High pressure and temperature (P-T) conditions were generated in a laser-heated diamond-anvil cell. We used pure iron foil as a starting material. Xe was loaded cryogenically. Angle-dispersive X-ray diffraction (XRD) measurements in-situ at high P-T were conducted at BL10XU, SPring-8. The textural and chemical characterizations of recovered samples were made by using a field-emission-type scannning electron-microprobe (FE-SEM) equipped with energy dispersive x-ray spectrometry (EDS). Both cross section and surface of a sample were carefully examined by combining a focused Ga ion beam (FIB) with FE-SEM.

Any evidence for the reaction was not observed at least up to 83 GPa and 3810 K based on both XRD measurements and chemical analyses. On the other hand, chemical analysis on the sample recovered from 86 GPa and 6450 K, the highest P-T condition achieved in this study, showed Fe alloyed with up to ˜1.6 wt.% Xe as tiny grains. This sample had a difference in the texture between heated and unheated regions. We calculated the concentration of Xe in the entire molten area by assuming the heated region and the small grains of Fe-Xe alloy as a cylinder and spheres, respectively. The xenon content was estimated to be 0.02 wt. % for the heated area which is high enough to account for the missing xenon problem (10^{-10} wt.% Xe in the core). The present results could be a clue to solve the "missing xenon" paradox. Since the temperature of the present Earth's core is most likely lower than 6000 K, xenon might be incorporated into the core during Earth's early history at higher temperature.

Whole-mantle P-wave radial anisotropy tomography

KITAGAWA, Hiroki[1*] ; ZHAO, Dapeng[1] ; TOYOKUNI, Genti[1]

[1]RCPEVE, Tohoku Univ.

1. Introduction

When studying seismic anisotropy, it is generally assumed that the medium under study has a hexagonal symmetry (i.e., transverse isotropy). In most cases, the axis of symmetry is assumed in the vertical direction (i.e., azimuthal anisotropy) or in the horizontal plane (i.e., radial anisotropy). Seismic anisotropy is induced mainly by the lattice-preferred orientation (LPO) of anisotropic minerals, especially for the olivine in the mantle (e.g., Zhang & Karato, 1995; Tommasi et al., 2000; Kaminski & Ribe, 2001). Studying seismic anisotropy is very important for understanding the structure and dynamics of the Earth's interior (e.g., Silver, 1996). Many previous studies have investigated P-wave azimuthal anisotropy tomography for several regions including the Japan Islands. Recently, Wang & Zhao (2013) studied P-wave radial anisotropy tomography of the Kyushu and Tohoku subduction zones. In this work, we have attempted to conduct global tomography to understand 3-D P-wave radial anisotropy in the whole mantle.

2. Data and method

In this study we used 12,657 earthquakes recorded by 6765 seismic stations which were selected from the ISC-EHB catalog by Yamamoto & Zhao, 2010. About 1.4 million arrival times of P, pP, PP, PcP and Pdiff waves are used in the tomographic inversion. The method of radial anisotropy tomography by Wang & Zhao (2013) is combined with the flexible-grid global tomography of Zhao et al. (2013) to conduct the whole-mantle tomographic inversion in this work.

3. Result

In comparison with the isotropic tomographic model, our anisotropic tomography model results in a smaller root-mean-square travel-time residual, suggesting that the anisotropic tomography model fits the data better. The isotropic component of this model is very consistent with the previous isotropic tomography. In upper mantle, low-velocity anomalies along the Pacific Rim, and high-velocity anomalies under the stable continents are visible. In addition, low-velocity anomalies exist from the surface down to the core-mantle boundary under South Pacific and East Africa, which represent two superplumes. The anisotropic results show that vertical velocity is greater than horizontal velocity under some regions such as South Pacific, which may reflect the mantle upwelling.

Melting experiments on the MgO-$MgSiO_3$ system using double CO_2 lasers heated diamond anvil cell

OHNISHI, Satoka[1*] ; KIMURA, Tomoaki[1] ; KUWAYAMA, Yasuhiro[1]

[1]Geodynamics Research Center, Ehime University

Seismological studies suggest the presence of ultralow-velocity zones (ULVZ) near the core mantle boundary (CMB). Partial melting of the lower mantle materials has been proposed to explain these zones, but experimental validation at the appropriate temperature and pressure regimes remains challenging. The melting curve of the lower mantle material is a key to constrain the existence of melt at the base of the mantle. A laser heated diamond anvil cell (LHDAC) provides an enabling tool for determination of melting temperatures of materials under high *P-T* conditions. Although YAG, YLF lasers (the wavelengths are about 1 μm) have been generally used for LHDAC experiments, the use of metal absorber is required to heat silicate materials. However, the thermal absorber may cause a chemical reaction and a temperature gradient in the sample. The accuracy of temperature determination is suffered from the chemical reaction and the temperature gradient. In contrast, the CO_2 laser with the wavelength of about 10 μm can directly heat silicate materials. For the minimization of temperature gradients, double-sided heating system for LHDAC was suggested by Shen *et al*. (1996). This technique using the YAG laser has been widely used to study the behavior of materials under high *P-T* conditions. However, the double CO_2 laser heating system has not been used due to the wavelength of this laser is different from that of visible light.

The requirements for the pressure medium in laser heating experiments are low thermal conductivity and chemical inertness. Ar, which is a noble gas, is one of the suitable pressure mediums. However, loading Ar into the DAC is difficult under room temperature and ambient pressure. Therefore, a simplified method to load Ar into the DAC is required. In this study, I established new experimental technique for the minimization of temperature gradients and chemical reactions and performed melting experiments of the lower mantle materials using LHDAC.

First, a double-sided heating system using CO_2 laser was developed by separating optical elements. This system consists of the heating system using two CO_2 lasers which have the high power (100 W), the observation systems and the temperature measurement system. By using lenses designed for the CO_2 laser wavelength, the laser system is separated from observation and temperature measurement system. Two dimensional images and radiation spectrums are observed by Charge Coupled Device (CCD) camera and spectrometer, respectively.

Second, a simplified method to load Ar into the DAC was developed by the cryogenic technique. In this technique, Ar is cooled using liquefied N_2 until it forms a liquid, and the liquefied Ar is loaded into the sample chamber of the DAC. Cu was used to enhance cooling efficiency.

Finally, I performed melting experiments of the lower mantle materials using the double CO_2 lasers heated diamond anvil cell and Ar as the pressure medium. I used forsterite (Mg_2SiO_4) and mixtures of MgO and $MgSiO_3$ as the starting material. After the complete pressure release, the sample was recovered from the DAC and examined by FE-SEM. From the surface texture of recovered samples, I discussed melting temperatures of the lower mantle materials under high *P-T* conditions.

The double CO_2 laser heating and loading Ar methods developed in this study could powerful tool for determination of melting temperatures of the lower mantle materials.

1 TPa region is still far frontier for the high pressure physics. The maximum pressure generated by diamond anvil cell is about 400 GPa (Akahama and Kawamura, 2010). On the other hand, recently Dubrovinsky et al. (2012) reported the generation of 640 GPa using double stage diamond anvil cell. This new technique makes 1TPa reagion a realistic goal for static compression experiments. But there are some technical difficulties such as a second-stage anvil's shape controllability, shift under pressure, and the difficulty of a sample filling. These problems depress the reproducibility of experiment.

In this study, second-stage microanvils were made by focused ion beam system from the nano-polycrystalline diamond (NPD) or single crystal (SC) diamond. Micro manufacturing using focused ion beam system enables us to control anvil shape, process any materials (NPD, SC and also sample), and fill the sample between the second-stage anvil gap precisely. Using this method, we generated up to 340 GPa. This method has a high reproducibility of the experiment. Thus, we can optimize the experimental parameters such as an anvil shape, confining pressure and so on.

Ab initio molecular dynamics study on a phase separation in liquid Fe-O

OHSUMI, Masanao[1*] ; TSUCHIYA, Taku[1] ; ICHIKAWA, Hiroki[1]

[1]Geodynamic Research Center, Ehime University

The Earth's outer core is mainly composed of liquid Fe-Ni alloy. The density of the outer core is, however, ˜10% smaller than this alloy. The density deficit indicates that substantial amount of light elements are present in the outer core [Birch, 1964]. Recent seismological observations proposed that seismic wave velocity is ˜3% slower than PREM below a few hundred kilometers of the CMB [Helffrich and Kaneshima, 2010]. The low-velocity anomaly is considered to be cause by stratification. However, mechanisms of the stratification have not been clarified yet. One possible cause is phase separation into Fe-rich and light element-rich liquid. Oxygen is one of the most important light elements, because an iron-oxygen phase separation was observed experimentally at low-pressure condition [Tsuno et al., 2007]. This immiscible behavior is, however, still unclear at the outer core pressure.

In this study, we calculated liquid Fe-O alloy at the outer core condition by means of *ab initio* molecular dynamics simulations. First, we analyzed local structures of liquid Fe-O alloy to detect signs of phase separation. Second, we evaluated its excess enthalpy. Both indicate that the liquid was well-mixed. Finally, we computed P-wave velocity in liquid Fe-O alloy. P-wave velocity was found to increase with increasing the oxygen concentration. All these results suggest that the simple enrichment process is less suitable to explain the low-velocity anomaly.

In situ X-ray observations of phase transitions in MgCr2O4 to 30 GPa using Kawai-type multianvil apparatus

KUNIMOTO, Takehiro[1*] ; IRIFUNE, Tetsuo[1] ; FUJINO, Kiyoshi[1]

[1]Ehime University

Phase relations in $MgCr_2O_4$ (magnesiochromite) have been studied up to 30 GPa and 1600 ℃, using a large volume Kawai-type multianvil apparatus and in situ X-ray diffraction measurements system installed at SPring-8/BL04B1. $MgCr_2O_4$ spinel dissociates into $Mg_2Cr_2O_5$ (orthorhombic type) + Cr_2O_3 (eskolate) at 9 GPa and 1200 ℃, and then reunion to higher pressure phase ($CaTi_2O_4$ type) at 22 GPa and 1200 ℃. Moreover, another high-pressure phase was observed above $CaTi_2O_4$ type structure phase, and this phase was unquenchable to ambient condition. In addition, pressure-induced phase transition in $MgCr_2O_4$ was confirmed without decomposition under cold compression process. In this cause, Magnesiochromite is directly transformed to high-pressure phase through the mixture of spinel and high-pressure phase. In this study, $CaFe_2O_4$ type and ε-phase, which reported in earlier studies in $MgAl_2O_4$ were not observed. The Birch-Murnaghan equation of state was used for least-squares fitting of the volume data (assuming $K_0{}'$ =4). Thus, determined zero-pressure bulk modulus (K_0) of the $CaTi_2O_4$ type $MgCr_2O_4$ was 195 GPa.

In this presentation, we will discuss further details of high-pressure phase relation and physical properties of high-pressure phases in $MgCr_2O_4$ series.

Sound velocities of laser-shocked Fe-Ni alloys under Earth core conditions

SAKAIYA, Tatsuhiro[1*] ; YOKOYAMA, Naoya[1] ; HOSOGI, Ryota[1] ; KONDO, Tadashi[1] ; TERASAKI, Hidenori[1] ; SHIGEMORI, Keisuke[2] ; HIRONAKA, Yoichiro[2]

[1]Graduate School of Science, Osaka University, [2]Institute of Laser Engineering, Osaka University

When we consider the structure of Earth's interior, the sound velocity is one of the important physical properties of the interior materials because it can be directly compared with the seismological data (1) which can yield the physical properties of the Earth's interior. Cosmochemical data and the composition of iron meteorites suggest that Earth's core contains mainly Fe-Ni alloy with 5-25 wt.% Ni. Although Lin et al. (2) and Kantor et al. (3) measured compressional sound velocities of Fe-Ni alloys at room temperature by inelastic x-ray scattering (IXS) at diamond anvil cell (DAC), the sound velocity data of liquid Fe-Ni alloys is very few (4).

We performed laser-shock experiments of liquid Fe-Ni alloys at HIPER system of Gekko-XII laser in Institute of Laser Engineering, Osaka University (5). Sound velocities were measured by side-on radiography (6, 7). We obtained sound velocities of Fe-Ni alloys at pressures up to 770 GPa. The sound velocity of Fe-Ni alloy was about 10% lower than that of liquid Fe at inner core boundary (ICB) pressure.

Part of this work was performed under the joint research project of the Institute of Laser Engineering, Osaka University.

3D imaging of geofluid by wideband magnetotellurics

OGAWA, Yasuo[1*] ; ICHIKI, Masahiro[2] ; KANDA, Wataru[1]

[1]Volcanic Fluid Research Center, Tokyo Institute of Technology, [2]Graduate School of Science, Tohoku University

Magnetotelluric measurements have been conducted over the five years in the central part of NE Japan arc surrounding the Naruko Volcano with approximately 3km grid. Over 200 sites were used for modeling the crustal resistivity structure in detail. Full impedance tensors for 8 periods were used for inversion. To alluviate the computational load, first four short periods were used to image upper crustal features and the resultant model was used for a prior model for another set of inversions with longer 4 periods.

The obtained model show the crustal conductor underneath the Mukaimachi caldera and Sanzugawa caldera. Seismic tomography shows low S-wave velocity for both, however, the resistivity image show clear low resistivity for Mukaimachi Caldera, but not for Sanzugawa Caldera. This difference may be due to the salinity of the fluids underlying the volcanic regions.

Three dimensional electrical conductivity model in the subduction zone beneath northeastern Japan

ICHIKI, Masahiro[1*] ; OGAWA, Yasuo[2] ; KAIDA, Toshiki[1] ; DEMACHI, Tomotsugu[1] ; HIRAHARA, Satoshi[1] ; HONKURA, Yoshimori[2] ; ICHIHARA, Hiroshi[3] ; KANDA, Wataru[2] ; KONO, Toshio[1] ; KOYAMA, Takao[4] ; MATSUSHIMA, Masaki[5] ; NAKAYAMA, Takashi[1] ; SUZUKI, Shu'ichi[1] ; TOH, Hiroaki[6] ; UYESHIMA, Makoto[4]

[1]Grad. School of Sci., Tohoku University, [2]VFRC, Tokyo Institute of Technology, [3]IFREE, JAMSTEC, [4]ERI, The University of Tokyo, [5]Grad. School of Sci. & Eng., Tokyo Tech, [6]Grad. School of Sci., Kyoto University

Our final goal is to infer a geofluid map (GFM) from both of the seismological (seismic velocity, Vp/Vs, Q etc.) and electrical conductivity structures in the wedge mantle of subduction zone beneath northeastern Japan. While plenty of high-resolution three dimensional (3-D) seismic tomographic images has been revealed there, none of 3-D electrical conductivity distribution model, of which the resolution is comparative to those of seismic tomography, has been proposed in terms of wedge mantle in subduction zones. Here, we show a high-resolution 3-D electrical conductivity distribution model in the wedge mantle beneath northeastern Japan used as input of GFM.

We carried out long-period MT observation using the state-of-the-art equipments, LEMI-417 and NIMS. The total 72 site observation has been completed. To remove tilt changes, baseline steps and drifts of fluxgate magnetometers, we first subtracted magnetic field variations to which a median filter was applied, from raw data. The horizontal coordinate of magnetic field data in each site was rotated before the response calculation such that the declination of the averaged horizontal component should be consistent with the 2010 absolute geomagnetic observation map provided by Geospatial Information Authority of Japan. We used the BIRRP processing code (Chave and Thomson, 2004) to estimate MT responses and have successfully retrieved them up to 61440 seconds in period.

The MT impeadance responses were inverted into 3-D electrical conductivity model using WSINV3D (Siripunvaraporn et al, 2005), the data-space Occam inversion method. The all input data error floor was assigned to be 10 percent. We investigated the optimal reference model with trial and errors. The test model was (1) uniform models, (2) layered models and (3) layered models with subducting slab models. The best RMS in each reference model was (1) 2.81, (2) 2.71 and (3) 2.48, respectively. Hence, we adopted the reference model of the layered model with subducting slab.

The conductivity profiles normal to the trench axis in higher latitude than N 39 degrees delineate conductive region on the subducting slab, and the conductive region is raised just beneath the central range of northeastern Japan (Ou-backbone range). This electrical image is well consistent with that obtained by the seismic tomographic model. On the other hand, a profile in lower latitude than N 39 degrees reveals that the conductive region is overturned towards backarc. The top of the overturned conductive body coincides with Gassan Volcano location, one of the outstanding backarc volcanism. However, Chokai Volcano, another distinctive backarc volcanism has no subsurface conductive root originated from deep upper mantle. The overturned mantle convection image is not found in the seismic tomographic image.

