the locations where rock instabilities can occur according to the identified discontinuity sets that may allow sliding. Conefall was then used to compute and estimate the potential rockslide extent. Results show that the area has zones of potential rockslides with generated simulation of rockslide propagation extent. There is a high probability of landslides in Ormoc area where continuous monitoring of such danger zones should be done.

[1]Nationwide Operational Assessment of Hazards, Department of Science and Technology, [2]2National Institute of Geological Sciences, University of the Philippines, Diliman, Quezon City, Phi, [3]Istituto per la Dinamica dei Processi Ambientali, Consiglio Nazionale delle Ricerche, Italia, [4]Universita degli Studi di Napoli Federico II, Napoli, Italy

On Nov. 14, 2004, flashfloods from Subsob River struck Barangay(village) Paltic in Dingalan, Aurora Province around 4 a.m. when most residents were asleep - leaving hundreds homeless and 135 people dead. The series of floods caused by Violeta, Winnie, and Yoyong until December 2004 killed at least 300 people in Dingalan, Aurora alone. Mud buried 300 houses and residents were forced to stay on rooftops or seek higher ground. Because of these incidents, measures were devised to improve available geohazard maps to raise public awareness about landslides, debris flows and alluvial fans. This study developed a method to rapidly identify alluvial fans, thereby, hastening geohazard mapping in the region. Alluvial fans are fan shaped geologic formations deposited from tributaries from a mountainous terrain which flows out from the sudden break of a slope. Intense rainfall increases the discharge of sediments and water on these areas which could induce disastrous events such as flooding and debris flows. In this study, manual and automated methods in delineating fans in Aurora Province were compared. Manual delineation of alluvial fan boundaries were done through the contour lines generated from the 10-meter synthetic aperture radar (SAR)-derived digital elevation model (DEM). However, manual mapping of alluvial fan boundary which makes use of topographic interpretation of geomorphic features is subjective and time consuming. Biases were addressed by the second method by including factors such as 1) fan area of slope ranging from 1 to 8 degrees, 2) contributing stream networks from fan apex to fan toe , and 3) the fan potential lateral extent within the buffer zones based on the relief of the sediment source area in the GIS-based model. The outputs were compared with the manually delineated fans. Manual delineation identified 14 alluvial apex of 14 alluvial fans in 6 municipalities affecting 36 barangays . On the other hand, automated method identified 183 apex of 126 alluvial fans in 7 municipalities affecting 105 barangays. Although greater number of fans and wider fan area were identified using the automated method, manual delineation is still needed to check the results especially in volcanic regions. In addition, inactive alluvial fans are not accounted by the automated method.

Strong Explosive Eruptions of Kamchatkan Volcanoes in 2013

GIRINA, Olga[1*] ; MANEVICH, Alexander[1] ; MELNIKOV, Dmitry[1] ; NUZHDAEV, Anton[1] ; DEMYANCHUK, Yury[1] ; PETROVA, Elena[2]

[1]Institute of Volcanology and Seismology FEB RAS, KVERT, [2]Lomonosov Moscow State University, Geographical faculty

There are 30 active volcanoes in the Kamchatka, and three of them (Sheveluch, Klyuchevskoy, and Karymsky) continuously active. In 2013, two of the Kamchatkan volcanoes ? Sheveluch and Klyuchevskoy - had strong explosive eruptions.

Powerful explosive eruption of volcanoes is the most dangerous for aircraft because in a few hours or days in the atmosphere and the stratosphere can produce about several cubic kilometers of volcanic ash and aerosols. Ash plumes and the clouds, depending on the power of the eruption, the strength and wind speed, can travel thousands of kilometers from the volcano for several days, remaining hazardous to aircraft.

The eruptive activity of Sheveluch Volcano began since 1980 (growth of the lava dome) and is continuing at present. Strong explosive events of the volcano occurred in 2013: on June 26, on October 18, and on December 03: ash plumes rose up to 10 km a.s.l. and extended about 200-400 km, respectively, to the south-west, south-southeast, and north of the volcano. A form of pyroclastic flow deposits with run-out 12 km accompanied these explosive eruptions. Ashfalls occurred at Klyuchi Village (on June 26) and Ivashka Village (on December 03). Activity of the volcano was dangerous to international and local aviation.

Klyuchevskoy volcano had two eruptions in 2013: moderate Strombolian explosive eruption from October 14, 2012, till January 15, 2013; and strong Strombolian-Vulcanian explosive and effusive eruption from August 15, 2013, till December 20, 2013. There were four lava flows to effuse on the north-west, west and south-western volcanic flanks. Probably a flank eruption began at the pass between Klyuchevskoy volcano and Kamen volcano on October 06. Culmination of strong Vulcanian explosive activity of the volcano occurred on October 15-20: ash column rose up to 10-12 km a.s.l. and ash plumes extended to the different directions of the volcano according to cyclonic activity in the this area. Phreatic ash plumes on the fronts of lava flows rose up to 5 km a.s.l. Weak ash falls were noted at Klyuchi Village on October 09 and 13, and Mayskoe Village on October 16. Activity of the volcano was dangerous to international and local aviation.