S-wave attenuation on the western side of Nankai subduction zone: implications for geofluid distribution and dynamics

TAKAHASHI, Tsutomu[1*] ; OBANA, Koichiro[1] ; YAMAMOTO, Yojiro[1] ; NAKANISHI, Ayako[1] ; KODAIRA, Shuichi[1] ; KANEDA, Yoshiyuki[1]

[1]JAMSTEC

One major cause of seismic wave attenuation is the presence of fluid in rocks. In this study, we estimated the attenuation structure in southwestern Japan and western Nankai trough by applying the attenuation tomography that takes account of apparent amplitude attenuation due to multiple forward scattering [Takahashi, 2012]. Because the estimated attenuation 1/Q in our tomographic study was much larger than 1/Q due to wide-angle scattering, our estimated 1/Q is composed mainly the intrinsic 1/Q.

High 1/Q (>1/500 at 4-8 Hz) was imaged beneath the Quaternary volcanoes. The highest attenuation (1/Q ˜1/250 at 4-8 Hz) distributes beneath the Beppu-Shimabara rift zone at 40-60km depth. Beneath this rift zone, 1/Q becomes larger as depth increases. Random inhomogeneities in this zone are relatively strong at 0-40 km depth; whereas at 40-60 km depth random inhomogeneities are almost comparable to those in non-volcanic area. Meanwhile, in northeastern Japan, uppermost mantle beneath the volcanoes shows strong inhomogeneities and high attenuation. Apparent attenuation at the uppermost mantle beneath the Quaternary volcanoes is high in both study areas, but relative contributions of scattering and intrinsic attenuation differ between northeastern Japan and the Beppu-Shimabara rift zone. If we consider random inhomogeneities and 1/Q in other areas, the weak random inhomogeneities and high 1/Q beneath this rift zone suggest that random inhomogeneities due to the presence of igneous rocks are not significant, and that any magma inclusions are too small to excite S-wave scattering at 4-32 Hz.

At off Shikoku region, moderate 1/Q (1/800 ˜1/1000 at 4-8 Hz) is imaged at 0-20 km depth. This moderate 1/Q is estimated as 1/Q (f) ˜$10^{-2.5}f^{-0.5}$. Similar moderate attenuation can be found beneath the south of Shikoku at 20-40km, beneath the northern edge of Shikoku at 40-60km depth, and beneath Chugoku area at 40-60km depth. From geometry models of subducting Philippine Sea plate, most of the moderate 1/Q zone is located in and around the oceanic crust of subducting Philippine Sea plate except beneath Chugoku region. In this area, Shelly et al. [2006] pointed out fluid existence in the oceanic crust by estimating Vp/Vs structure. This correspondence implies this moderate 1/Q reflects fluid in the subducting slab. If we suppose that 1/Q of P- and S-wave have the same frequency dependences and that random inhomogeneities of P- and S-wave has the same scale dependences, we can show possible cases of fluid flow induced by the passage of low frequency seismic waves (<1 Hz) by applying a theoretical model of wave attenuation in saturated porous random media [Muller and Gurevich, 2005]. As a phenomenon suggesting such fluid flow by lower frequency seismic wave, triggering of non-volcanic tremors by surface waves passing has been observed [e.g., Miyazawa and Brodsky, 2008]. Even though we further need P-wave studies for detailed examination of this topic, it is likely that random inhomogeneity, intrinsic at 4-32 Hz and triggered tremors can be used to investigate medium properties and fluid dynamics.

Seismic activity near the Moriyoshi-zan volcano in northeastern Japan: Implications for geofluid migration

KOSUGA, Masahiro[1*]

[1]Graduate School of Science and Technology

The 2011 Off the Pacific coast of Tohoku (Tohoku-oki) Earthquake caused increased seismicity in many inland areas. A seismic cluster that occurred north of the Moriyoshi-zan volcano in the Akita prefecture of the Tohoku District is of interest in light of contribution of geofluids to seismic activity. We observed a seismic cluster characterized by the migration of seismicity, reflected/scattered phases, and deep low-frequency earthquakes. We relocated hypocenters by using the data of temporal observation and by using the Double-Difference location technique, which increased the depth accuracy. We interpreted the spatiotemporal variation of the hypocenters in the most active cluster by estimating the migration of pore fluid pressure. The hydraulic diffusivity of the cluster was in the range of 0.01?1.0 m2/s, and increased with time, implying that the migration of hypocenters accelerated after a pathway for fluids was formed by the fracturing of the wallrock that produced the initial stage of seismic activity. A prominent feature of the seismograms is a reflected/scattered phase observed at stations around the volcano. We have interpreted the phase as S-to-S scattered waves and estimated the location of scatterers using a back-projection method. The scatterers are located about 5 km northwest of the Moriyoshi-zan volcano and at an approximate depth of 13 km. The Moriyoshi-zan area is one of the source areas of deep low-frequency earthquakes that have previously been interpreted as events generated by the migration of geofluids. The depth of scatterers is close to the upper limit of the depth at which low-frequency earthquakes occur. Thus, we regard the observed scatterers to be a reservoir of geofluid that came from the uppermost mantle accompanying contemporaneous low-frequency earthquakes. The geofluid reservoir is the probable source of overpressurized fluid that induces the migration of seismicity in the upper crust. A time delay in seismic activity from the Tohoku-oki Earthquake was considered as the time needed to migrate across a gap between the reservoir and the earthquake cluster with a hydraulic diffusivity comparable to that observed for the initial stage of seismicity, i.e., fracturing of the wallrock.

Is H_2O-NaCl fluid enough to explain high electrical conductivity in the earth's crust?

SAKUMA, Hiroshi[1*] ; ICHIKI, Masahiro[2]

[1]National Institute for Materials Science, [2]Tohoku University

Old continental crust has a high electrical conductivity layer at 20 to 30 km in depth [1]. Presence of aqueous fluids is a plausible hypothesis for explaining the high conductivity zone [2]. Therefore the electrical conductivities of aqueous fluids under high pressure (P), temperature (T) conditions should be investigated in order to evaluate the hypothesis. The phases of water and aqueous NaCl solutions at the P-T conditions of the Earth's crust correspond from liquid to supercritical states.

Experimental approaches to measure the electrical conductivities at high P, T and salt concentration (c) conditions are limited and the data at P <400 MPa, T <1073 K and c <0.6 wt% for aqueous NaCl solutions is only available [3]. Classical molecular dynamics (MD) simulations are useful to obtain the electric conductivities at high P, T and c conditions and for understanding the underlying mechanism controlling the conductivities.

We used the flexible and induced point charge (FIPC) H_2O model [4] for MD simulations of aqueous NaCl solution. The technical details of the model and computational methods are explained in the literature [4]. The unit cell contained 2222 H_2O and 4 NaCl, 2035 H_2O and 22 NaCl, and 2035 H_2O and 66 NaCl for c = 0.6, 3.4, and 9.6 wt% NaCl solutions, respectively.

The isotherms indicate that the conductivity increases with increasing pressures and saturated at high pressures. The conductivity decreased with increasing temperature. This behavior may seem to be strange, since the ionic mobility should be high at high temperatures. This can be explained by the mixed effects of the change of (i) the density, (ii) ionic mobility, and (iii) dielectric constant of water as discussed in Quist and Marshall (1968) [3]. We concluded that the change of the conductivity of H_2O-NaCl fluids along with a geotherm model can explain one order of the increased magnitude at the high conductivity layer in depth, but more change observed by the Magnetotelluric method should be explained by the additional mechanism such as the connectivity of the fluids and the conductivity of H_2O-CO_2 fluids.

Connectivity of cracks and pores in a granitic rock

WATANABE, Tohru[1*] ; HIGUCHI, Akiyoshi[1] ; YONEDA, Akira[2]

[1]Graduate school of science and engineering, University of Toyama, [2]Institute for Study of Earth's Interior, Okayama University

Seismic velocity and electrical conductivity are used to map the fluid distribution in the crust. Seismic velocity reflects the contiguity of solid phases, while electrical conductivity the connectivity of fluid phases. The combination of velocity and conductivity could provide us a strong constraint on the fluid distribution. However, mapping of the fluid distribution has not been successful. The connectivity of fluid phases in rocks is poorly understood. In order to understand the connectivity of fluid phases in rocks, we have made conductivity measurements on a fluid-bearing granitic rock under various confining pressures.

Fine grained (100-500μm) biotite granite (Aji, Kagawa pref., Japan) was used as a rock sample. The sample is composed of 52.8% plagioclase, 36.0% Quartz, 3.0% K-feldspar, 8.2% biotite. The density is 2.66(1) g/cm^3, and the porosity 0.8(1) %. The porosity was estimated from the mass of the dry and wet samples. Cylindrical samples have dimensions of 25 mm in diameter and 30 mm in length, and saturated with 0.01 mol/l KCl aqueous solution. Simultaneous measurements of elastic wave velocity and electrical conductivity were made using a 200 MPa hydrostatic pressure vessel. The pore-fluid is electrically insulated from the metal work by using plastic devices (Watanabe and Higuchi, 2013). The confining pressure was progressively increased up to 125 MPa, while the pore-fluid pressure was kept at 0.1 MPa. It took five days or longer for the electrical conductivity to become stationary after increasing the confining pressure.

Elastic wave velocities and electrical conductivity showed reproducibly contrasting changes for a small increase in the confining pressure. Elastic wave velocities increased only by 5% as the confining pressure increased from 0.1 MPa to 25 MPa, while electrical conductivity decreased by an order of magnitude. The increase in velocities is caused by the closure of cracks. Most ($\sim$80%) of the decrease in electrical conductivity occurred below the confining pressure of 5 MPa. The decrease in electrical conductivity must also be caused by the closure of cracks. The decrease in porosity was only 0.07(1) %. Such a small change in porosity caused a large change in electrical conductivity. The connectivity of fluid was maintained at least up to the confining pressure of 125 MPa. A calculation with the effective medium theory (Kirkpatrick, 1973) suggests that the fluid forms a network with small coordination number (average coordination number=2.3), and that the connectivity at higher pressures is maintained by stiff pores. More cracks are open at lower pressures to link pores, drastically increasing electrical conductivity.

Geometry of intergranular fluids in the mantle xenoliths: Implications for the physical properties of upper mantle

NAKAMURA, Michihiko[1*] ; OKUMURA, Satoshi[1] ; YOSHIDA, Takeyoshi[1] ; SASAKI, Osamu[2] ; TAKAHASHI, Eiichi[3]

[1]Graduate School of Science, Tohoku University, [2]Tohoku University Museum, [3]Graduate School of Science and Engineering, Tokyo Institute of Technology

Recent magnetotelluric (MT) studies have revealed that crust and uppermost mantle are less resistive than dry rocks in various localities in the world. This suggests that interconnected fluid phases present more ubiquitously than previously realized. Intergranular fluids also decrease seismic wave velocities and changes Vp/Vs ratio, thus interpretation of the seismic tomographic images largely depends on the volume faction and geometry of the fluid phase. The conventional view on grain-scale fluid distribution is based on dihedral angle between minerals and fluids in isotropic monomineralic rocks (i.e. ideal equilibrium geometry). Natural rocks are, however, composed of ani-sotropic multiple phases and undergo textural adjustment to minimize interfacial and strain energy such as grain growth and dynamic recrystallization, which results in microstructural complexity. In order to understand real fluid distribution in deep-seated rocks, we conducted an X-ray CT study of xenoliths from the uppermost mantle from various localities.

The mantle xenoliths samples investigated were from Ichinomegata (NE Japan), Eifel (W Gernamy), San Carlos (AZ, USA), Bullen Merri and Shadwell (Victoria, AU), Kilbourne Hole (New Mexico, USA), Longang-hu (NE China), Gi-rona (Spain), Lanzarote (Canary islands), and Moses Rocks (Uta, USA). The micro-focus X-ray CT imaging was performed using Comscantecno ScanXmate-D160TSS105 in Tohoku University Museum with a tube voltage of 100 – 130 kV and current of 90 – 120 mA. The voxel size was typically 43 – 73 μm^3. The 3-D image analysis was carried out with a software package Slice[1].

All the observed spinel lherzolite and Harzburgite xenoliths contained up to a few vol% of intergranular pores, indicating that the rocks were saturated with a free-fluid phase. The imaged pore fluids are typically polyhedral and tens – hundreds of micrometers in scale; this suggests that they were formed via coalescence of smaller pore fluids. The fluids are localized in interphase boundaries (between different mineral phases), while most of the monomineralic triple junctions lack pore fluids. All these characteristics are consistent with the results of grain-growth experiments in a fluid-bearing bimineralic system[2]; in other words, the role of interfacial energy anisotropy and grain growth are crucial in determining fluid distribution in nature. In the ellipsoid approximation, the 3-D shape of the intergranular fluids show deformed rugby-ball shape with aspect rations larger than those of the equilibrium fluid geometry determined by the dihedral angle[3]. The geometry, distribution and thus connectivity of fluids cannot be assessed simply from dihedral angles.

The results of CT imaging suggest that no pervasive grain-scale fluid interconnection is established in the uppermost mantle. To explain the observed low electrical resistivity in the mantle which does not undergo partial melting, concentration (localization) and interconnection of CHO fluids in a larger spacing, such as in meter-scale shear zones should be necessary. Given the observed geometry of the inter-granular fluids, their effects on Vp/Vs ration is limited.

It is important for the evolution of the Earth to understand the role of grain boundaries during melts/fluids migrations in mantle peridotites. There are, however, very limited numbers of studies on grain boundaris in natural samples, although many experimental and theoretical approaches have been carried out (e.g., Drury and Fitz Gerald, Geophys. Res. Lett., 1996; Hiraga et al., Nature, 2004).

We focus on nanoscale microstructures of crystal surface (grain boundary) in " nominally fresh " peridotite xenoliths from the San Carlos, USA, which is one of the most famous localities of peridotite xenolith in the world. Thin amorphous films along grain boundaries were already reported in some San Carlos xenoliths (Wirth, Contrib. Mineral. Petrol., 1996).

We recovered mineral grains with a selFrag at the Japan Agency for Marine-Earth Science and Technology (JAMSTEC) in order to minimize mechanical damages during mineral separations. We observed multiple grains of peridotite xenoliths using a high-resolution electron microscope (FE-SEM) at JAMSTEC.

Microstructures of crystal surface of these peridotite xenoliths are classified as follows. (1) over micron scale structures such as moth-eaten structures, vermicular structures, automorphic crystals and etch pits. (2) submicron scale structures. It is interesting to note that (2) submicron scale structures are frequently observed on (1) over micron scale structures. These textures suggest that microstructures were developed by several stages. We analysed on the surface of these textures using a micro-Raman and SEM-EDS techniques. We are also planning to perform transmission electron microscope, combined with chemical analyses in order to identify the surface materials that constrain P-T conditions and fluids for the formation of these textures.

Elemental transport under lower-middle crustal condition: example from hydration of basic schist, Sanbagawa belt, Japan

UNO, Masaoki[1*] ; NAKAMURA, Hitomi[2] ; IWAMORI, Hikaru[3]

[1]Graduate School of Environmental Studies, Tohoku University, [2]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [3]Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology

To constrain the behavior of geofluids under the lower to middle crustal conditions, hydration reactions and trace element and Sr-Nd-Pb isotopic compositions of basic schists in the Cretaceous Sanbagawa metamorphic belt, a typical regional metamorphic belt in the circum-Pacific orogeny, have been investigated based on the observations of thin-sections and outcrops. The basic schists have undergone significant hydration from 0.8 GPa, 550 ^{o}C to 0.3 GPa, 400 ^{o}C during decompression towards the surface at the final stage of metamorphism. High-field-strength and rare-earth element compositions of the basic schists, as well as the Sr-Nd-Pb isotopic ratios, are different among three mineral zones with different peak P-T metamorphic conditions; the basic schists in the low-grade chlorite zone shows N-MORB-like compositions whereas those in the higher-grades, garnet and oligoclase-biotite zones, show more enriched compositions (E-MORB-like). On the other hand, there is a common feature to all the metamorphic zones; the enrichment degree of some group of elements (e.g., large-ion lithophile elements) relative to high-field-strength and heavy-rare-earth elements is proportional to loss on ignition that approximately measures the bulk rock H_2O content. This correlation suggests that Li, B, K, Cr, Ni, Rb, Sr, Cs and Ba have been added to the basic schists during hydration. The addition of these elements amounts to as much as 60-80% of the bulk abundance, indicating that significant amounts of elements were transported via pervasive fluid flow, which overprinted the variation in the bulk rock compositions of the protolith. The estimated compositions of hydration fluid show high concentrations in large-ion lithophile elements, lead and light-rare-earth elements (10-100 times denser than primitive mantle, Fig. 1) and are similar to those of the slab-derived fluids[1] that induce arc volcanism. These elements (Cs, Rb, Ba, K, La, Ce and Pb) are thought to have been preferentially partitioned into the fluid when it was generated at depth. Such high concentrations indicate a high temperature origin of the hydration fluid, and are consistent with a model of hot slab subduction during exhumation of the Sanbagawa belt.

Progress of serpentinization in the mantle wedge and its effect on the redox state

KOGISO, Tetsu[1*] ; MIYOSHI, Akane[2]

[1]Human Environ. Stds., Kyoto Univ., [2]JX Nippon Oil & Energy Corporation

Serpentinization of peridotite in the mantle is a key process that significantly changes the physical properties of the mantle. Serpentinization also produces hydrogen, which is essential not only for the activity of microbial systems in hydrothermal fields on the seafloor, but also for controlling the oxidation state of the mantle in subduction zones. Hydrogen is generated along with the formation of magnetite during serpentinization. However, there still remains controversy about what factors promote the mineralogical reactions responsible for magnetite formation during serpentinization in natural ultramafic rocks. Recent petrologic studies have proposed that serpentinization reactions proceed via a two-stage process involving the early formation of serpentine and brucite and subsequent magnetite formation. Many studies proposed that magnetite forms by the break down of ferrous brucite promoted by the addition of aqueous silica, but others proposed that magnetite forms by the breakdown of ferrous serpentine which releases silica component. To solve this controversy, we examined a number of variably serpentinized harzburgite and dunite samples taken from the Iwanaidake ultrama?c body in Kamuikotan belt, Japan (Miyoshi et al. 2014). Petrographic observations of these samples revealed that successive changes in textures, mineral chemistry, whole-rock H_2O contents, and magnetic susceptibility with the progress of serpentinization of harzburgite involved two stages: replacement of olivine by serpentine and brucite, and subsequent formation of magnetite along with more-magnesian serpentine and brucite. The later reactions occurred concurrently with serpentinization of orthopyroxene, which supplied the silica component. In serpentinized dunite, which doesn't contain orthopyroxene, serpentinization involved replacement of olivine by serpentine and brucite, and the fraction of magnetite did not increase with the progress of serpentinization. These observations, and the fact that the Iwanaidake ultramafic body originated from the forearc mantle of the Northeast Japan arc, suggest that the silica supply from serpentinization of orthopyroxene is an essential factor for the formation of magnetite during serpentinization in mantle wedge.

Our observations imply that serpentinization in the mantle wedge of subduction zone produces H_2 along with magnetite if sufficient amounts of silica component are supplied from subducting slab, which will probably occur because dehydration in subducted sediments can supply silica-rich fluids. Since H_2 is expected to exist as immiscible hydrogen-rich gas phases that coexist with H_2O fluids in normal subduction zone conditions, it will be rapidly migrate upwards owing to its very low density. Then the remaining serpentinites will become oxidized. Such oxidation associated with serpentinization would occur in the shallow part of the wedge corner where temperatures are lower than ~600 ℃, but the oxidized (magnetite-bearing) serpentinite will be dragged downwards in the mantle wedge. Thus serpentinization reactions can be one of the main processes to increase the oxygen fugacity of the mantle wedge. On the other hand, the H_2 gas removed from the wedge corner will produce highly reduced fluid phases, which may result in reducing the shallowest part of the forearc mantle and the lower part of the forearc crust. This could be the cause of rare presence of metal phases in subarc peridotite.

Evolution of porosity structures in a fracture during quartz vein formation

YAMADA, Ryo[1*] ; OKAMOTO, Atsushi[1] ; SAISHU, Hanae[1] ; NAKAMURA, Michihiko[2] ; OKUMURA, Satoshi[2] ; SASAKI, Osamu[3] ; TSUCHIYA, Noriyoshi[1]

[1]Tohoku university, [2]Tohoku university, [3]The Tohoku university museum

Ubiquitous occurrences of quartz veins suggest that dissolution/precipitation of silica provides significant effects on the hydrological and mechanical properties within the crust. For example, a model has been proposed that fracture sealing processes control the change of pore fluid pressure and thus earthquake cycle. Previous studies on natural quartz veins have focused on estimates of P-T conditions, stress and strain fields and fluid compositions; however, details of dynamics of fluid flow and how fractures are sealed during vein formation are still unclear. In this study, we synthesized quartz veins by the hydrothermal experiments, and observed the aperture structures by using X-ray CT to clarify how aperture structures evolve during vein formation.

We conducted the hydrothermal flow-through experiments for quartz precipitation from Si-supersaturated solutions under controlled high temperature and high pressure condition. The experimental apparatus consists of two vessels for preparation of the Si-supersaturated solution and for precipitation, respectively. The precipitation vessel has double-structure : the main flow path was the inner alumina tube (diameter=4mm), and the outer SUS tube was filled with static solutions. The advantage of this system is that we can take out the non-destructive sample for the X-ray CT analyses. We conducted two types experiments: first one is precipitation in porous media with alumina balls, the second one is rock slice as analog of a fracture.

In the alumina-ball experiments, we carried out the precipitation experiment at supercritical (430C, 30MPa) and vapor condition (370C, 20MPa). In both experiments, the significant silica precipitation within few days, but showed contrasting porosity structures. Under supercritical condition, amorphous silica was predominantly formed with covering the surfaces of the alumina balls and alumina tube, and discrete quartz crystal (50 um) within the amorphous silica layers. The porosity (ϕ) gradually decreases with minimal porosity (ϕ = 0.4) at $\sim$ 38mm from the inlet. In contrast, under vapor condition, fine-grained quartz grains (0.1-1 um) were directly nucleated in solutions using surface of vapor, and immediately settled on the bottom. The porosity rapidly decreases from 18 mm (ϕ = 0.8) to 25 mm (ϕ <0.1) from the inlet. These results suggest that a depressurization of crustal fluids related to fault dilation by earthquakes would cause a formation of fine-grained silica particles, and their mineralogy and transport/deposition properties strongly depend on properties water.

In the experiment with rock slits, we evaluated the effect of rock substrate (amount and distribution quartz in the fracture wall). The P-T conditions and solution chemistry are similar to the previous experiments, but we used granite core with a slit ($\sim$ 300 um). The mineralogy and aperture structures changes systematically along the fluid flow path. From the inlet to 35 mm of fracture, nucleation of quartz and other silica polymorphs predominantly occurred, regardless of vein wall minerals. From >35mm low Si concentration, silica precipitates occurred as epitaxial overgrowth from quartz crystal. The wavelength of aperture structures is controlled by distribution and grain size of quartz of the host granite. Accordingly, fractures are not sealed homogeneously, but complex flow pathways are evolved during vein formation. Such a variation in the precipitation mechanism and porosity structures during quartz vein formation may affect the evolutions of permeability and strength of rock fractures in the Earth's crust.

High precision in situ Pb isotope analysis of galena by LAL-ICPMS technique

WAKAKI, Shigeyuki[1*] ; TANIMIZU, Masaharu[1]

[1]Kochi Insititute for Core Sample Research, JAMSTEC

Radiogenic Nd and Pb isotopic compositions of the fluids originated from subdcting Pacific and Philippine Sea plates have been characterized from isotopic trends observed among arctic volcanic rocks (Nakamura et al., 2008). Origin and evolution of the fluids that produced hydrothermal ore deposits may now be investigated by radiogenic isotopic compositions of ore deposits. In this study, we analyzed the micro scale isotopic variation of Pb in a hydrothermal galena to shed light on the macro scale dynamics of the fluids. To investigate the possibly small degree of isotopic changes within a galena sample, both high spatial resolution and high precision are required for the isotopic analysis. We employed the combination of laser ablation in liquid (LAL) micro sampling technique (Okabayashi and Hirata, 2011) and solution-based Pb isotopic analysis by MC-ICPMS technique to meet the analytical requirements. In the LAL micro sampling, laser-ablated sample particles are trapped in the liquid that placed above the sampling area. The trapped samples are then dissolved and introduced to the ICPMS as a solution. The advantage of the combined LAL-ICPMS technique over laser ablation (LA) ICPMS technique is the stable ion signals due to solution form, which allows high-precision isotope ratio measurement.

Sample analyzed in this study was a hydrothermal galena from Hosokura mine (Miyagi, Japan). A microscopic texture of the sample was observed in detail with FE-SEM-EDS system (JEOL JSM-6500F) prior to the isotopic analysis. A fs laser (IFRIT, Cyber Laser, Japan) with a wavelength of 780 nm (˜200 fs pulse width) was used for the LAL micro sampling. Care was taken to avoid sampling of grain boundaries and inclusions. Typical special resolution was 150 micron in diameter and 30 micron in depth. The laser-sampled PbS (300-400ng Pb) trapped in Milli-Q water was dissolved in conc. HNO3, and adjusted to 200 ng/mL Pb solution in 0.15 M HNO3 for Pb isotopic analysis. Pb isotope ratios were determined with a MC-ICPMS, Neptune (Thermo Instruments, Bremen, Germany). An isotopic reference material of Tl (NIST-SRM 997) was added to the final sample solutions for the correction of mass discrimination of Pb in the instrument to have a concentration of 20 ppb Tl.

Galena occurs as discrete layers of ca. 1cm width in between layered CaF_2 as well as sub mm-sized inclusion within thick CaF_2 layer. Galena inclusion and layers were numbered from 1 to 3 according to its precipitation order. Grain size of the galena in each of the layer is several hundred microns to several millimeters. Euhedral quartz with a size of 10-100 micron occurs along the grain boundary of galena and as an inclusion within galena grains.

Small but significant Pb isotopic variation of sub-permil order was observed among and within the 3 galena layers. The analyzed samples clearly form a linear trend in the $^{208}Pb/^{207}Pb$ vs. $^{206}Pb/^{207}Pb$ diagram. The observed Pb isotopic trend indicates that the Pb isotopic composition of the fluid that produced the galena has slightly changed during galena precipitation. The Pb isotopic composition of the galena is consistent with mixing of a sediment component of the Pacific plate (Nakamura et al., 2008) with a deep fluid derived from Pacific Ocean plate (Nakamura et al., 2008) and/or the DMM. With the high-precision isotopic analysis as demonstrated in this study, LAL-ICPMS may have an important contribution to high-spatial-resolution geochemical studies in the future.

Origin of saline waters distributed along the Median Tectonic Line in southwest Japan

AMITA, Kazuhiro[1*] ; OHSAWA, Shinji[2] ; NISHIMURA, Koshi[3] ; YAMADA, Makoto[4] ; MISHIMA, Taketoshi[2] ; KAZAHAYA, Kohei[5] ; MORIKAWA, Noritoshi[5] ; HIRAJIMA, Takao[6]

[1]Department of Earth Science & Technology Faculty of Engineering and Resource Science Akita Universit, [2]Institute for Geothermal Sciences, Graduate School of Science, Kyoto University, [3]Faculty of Economics, Toyo University, [4]Research Institute for Humanity and Nature, [5]Geological Survey of Japan, AIST, [6]Department of Geology and Mineralogy, Graduate School of Science, Kyoto University

To identify of metamorphic dehydrated fluid as source fluid of hot spring water, we conducted chemical and isotopic analyses of water and accompanied gas samples collected from hot-spring wells along the Median Tectonic Line (MTL) in the forearc region of the southwestern part of Japan. As a result, we found hot spring waters having anomalous dD and $d^{18}O$ compositions as compared with modern seawater and shallow groundwater in Wakayama and Shikoku regions. Judging from data in relative B-Li-Cl composition and He isotopic systematics, the source fluid of the hot springs in Shikoku could be identified to be one of diagenetic fluids. On the other hand, the source fluid of the hot springs of Wakayama had different B-Li-Cl composition and higher 3He/4He ratio in comparison with diagenetic dehydrated fluids and then the fluid was thought to be originated from metamorphic dehydrated fluid as well as Oita plain. There was another striking contrast between the source fluid of Wakayama and Oita and that of Shikoku and Miyazaki; accompanied gases by the former were rich in CO_2, whereas those with the latter were rich in CH_4, and CO_2 in the accompanied gases of Wakayama and Oita is mostly derived from marine carbonate like volcanic gases in subduction zones. Moreover, the Li-B-Cl compositions of them showed transitive values between the relative composition of diagenetic fluids and those of volcanic thermal waters. Consequently, the source fluid of hot springs in Wakayama and Oita was likely to be dehydrated metamorphic fluids released from the subducting Philippine-Sea plate.

Distribution of the helium isotope ratios in northeast Japan in terms of geological setting

HORIGUCHI, Keika[1*] ; KAZAHAYA, Kohei[1] ; TSUKAMOTO, Hitoshi[1] ; MORIKAWA, Noritoshi[1] ; SATO, Tsutomu[1] ; OHWADA, Michiko[1] ; NAKAMA, Atsuko[1]

[1]Geological Survey of Japan, AIST

The distribution of slab fluid defined by high Li/Cl ratios conforms the area of ”hot fingers”(Tamura et al., 2002) in Northeast Japan (Kazahaya et al., submitted). Conversely, the high $^{3}He/^{4}He$ ratios distribute wider and do not match with slab-derived fluids indicating that some of the mantle-derived helium would not be transported with magmas or slab fluids but directly upwells as mantle-derived fluid. The $^{3}He/^{4}He$ ratios vary along the volcanic front showing an areal contrast; such as a low-ratio-area close to volcanoes are observed in the central part of Tohoku. We propose here an extended helium upwell model which can explain the spatial variation of $^{3}He/^{4}He$ ratios with the following concept; 1) The most important constraint for mantle helium upwelling is the crustal structure divided by tectonic lines; Hatagawa Tectonic Line (HTL) divides the Kitakami and Abukuma belts. Ryoke belt and north part of Abukuma belt is torn apart by number of faulting events. The rest of parts, Abukuma granitic province and Kitakami province form very large stable blocks which might prohibit helium to upwell from mantle. 2) A view from U-Th content in the crust is im-portant to understand the flat distribution of mantle helium in back-arc region; Low U-Th crust in the back-arc with less crustal ^{4}He production is favora-ble to explain the flat and high $^{3}He/^{4}He$ signature, such as oceanic crust might have.Tanakura Tectonic Line (TTL) divides the thick crust of con-tinental margin (sedimentary prism and granite) with Ryoke belt.

The Li-Cl-Br systematics of saline groundwater: A new indicator for slab fluid

KAZAHAYA, Kohei[1*] ; TAKAHASHI, Masaaki[1] ; IWAMORI, Hikaru[2]

[1]Geological Survey of Japan, AIST, [2]Geochemical Evolution Research Program, Japan Agency for Marine-Earth Science and Technology

In this study, we propose Br/Cl ratio as a new indicator for slab-derived fluids, which is useful to distinguish their sources between pore water and hydrous minerals in subducting slab. The areal distribution of slab-derived fluids and their sources using Li/Cl and Br/Cl as geochemical evidences will provide a view for water circulation in subduction zones.

Subducting slab contains waters (originally seawater) as pore water and many kinds of hydrous minerals. Hydrous minerals such as opal, clay or mica will decompose to release water during subsiding, and pore water will be released by compaction. Even though such complex process occurs, behavior of halogen ions in the subducting slab may be simple because they are always enriched in aqueous phase (pore water) and the rest are in minerals as a replacement of OH. Some metamorphic fluids in wedge mantle peridotite with Br-enriched signature have been observed and were indicated to be from pore water in the slab. The mineral dehydration process is supposed to be responsible for Br-depletion in slab-derived aqueous fluid. Therefore, halogens are potentially good indicators concerning with the water behavior in subduction processes.

The higher Br/Cl ratios ($>$0.0035 in wt.) have been observed in fossil seawater and oil field brines due to the addition of Br from organic matters. The very low Br/Cl waters ($<$0.0025 in wt.) have feature of ^{18}O-shift to the slab (magmatic) fluid end member, which is quite lower than that in seawater (Br/Cl = 0.0034 in wt.), indicating that these waters originate from dehydration of the slab.

Origin of U-Th disequilibrium in subduction zone volcanic rocks

YOKOYAMA, Tetsuya[1*] ; IKEMOTO, Akihiko[1] ; IWAMORI, Hikaru[2] ; UEKI, Kenta[1]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [2]JAMSTEC

Subduction zone magmatism is induced by the addition of slab derived fluids to the mantle wedge [1]. Chemical compositions of subduction zone volcanic rocks are largely controlled by the chemical and physical properties of the slab fluid. The nature of slab fluids have been extensively studied by geochemical approach utilizing trace element abundances and isotope compositions in arc basalts [2]. U-series disequilibrim in arc volcanic rocks is a useful tracer to understand the origin of arc magmas as well as the timescales of fluid/melt migration in subduction zones. However, detail of the process that producing ^{238}U-^{230}Th disequilibrium in primary melts in the mantle wedge is still poorly constrained.

In this study, we determined ^{238}U-^{230}Th disequilibrium in volcanic rocks from the Northeast Japan Arc (Iwate, Akitakoma, Yakeyama, Hachimantai, and Kampu). In addition, we performed a numerical simulation that reproduced (^{238}U/^{232}Th) and (^{230}Th/^{232}Th) ratios in primary melts in a subduction zone, by simultaneously calculating mantle dynamics, hydro phase reactions and trace elements transport. To discuss the origin of U-Th disequilibrium in arc volcanic rocks, the new data and previously published U-Th data around Japan were evaluated based on the result of the numerical simulation. The numerical simulation performed in this study

Most of arc volcanic rocks possess ^{238}U-^{230}Th disequilibrium with 238U excesses, suggesting the addition to the mantle wedge of slab fluid enriched in U relative to Th. The feature of ^{238}U enrichment is well reproduced by the numerical simulation. Interestingly, the simulation produced two positive trends in the U-Th diagram; the shallow trend matches data from the Izu-Mariana arc, while the steep slope is consistent with data from the Kamchatka arc. This strongly suggests that the positive trend in the U-Th diagram for a single arc samples simply reflects the variation of (^{238}U/^{232}Th) and (^{230}Th/^{232}Th) ratios in primary melts produced in the mantle wedge, and the slope does not have any age significance. Thus, as discussed in [3], the decoupling of U-Th and Th-Ra ages for arc samples would be explained by assuming that the slab derived fluid have (^{230}Th/^{232}Th) ratios higher than the mantle wedge composition.