Magnitude of the Solomon Tsunami of February 6, 2013

HATORI, Tokutaro[1*]

[1]nome

The great earthquake occurred on February 6, 2013 at the junction of Solomon and New Hebrides trenches (10.738S, 165.138E, 28.7km depth, M8.0, USGS). Moderate tsunami was widely observed in the Pacific zone (WC/ATWC, NOAA, JMA). The tsunami killed 10 persons and 590 houses destroyed at Nendo Is.(Santa Cruz Is.) located near the source region. The estimated source lies 250km length toward E-W direction. Judging from the attenuation of tsunami height with distance, tsunami magnitude is determined to be m=2 that the grade is the mean value for earthquake magnitude. For tsunami magnitude, semi-amplitudes of the following regions are relatively large: 20cm at Crescent City, California, 18cm at Maui, Hawaii, 17-19cm in Galapagos and Coquimbo, South America and 40cm at Hachijo Is., 19cm at Chichijima ,Japan. The pattern of amplitude distribution is similar to other Solomon-Vanuatu tsunamis.

Arrival times of reflected waves and the maximum phases of tsunami?the 1993 Hokkaido Nansei-oki Tsunami

ABE, Kuniaki[1*] ; OKADA, Masami[2] ; HAYASHI, Yutaka[3]

[1]none, [2]MRI, [3]MRI

Tsunami maximum phases are frequently attained by reflected waves. Arrivals of reflected waves were studied in relation with arrivals of maximum phases. Arrival times of reflected waves are calculated from combination of refraction diagrams of direct wave and arbitral reflected wave. The arrivals are recognized in coincidence between the prediction and the observation. Under this circumstance travel times of first and maximum waves were obtained for the 1993 Hokkaido Nansei-oki Tsunami and predicted travel times of reflected wave from Russia, Korea and double reflected waves from Honshu and Korea are plotted in figure 1. As the result arrivals of maximum phases are classified into three groups. First one, the direct wave from the source, is earlier arrivals before the reflected wave from Russia. Second one is a group found between arrival times from Russia and Korea. This is recognized as reflected wave from arbitral coast of Eurasia continent. Third group is one found at arrival times shorter than those of the double reflection. This group is interpreted from double reflections from coast near the source and Korea.

Quantitative comparison of the 2011 Tohoku earthquake and past tsunami heights

SATAKE, Kenji[1*] ; TSUJI, Yoshinobu[2] ; HARADA, Tomoya[3] ; ISHIBE, Takeo[1] ; NISHIYAMA, Akihito[1] ; KUSUMOTO, Satoshi[4]

[1]Earthquake Research Institute, the University of Tokyo, [2]ERI, the University of Tokyo, Now at Fukada Geological Institute, [3]CIDIR/ERI, the University of Tokyo, [4]ERI, the University of Tokyo, Now at Dia Consultants

The tsunami heights from the 2011 Tohoku earthquake were on the average 1.5 times the 1896 Meiji Sanriku tsunami, 3 times the 1933 Showa Sanriku tsunami, 4 times the 1960 Chilean tsunami, and 14 times the 2010 Chilean tsunami along the Sanriku coast. The Sanriku coast is a typical ria coast, a sawtooth-shaped irregular coastal shape, and the local variation of tsunami heights is very significant. We carefully selected the sites where the past measurement points are known, and comparisons were made at the same villages or small-scaled bays (roughly a km scale).

Along the Sanriku coast, the median value of 1896/2011 tsunami height ratio at 83 measurement points is 0.69, and a correlation coefficient is 0.34. The median 1933/2011 ratio at 94 points is 0.33 with a correlation coefficient of 0.47. The 2011 tsunami was higher along the southern Sanriku coast (Miyagi prefecture). In the central Sanriku coast (Iwate prefecture), the 2011 tsunami was 1.2 times the 1896 tsunami and 2 times the 1933 tsunami. The comparison was made at 98 points for the 1960 tsunami with a median ratio of 0.25, and at 12 points for the 2010 tsunami with a median ratio of 0.07. The correlation coefficients are lower, 0.17 and 0.14 for the 1960 and 2010 Chilean tsunamis, than the past Sanriku tsunamis. All the Sanriku tsunamis (1896, 1933 and 2011) had different earthquake source area and types, but the tsunami height distributions were similar, indicating that the tsunami heights are more sensitive to the local topography for the near-field tsunamis. The lower correlation with the Chilean tsunami may be due to the fact the dominant period of incoming tsunami was more than twice longer for the trans-Pacific tsunamis.

Comparisons with the two Chilean tsunamis were also made on the Ibaraki and Chiba coasts. The tsunami heights were compared at 24 points for the 1960 tsunami and 14 points for the 2010 tsunami. The median 1960/2011 ratio is 0.62, while the median 2010/2011 ratio is 0.28. The correlation coefficients with the 2011 tsunami heights are higher, 0.63 and 0.41 for the 1960 and 2010 Chilean tsunamis. The high correlation may be due to general decrease of tsunami heights toward south, and the fact that the tsunamis were locally high near peninsula such as Asahi city in Chiba prefecture.

We used the 2011 tsunami heights at 120 points measured and reported by Tsuji et al. (2011 BERI); the 1896 tsunami heights reported by Yamana, Iki and Matsuo, the 1933 heights by Matsuo, Kunitomi and ERI, the 1960 heights by Comm. Field Investigation and Japan Meteorological Survey, and the 2010 heights by Tsuji et al. and Imai et al. The full data and reference are given in Tsuji et al. (Pageoph in press).