Although the NEJ frontal-arc lavas (Iwate) possess ^{238}U-^{230}Th disequilibrium with ^{238}U excesses, the extent of 238U enrichment is moderate ($<$10%) compared to the other frontal-arc samples. In addition, Iwate lavas have relatively low (^{230}Th/^{232}Th) ratios that cannot be explained by the numerical simulation. This implies that the (^{230}Th/^{232}Th) in mantle wedge beneath Iwate volcano is lower than that in the depleted MORB mantle (DMM), due presumably to ancient mantle metasomatism by Th-enriched fluids derived from sediments.

In contrast to the frontal arc samples, the extent of ^{238}U enrichment in the NEJ samples decreases as the slab depth increases, and the rear-arc lavas (Kampu) show 230Th enrichments relative to ^{238}U ($<$10%). This generally reflects gradual decrease of the amount of slab derived fluid mixed into the wedge mantle. The ^{230}Th excesses in rear-arc lavas would be produced by the melting of garnet-bearing upwelling mantle, as reproduced by the simulation. However, our data for Kampu show 230Th excesses with an extremely low (^{230}Th/^{232}Th) ratio (˜0.8) that plots outside the simulation data. This is explained by assuming the existence of metasomatised mantle beneath the NE Japan as discussed above, although the possibility of direct addition of Th-enriched fluid to the DMM-like mantle cannot be ruled out for the generation of rear-arc magmas.

Water transport coupled dynamically with a plate-mantle convection system involving a shallow to deep subduction zone

NAKAKUKI, Tomoeki[1*] ; KANEKO, Takeo[1] ; NAKAO, Atsushi[2] ; IWAMORI, Hikaru[3]

[1]Dept. Earth and Planetary Systems Science, Hiroshima Univ., [2]Dept. Earth and Planetary Sciences, Tokyo Inst. Technology, [3]Geochemical Evolution Research Program, JAMSTEC

Numerical study for water transport under a volcanic arc revealed dynamics of the water processes inducing melt generation (Iwamori, 1998; 2007). Back-arc and intra-plate volcanisms also indicate water migration from a deeper section of the subduction zone. Aiming to understand geodynamical processes of water derived and transported from the subducted slab in the deep subduction zone, we developed a numerical model of water transport coupled dynamically with plate-mantle convection system with a whole mantle scale. We here focus on the mechanism of dehydration from stagnating or penetrating slab and water transport from the mantle transition zone (MTZ). We also consider water transport to deeper mantle and the effects on the global distribution of water-compatible elements (Iwamori and Nakamura, 2012).

We assume that a viscous fluid in a 2-D rectangular box with an extended Boussinesq approximation represents the mantle convection system with integrated lithospheric plates (Tagawa et al, 2007). We incorporate water transport and hydrous mineral phase diagram (Iwamori, 1998; 2007) into the numerical plate-mantle model. We assume that the water dehydrated from water-saturated minerals migrates upward with porous flow that is much faster than mantle flow. In our model, the emitted water is instantaneously transported only to the upward direction. We introduce reduction of the density and the viscosity due to the hydration into the density and rheology model according to experimental study (karato and Jung, 2003). We also consider viscous weakening of serpentine or chlorite that is important for water transport in shallow subduction zone [6]. A numerical method developed by Tagawa et al. (2007) is used to solve momentum and energy conservation equations for the mantle convection. To solve an equation for water transport advected by the mantle flow in which the diffusion term is negligible, a Marker-And-Cell (MAC) method is employed to avoid artificial diffusion.

A serpentine layer generated by dehydration of the oceanic crust plays a key role to control water transport by the subducted slab shallower than about 150 km (Iwamori, 1998; 2007; Horiuchi, 2013). To continuously generate this layer, coupling between the serpentine layer and the plate boundary fault is essential. After dehydration of serpentine, nominally anhydrous minerals (NAMs) (Iwamori, 1998; 2007) are a main veneer of the water. In this stage, water capacity of NAMs, which depends on the grain boundary storage as well as that of the hydrous minerals, is the primary factor to control the amount of transported water. This is not so large as about 0.4 wt. % to maintain water-filled region under the arc. The water is carried without dehydration above the 660 km boundary. If the water capacity in the lower mantle is as large as that of NAMs in the mantle shallower than 410 km (˜0.2 wt. %), the water is entirely transported to the lower mantle. When the lower mantle water capacity is lower than that, the water is expelled at the post-spinel phase transition. While the water ascends with the porous flow, the medium rocks descend with asthenospheric flow dragged by the downwelling slab. The repetition of these processes broadens the hydrous layer at the 660 km boundary. A thin water-saturated layer is formed at the 660 km boundary around the penetrating slab. Because of the buoyancy, this becomes unstable so that hydrous plumes are generated. On the contrary to this, the hydrous plume was not formed from the hydrous NAMs layer over the stagnant slab. At the 410 km boundary, the water is ejected from the hydrous plume as the olivine phase minerals can bear the water much less than MTZ minerals. The ejected water rises with porous flow till the emission is completed. The hydrous plumes fill the water within the mantle wedge from the edge to the 500 to 1000 km distant back-arc area, and those erode to thin the overriding lithosphere.

An overview of seismic coupling and crustal deformation on the basis of geofluid and shallow slow earthquakes

ARIYOSHI, Keisuke[1*] ; MATSUZAWA, Toru[2] ; HINO, Ryota[3] ; HASEGAWA, Akira[2] ; HORI, Takane[1] ; NAKATA, Ryoko[1] ; KANEDA, Yoshiyuki[1]

[1]Japan Agency for Marine-Earth Science and Technology (JAMSTEC), [2]Research Center for Prediction of Earthquakes and Volcanic Eruptions, Tohoku University, [3]International Research Institute of Disaster Science, Tohoku University

Due to the use of broadband seafloor seismometers near the trench and dense inland networks of highly sensi-tive seismic stations, very low-frequency events (VLFEs) have been observed in the shallow transition zone near the trench of subduction plate boundaries as well as the deep one. Following the 2004 Sumatra Earthquake, the Japanese government has established the Dense Oceanfloor Network system for Earthquakes and Tsunamis (DONET) along the Nankai Trough. In the Tonankai district, M8-class megathrust earthquakes will probably occur in the near future; DONET-I has now operated since August 2011. In this study, we perform numerical simulations of multiscale earthquake cycles, including a megathrust earthquake and VLFEs, on a 3-D subduction plate boundary, in order to understand the change in VLFE activity after megathrust earthquakes and hydraulic pressure gauge data.

In our simulation, the motion equation for a subduction plate boundary is described by a quasi-dynamic equi-librium between the shear stress (due to reverse dip-slip on the discretized faults) and the frictional stress based on a rate- and state-dependent friction (RSF) law. To perform multiscale earthquake cycle simulations, we as-sumed single large asperity and numerous small asperities arranged along the strike direction, where the large asperity generates megathrust earthquakes and a chain reaction of numerous small asperities generate a migra-tion of slow earthquakes along the strike direction.

From our simulation results, we concluded as follows: (i) For a megathrust earthquake in which the coseismic slip penetrates to the trench, plate coupling in the postseismic stage will be strong in the region from the central part of the source region to the shallower part toward the trench, which will cause the shallow VLF after-events to be quiescent or to occur infrequently in isolation. On the outer rim, shallow VLF after-events will be reac-tivated earlier than they will be in the center because of weak plate coupling. (ii) Since leveling change due to slow earthquakes at DONET is expected to be local and incoherent in the same node because of the short dis-tance between their sources and the (DONET) receiver, it is useful to remove an average from original data in the same node in order to extract a signal.

Three-dimensional seismic attenuation structure beneath Kyusyu

SAITA, Hiroto[1*] ; NAKAJIMA, Junichi[1]

[1]Tohoku University

The Philippine Sea (PHS) plate is subducting beneath Kyusyu and a clear volcanic front is formed through the middle of the arc. Furthermore, there is a volcanic gap between Aso and Kirishima volcanos. Seismic attenuation provides additional insights into subduction-zone dynamics, because higher-temperature environments or the existence of fluids may have different effects on seismic attenuation from on seismic velocity. Therefore the estimate of seismic attenuation is very important to understand arc magmatism and mantle dynamics in subduction zone. This study estimates seismic attenuation structure beneath Kyushu using a large number of high-quality waveform data. Data and method

We used 5195 earthquakes that occurred from April 2003 to December 2013 by applying the method of Nakajima et al. [2013] to waveform data recorded at a nation-wide seismograph network in Japan. We determined the corner frequency of earthquakes by using the spectral ratio method of S-coda waves. Then, we determined a whole-path attenuation term (t∗), site-amplification factors and spectrum level simultaneously by a joint inversion. Finally, these t∗values (N= 75207) were inverted to obtain three-dimensional attenuation structure.

The obtained results show several interesting feature. First, the subducting PHS slab is imaged as a low attenuation zone. Second, an inclined high-attenuation zone that is interpreted as mantle upwelling flow is served in the back-arc mantle. However, the inclined high-attenuation zone is less developed in the volcanic gap between Aso and Kirishima volcanos. This correspondence suggests the important role of mantle-wedge processes in the genesis of arc magmas.

The Kyushu island in the Southwest Japan Arc has many Quaternary active volcanoes in relation to the subduction of the Philippine Sea Plate (PSP). The volcanoes exist along the volcanic front of N30^{o}E-S30^{o}W, whereas the volcanoes are densely located in the northern and southern regions of the island. The Kyushu island has a non-volcanic region in the central region of the island between the two volcanic regions. We performed three-dimensional (3D) inversion analyses to obtain a litospheric-scale electrical resistivity model beneath the entire Kyushu island using the Network-Magnetotelluric (MT) data. The electrical resistivity model, however, has a limited resolution in a horizontal direction because of the sparse Network-MT data in several areas of Kyushu. Thus data of geomagnetic variations are used anew to improve the uncertainty of the electrical resistivity structure in a horizontal direction. Data of geomagnetic variations were obtained at the entire Kyushu island and several islands off the western coast of Kyushu from 1980's to 1990's [e.g., Handa et al., 1992; Shimoizumi et al., 1997; Munekane et al., 1997]. In this study, accessible data of geomagnetic variations around Kyushu are compiled. Geomagnetic transfer functions for the data of geomagnetic variations in the northern Kyushu are re-estimated using the BIRRP code [Chave and Thomson, 2004] in order to enhance the quality of the transfer functions and their error estimation. The transfer functions at about 150 sites, which are 12 periods between 20 and 960 s, are obtained with improving quality at the entire Kyushu island. The induction vector representation [Parkinson, 1962] is generally used to delineate the lateral variation of electrical resistivity structure because the vectors point to current concentration in conductive anomalies. Induction vectors determined using the improved transfer functions have the following specific features. First, the vectors on the northern and central Kyushu do not point to the Pacific ocean off the eastern coast of Kyushu but point to the East China Sea of the shallow sea off the western coast of Kyushu. Second, the induction vectors on the southern Kyushu point to the Pacific ocean in the eastern part and point to the East China Sea in the western part at short period, whereas the vectors are arranged along a direction parallel to a direction of the coast line at longer period ($>$300 s). These results are consistent with the previous work [Handa et al., 1992; Shimoizumi et al., 1997; Munekane, 2000]. It is considered that the complex behavior of the induction vectors are influenced by conditions of the Earth's mantle relating to the igneous activities. Then we applied three-dimensional (3D) inversion analyses for geomagnetic transfer functions using the WSINV3DMT inversion code [Siripunvaraporn and Egbert, 2009]. The electrical resistivity of a starting model is based on values of the 3D electrical resistivity model estimated by using the Network-MT data. In this presentation, we will mainly describe features of the 3D electrical resistivity structure using the geomagnetic transfer functions and them of the 3D electrical resistivity structure using only the Network-MT data [Hata et al., 2013].

Influence of confining and pore-fluid pressures on velocity and conductivity of a fluid-saturated rock

SEMA, Fumie[1*] ; MAKIMURA, Miho[1] ; HIGUCHI, Akiyoshi[1] ; WATANABE, Tohru[1]

[1]Department of Earth Sciences, University of Toyama

Pore-fluid pressure in seismogenic zones can play a key role in the occurrence of an earthquake (e.g., Sibson, 2009). Its evaluation via geophysical observation can lead to a good understanding of seismic activities. It is critical to understand how pore-fluid pressure affects seismic velocity and electrical conductivity. We have studied the influence of pore-fluid pressure on elastic wave velocity and electrical conductivity of water-saturated rocks.

Measurements have been made using a 200 MPa hydrostatic pressure vessel, in which confining and pore-fluid pressures can be separately controlled. An aqueous pore-fluid is electrically insulated from the metal work by using a specially designed device (Watanabe and Higuchi, 2013). Elastic wave velocity was measured with the pulse transmission technique (PZT transducers, f=2 MHz), and electrical conductivity the four-electrode method (Ag-AgCl electrodes, f=100 mHz-100 kHz) to minimize the influence of polarization on electrodes.

Berea sandstone (OH, USA) was used for its high porosity (19.1%) and permeability (~10^{-13} m^2). It is mainly composed of subangular quartz grains. Microstructural examinations show clay minerals (e.g., kaolinite) and carbonates (e.g., calcite) fill many gaps between quartz grains. A small amount of feldspar grains are also present. The grain size is 100-200 micrometers. Cylindrical samples have dimensions of 25 mm in diameter and 30 mm in length. Their axes are perpendicular to sedimentation bed. Elastic wave velocity is slightly higher in the direction perpendicular to the axis than in that parallel to the axis.

Confining and pore-fluid pressures work in opposite ways. Increasing confining pressure closes pores, while increasing pore-fluid pressure opens them. For a given pore-fluid pressure, both compressional and shear velocities increase with increasing confining pressure, while electrical conductivity decreases. When confining pressure is fixed, velocity decreases with increasing pore-fluid pressure while conductivity increases. The closure and opening of pores can explain observed changes of velocity and conductivity.

Effective confining pressure is defined by the difference between confining and pore-fluid pressures. Velocity increases with increasing effective confining pressure, while conductivity decreases. However, neither velocity nor conductivity is unique function of the effective confining pressure. For a given effective confining pressure, conductivity significantly increases with increasing confining pressure. Velocity also increases with increasing confining pressure, though it is not so significant. Increasing pore-fluid pressure can compress clay minerals to increase pore space. This might explain observed conductivity change.

Keywords: pore-fluid pressure, seismic velocity, electrical conductivity, geofluid

A study on grain boundary brine in halite rocks using electrical conductivity measurements

WATANABE, Tohru[1*] ; KITANO, Motoki[1]

[1]Graduate school of science and engineering, University of Toyama

Intercrystalline fluid can significantly affect rheological and transport properties of rocks. Its influences are strongly dependent on the style of distribution. When a fluid fills grain boundaries in a rock, it will significantly reduce the strength of the rock. The fluid distribution is mainly controlled by the dihedral angle between solid and fluid phases. The grain boundary wetting is expected only when the dihedral angle is 0o. The dihedral angle of the halite-water system was studied through microstructural analyses of quenched materials (Lewis and Holness, 1996). The dihedral angle is 50˜70o at P<200 MPa and T<300 oC. However, deformation experiments (e.g., Watanabe and Peach, 2002) and cryo-SEM observations (e.g., Schenk et al., 2006) on halite rocks have indicated the coexistence of grain boundary brine with a positive dihedral angle. In order to understand the nature of grain boundary brine, we have conducted electrical impedance measurements on synthetic wet halite rocks over a wide range of pressure and temperature.

Wet halite rock samples (9 mm diameter and 6 mm long) are prepared by cold-pressing (P=140 MPa, 40 min.) of wet NaCl powder and annealing (T=180oC, P=180 MPa, 160 hours). Grains are polygonal and equidimensional with a mean diameter of 50-100 ?m. The porosity is less than 1 %. The volume fraction of brine is estimated to be 11.1% by the thermo gravimetric analysis. Microstructural observation shows that most of brine is enclosed inside halite grains. Electrical impedance is measured in the axial direction of a sample by a lock-in-amplifier (SRS, SR830) with a current amplifier (SRS, SR570). The cylindrical surface of a sample is weakly dried and coated with RTV rubber to suppress the contribution of surface conduction. A conventional externally heated, cold-seal vessel (pressure medium: silicone oil) is used to control pressure and temperature.