Tsunami reflected from Chilean coast and observed in Japan - the 2011 off Tohoku Tsunami

OKADA, Masami[1*] ; ABE, Kuniaki[2] ; HAYASHI, Yutaka[1]

[1]MRI, JMA, [2]None

We identified reflected waves from Chilean coast at Kushimoto and Owase tide stations in Japan on the 2011 off Tohoku Tsunami. It is based on amplitude increases at predicted travel times. The travel times were calculated by using the tide gage records of the 2011 tsunami at Talcuano in Chile and those of the 1960 Chilean Tsunami observed at Kushimoto and Owase. For the latter we noticed reflected waves from Chilean coast and obtained the travel times between Chile and Japan. Then, two phases of large amplitude of the 2011 tsunami observed at Talcuano were selected, and travel times of 46.7, 47.9 hrs for Kushimoto and of 48.1, 49.3 hrs for Owase were estimated. Amplitude increases at the predicted times were recognized in both tide stations. Waveforms and predicted travel times are shown in Fig.1. The identification is supported by amplitude increases at almost same travel times for two different tide stations.

Disaster Warning System in Thailand through Enterprise Engineering Perspective

LEELAWAT, Natt[1*] ; SUPPASRI, Anawat[2] ; IMAMURA, Fumihiko[2]

[1]Tokyo Institute of Technology, [2]Tohoku University

Introduction

Identify, assess and monitor disaster risks and enhance early warning has been set as one of the five priority areas of action in the Hyogo Framework for Action 2005-2015. This study is a part of our research project on disaster warning process management analysis as well as Leelawat et al. (2013).

Enterprise Engineering & DEMO

Enterprise engineering is an interdisciplinary field focusing on investigating of each aspect of the enterprise, including a business process, information flow, and organizational structure (Dietz, 2006). While most of the current modeling tools (e.g., BPMN) cannot achieve the enterprise engineering principles, *Design and Engineering Methodology for Organizations (DEMO)* (Dietz, 2006; Perinforma, 2012), an enterprise engineering and business process modeling language, has capability to demonstrate the validity of some principles (Dietz & Hoogervorst, 2012). Thus, DEMO has been selected in this study.

Data Collection

(Primary and Secondary) Data collection took place during Aug.-Dec. 2013. The face-to-face interviews with the acting Director of National Disaster Warning Center (NDWC) of Thailand and the Director of the Seismological Bureau, Thai Meteorological Department (TMD) were conducted in Sep. 2013 through the semi-structured style interviews, together with the observation.

Findings and Discussion

There are 2 main actual players in the Thai warning system as mentioned. The case has been analyzed by DEMO. According to Perinforma (2012), the *Organization Construction Diagram (OCD)* and *Transaction Product Table (TPT)* have been created to show the compact form of the system. DEMO shows its capability to express the sketch of the organization, together with some interesting issues.

First, we can understand the authority and responsibility from OCD and TPT. It can be seen that announcement decision is authorized to only NDWC (i.e., one actual warning announcer). It is a good practice because it does not create the confusion that may occur from many announcing sources.

Second, through the TPT, we can see the chain of warning message announcement, from monitoring information to seismological information. It means that the duty of declaring seismological disaster and declaring warning is separated to different actor roles which in turn increase the performance because each executor can focus on their responsibility works and increase the accuracy since the seismological information has been confirmed by the initiator.

Third, by comparing with Japanese case, it can be seen that the warning system in Japan is mainly executed by one organization (i.e., JMA) while Thai case contains 2 main organizations plus other 4 monitoring organizations regarding to the aspect of information. One reason is probably from the different government hierarchical structures which separated the expertise into each departments (in different ministries) in Thai case.

Acknowledgements

The study was supported by the ACEEES and the Risk Solutions 2013 project of Tokyo Tech. The authors would like to acknowledge Capt. Song Ekmahachai (acting Director of NDWC), Mr. Burin Wechbunthing (Director of Seismological Bureau), Prof. Junichi Iijima (Tokyo Tech), and Dr. Jing Tang for their advice and support.

A methodology for near-field tsunami inundation forecasting and its application to the 2011 Tohoku tsunami

GUSMAN, Aditya[1*] ; TANIOKA, Yuichiro[1]

[1]Institute of Seismology and Volcanology, Hokkaido University

We develop a new methodology for near-field tsunami inundation forecasting (NearTIF). This method required site-specific pre-computed tsunami inundation and pre-computed tsunami waveform database. Information about tsunami source of an event is required as an input for the method to work. By this method, we will not attempt to obtain a reliable earthquake source model for an event. Instead, any available information about tsunami source such as earthquake moment magnitude, earthquake fault model, or tsunami source model will be used. After information about the tsunami source is obtained, tsunami waveforms at near-shore points can be simulated in real-time during an event. Simulating tsunami waveforms by solving the linear shallow water equation on low-resolution bathymetric data does not take long time, therefore it is suitable to be used in real-time. By using root mean square analysis, a scenario that gives the most similar tsunami waveforms in the database is selected as the best-fit site-specific scenario. Then the corresponding pre-computed tsunami inundation of the best scenario is selected as the tsunami inundation forecast.

The pre-computed tsunami database is built from thrust earthquake scenarios of simple rectangular fault models with moment magnitude ranged from Mw 8.0 to 9.0. We arrange a total of 56 reference points along the subduction zone off the east coast of Honshu, Japan as the center top of the fault planes. The points are grouped into four depth categories of shallowest, upper intermediate, lower intermediate, and deepest plate interface. The earthquake scenarios for each depth category have moment magnitude range of Mw 8.0 to 9.0, Mw 8.0 to 8.9, Mw 8.0 to 8.8, and Mw 8.0 to 8.7, respectively, from the shallowest to the deepest plate interface, making a total of 532 scenarios.