Electrical conductivity of wet halite rocks is higher than that of NaCl by orders of magnitude even at the conditions of the dihedral angle larger than 60 degrees. The conduction through brine dominates the bulk conduction. This is also supported by the quick conductivity change in response to the change in pressure. Brine is interconnected over a whole range of pressure and temperature.

No remarkable change in conductivity is observed around the condition of the dihedral angle of 60 degrees. Although the interconnection of triple-junction tubes might drastically change at the dihedral angle of 60 degrees, its influence on the bulk conductivity is masked by more conductive paths. A triple-junction tube is so stiff that it cannot give observed conductivity changes in response to changes in pressure. The dominant conduction paths are not triple-junction tubes. Grain boundary brine must be the dominant conduction paths.

Electrical conductivity decreases with increasing pressure. Larger change is observed for lower temperatures. A simple model of fluid tube with elliptical cross-section shows that the thickness of a fluid tube decreases by less than 10%. The observed large change in conductivity suggests that the conductivity of brine is strongly dependent on the fluid thickness. When the thickness is comparable to the molecular size, the mobility of ions must be sensitive to the thickness. The observed large change in conductivity might be caused by the decrease in ionic mobility.

Estimation of the maximum burial depth of siltstones from the Kazusa Group by laboratory experiments

TAMURA, Yukie[1] ; MARUMO, Haruna[2] ; MITSUHASHI, Shunsuke[1] ; UEHARA, Shin-ichi[1*]

[1]Faculty of Science, Toho University, [2]Graduate School of Science, Toho University

To evaluate maximum burial depth of sedimentary formations is important for many topics in earth science and engineering such as estimating uplift and erosion of sedimentary basins. As a one of effective methods of the evaluation, a laboratory-based method for determining the maximum effective stress have been proposed. This method is based on a conventional method to evaluate preconsolidation stress (maximum effective stress experienced) of soil. However, this method cannot be necessarily applied to sedimentary rocks in simple ways, because sedimentary rocks have experienced not only mechanical compaction but also other processes such as cementation between grains, which should affect the mechanical properties of the rock. Thus applicability of this method to sedimentary rocks should be examined for several sedimentary basins. We performed laboratory experiments to measure porosity of siltstone specimens collected from several formations of the Kazusa Group, Boso peninsula, Japan, and tried to estimate the maximum burial depth based the results. We then compared the results with differences of burial depth ($\Delta Depth$) among locations of collecting samples which were estimated from geological setting, and examined the applicability of this method for estimation of the maximum burial depth in this site.

We collected rock blocks from Umegase (UMG), Otadai (OTD), Kiwada (KWD), Ohara (OHR), and Katsuura (KTR) Formations (in the descending order of stratigraphic horizon), and prepared cylindrical specimens of approximately 40 mm in diameter and 30 mm in length from these blocks. The porosity of these specimens was measured under different confining pressure (up to 35 MPa) and constant pore pressure (1 MPa) by using an intra-vessel deformation fluid-flow apparatus at Toho University. We used water as a pore fluid, and the measurements were performed at room temperature. Porosity under each effective pressure (the difference between confining pressure and pore pressure) was estimated by measuring volume of water drained from a specimen when confining pressure was loaded. The relation between measured porosity and effective pressure could be bilinear in log?log scale. The maximum effective stress experienced ($P_{e,B}$) of the tested rocks was determined from the intersection point of the two straight lines of the compaction curve. The maximum burial depth (D_{max}) was obtained by $D_{max} = P_{e,B} / [(\rho_r - \rho_w)g]$, where ρ_r, ρ_w and g are density of rock, water and gravity acceleration, respectively.

In the case of UMG, OTD and KTR, porosities decrease as the burial depth increases. Porosities of OHR and KWD, however, were relatively high although their burial depth is relatively large. There was a linear correlation between D_{max} and $\Delta Depth$ except for OHR, but the slope of the relationship was less than one (approximately 0.27). Therefore, further investigation is necessary to examine the applicability of this methods to this site. $P_{e,B}$ of OHR was less than that of other specimens, which supports the possibility that pore pressure in this formation was approximately 5 to 12 MPa higher than hydrostatic conditions.

Experimental constraints on the serpentinization rate under the antigorite-stable P-T condition

NAKATANI, Takayuki[1*] ; NAKAMURA, Michihiko[1]

[1]Earth and Planet Materials Sci., Tohoku Univ.

Water transport into the Earth's interior can be limited by the rate of serpentinization reaction proceeding at slow spreading ridges and along bending related faults (Iyer et al., 2012). Moreover, the distribution of H_2O in the mantle wedge may be controlled by the extent of progression of the reaction between the slab-derived fluid and the hanging wall mantle, as suggested by theoretical models (Iwamori, 1998). Previous hydration experiments for kinetic studies have been vigorously conducted at relatively low P-T condition (up to ca. 400 ℃ and 0.3 GPa) where the low T serpentine variety lizardite or chrysotile is stable. In contrast, antigorite is expected to be the dominant serpentine variety under the higher P-T condition corresponding to the deep oceanic lithosphere and the mantle wedge.

In order to constrain the serpentinization rates of peridotite under the antigorite- stbale conditions, we conducted piston-cylinder experiments at 580 ℃ and 1.3 GPa. Four types of starting materials were prepared from the crushed powder of a San Carlos lherzolite xenolith: 1) olivine (Ol), 2) orthopyroxene (Opx) + clinopyroxene (Cpx), 3) Ol + Opx, and 4) Ol+ Opx + Cpx + spinel. These systems were abbreviated as OL, OPX+CPX, OL+OPX, and LHZ, respectively. The starting materials were reacted with 15 wt% distilled water for 4-15 days. The formation of serpentine + talc + magnetite was observed in all the systems except for OL. Based on Raman spectroscopy results and crystal shapes, the synthesized serpentine mineral was identified as lizardite with 6?9 wt% Al_2O_3, rather than antigorite. The high Al_2O_3 content in the system possibly stabilized the aluminous lizardite at the experimental temperatures. Low silica activity precluded olivine reaction in the OL system, whereas olivine reacted with the SiO2 com-ponent in orthopyroxene to form lizardite and talc in the other systems. The reaction progress followed an interface-controlled rate law. The growth rate, G, was estimated to be 2.31 $\pm$ 0.37, 1.23 $\pm$ 0.20, and 2.78 $\pm$ 0.64 μm/day in the OPX+CPX, OL+OPX, and LHZ systems, respectively. As an example, we applied the hydration rates of peridotites, which were obtained experimentally, to a reactive-transport model for the convecting mantle wedge hydartion. In the case of grain-scale pervasive flow, the mass flux ratio of water fixable in the hanging wall peridotites to that supplied from the dehydrating oceanic lithosphere was calculated to be 2.7 $\times$ 105 - 1.5 $\times$ 108. This indicates that the water is completely fixable in the convecting mantle wedge and carried down to the stability limit of serpentine as soon as it is supplied from the slab. Aqueous fluid may penetrate all the way through the serpentine stable layer and reach the hot center of the mantle wedge only when the fluid migrates via crack-like pathways with a spacing $>$270-15000 m, which is not consistent with observations of natural serpentinites.

[1]Department of Natural History Science, Hokkaido Unicersity, [2]Deparement of Earth Science, Tohoku University

Oversaturation of dissolved volatiles in an ascending magma leads to bubble nucleation and growth, which depend on volatile solubility and diffusivity, and drives explosive volcanic eruptions in the Earth. It is thus important to clarify the behaviors of volatiles in silicate melts in understanding the mechanism and dynamics of volcanic eruptions.

Hydrogen isotopes record the degassing processes of hydrous magmas due to isotopic fractionation between dissolved and exsolved water. The degree of hydrogen isotopic fractionation is correlated with the water content in natural volcanic rock samples; Deuterium is more deficient in water-poor samples, and the degree of D-deficiency increases as the water content decreases. This trend has been interpreted to reflect the transition of degassing model from that in a closed-system to in an open-system. However, these two extreme degassing schemes do not take the diffusive transport of water in magmas into account, which should be included in a realistic degassing model, because the timescale of diffusion is not necessarily negligibily small compared to that of degassing during magma ascent. Moreover, diffusion of water in silicate melts may cause kinetic isotope fractionation between silicate melt and explosive fluid phases because H_2O is likely to diffuse faster than HDO, of which effect can be overprinted in the D/H ratios of natural samples. The hydrogen isotopic fractionation during water diffusion in silicate melts, however, has not yet been fully determined. In order to determine the isotopic fractionation factor of hydrogen due to water diffusion in silicate melts, we performed diffusion experiments of water in SiO_2 and synthetic rhyolite glasses in a D-enriched systems(H/D=10, 5 and 1).

The experiments were performed for SiO_2 and rhyolite glasses at 850 ℃ and water pressure of 50 bar in sealed silica tubes and at 650 ℃ and water pressure of 500 and 1000 bar in a hydrothermal furnace developed at Tohoku University. Concentration profiles of H and D in run products were measured with the ion microprobe (Cameca ims-6f at Hokkaido University) to evaluate diffusion coefficients of water (including H_2O and HDO) in glasses. The obtained diffusivity (a diffusion coefficient divided by a water content) in SiO_2 glass at 650 and 850 ℃ were consistent with the values reported in previous studies (Davis and Tomozawa, 1995; Berger and Tomozawa, 2003). The D/H ratios along the diffusion profile were also analyzed for SiO_2 glasses with the ion microprobe. The D/H ratio first decreases, but apparently increases along the profile. The decrease of D/H ratio may imply the kinetic isotope fractionation during diffusion. However, the increase of D/H ratio cannot be explained simply by diffusion and may reflect the change of instrumental mass fractionation with water content (Hauri et al., 2006), which should be precisely determined to correct the profile of hydrogen isotopic ratio.

Development of high-precision geobarometer

TAKAHATA, Kohei[1*] ; TORIMOTO, Junji[2] ; YAMAMOTO, Junji[2]

[1]Earth and Planetary System Science, Hokkaido University, [2]Hokkaido University Museum

Fluid inclusions in mantle-derived minerals can serve as a messenger from deep Earth. If CO_2 is a dominant phase of the fluid, the relationship between intensity ratio and frequency separation of the Fermi diad bands in the Raman spectra of CO_2 can be used for determination of density of the inclusions.

In this study, we installed new Raman spectrometer that was improved spectral resolution. And we also measured its precision of frequency separation (Δ). As a result of this study, we determined that the error of Δ is $\pm$ 0.003 cm^{-1} (1σ) . Converted into the error of density, this value is $\pm$ 0.0025 g / cm^{-1} .

Applications of rapid and precise 11B/10B isotopic analysis to water and rock samples

TANIMIZU, Masaharu[1*] ; NAGAISHI, Kazuya[2] ; ISHIKAWA, Tsuyoshi[1]

[1]Kochi Institute, JAMSTEC, [2]Marine Works Japan Ltd.

Boron isotope ratio is a powerful tracer in the fields of geochemistry, biochemistry, and environmental chemistry. Boron isotope ratios are determined by TIMS or MC-ICP-MS with precisions of better than 0.1 % RSD, but a large inter-lab discrepancy of 0.6 % is still observed for actual carbonate samples (Foster, 2008). Here, we are trying to determine B isotope ratio by MC-ICP-MS with a simple and common analytical techniques using a quartz sample introduction system with a PFA nebulizer, and compared to recently developed precise B isotope ratio analysis techniques by TIMS in positive ion detection mode determined as Cs2BO2+ ions with sample amount of <100 ng (Ishikawa and Nagaishi, 2011) and by MC-ICP-MS (Foster, 2008, Louvat et al., 2011).

In this year, our developed B analytical method above for carbonate and water samples are applied to rock samples. Resultant analytical reproducibility (twice standard deviation) was +/-0.04 % with a consumption of 50 ng B for several geochemical reference rocks issued from GSJ. Their relative differences from the standard were consistent with those determined by the positive TIMS within analytical uncertainty. Current potential B isotopic analysis by MC-ICP-MS will be discussed.

Water migration with a subducting slab and the dynamic effects on whole mantle convection

KANEKO, Takeo[1*] ; NAKAKUKI, Tomoeki[1] ; IWAMORI, Hikaru[2]

[1]Dept. Earth and Planetary Systems Science, Hiroshima Univ, [2]Geochemical Evolution Research Program, JAMSTEC

Existence of liquid water is a characteristic of the earth. The water of interior of the Earths involved with the subducting plate reduces density and viscosity of the crustal and mantle rocks. These effects are essential to emerge the solid Earth activity such as, plate tectonics and island arc volcanism. Although the most of subducted water circulates through upper mantle, there is a possibility that portion of the water penetrates into lower mantle. Where does the water migrate? How much does the water affect mantle dynamics through the rock rheology and property? We performed numerical mantle convection simulation to investigate the water cycle and dynamic effects on the whole mantle convection.

In this study, we use the numerical model based on the model (Tagawa et al., 2007; Nakakuki et al., 2010) including the subducting oceanic plate driven dynamically. This model includes migration of water with the plate motion. We consider influences of reducing density and viscosity due to the water on the mantle flow (Karato and Jung, 2003). The maximum water content in the upper mantle is determined using phase relations of the basalt and the peridotite (Iwamori, 2004; 2007). We use various values of the maximum water content of rocks in the lower mantle, because it has been not clearly defined. We also treated the following physical properties as varying parameters: friction coefficient at the plate boundary, amount of the water injection at the trench, density-water dependence coefficient, and maximum water content in the lower mantle. Addition to we calculated dislocation creep by non-newtonian fluid or newtonian fluid.

A part of subducted water associate with the subducting oceanic plate is absorbed into peridotitic rocks and transported to about 150 km deep mantle. After that, dehydration with the serpentine decomposition occurs, and transported to deeper mantle by hot nominally anhydrous minerals (NAMs). The amount of dehydration at the 660 km phase boundary depends on the maximum water content of lower mantle, when the slab penetrates into lower mantle. The ejected water forms thin and high-water-content layer over the 660 km phase transition. As a result, the buoyancy of this layer induces instability, so that hydrated plumes are generated. We propose that this mechanism is important for the water cycle in the upper mantle. On the other hand, considerable portion of the water is transported into lower mantle with subducting slab, although notable water capacity of the lower mantle much smaller than that of the upper mantle, and reach core-mantle boundary. We have not yet observed notable water influence on mantle convection at lowermost mantle because of the small water concentration. Also, the hydrated materials do not rise to surface with hot plumes generated at the core-mantle boundary.

Microstructural and fabric characteristics of the uppermost mantle peridotites in the Taitao ophiolite, South America

YOSHIDA, Yoshiaki[1*] ; MICHIBAYASHI, Katsuyoshi[1] ; ANMA, Ryo[2]

[1]Institute of Geosciences, Shizuoka University, [2]Faculty of Life and Environmental Science, University of Tsukuba

The <6Ma young Taitao ophiolite, exposed at the westernmost promontory of the Taitao Peninsula, is located approximately 40 km southeast of the Chile triple junction and consists of a complete sequence of oceanic lithosphere, including ultramafic rocks, gabbros, a dyke complex and volcaniclastic rocks. The ophiolite is surrounded by several contemporaneous granite plutons intruded in between the ophiolite and the Pre-Jurassic metamorphic basement. Several studies have been carried out on the Taitao ophiolite and surrounding granites. Whereas they have focused mostly on petrology and geochemistry, we investigated microstructures and crystal-fabrics of the ultramafic rocks, aiming to understand the origin of the ophiolite. 6 out of 16 ultramafic rocks preserved peridotite textures despite of intense serpentinization and show mostly porphyroclastic textures consisting of pyroxene porphyroclasts with a fine-grained olivine-pyroxene matrix. Their olivine crystal-fabrics shows [100]{0kl} and [100](001) patterns. These indicate that the uppermost mantle section have remarkably been deformed before and/or during the obduction process after their formation beneath the mid-ocean ridge.

Gabbroic petrology of oceanic lithosphere: comparison between Godzilla Megamullion and megamullions in mid-ocean ridges

YAMASHITA, Hiroyuki[1*] ; OHARA, Yasuhiko[2] ; ARIMA, Makoto[3]

[1]Kanagawa Prefectural Museum of Natural History, [2]Hydrog. & Oceanog. Dept. of Japan, [3]Yokohama National University

Godzilla Megamullion is the largest oceanic core complex on the Earth, with the dimension 125 km (along axis) and 55 km (across axis) (Ohara et al., 2001). Our study has revealed systematic petrological characteristics of the gabbroic rocks from the Godzilla Megamullion. In this contribution, we will report these characteristics and compare the results with those of gabbroic rocks from mid-ocean ridges.

Low modal abundance of olivine and high abundances of amphibole and iron oxide minerals are the prominent feature of the majority of the gabbroic rocks recovered from the Godzilla Megamullion. The studied gabbroic rocks are classified into troctolite, olivine gabbro, gabbro, hornblende pyroxene gabbro, pyroxene hornblende gabbro, hornblende gabbro on the basis of the classification by Streckeisen (1976). The chemical compositions of constituent minerals show systematic variations that are indicative of magmatic differentiation. Anorthite content in plagioclase, XMg (Mg/ (Mg + Fe) value in olivine and clinopyroxene decrease from less differentiated to highly siliceous evolved rocks. The mineral compositions indicate that troctolite is the most primitive variety and that trondhjemite is the most differentiated variety in the Godzilla Megamullion.

Troctolite, olivine gabbro and gabbro were recovered only from the distal parts of the Godzilla Megamullion. An age of ˜13 Ma has been reported from this region (Tani *et al*., 2011). On the other hand, trondhjemite was recovered from the medial and proximal parts of the megamullion, with ages of 11 and 8.7 Ma (Tani *et al*., 2011), respectively. Gabbroic rocks with relatively primitive composition were recovered from the Neck Peak region (age of 8.4 Ma; Tani *et al*., 2011). The spatial and temporal distribution of gabbroic rocks in the Godzilla Megamullion suggests the following magmatic model: a robust magmatic activity was predominant in the distal part, a declined magmatic activity in the medial to proximal parts, and a resurgent magmatic activity in the Neck Peak region. This model is consistent to the results obtained independently from petrological analysis on the peridotites from the Godzilla Megamullion (Snow *et al*., in preparation).

The lithological proportions of the gabbroic rocks in the Godzilla Megamullion are characterized by lower primitive gabbro (troctolite and olivine gabbro) ratio than in the Kane Megamullion in the Mid-Atlantic Ridge and in the Atlantis Bank in the Southwest Indian Ridge.

The Po/So waves propagating in the Philippine Sea

SHITO, Azusa[1*] ; SUETSUGU, Daisuke[2] ; FURUMURA, Takashi[3]

[1]Institute for Geothermal Science, Kyoto University, [2]JAMSTEC, [3]Earthquake Research Institute, The University of Tokyo

The Po/So waves which have high-frequency content, large amplitude, and long-duration propagate for large distance (up to 3000 km) across the oceanic lithosphere. In our previous study, we analyzed Po/So waves from deep-focus earthquakes occurring in the subducting slab beneath Japan, recorded by broadband ocean bottom seismometers (BBOBSs) at northwestern Pacific [Shito et al., 2013]. We demonstrated that the Po/So waves are developed by multiple forward scattering of P and S waves due to laterally elongated heterogeneities in both the subducting and laterally extending oceanic lithosphere. Following this study, the question when and where do the small-scale heterogeneities form in the oceanic lithosphere comes about. In order to answer this question, the Po/So waves in younger oceanic lithosphere need to be analyzed. Therefore in this study, we investigate the Po/So waves in the Philippine Sea plate (15-60 Ma), which is much younger than the Pacific Plate (130 Ma).

The Philippine Sea is one of the marginal seas of the Pacific Ocean. It is fundamentally divided into two regions bounded by the Kyushu-Palau Ridge. It is thought that these two regions were formed in different episodes of back-arc spreading and that western part (45-60 Ma) is older than eastern part (15-30 Ma) [e.g., Seno and Maruyama, 1984]. The comparison of Po/So waves propagation in the different ages of the oceanic lithosphere is expected to reveal the origin of the small-scale heterogeneities.

Seismological observations using BBOBSs was conducted in the Philippine Sea from 2005 to 2008, and high-quality Po/So waves from earthquakes in subducting Philippine Sea plate were recorded very clearly. The findings from the observed Po/So waves in the Philippine Sea plate are summarized as follows. (1) The Po/So waves propagate much effectively in western part than eastern part of the Philippine Sea. (2) The Po/So waves propagate even in youngest oceanic lithosphere (15 Ma) near the past spreading center of the Shikoku Basin.

In order to reveal the structure of the oceanic lithosphere and propagation efficiency in the Po/So waves, we performed numerical FDM simulations of 2-D seismic wave propagation in a realistic oceanic lithosphere model. The model is developed in the same procedure as the case of the Pacific plate [Shito et al., 2013]. In the oceanic lithosphere, we introduce laterally elongated small-scale heterogeneities, which are described by von Karman type stochastic random distribution function. Because the thickness of the oceanic lithosphere is considered to correlate with the age [e.g., Kawakatsu, et al. 2009], we vary the thickness of the oceanic lithosphere from 80 km to 20 km. To evaluate the fit of the computed waveforms to the data, we use the spatial attenuation of the seismic wave energy along the record section (up to 1500 km). The seismic wave energy is defined as integrated squares of amplitudes in a certain tine window (25 s from the Po/So wave onset). The model with the thickness of the oceanic lithosphere of 60 km and 30 km successfully explain the spatial attenuation of the Po/So waves record section observed at western and eastern parts of the Philippine Sea, respectively. The thicknesses are consistent with those obtained by previous studies [Kawakatsu et al., 2009]

This result suggests that the oceanic lithosphere including small-scale heterogeneities grow as it ages and develop large-amplitude and long-duration of high-frequency Po/So waves. The small-scale heterogeneities may form at the bottom of the lithosphere as it cools. They suggest that small-scale melts in the asthenosphere are frozen and attached at the bottom of the lithosphere, which remain even after the lithosphere is subducted into the mantle.

Multi-scale heterogeneity of abyssal peridotite

TAMURA, Akihiro[1*] ; MORISHITA, Tomoaki[1] ; ARAI, Shoji[1]

[1]Earth Sciences, Kanazawa University

Petrological studies of peridotite have increasingly revealed the origin of magma as well as materials and processes of Earth interior. Although we now only access to the interior indirectly, we can obtain the mantle-derived material brought by magma transporter or by large tectonic reconstruction of the earth surface. At the ocean floor near the mid-ocean ridge spreading center, where the deep seated rock is exposed along spreading axis or fracture zone, abyssal peridotite is collected. The abyssal peridotite studies significantly contribute not only to understanding of the formation of oceanic lithosphere but also to development of analytical way for the mantle material. In mineralogical and geochemical approaches, chromian spinel is a good indicator for the origin; for example, the spinel Cr# reflects a partial melting degree of the upper mantle material (e.g., Dick and Bullen, 1984; Arai, 1987). Trace-element compositions of clinopyroxene allow us to discuss the melting process quantitatively (e.g., Johnson et al., 1990). Recently, further discussions can be available by using ultra-trace elements and PGE isotopes (e.g., Harvey et al., 2006; Ishikawa, 2012).

Several petrological studies of abyssal peridotite samples have demonstrated ”regional-scale” heterogeneity of the upper mantle along Mid-Atlantic Ridge based on their spinel Cr# (e.g., Dick et al, 1984; Michael and Bonatti, 1985). In ”Global-scopic” differences between Atlantic, Indian and Pacific oceans, Niu and Hekinian (1997) proposed that the spinel Cr# of abyssal peridotite is dependent on spreading rate. Contrasting to such a heterogeneity, Ghose et al. (1996) and Dick et al. (2010) showed that the compositional variation of the abyssal peridotite is controlled by local structures at the mid-ocean ridge: for example, spreading axis, fracture zone, abyssal plane and oceanic core complex. Geochemical heterogeneity of each abyssal peridotite sample is recently discussed in aspects of magmatic event during or after partial melting stage (Tamura et al., 2008; Warren and Shimizu, 2010).

In our presentation, to review petrological characteristics of abyssal peridotite, we will demonstrate our compiling data set focused on relationship between their spinel Cr# and sample localities, such as ocean floor structures at the mid-ocean ridge. The example of abyssal peridotite sample heterogeneity are also discussed. Then, we would like to discuss the factor and significance of compositional variation of abyssal peridotite.

Heterogeneity from mantle to crust at the central Southwest Indian Ridge (1) -Upper mantle-

MATSUNO, Tetsuo[1*] ; SEAMA, Nobukazu[2] ; SATO, Hiroshi[3] ; SATO, Taichi[4] ; SENDA, Ryoko[5] ; MACHIDA, Shiki[6] ; NAKAMURA, Kentaro[5] ; MORISHITA, Tomoaki[7] ; MIZUMA, Keiko[2] ; NOGI, Yoshifumi[1] ; OKINO, Kyoko[8]

[1]National Institute of Polar Research, [2]Kobe University, [3]Senshu University, [4]National Institute of Advanced Industrial Science and Technology, [5]Japan Agency for Marine-Earth Science and Technology, [6]Waseda University, [7]Kanazawa University, [8]University of Tokyo

Mantle is heterogeneous in terms of geophysical (e.g., bathymetry, geomagnetics, and gravity) and geological (e.g., petrology and geochemistry) aspects. Because heterogeneity is enhanced at slow spreading ridge, the ultra-slow spreading Southwest Indian Ridge (SWIR) is suitable for understanding the heterogeneity. We conducted geophysical and geological investigations since 2007 at the segment along the central SWIR between 35^{o}E and 40^{o}E, where the ridge segment is close to the Marion hotspot.

Serpentinised mantle peridotites occurring as clasts in the conglomerate were dredged from a topographic high within the Prince Edward fracture zone at 35^{o}E. A marine electromagnetic experiment was conducted along a 110 km transect across a subsegment at 37^{o}E to reveal an electrical resistivity structure of the upper mantle.

The peditotites are considered to have originally been lherzolite based on petrographic and mineral chemical composition analyses. Chemical compositions of spinel (Cr# and Mg#) in the peridotites suggest that the peridotites have undergone moderate partial melting without enhancement of melting by the hotspot regardless of proximity of the dredge site to the Marion hotspot. Light rare earth elements of clinopyroxene are more depleted than were previously reported for SWIR peridotites, suggesting that the peridotites have undergone little to no metasomatism of a melt-mantle interaction. Osmium isotope ratios are highly depleted, resulting in that a model age of rhenium depletion (T_{RD}) is 1 billion years. These results suggest that the dredged peridotites have not been enriched after the last melt extraction event 1 billion years ago, preserve their initial depleted compositions without hotspot effects, and show the presence of a refractory mantle domain under the central SWIR.

A preliminary 2-D electrical resistivity structure of the upper mantle down to 200 km depth does not show a remarkable conductive melting region beneath the ridge axis and a more conductive asthenospheric mantle than those observed at other mid-ocean ridges. The resistivity model suggests that the presence of the Marion hotspot does not result in enhancement of melt production beneath the ridge and enrichment of conductors like water in the upper mantle at present.

The result of this study suggests that the source mantle contain ancient, refractory, and depleted portion. This mantle may be a part of the depleted mantle prevailed under the Marion Rise, which was proposed by Zhou and Dick (2013) and may be supported by the absence of slow velocity anomalies around the Marion hotspot in upper mantle seismic tomography images (e.g., Zhao, 2007).

Heterogeneity from mantle to crust at the central Southwest Indian Ridge (2) -Crust-

SATO, Hiroshi[1*] ; SATO, Taichi[2] ; MACHIDA, Shiki[3] ; SENDA, Ryoko[4] ; MATSUNO, Tetsuo[8] ; SEAMA, Nobukazu[5] ; NAKAMURA, Kentaro[6] ; MORISHITA, Tomoaki[7] ; NOGI, Yoshifumi[8] ; OKINO, Kyoko[9]

[1]Senshu Univ., [2]AIST, [3]Waseda Univ., [4]JAMSTEC, [5]Kobe Univ., [6]Dept. System Innovation, Univ. of Tokyo, [7]Kanazawa Univ., [8]NIPR, [9]AORI, Univ. of Tokyo

Mantle is heterogeneous in terms of geophysical (e.g., bathymetry, geomagnetics, and gravity) and geological (e.g., petrology and geochemistry) aspects. Because heterogeneity is enhanced at slow spreading ridge, the ultra-slow spreading Southwest Indian ridge is suitable for understanding the heterogeneity. We conducted geophysical and geological investigations since 2007 at the segment along the central Southwest Indian Ridge (SWIR) between 35E and 40E, where the ridge segment is close to the Marion hotspot.

Recent investigations of topography and geophysics along the central Southwest Indian ridge between 35E and 40E (Sato, T. et al., 2013) classify the segment between the Prince Edward and Eric Simpson fracture zones as four subsegments: PE-1, PE-2, PE-3, and PE-4 from west to east. A long oblique axial valley (NTD-1) is recognized between PE-1 and PE-2. Geochemical and isotopic compositions of MORB samples from these subsegments consist with previously reported MORB and/or SWIR basalts. However, small scale geochemical and isotopic heterogeneity are recognized in these samples. Sato, T. et al. (2013) considered that strong melt-focusing could be principle process to produce volcanic and low volcanic subsegment rather than the effect of proximity to the Marion hotspot. Continuous seafloor morphology and isochrons over off-axis areas of segment PE-1 and NTD-1 suggest that PE-1 shortened after the C2An chron, indicating the magmatic process has changed for several million years.

Among MORB from the subsegments, PE-1 and NTD-1, geochemically enriched sample (e.g. those with La/Sm>1) are enriched in isotope (higher Sr and lower Nd), suggesting that enrichment is due to source enrichment rather than smaller degree of melting of the homogeneous source mantle. Although geochemical and isotopic compositions could be explained by the mixture of depleted MORB source and the Marion components, contribution of the Marion component is limited only in the eastern part of PE-1 and NTD-1 subsegments. Therefore, it is reasonable to consider that source mantle beneath eastern part of PE-1 segment contains the enriched Marion components rather than direct contribution from Marion hotspot. Degree of enrichment (i.e. amount of enriched component) is higher beneath the present eastern part of PE-1 subsegment.

Sato, T. et al. (2013) pointed out that the melt supply center (tip of V-shaped bathymetric structure) between segment PE-1 and NTD-1 has migrated westward. It means that the enriched portion in the source mantle beneath PE-1 and NTD-1 subsegments has migrated westward. Melting of enriched, probably preferentially melting, components induced the strong melt-focusing process to form the V-shape bathymetric structure between PE-1 and NTD-1. This constraints the spatial scale and type of enriched component in depleted mantle.

Origin of Magnetization High at the Yokoniwa Hydrothermal Vent Fields, the Central Indian Ridge

FUJII, Masakazu[1*] ; OKINO, Kyoko[1] ; SATO, Taichi[2] ; SATO, Hiroshi[3] ; NAKAMURA, Kentaro[4]

[1]AORI, University of Tokyo, [2]Geological survey of Japan, AIST, [3]Senshu University, [4]University of Tokyo

Measurement of near bottom magnetic anomalies is an effective method to reveal the spatial extent of hydrothermal alteration zone and to find buried hydrothermal vent fields because hydrothermal alteration processes can change crustal magnetization by destruction and creation of magnetic minerals. In the Yokoniwa vent field (YVF), which is located at the top of the non-transform offset massif, called the Yokoniwa Rise, in the southernmost part of the Central Indian Ridge, a high magnetization zone was discovered by AUV r2D4 in 2009. Basalts and ultramafic rocks were found around the YVF, however the origin of positive magnetization and the relationships between high magnetization and hydrothermal activity are remains to be investigated.

In order to constrain the origin of magnetic source near the YVF, we conducted deep-sea geological observation and magnetic measurements using submersible Shinkai 6500 during the R/V Yokosuka cruises, YK09-13 and YK13-03. Vector geomagnetic field were successfully obtained along the all dive tracks at an altitude of ˜10 m. The distribution of crustal magnetization is estimated by vertical and horizontal components of magnetic anomalies using the 2-dimesional forward modeling technique and frequency analysis.

In the southern slope of the Yokoniwa Rise, serpentinized-peridotites were discovered and absolute magnetization shows entirely low (˜6 A/m). On the other hand, just around the YVF, hydrothermal sulfide deposits, tiny dead chimneys, shimmering and talc were observed and absolute magnetization shows relatively high (9 A/m). This magnetization contrast between the YVF and the surrounding area may be attributed to the difference in amount of magnetite, controlled by the degree and the temperature of serpentinization. One of the serpentinized-peridotite recovered during the cruises showed large amount of magnetite and high natural remanent magnetization. However, the highest absolute magnetization (20 A/m) was discovered at pillow basalt area with thin sediment just ˜700 m away from the YVF, implying recent off-axis volcanic activity. Therefore basaltic intrusion beneath the YVF is also possible for the origin of high magnetization. In addition, magnetic iron sulfide (pyrrhotite) grown during hydrothermal circulation, which is proposed at the Rainbow hydrothermal vent field, is also possible.

Consequently, we proposed three possibilities for the origin of high magnetization at the YVF; serpentinized peridotites with high temperature hydrothermal alteration, basaltic intrusion bodies, and pyrrhotites concentration. All of these hypotheses are related to hydrothermal activity. For the further inspection, recovering subseafloor rocks and inspection of rock magnetic properties are absolutely necessary.