Sites are chosen based on their coastal geomorphology (i.e. bay, lagoon, isthmus) or location of coastal community. Virtual observation points at which tsunami waveforms is computed are placed strategically near-shore, around a bay at depth of deeper than 30 or 50 m depending on the bathymetry.

We test the algorithm to hindcast tsunami inundation along the Sanriku coast that was generated by the 2011 Tohoku earthquake. To produce accurate tsunami inundation map, accurate information about tsunami source is required. We used source models for the 2011 Tohoku earthquake previously estimated from GPS, W phase, or offshore tsunami waveform data. These source models could be available before tsunami hits the shore. The forecasting algorithm is capable of providing a tsunami inundation map that is similar to that obtained by numerical forward modeling, but with remarkably faster speed. Using a regular laptop computer, the time required to forecast tsunami inundation in coastal sites from the Sendai Plain to Miyako City is approximately 3 min after information about the tsunami source is obtained. We found that the tsunami inundation forecasts from the GPS (5 min), W phase (5 min and 10 min) fault models, and tsunami source model (35 min) are reliable for tsunami early warning purposes and considerably similar to the observation. This method can be used to develop a future tsunami forecasting systems with a capability of providing tsunami inundation forecasts in the near field locations.

An offshore type of GPS tsunami meter using QZSS and ETS-VIII satellites

TERADA, Yukihiro[1*] ; HASHIMOTO, Gousei[2] ; MOTOHASHI, Osamu[2] ; YAMAMOTO, Shinichi[3] ; WADA, Akira[4] ; KATO, Teruyuki[5]

[1]Kochi National College of Technology, [2]Japan Aerospace Exploration Agency, [3]National Institute of Information and Communications Technology, [4]Hitachi Zosen Corporation, [5]The University of Tokyo

A new tsunami observation system has been developed, which employs the GPS technology to detect a tsunami before it reaches the coast. The GPS antenna attached on the top of a buoy floating at the sea surface is one of the important apparatus in this system. The estimated positions of the antenna includes not only tsunami but also all kinds of sea surface changes including wind waves, tides etc. The low pass and high pass filters are used for detection of tsunami. After a series of preliminary experimental studies, the operation-oriented experiments were conducted at two offshore sites. These results showed that a GPS buoy was useful to early detection of tsunami. And the Ministry of Land, Infrastructure, Transport and Tourism has established the GPS buoy system for monitoring sea waves with fifteen GPS buoys along the Pacific coast and Japan sea coast since the year of 2008. These system succeeded to detect the tsunami of the 2011 off the Pacific coast of Tohoku Earthquake.

Currently, the GPS buoy system uses RTK (Real Time Kinematic) method which requires land base for precise positioning of the buoy. This limits the distance of the buoy from the coast at most 20km. There are two problems to be conquered, one is the precise GPS positioning and the other is the data transmission methods. The algorithm of PVD (Point precise Variance Detection) method and PPP-AR (Precise Point Positioning method with Ambiguity Resolution) method are successfully under examination in the Muroto GPS buoy. Also, the satellite communication system using QZSS (Quasi-Zenith Satellite System) and ETS-VIII (Engineering Test Satellite VIII) were introduced for this GPS tsunami observation system experimentally.

Long-term deployment of Wave Glider for a real-time tsunami monitoring system using the Vector Tsunameter

HAMANO, Yozo[1*] ; SUGIOKA, Hiroko[1] ; TOH, Hiroaki[2]

[1]JAMSTEC, [2]Kyoto University

We have been developing a real-time tsunami monitoring system by using the Vector Tsunameter(VTM), in which we use an unmanned surface vehicle called Wave Glider, manufactured by Liquid Robotics Inc. The WG, equipped with both an acoustic and a satellite communication modems, can be used to transmit data messages from the VTM to shore. In order to investigate the feasibility for this type of station-keeping operation, we made a long-term deployment of the WG at sea area. We deployed the WG on September 22, 2013 at 38 14.99N, 143 35.13E, water depth = 3420.1 m. We set 6 waypoints along a circle (200m in diameter) centered at the above position, so that the WG trace the watch circle. The experiment had been continued until the WG was caught by a drift net and delivered to the Kesennuma port on December 6,2013.

The 75-days deployment of WG gives valuable information on the performance of the WG. As for the feasibility of WG for the station-keeping operation, two problems become apparent. During the experiment, the WG sporadically escaped from the watch circle and drifted away following the ambient water current, and it returned to the circle after several days of trip. Four excursions occurred during the first 50 days, and the total of the excursion period is 20 days. For monitoring slow activities such as crustal deformation, this performance is acceptable. However, some improvements are required for monitoring the short period signals such as tsunami. The other problem is the reduction of speed over water occurred after about 2 months operation. In the middle of November, the speed abruptly decreased to less than 0.5 knots and remains low until the end of the experiment.

Based on the detailed analyses of the navigation data sets and inspection of the WG, we conclude that the twist of the umbilical cable, which connects the surface float to the sub-surface glider, triggered both the excursion and the speed reduction. The small size of the watch circle and the short distance between the waypoints (about 100 m) are main cause of the twist. The short distance causes large and frequent changes of glider heading. Since the float can not follow the abrupt changes of heading, differential rotation of the glider relative to the float arises and enhances the twist of the cable. This twist of the cable increases water drag to the WG, and the stress of the cable due to the twist inhibit the rotation of the WG. These effects reduce the movability of WG, and the speed reduction start the drift of WG following the ambient current motion. The twist of the cable mainly occurs while the WG follows the path along the watch circle. On the other hand, during the excursions, glider heading is fixed and rewinding of the cable was observed. This rewinding reduces the drag force to the WG and assist the WG in returning to its home circle.

Extreme reduction of the speed is observed after 2 months of deployments. Inspection of the WG right after the recovery indicates that the propulsion system of the sub-glider had been working well until the end of the experiment, whereas the float suffered by the biofouling of eboshi-gai (goose barnacle). The biofouling seems responsible for the speed reduction, but theoretical estimate suggests that the hydrodynamic drag due to the biofouling is not sufficient to explain the observed speed reduction. The twist of the cable and the biofouling both contribute to the speed reduction. These analyses suggest larger size of the watch circle may improve or solve the present two problems of the excursion and the speed reduction.

Enhancement of GEONET Real-time Analysis System for Covering over Japan

YAHAGI, Toshihiro[1*] ; MIYAGAWA, Kohei[1] ; KAWAMOTO, Satoshi[1] ; OSHIMA, Kennichi[1] ; YAMAGUCHI, Kazunori[1] ; MURAMATSU, Hiroki[1] ; OHTA, Yusaku[2] ; DEMACHI, Tomotsugu[2] ; MIURA, Satoshi[2] ; HINO, Ryota[2] ; SAIDA, Yuichi[3] ; DOUKE, Yuki[3]

[1]Geospatial Information Authority of Japan, [2]Graduate School of Science, Tohoku University, [3]Hitachi Zosen Corporation

Geospatial Information Authority of Japan (GSI) has been operating a continuous GNSS observation network system, known as GEONET (GNSS Earth Observation Network System), since 1994. Currently, GEONET consists of approximately 1,300 nationwide GNSS stations and its analysis center. Each station collects GNSS data with 1Hz sampling and those data are transmitted to the analysis center in real-time. GSI offers the observation data to the public in order to support various types of public surveys in Japan and precise positioning services using GNSS.

In the field of disaster prevention or mitigation, GEONET also plays very important roles by monitoring crustal deformation occurred by such as earthquakes or volcanic activities. In addition, after the 2011 off the Pacific coast of Tohoku Earthquake (Mw9.0), it is pointed out by a governmental committee that GEONET should be utilized for tsunami early warning by offering a first realistic estimation of moment magnitude (Mw) after large earthquakes. It is based on the fact that GNSS real-time positioning generally has big advantages in estimating moment magnitude (Mw) of the large earthquakes compared to short-period seismometers in terms of avoiding underestimation problem.

Since then GSI has been developing a new GEONET real-time analysis system, named REGARD (Real-time GEONET Analysis System for Rapid Deformation Monitoring), jointly with Tohoku University. It is designed for estimating permanent displacement field and Mw of giant earthquakes and notify the results in real-time. First, the GEONET data are processed by RTKLIB ver.2.4.1 (Takasu, 2011) for real-time GNSS positioning. We adopt both 'RAPiD' technique (Ohta et al., 2012) and the Early Earthquake Warning (EEW) information (Kamigaichi et al., 2009) for automated detection process of permanent displacements. Once the displacements are detected, corresponding fault source model is immediately estimated and the system sends the results to registered addresses by e-mail.

GSI launched its prototype system in April 2012 with 143 stations covering mainly Tohoku region and also has been evaluating its performances using archived data of some past earthquakes. We verified that the system successfully could estimate appropriate Mw values just after a couple of minutes in case of large events (e.g. Mw8.9 in the 2011 Tohoku earthquake), whereas it hardly detect proper values if the size of earthquake is less than Mw7.5. Based on the results and performances of the prototype system, we upgraded REGARD in 2013 for covering all over Japan by using most GEONET stations and enhancing its redundancy by carrying out two independent processing in parallel. This new system was launched in April 2014.

We present the evaluation results of the prototype system and introduce the upgraded REGARD including future plans focusing on exploiting to tsunami warning.

Tsunami inundation modeling of the 2011 Tohoku tsunami using the source estimated from the offshore tsunami records

BABA, Toshitaka[1*] ; TAKAHASHI, Narumi[1] ; KANEDA, Yoshiyuki[1]

[1]JAMSTEC

As the number of offshore tsunami stations comes up, it is becoming possible to estimate tsunami source in real time by exclusively using offshore tsunami information. The issue we would like to discuss in this study is how accurate is it in terms of coastal tsunami prediction? In order to investigate this, we performed a tsunami inundation modelling of the 2011 Tohoku tsunami and compared with the tsunami field survey. We used the Saito et al. (2011) source model inverted from the offshore tsunami waveforms alone, although it was not a real-time solution, in the numerical simulation. The nonlinear Boussinesq equations were solved for the tsunami propagation because tsunami soliton fission was observed during the 2011 tsunami, which is split short-period waves around tsunami crest caused by combination of wave nonlinearity and dispersion. We also applied a variable nested algorithm which allows the spatial resolution of the study region to be easily increased. The finest grid spacing was set to be 2/9 arcsec (about 5m). The three dimensional shape of buildings and structures from lidar measurements were directly embedded on the digital elevation model to include the effect of them on tsunami inundation. Our dispersive tsunami code (JAGURS) was fully parallelized with MPI and OpenMP libraries so that the large scale dispersive modeling could be implemented within realistic computation time. According to Aida (1978), the geometric mean K and geometric standard deviation k was used to evaluate the reproducibility of the numerical simulation. For our numerical simulation results, the K and k were calculated to be 0.97 and 1.27, respectively. These values satisfy the adequacy criteria for tsunami numerical modeling established by the Japan Society of Civil Engineers (2002) ($0.95 < K < 1.05$, $k < 1.45$). Accordingly, the present study showed the reliability of the tsunami prediction procedure that uses tsunami sources obtained with the offshore tsunami records alone.