Three-dimensional seismic structure of the Rainbow area, Mid-Atlantic Ridge 36 degree N

ARAI, Ryuta[1*] ; DUNN, Robert[1] ; CANALES, Pablo[2] ; SOHN, Robert[2]

[1]University of Hawaii, [2]Woods Hole Oceanographic Institution

Oceanic lithosphere formed along slow-spreading mid-ocean ridges is structurally and compositionally heterogeneous due to spatial and temporal variations in tectonic extension, magmatic accretion, and mantle temperature and composition. While mid-ocean ridges with greater magma supply host a greater abundance of hydrothermal systems, the relative roles of magmatic input, heat advection and faulting in controlling ridge structures are still poorly understood. These are particularly important to understanding formation and evolution of oceanic core complexes where ultramafic-hosted lithologies are exhumed at the seafloor by long-lived detachment faulting. The MARINER (Mid-Atlantic Ridge INtegrated Experiments at Rainbow) seismic and geophysical mapping experiment was designed to examine the relationship between tectonic rifting, heat/melt supply, and oceanic core complex formation at a non-transform offset of the Mid-Atlantic Ridge, 36 ^{o} 14 $'$ N, the site of the ultramafic-hosted Rainbow hydrothermal system. Using the seismic refraction data from this experiment, we constructed three-dimensional tomographic images of the crust and upper mantle around the Rainbow area. The seismic velocity images reveal undulations in crustal thickness across the ultramafic Rainbow massif, indicating temporal variations in melt supply, magmatic processes, and crustal construction. Previous studies suggest that a current heat source for the vents, which probably arises from a magmatic body, is required just beneath the hydrothermal vent, but the tomography does not detect a low-velocity anomaly indicating a significant magmatic system or high-temperature region beneath the Rainbow vent site. The only candidate region for high-temperatures and perhaps melt at shallow levels is much further to the south, and located roughly beneath the central valley of the spreading center. At the Rainbow massif, where mantle rocks have been recovered by direct sampling, mantle velocities near the seafloor are significantly reduced to ~ 5 km/s. This velocity reduction implies that an active hydrothermal circulation system altered the mantle via recharge and discharge of seawater.

Thermal structure of old oceanic upper mantle: Constraints from electrical conductivity imaging in the NW Pacific

BABA, Kiyoshi[1*] ; TADA, Noriko[2] ; LIANG, Pengfei[1] ; ZHANG, Luolei[1] ; SHIMIZU, Hisayoshi[1] ; UTADA, Hisashi[1]

[1]Earthquake Research Institute, The University of Tokyo, [2]Japan Agency for Marine-Earth Science and Technology

Northwestern part of Pacific plate is very old as the crustal age is over 100 Ma. Seafloor subsidence and heat flow change with age for such old ocean have been explained by cooling of a plate with constant thickness (e.g., Parsons & Sclater, 1977; Stein & Stein, 1992). Electrical conductivity of the upper oceanic mantle typically has resistive layer over a conductive zone reflecting the thermal structure. However, our recent results on the electrical conductivity of the upper mantle beneath northwestern Pacific suggest that a simple plate cooling model can not explain the observations.

We have run marine electromagnetic observation in two areas (Areas A and B) of the northwestern Pacific since 2010. Areas A and B locate northwest and southeast of Shatsky Rise, respectively. Although a part of the observation is still going on, we analyzed the data collected by the last year to obtain magnetotelluric responses and one-dimensional (1-D) electrical conductivity structure beneath the observation areas. Here, we compare the results together with a model obtained for the mantle beneath the Pacific ocean off the Bonin Trench (Area C) by a past project. The mean lithospheric ages of Area A, B, and C are about 130, 140, and 147 Ma, respectively. Based on a plate cooling model, the age differences for the thermal structure among the areas are very small. However, the obtained electrical conductivity models show significant difference in the thickness of the resistive layer. The depth the mantle become more conductive than 0.01 S/m are about 80 km for Area A, about 110 km for Area B, and about 200 km for Area C. These differences can not be reconstructed from the age difference of a single plate cooling model.

Our observations revealed that there is large scale lateral heterogeneity in electrical conductivity. We need to consider another factors rather than age difference of the thermal structure to explain such the lateral heterogeneity.

PGE abundances and Os isotope ratios of troctolites from pacific oceanic lithosphere

SENDA, Ryoko[1*] ; ISHIKAWA, Akira[2] ; MORISHITA, Tomoaki[3] ; SUZUKI, Katsuhiko[1] ; ISHII, Teruaki[4]

[1]JAMSTEC, [2]Department of Earth Science and Astronomy, The University of Tokyo, [3]School of Natural System, Colleage of Science and Technology, Kanazawa University, [4]Fukada Geological Institute

The structure of oceanic lithosphere becomes much clear in these days. Troctolite is a kind of gabbro, mainly consisting of olivine and calcic plagioclase with minor pyroxene, found in oceanic lithosphere. Melt-rock interactions at mantle-crust transition zone are believed to play a main role for troctolite formation. Troctolites are locally found at Atlantis Massif oceanic core complex, Mid Atlantic Ridge 30 iii N (Blackman et al., 2006), at Kane Megamullion, Mid Atlantic Ridge 23N (Dick et al., 2008; 2010), at Uraniwa Hills, Central Indidan Ridge (Nakamura et al., 2009), and at Godzilla Megamullion, Parece Vela Basin of the Philippine Sea (Sanfilippo et al., 2013). They also occurred as sections of the oceanic lithosphere in ophiolites and show similarity to lower crust sections from slow and ultra-slow spreading ridges (e.g., Herbert et al., 1989; Sanfilippo and Tribuzio, 2013). The formation process of the troctolites is in debate. From the ophiolite studies, troctolites were formed as cumulates from primitive basalts in a closed system (Bezzi and Piccardo, 1970; 1971; Borghini and Rampone, 2007). Alternatively, troctolites were the results of a substantial amount of mantle olivine incorporated into the lower oceanic crust (Suhr et al., 2008; Drouin et al., 2009; 2010) based on the studies of oceanic core complex.

Troctolites were also found in the drilled core at site 895 of ODP Leg 147 in Hess Deep, located at a triple junction between EPR and Cocos-Nazca plate boundary. Hess Deep is a small rift with intra-rift ridges, where deep-seated rocks probably formed at EPR are exposed (Francheteau et al., 1990; 1992). Ultramafic and related rocks were expected to be found at the site in fast-spreading ridge system and sequences of dunite, harzburgite, troctolite, and gabbro were actually drilled (Allan and Dick, 1996; Dick and Natland, 1996; Arai and Matsukage, 1996). Troctolite appears to be transitional from dunite to olivine gabbro (Arai and Matsukage, 1998).

Major, trace and platinum group element (PGE) abundances and Os isotope ratios of troctolites from Holes 895C, 895D and 895E were newly measured using XRF, ICP-MS, and TIMS. The samples are clearly divided in two groups by Al_2O_3, MgO and NiO. Prichard et al. (1996) reported the PGE and trace element abundances of the ultramafic rocks from Holes 895. Their PGE concentrations of the troctolites were in a similar range to hartzburgites and dunites from the same sites and Pt and Pd are enriched in some troctolites. They also found platinum-group alloys and base metals in troctolites. New data set with Os isotope ratios possibly make constraints on the forming process of troctolites under the oceanic ridge.

The origin for the olivine-rich troctolites from the oceanic lithosphere: remnants of a reactive MOHO

SANFILIPPO, Alessio[1*] ; MORISHITA, Tomoaki[2] ; HARA, Kaori[2] ; TAMURA, Akihiro[2] ; ARAI, Shoji[2]

[1]University of Pavia, Kanazawa University, [2]Kanazawa University

Olivine-rich troctolites are documented since the early 1970s in the lower crust and mantle sections of the Jurassic oceanic lithosphere exposed along the Alpine-Apennine belt (Italy). These rocks were first interpreted to be cumulates formed by precipitation of olivine and accessory spinel from primitive basalts (Bezzi A. and Piccardo G.B., 1971. Mem. Soc. Geol. It.). The founding of olivine-rich troctolites bodies within the gabbroic sections of the Hess Deep (East Pacific Rise) and Atlantis Massif and Kane Megamullion (Mid Atlantic Ridge) called into question this idea, suggesting that they may represent portion of the crust-mantle transition entrapped during the growth of the lower crust (Arai and Matsukage, 1996, Lithos; Suhr et al., 2008, G-cubed). Recently, Japanese scientific cruises found olivine-rich troctolites associated with mantle harzburgites at the Godzilla Megamullion (Philippine Sea) [3] and at the Uraniwa Hills (Central Indian Ridge) (Nakamura et al., 2009, EPSL; Sanfilippo et al., 2013, J. Petrol.). We show that the olivine-rich troctolites from all these occurrences show peculiar structural and compositional features: i) highly variable forsterite, Ni and Co contents of olivine; ii) high Mg/(Mg+Fe), high Cr_2O_3 contents, and fractionated incompatible element compositions (i.e. Ti/REE and Zr/REE) of clinopyroxene; iii) the occurrence hydrous silicate mineral inclusions in spinels anomalously enriched in TiO_2. These features agree with the idea that olivine-rich troctolites formed through reactions between a pre-existing olivine-matrix and migrating melts [see also Renna and Tribuzio, 2011, J. Petrol.). In particular, we suggest that these chemical features were acquired at the crust-mantle transition, through interactions between mantle peridotites and melt stagnating at the base of the igneous crust. The occurrence of olivine-rich troctolites both at slow- to intermediate spreading ridges and at back-arc settings suggests that melt-peridotites reaction processes constrain the Moho under the totality of the oceanic plates.

Experimental study of anelasticity of a polycrystalline material for seismological application

TAKEI, Yasuko[1*] ; YAMAUCHI, Hatsuki[1] ; KARASAWA, Fumiya[2]

[1]Earthquake Research Institute, Univ. of Tokyo, [2]Yahoo, Japan

Rock anelasticity causes dispersion and attenuation of seismic waves. Therefore, for the quantitative interpretation of seismic low velocity and/or low Q regions in the upper mantle, understanding of rock anelasticity is necessary. However, due to the difficulty of forced-oscillation experiment under high-temperature (>1000^{o}C) and small strain (<10ˆ-6) conditions, systematic data on rock anaelasticity, needed for the understanding of underlying mechanisms, have not been obtained adequately. To address this lack of data, data from rock analogue (polycrystalline organic borneol) will be of merit. Our recent result published in McCarthy et al (2001) has shown that anelasticity of polycrystalline materials is subject to the Maxwell frequency scaling: Q = Q(f/fm). However, the applicability of this scaling to the seismic dispersion and attenuation has not been guaranteed because experimentally testing frequencies normalized to the Maxwell frequency fm of the laboratory samples are usually much lower than the seismic range in the upper mantle (10^6 <f/fm <10^9). In this study, by using borneol as an analogue to mantle rock, we measured anelasticity up to higher normalized frequencies (0.1 <f/fm <10^8), and examined the applicability of the Maxwell frequency scaling to these new data. The obtained data show that the Maxwell frequency scaling is no more applicable to higher normalized frequencies than f/fm = 10^4, where attenuation spectra plotted as functions of f/fm scatter significantly by temperature, grain size, and impurity. Especially, a small amount of impurity (diphenylamine) significantly enhanced the anelastic relaxation. The addition of dyphenylamine to borneol significantly lowers the melting temperature from Tm=477 K to Tm=316 K. From these results, we have speculated that the enhancement of anelasticity with impurity and/or temperature might be scaled by T/Tm. If this speculation is true and can be generalized to the other polycrystalline materials, it will give a crucial insight for the underlying mechanism. Because T/Tm is close to one in the upper mantle and it is important to investigate the detailed behavior of anelasticity near T/Tm=1.

Seismic structural changes in the incoming oceanic plate beneath the well-developed horst and grabens

FUJIE, Gou[1*] ; TAKAHASHI, Tsutomu[1] ; KODAIRA, Shuichi[1] ; OBANA, Koichiro[1] ; YAMADA, Tomoaki[2]

[1]JAMSTEC, [2]ERI, Univ. of Tokyo

Recent seismic, electromagnetic, and thermal structure studies in the trench-outer rise region have revealed the structural changes of the incoming plate in the trench-outer rise region. These structural changes are considered to be caused by the plate bending-related faulting and water penetration. However, there are many unresolved questions such as the maximum depth of the structural changes, the mechanisms of the water penetration, and the source of the water.

The northwestern Pacific margin, where extremely old (more than 120Ma) oceanic plate is subducting, is a good place to study structural changes in the incoming plate prior to subduction, because the horst and graben structure, which is caused by the bending-related faulting, is well developed in this region. However, the former seismic survey could not revealed the seismic structure around the trench axis, where seismic structure is expected to be significantly changed, because of the large water depth in the vicinity of the trench axis.

In 2013, we conducted extensive wide-angle seismic reflection and refraction surveys across the Japan trench with use of ultra-deep Ocean Bottom Seismometers (OBSs). Our obtained data enabled us to reveal the seismic structure in the vicinity of the trench axis, and we confirmed that the bending-related structural changes reach to the top of the oceanic crust. In addition, in the record sections obtained at the deep grabens, we observed seismic waves that laterally propagate within the sedimentary layer as well as the phases vertically propagate within the sedimentary layer. These two phases provided us new insights to the sedimentary structure, which implies that the bottom of the sedimentary layer can be the water source to the oceanic crust in the trench-outer rise region.

Mariana Trench is one of the deepest oceans in the world more than 10,000 m depth. Although the mantle section outcrops along the land-side slope of the southern Mariana Trench, the studied depth so far is approximately shallower than 7,000 m and therefore few geological information is available for the mantle section deeper than 7,000 m. In 2008, a sediment core has been sampled at 10,350 m in Challenger Deep of Mariana Trench by ABISMO (Automatic Bottom Inspection and Sediment Mobile) during KR08-05 cruise. The sediment core is 161.5 cm in length and contains mafic sandy grains such as olivine and spinel. In this study, we sampled the mafic minerals from the sediment core and analyzed their major element compositions. As a result, the chemical compositions of the mafic sandy grains were compatible with those of mafic minerals within the peridotites along the land-side slope of Mariana Trench shallower than 7,000 m. We will discuss the origin of these sandy grains.

High Ni and Mg olivine as a time recorder of chromitite P-T history

MIURA, Makoto[1*] ; ARAI, Shoji[1] ; YAMAMOTO, Shinji[2] ; SHMELEV, Vladimir[3]

[1]Department of Earth Sciences, Kanazawa University, [2]Department of Earth Science and Astronomy, University of Tokyo, [3]Institute of Geology and Geochemistry, Ural Brance Russian Academy of Sciences

High Ni and Mg olivines were found in dunites enveloping podiform chromitites from Oman, Ray-Iz and Luobusa ophiolites. These high Ni and Mg olivines occur only in dunite adjacent to chromitite. This characteristic suggests subsolidus Ni and Mg diffusion from the chromites of the chromitite. In the case of dunite enveloping concordant chromitite from Oman ophiolite, olivines show high NiO (up to 0.5 wt %) and Fo (around 92 mol %) contents. This is not the case, however, for the dunite envelope around the discordant chromitite in the Oman ophiolite. On the other hand, olivines in dunite enveloping UHP chromitites from Ray-Iz and Luobusa ophiolites are extraordinarily high in Fo value (94 - 96) and NiO (around 0.5 wt %). Silicate exsolution lamellae in spinel from UHP chromitites and concordant chromitite suggest that these chromitites have experienced substantial cooling, and probably decompression, for a longer priod than the discordant chromitite from Oman. According to the well-known Ni and Mg diffusion coefficients in olivine, the high-Ni and -Mg olivine in the dunite envelope may constrain the cooling duration of the chromitite and the history of ophiolite. Podiform chromitites are enigmatic in origin, and their origins should be systematically classified to understand concerning mantle processes. Their temporal relationship is a clue to solve this problem.

Geochemistry and genetic conditions of primary boninites from the Ogasawara Island Group and Oman ophiolite

KITAMURA, Keitaro[1*] ; KANAYAMA, Kyoko[1] ; UMINO, Susumu[1] ; ISHIZUKA, Osamu[2] ; KUSANO, Yuki[1]

[1]Department of Earth Sciences, Kanazawa University, [2]Geological Survey of Japan/AIST

Subduction initiation and arc crust evolution along oceanic plate boundaries are fundamental processes that modify oceanic lithosphere and promotes the material evolution of the Earth. How subduction of oceanic plates initiates and develops largely depend on the thermochemical structure and mechanical strength of the colliding two plates. The resulting conditions of the wedge mantle can be best represented by the varying geochemistry of primary magmas produced through the subduction initiation. For example, the subduction zone in the Izu-Bonin (Ogasawara)-Mariana (IBM) arc started with an intense high-Si to low-Si boninite magmatism during 48-45 Ma (Ishizuka et al., 2006; Kanayama et al., 2012). By contrast, the subduction stage of the Oman Ophiolite lacked typical boninite and is characterized by the low-Si boninite magmatism (Ishikawa et al., 2002; Kusano et al., 2014). Because of its high Mg#s and andesitic chemistry, boninite is generally considered to be a candidate of a primary magma derived from the hydrous upper mantle, and therefore, its compositional variations reflect various thermochemical conditions of the source mantle. The geochemical and petrological studies on boninite magma genesis can provide crucial information on the evolution of arc and the formation of continental crust. Boninites are distinct from ordinary arc magmas in highly depleted U-shaped and depleted spoon-shaped chondrite-normalized rare earth elements (REE) patterns.