Real-time tsunami simulation and visualization system using rapid CMT solutions in Southeast Asia

INAZU, Daisuke[1*] ; SAITO, Tatsuhiko[1] ; KUMAGAI, Hiroyuki[2] ; PULIDO, Nelson[1] ; FUKUYAMA, Eiichi[1]

[1]NIED, [2]Nagoya University

Southeast Asia, especially Indonesia and Philippines, is one of the most seismically active region in the world. NIED carries out real-time estimation of moment tensors of earthquakes and maintains a CMT catalogue in this region using the SWIFT system (Nakano et al. 2008), as well as waveform data from dense broadband regional seismic networks in Indonesia and Philippines, under a cooperative research with BMKG (Indonesia), PHIVOLCS (Philippines), and GFZ (Germany). Developing a rapid forecast/hindcast system of the tsunami is also necessary in particular for the tsunamigenic earthquakes.

We have been constructing an automated system for the tsunami simulation (Inazu et al. 2013 SSJ meeting). The current version of the system conducts simulations and visualizations of the followings procedures (1-4). The tsunami simulation is numerically carried out with a finite difference scheme from an initial condition given by a rectangular fault model.

1) Estimate a CMT solution by the SWIFT system.

2) Calculate the width, length, and slip amount of the rectangular fault model from Mw using an empirical scaling law. We here employ two scaling laws for the sake of evaluation of the uncertainties among the tsunami simulation results. Two parameters with small/large slip amount (or large/small rupture area) are then obtained for an estimated Mw.

3) Two fault mechanisms are obtained based on the double couple solutions, and then we expect four scenarios of the initial tsunami conditions. The seafloor deformation or initial tsunami condition are calculated by the Okada's (1985) theory for each scenario.

4) Carry out numerical simulations for the respective scenarios. We visualize the regional tsunami height distribution and the time series of the tsunami height at selected sites around the epicenter. The visualization is carried out in parallel to the simulation for an integral time interval. The maximum tsunami heights are displayed on a regional map and on coastal areas as well in parallel to the simulation.

We will present typical graphical outputs produced by the above procedures for several tsunami events.

Proper scoring systems with definite connections to information values of tsunami warnings

HAYASHI, Yutaka[1*]

[1]Meteorological Research Institute

Necessary conditions which newly introduced method can improve forecast are, existing proper scoring system, and that the new method marks better score than the present method do. Up to now, these scoring system have never applied to tsunami warning system.

Some scoring rules being applied widely to binary forecasts in weather forecasting, such as having precipitation or not, have close connections to change of utility for users. These scores are based on assumption that all user know their cost to make counter measures (C) and loss in case of no counter measure (L). When the forecast says the event will occur, and all users are assumed to make counter measures. In addition, a simple probability density distribution of U(-C)/U(-L) is assumed for cost-loss model, where U is the utility function. In general, a score is calculated by using a targeted dataset, e.g., a fixed period of time, and frequencies: occurrence of targeted phenomena is forecasted and observed (hit: N_a), forecasted but not occurred (false alarm N_b), not forecasted but occurred (misdetection: N_c), and not forecasted and not occurred (hit: N_d). For example, equitable threat score (ETS $\equiv$ (N_a-K)/(N_a+N_b+N_c-K), where K $\equiv$ (N_a+N_b)(N_a+N_c)/(N_a+N_b+N_c+N_d)) is one of their scoring system.

In this paper, suitable scoring rules for tsunami warnings are derived by considering the characteristics of tsunami warnings and following assumptions.

(1) Scores can be defined without N_d, because counting N_d does not make sense for tsunami warning.

(2) In case of tsunami warning, users of forecasts can select actions to take a counter measure or not. In case of no warning, users do not take a counter measure. Change of utilities are U(-C) and U(-L) for taking a counter measure and for when a phenomenon happens without a counter measure, respectively.

(3) All users know the fault alarm ratio (FAR $\equiv$ N_b/(N_a+N_b)) of the warning, their utilities for each condition (U(-C), U(-L)), and then their rational decision-making choose the option so that their expectation of utility (E_x(U)) become maximum. Here, if U(-L)/U(-C) <FAR/(1-FAR) is satisfied, not taking a counter measure is the more reasonable decision. According to this assumption, larger the FAR is, larger the cost-loss ratio is, warning become easier to be ignored.

(4) Assuming three types of probability density functions on x=U(-C)/U(-L). a) Uniform model: f(x)=1, b) Low-cost model: f(x)=2-2x, and (c) High-cost model: f(x)=2x for the range of 0 $\leq$ x $\leq$ 1.

(5) The scores are set to be proportional to the information value of the warning. Here, $\triangle$U can be calculated as the integral corresponding to each distribution of (4) and utilities of selected actions at the N_a+N_b warnings based on the rational decision-making described in (3). Besides, if there were not for warning system, users should have lose utility as much as -U(-L) at every event. Then, V $\equiv$-ΔU/((N_a+N_c)U(-L)).

Scores corresponding to models a)-c) in (4) are derived as follows.

a) V=$N_a{}^2$/(2(N_a+N_b)(N_a+N_c)). For good warning which satisfies both $N_a \gg N_b$ and $N_a \gg N_c$, the score can be approximated to V $\fallingdotseq$ CSI/2, where CSI $\equiv$ N_a/(N_a+N_b+N_c) is threat score or critical success index.

b) V=(2/3)(1-FAR)(1-M)(1+M/2), where M $\equiv$ N_c/(N_a+N_c) is missing ratio. For warnings with few misdetection which satisfies Nc $\ll$ Na, the score can be approximated to be V $\fallingdotseq$ (2/3)(1-FAR)(1-M/2).

(c) V=(1-FAR)^2(1-M)/3.

The proper score system thus changes according to the cost-loss ratio, which have close relation to preparedness. It is necessary to choose suitable forecast method using proper scoring system which is corresponding to a social structure. In the meeting, the author would like to discuss also on the problem for the practical application of the scoring systems.

A large earthquake occurred in the sea area east offing Nenuro, Hokkaido at 6 AM, April 25, 1843 and is called Tenpo Nenuro-Oki earthquake whose magnitude is estimated at M7.5. A tsunami was accompanied with this earthquake, and hit the Pacific coast of Hokkaido and the east coast of Sanriku district, the north part of Honshu. Historical documents which record the tsunami were published by Musha (1941) and ERI, university of Tokyo(1984). It is recorded in the diary kept by a priest of Kokutaiji Temple at Akkeshi town, Kushiro district, Hokkaido that the Akkeshi branch office of the Tokugawa Government and huts of Ainu race were swept away in the residential area around the temple, and in Muko-Gishi area, north opposite coast of Akkeshi all houses were washed away and 34 Ainu people were killed. The official report written by an officer at Kushiro described that one hut and one barn were swept away at Betsufuto, about 36 kilometers east of Kushiro, and 2 houses were swept away at Atoega village. Documents written by the local meteorological observatory of Namuro described that 50 houses village were swept away at Hanasaki, about 8 kilometers south west of Nemuro Town, and survived people moved their residences to Honioi village about 6 kilometers north of Hanasaki. In this official report also it was recorded that a boy called Yamamoto Koshichi was lived on the coast of Notsuke peninsula. He experienced the tsunami there when he was 12 years old. He mentioned that the wave was divided into two waves in the offing of Notsuke coast, and the bigger wave hit the south coast of Shiretoko Peninsula. On the basis of those records, we conducted field survey for three times, and obtained the distribution of the tsunami height as the figure. The authors of the present study wish to express their thanks to JNES for its financial support in promoting our research.

A new calculation method for seabed displacement due to fault slip by boundary integration

AKIYAMA, Shinichi[1*] ; FUJIWARA, Hiroyuki[2] ; HASHIMOTO, Norihiko[1]

[1]CTC, [2]NIED

In tsunami simulation, initial water level of tsunami is often considered to be equal to vertical displacement of seabed generated by a source fault slip. Exact solution for displacement due to rectangular fault slip in elastic half space (Okada, 1985) has been generally applied to calculate the seabed displacement.

In order to calculate the displacement due to the source fault which has irregular form using this solution, the source fault should be modeled by patching many rectangular small faults along the irregular surface. As a result, the source-fault model has portions in which the rectangular small faults are overlapped each other or not covered the fault surface. Then, calculated displacement from the fault model is overestimated near the overlapped area or underestimated near the uncovered area. This kind of displacement discontinuity is not negligible when the fault is located near the seabed, while it is negligible in the case that it is far from the seabed. Therefore, a new technique to take the irregular form into consideration accurately is required to solve the above problem.

Under such a background, we developed a new method to calculate displacement of seabed due to slip of the source fault using boundary integration. It is well known that deformation of the medium due to a fault slip is represented by the boundary integration for the medium surface and the fault surface by applying Green's theorem to the governing equation. Considering the seabed as an elastic half space, it can also be expressed only with the boundary integration for the fault surface. Calculating the boundary integration numerically, we introduce the linear element which is used by Boundary Element Method (BEM) into the proposed method to guarantee continuity of the displacement. However the numerical integration based on Gauss quadrature formulae at the point near the fault surface is broken down by the influence of singularity of Green's function. We apply the Projection and Angular & Radial Transformation (PART) method (Hayami and Brebbia, 1988) to the proposed method to evaluate the effect of the singularity accurately. We will present formulation, validation, verification and application of this method.

This research was carried out as part of Tsunami Hazard Assessment for Japan by National Research Institute for Earth Science and Disaster Prevention (NIED).

A method to obtain probabilistic hazard information on tsunami run-up and inundation area is described in this study, as part of the probabilistic tsunami hazard assessment research work [NIED]. A tsunami hazard assessment has been conducted to estimate frequency of exceedance wave height at several monitoring sites along coastal region, and to be useful for the study of coastal vulnerability, based on results from a tsunami simulation with an earthquake scenario and occurrence probability. Although the main target of a tsunami hazard assessment has contributed to quantify risk in critical infrastructure facilities, inundation hazard information for urban and river regions are also important. In a study of a probabilistic tsunami hazard assessment for Japan, tsunami exceedance wave height in coastal region is probabilistically derived from numerical modelling of tsunami sources available. However, horizontal resolutions in the model is only 50 m of minimum in a land region due to computational cost constrained by tsunami simulation for Japan, which is not enough resolution to assess inundation hazard mapping on a urban area. A detailed inundation hazard assessment is expected as a result of implementing smaller grid size than 50 m.

Here we provides a technical note for estimation of inundation hazard mapping resulted from a simulation run at horizontal resolution 10 m, and show their results at Rikuzentakata, one of example. A horizontal distribution of the probabilistic inundation is calculated from hazard curves on every grid cells in inundation area. Earthquake scenarios are set by many tsunami sources and occurrence frequencies around Japan trench. An annual exceedance probability of inundation when reaching threshold is calculated from tsunami sources and occurrence probability of the earthquake scenarios. This describes the benefit of tsunami inundation hazard mapping. We could successfully show this point clearly for the first time.

In preparation for probabilistic tsunami hazard assessment for the whole of Japan, we discuss uncertainty for tsunami heights due to a difference in slip distribution of source models.

In the process of probabilictic tsunami hazard assessment, tsunami heights at assessment points are estimated by numerical simulations. We calculate crustal deformations from source models, which are assumed as initial sea surface displacements, and then simulate tsunami propagations till tsunamis arrive in coastal sites. A simulation result changes depending on fault parameters of a source model such as magnitude, location, dip, strike, rake and slip distribution. Therefore, tsunami hazard includes uncertainties due to variability of fault parameters.

For the cases of subduction-zone earthquakes, focal mechanism is thought to be subject to a plate boundary in the characterized tsunami source model defined by probabilistic tsunami hazard assessment for the whole of Japan (Toyama et al., 2014, JpGU). On the other hand, magnitude, location and slip distribution are thought to have large varieties and their variabilities will create a large difference in tsunami height distributions. We therefore take account of the variabilities by calculating a number of source models with the different fault parameters. In this study, we give a qualitative verification for the variation in tsunami height due to slip distribution for the purpose of simplifying the hazard assessment process by using a probabilistic model for the uncertainty due to slip distribution. We examine a parameter study for several models with different slip distributions using two topography models, an uniform water depth model and a real ocean floor topography model. As the result, there is little to distinguish of geometric standard deviations between the two topography models, the values are 0.09 at a maximum.

This study was performed as a part of research for ”Tsunami hazard assessment for the whole of Japan” in NIED.

Large slip area in characterized Tsunami source model toward Tsunami Hazard assessment

KORENAGA, Mariko[1*] ; AKIYAMA, Shinichi[1] ; ABE, Yuta[1] ; HASHIMOTO, Norihiko[1] ; HIRATA, Kenji[2] ; FUJIWARA, Hiroyuki[2] ; MATSUYAMA, Hisanori[3] ; MURASHIMA, Yoichi[4]

[1]CTC, [2]NIED, [3]OYO, [4]KKC

In previously deterministic Tsunami hazard assessment, it had been ordinary method in setting tsunami source model that it is accountable for signature of historical tsunami events. Therefore it is difficult to evaluate of tsunami risk for future events unascertained focal area or magnitude and so on. On the other hand, in probabilistic tsunami hazard assessment, it ' s necessary to be designed for all potentially tsunamigenic earthquakes considering target region in principle, in planning phase of modeling of elastic fault parameter (Toyama et al., 2014,JPGU). For our purpose, on setting for characterized tsunami source model for probabilistic tsunami hazard, it is essential to characterize tsunami source model and include the statistical variability. We focused on the " heterogeneous slip distribution " of tsunami source, and studied on how to setting area ratio of large slip.

According to the distribution of the fault plane slip obtained from the wave source inversion studies of the 2011 off the Pacific coast of Tohoku Earthquake (2011 Tohoku tsunami), the ratio of large slip area is said to have contributed significantly to the tsunami wave height, the ratio of the area is much the same.

Therefore, in this study, we analyzed the ratio of seismic moment by unit area regardless of the assumed size of the fault element to all mean of seismic moment. As a result from inversion models of 2011 Tohoku tsunami source and other magnitude of 9 level source, three stage characterized modeling is required, it was found that the model which accounts for 30% of the total area of 2 times the average slip, and 10% of the total area of 4 times the average slip is appropriate. And two stage characterized model for magnitude 8 level sources, its large slip (twice the average) region accounts for 30%. Comparing the maximum coast wave heights simulated using characterized model above with a detailed inversion fault model, we verified that the former covering the latter.

This study was conducted by a part of research project in NIED for tsunami hazard assessment for the whole of Japan.

Large tsunami remote observations from high altitude using the induced magnetic field of tsunami.

TATEHATA, Hidee[1*] ; HAMANO, Yozo[2]

[1]JMA, [2]JAMSTEC

On The 2011 off the Pacific coast of Tohoku Earthquake, massive tsunamis more than 10m attacked it in the wide range of Ibaraki from Aomori coast area. The tsunami warnings were not only sufficient but also no observation result of the tsunami, it was a big problem. The other side, at the Chichijima geomagnetic observation point had observed the tsunami induced magnetic field

As a result of example analysis for a past tsunami on Chichijima islands, the signal of the induced magnetic field was able to detect almost more than 1m tsunamis. The observation of the tsunami by the tsunami induced field has a weak point that sensitivity and a point of S/N ratio, but has a characteristic of the remote observation unlike the observation by tide gauges. If a geomagnetism sensor was installed in the hill of the Sanriku coast as a huge tsunami meter, they endured a massive tsunami and might continue observation without being destroyed.

We introduce the wave pattern of the prospective induced field of the tsunami and some character, if a sort of electromagnetic huge tsunami meter had been installed in the Sanriku coast.