We have investigated melt (glass) inclusions enclosed by boninite-derived chrome spinel grains in beach sand, called “uguisu-zuna” from Ogasawara islands, and in wadi sand from the Oman Ophiolite. We analyzed major- and trace-element compositions of the boninitic melt inclusions by EPMA and LA-ICP-MS (Kanazawa Univ.) and H2O by SIMS (Hokkaido Univ. Creative Research Institution). Glass inclusions in spinel have more Mg-rich compositions than aphyric whole rocks, indicating their primitive nature since derivation from the source mantle, which experienced least modification by the processes such as crystal fractionation, and assimilation and contamination by the crust. Volatile measurements of melt inclusions confirmed that they were only slightly degassed and retain primitive contents. Five geochemical types (BIC-1~5) are identified among boninites from the Ogasawara Islands and a single geochemical type from the Oman Ophiolite. Both Ogasawara and Oman low-Si boninites show lower H2O contents than high-Si boninites. Assuming that the most magnesium-rich melts of each geochemical type in Ogasawara and Oman boninites coexisted with olivine and orthopyroxene, the P-T conditions of these primary boninite magmas were estimated by using the geothermobarometers of Putirka et al. (2007) and Putirka (2008). High-Si boninites erupted on the Ogasawara Islands during 48-46 Ma were generated at 1400-1440 ℃ and 0.7-0.9 GPa, whereas the subsequent low-Si boninite at 45 Ma formed at 1380-1400 ℃ and 0.8-0.95 GPa. This suggest that the geothermal gradient descended from 48 Ma to 45 Ma. On the other hand, low-Si boninite from the Oman Ophiolite was generated at 1320 ℃ and 0.5 GPa. Hence, it is apparent that the wedge mantle beneath the proto-IBM arc was significantly hotter than that in the Oman paleoarc.

Thermo-chemical evolution of mantle wedge during the incipient stage of the Izu-Ogasawara-Mariana subduction zone

KANAYAMA, Kyoko[1*] ; KITAMURA, Keitaro[2] ; UMINO, Susumu[1] ; ISHIZUKA, Osamu[3]

[1]College of Science and Engeneering, Kanazawa University, [2]Graduate School of Natural Science and Technology, Kanazawa University, [3]Geological Survey of Japan/AIST

It is essential to understand the processes of subduction zone initiation and evolution of oceanic arcs which promote the development of Earth's structure and composition. We present the genetic conditions of the Eocene magmas from the Ogasawara (Bonin) Ridge and discuss the thermo-chemical structure of the mantle wedge beneath the Ogasawara region during the incipient stages of the IBM arc. On the Ogasawara Ridge, MORB-like basalt (forearc basalt: FAB) is generated just after the beginning of subduction of the Pacific Plate at 52 Ma, followed by ultra-depleted high-Si boninite activities began at 48Ma. This high-Si boninite magmatism gradually changed through less-depleted low-Si boninite at 45 Ma to arc tholeiite and calc-alkaline magmatism [1, 2].

Major element compositions of high- and low-Si boninites are similar to those of experimentally produced melts of harzburgite [3] and lherzolite [e.g. 4], respectively. Ultra low concentrations in rare earth elements (Yb$>$0.3 ppm) of high-Si boninite also indicate a depleted harzburgite source. On the other hand, characteristically high Zr/Ti ratio ($<$0.04) of boninites from the Ogasawara Islands reflects high contributions of slab melt [2]. FAB is produced by less than 10 % fractional melting of MORB source mantle, leaving residue of moderately depleted lherzolite. This suggests that the residue of FAB cannot be the highly depleted source of high-Si boninite.

P-T conditions at which the most primitive boninitic melts can coexist with harzburgite are 1430 ℃ and 0.83-0.96 GPa for high-Si boninite (MgO=23, H_2O=3.2 wt%) and 1380 ℃ and 0.86 GPa for low-Si boninite (MgO=19, H_2O=2.6 wt%) [5]. Genetic conditions of magmas other than boninite are dry, ˜1350 ℃ and 1.3-1.7 GPa for FAB and water-undersaturated (0-0.5 wt%), 1300-1350 ℃ and 1-1.2 GPa for arc tholeiitic and calc-alkaline magmas, which were estimated by comparing calculated primitive liquid compositions with experimentally produced liquid compositions of lherzolite melting [e.g.4].

Mantle potential temperatures (T_p) calculated based on MgO content of primary magmas are 1500 ℃ for high-Si boninite and 1450 ℃ for low-Si boninite, which are higher than the ambient mantle (T_p=1300-1400). Especially Tp for high-Si boninite is comparable to T_ps of mantle plumes [6]. This result is consistent with plume-related magmatism (51-45Ma) in the West Philippine Basin simultaneously with the high-Si boninite magmatism in the Ogasawara Ridge [7]. The ultra-depleted source of high-Si boninite is possibly the residue of the plume-related magmatism. T_p of FAB and arc tholeiitic and calc-alkaline magmas is 1400 ℃, equivalent to the ordinary oceanic mantle.

From the above, the thermo-chemical history of the mantle wedge beneath the Ogasawara Ridge during the incipient stage of the IBM subduction zone is advocated as follows; Spontaneous sinking of old, dense Pacific Plate induced upwelling of asthenosphere which melted to produce FAB in eastern margin of the Philippine Sea Plate at 52 Ma. At 48 Ma, depleted residual harzburgite of plume-related magmatism upwelled from deeper (˜3.5 GPa ?) asthenosphere to 1 GPa, suffering flux melting incorporating slab melt to generate the high-Si boninite magma. By 45 Ma, shallow mantle wedge was cooled by the subducted slab and asthenosphere began circulating in the wedge. As a result, magma composition changed from high-Si boninite through low-Si boninite to arc tholeiite and calc-alkaline magmas more fertile than the Quaternary frontal lava. Subsequently the IBM subduction zone changed to a stable arc-trench system.

Hot and ephemeral subduction zone magmatisms in the Oman Ophiolite

KUSANO, Yuki[1*] ; KITAMURA, Keitaro[1] ; ADACHI, Yoshiko[2] ; SHINJO, Ryuichi[3] ; UMINO, Susumu[1] ; MIYASHITA, Sumio[2]

[1]Kanazawa University, [2]Niigata University, [3]University of Ryukyus

Subduction zone is initiated by descending oceanic plate at the plate boundary and a counter flow of the mantle advances growth of the wedge mantle in the Izu-Ogasawara-Mariana arc (e.g. Stern, 2004). But it is questioned that do initial arc always develop a long-survived subduction zone? We present detailed volcanostratigraphy, petrology and geochemistry of short-lived juvenile arc tholeiite and subsequent boninite magmatism from the northern Oman ophiolite.

The Oman ophiolite belonging to the Tethys ophiolite belt is one of the best places to investigate magmatic and volcanic developing processes of an infant arc. The Ophiolite had formed on a spreading axis and followed by subduction stage magmatism at approximately 100 Ma. The V2 sequence was constructed by initial arc magmatism begun $<$2 m.y. after the spreading ridge stage (e.g. Hacker et al., 1996). Based on the radiolarian fossil age, the V2 volcanism ceased 2-3 m.y. after the ridge stage (Kurihara and Hara, 2012), therefore, it seems to record short-spanned island arc magmatism.

An 1110 m thick V2 sequence is divided into the lower 970 m (LV2) and upper 140 m (UV2) thick subsequences by a 1.0 m thick sedimentary layer in Wadi Bidi. Pahoehoe flows dominate in the lower part of the LV2, while the upper part consists mainly of sheet flows with intervened few pelagic sediments, a fissure vent and a cylindrical plug. In addition to the presence of feeder conduits, the flow-dominant lithofacies with a few thin sedimentary interbeds in the LV2 indicates that the study area was the center of a monogenetic volcano grown in a short period. The LV2 consist of arc tholeiite with orthopyroxene phenocrysts increasing in amount upward. The UV2 is composed of sheet flows overlain by a 2.0 m thick subaqueous pyroclastic fall deposit. They are boninite containing olivine and two-pyroxene phenocrysts with plagioclase in the groundmass. Successive orthopyroxene-bearing arc tholeiitic volcanism in the LV2 followed by a relatively small amount of boninite lavas in the UV2 overlain by thick pelagic sediments suggests that the infant arc volcanism was short lived and terminated long before the ophiolite obduction.

Fate of high-T subduction zone and the obduction of the Oman Ophiolite

UMINO, Susumu[1*] ; KUSANO, Yuki[1] ; KITAMURA, Keitaro[1] ; NAGAISHI, Kazuya[2] ; ISHIKAWA, Tsuyoshi[3] ; KANAYAMA, Kyoko[1]

[1]Department of Earth Sciences, Kanazawa University, [2]Marine Works Japan, [3]JAMSTEC

Obduction of ophiolitic bodies onto continental crust inevitably follows a tectonic event of conversion from divergence to convergence of plates. This is commonly accomplished by the formation of intraoceanic subduction zone near the ridge axis, where lithospheric lid is thinnest and weakest, and accompanies the boninite volcanism [3]. The upper part of the subducted slab is metamorphosed and later thrust over onto a continent with the overlying mantle to become ″ the metamorphic sole ″ . Known examples of metamorphic soles record peak T-P of 600˜840 ℃ and ˜1 GPa, whereas the thickness of overlying ophiolite sheets are only 10-20 km, yielding too small lithospheric load compared to the metamorphic pressure of the sole [4]. This discrepancy has been explained that the ophiolite sheet and the metamorphic sole formed at discrete places were emplaced and superposed at the same place during the obduction process [3].

However, we have demonstrated by examining the trace element geochemistry of the arc magmas and metamorphic sole of the Oman Ophiolite that fluid liberated from the metamorphic sole triggered flux melting of the overlying depleted mantle peridotite and produced arc tholeiitic basalt magma first, and subsequently low-Si boninite magma. Therefore, the ophiolite and the underlying metamorphic sole did not form independently at distant places, but were formed and transported together as an intact body with the present structural relationship. Genetic conditions estimated for a primitive boninite melt with 16 wt% MgO enclosed by Cr spinel indicate the segregation pressure of 0.5 GPa and 1320 ℃ from the mantle with the potential T of 1400 ℃ [1, Kusano et al., this session]. Thus, the boninite magma should have segregated from the mantle at a depth $>$17 km. Nevertheless, the present ophiolite body has the maximum thickness $<$15 km.

The above lines of evidence urged us to propose the following model; Conversion from spreading to closure of the Tethys resulted in the subduction of young and hot oceanic lithosphere beneath the Tethyan ridge axis. The oceanic crust of the subducted slab was metamorphosed to cpx-bearing amphibolite at a depth of ˜35 km and 800 ℃. Trace elements and Nd-isotopic evidence indicate fluids and partial melt of subducted sediments liberated from the dehydrated slab migrated upward and formed a partially melted column in the wedge mantle [6, 7]. Primary boninite magmas segregated from the residual harzburgite on the top of the melting column at a depth of ˜17 km and at 1320 ℃ and ascended to form dunite channels and depleted zones through the uppermost lithospheric mantle [8]. Because serpentine and chlorite are unstable $>$800 ℃, the subducted crustal rocks are metamorphosed to amphibolite and the overlying mantle peridotite becomes amphibolite-bearing lherzolite. The lack of mineral phases which could act as lubricant caused large friction and eventual cohesion of the metamorphic slab and hanging wall of the mantle peridotite. Because of the large mechanical strength of the upper crustal and the lower mantle section of the slab, the lower slab of lithospheric mantle are decoupled from the crustal upper slab and continued to subduct without dehydration because the lower slab was virtually anhydrous. This terminated the Oman arc volcanism in a few million years with the production of boninite magma. The strongly coupled upper slab with the overlying wedge mantle obducted together onto the Arabian Peninsula as the metamorphic sole. During the course of thrusting toward the continent, the hot and partially molten asthenospheric mantle in the wedge was squeezed and flattened by the load of the overlying lithosphere, resulted in the present structure of the thin ($<$15 km) ophiolite sheets underlain by the metamorphic sole formed at a high pressure ˜1 GPa.

Magmatic diversity of the ultramafic rock in the oceanic crustal sequence, Oman ophiolite

KANEKO, Ryu[1*] ; ADACHI, Yoshiko[2] ; MIYASHITA, Sumio[2]

[1]Graduate School of Science and Technology, Niigata University, [2]Niigata University

Although all the wehrlitic intrusions in the Oman Ophiolite are regarded as a single group (e.g. Koepke et al. 2009), there are two different types of wehrlitic intrusions. The first are ordinary wehrlitic intrusions that have similar features to the crustal sequence of V1 (MOR basalt). The second are a depleted type characterized by the appearance of true wehrlite and depleted mineral compositions (Adachi & Miyashita 2003; Yamasaki et al. 2006; Goodenough et al. 2010). The former and latter groups are linked to V1 and V2 magmatism, respectively.

We report the discovery of a new occurrence of the ultramafic rock in the oceanic crustal sequence from the Oman ophiolite, which does not intrude into the crustal sequence. This ultramafic rock is referred to as the Lasail-South complex, and the oldest rock in the study area because of being intruded by sheeted dyke complex. TiO2 and Na2O contents of clinopyroxene from the complex range 0.06-0.59 and 0.09-0.42 wt%, respectively, and are similar to the fractional crystallization trend of oceanic gabbro. Co-variation of Mg values of clinopyroxene and An contents of plagioclase show that most of samples plot in the Oman layered gabbro field. Although mineral compositions of the Lasail-South complex show characteristic of mid-ocean ridge magmatism, the complex mainly comprises plagioclase?hornblende lherzolite, olivine clinopyroxenite and clinopyroxenite. Such rock assemblage of is different from the assemblage of the oceanic crust of the Oman ophiolite. The Lasail-South complex shows intermediate characteristic of mid-ocean ridge and island arc magmatisms, and we attempt to discuss the origin of the complex.

Compositionally and genetically distinct domains found in the southernmost Salahi mantle section in the Oman ophiolite

FUJII, Satoru[1*] ; TAKAZAWA, Eiichi[2]

[1]Graduate school Science and Technology, Niigata University, [2]Faculty of Science, Niigata University

We investigate spatial variability in mineral compositions in the southernmost part of the Salahi mantle section and discuss genetic relationship between highly refractory peridotites and less refractory plagioclase-bearing peridotites in this region. The study separates the study area into two domains based on spinel Cr# such as high Cr# domain in the eastern part that is closer to Moho and low Cr# domain in the central part. Concordant dunites commonly occur in the low Cr# domain whereas discordant dunites are common in the high Cr# domain. Plagioclase-bearing peridotites and wehrlite also occur in the low Cr# region.

Highly refractory dunite with spinel Cr# >0.7 frequently occurs in the high Cr# domain. In the low Cr# domain, spinel Cr# is low and ranges from 0.47 to 0.57. We analyzed clinopyroxene (cpx) in dunites and harzburgite from both domains for REE abundances by LA-ICP-MS. The results show that harzburgite cpxs in the high Cr# domain and low Cr# domain are highly depleted in LREE ([Ce]CH =0.01˜0.02) with [Yb]CH=2˜3. Dunite cpxs in the low Cr# domain have REE abundances similar to the harzburgites in the same outcrop whereas those in the high Cr# domain are enriched in LREE relative to the harzburgite cpxs in the same outcrop. This implies that dunite cpxs in the high Cr# domain were reacted with LREE-enriched fluid infiltrated from the base of the ophiolite.

In the low Cr# domain, plagioclase-bearing dunite, plagioclase-bearing lherzolite vein occur and phlogopite-bearing wehrlite discordantly cuts them. The spinel Cr# of these dunites are in a range from 0.46 to 0.56. Abundances of REE in a melt in equilibrium with cpx in plagioclase-bearing peridotites and associated dunites are similar to those of N-MORB. On other hand, a melt in equilibrium with wehrlite cpx resembles to those of boninitic dikes from the Fizh block in the northern Oman ophiolite (Yamazaki, 2013). From the field occurrence, plagioclase-bearing dunite and plagioclase-bearing lherzolite formed by a reaction with MORB melt beneath spreading ridge whereas cumulative wehrlite was crystalized from a boninitic melt.

Mafic and ultramafic rocks along the southern Central Indian Ridge close to the Kairei Hydrothermal Field

NISHIMURA, Takuma[1] ; HARIGANE, Yumiko[2] ; MICHIBAYASHI, Katsuyoshi[3*] ; MORISHITA, Tomoaki[4] ; SATO, Hiroshi[5]

[1]Institute of Geosciences, Shizuoka University, [2]AIST/GSJ, [3]Institute of Geosciences, Shizuoka University, [4]School of Natural System, Colleage of Science and Technology, Kanazawa University, [5]School of Business Administration, Senshu University

The central Indian Ridge (CIR) is situated at the north of the Rodrigues Triple Junction (RTJ) and is a slow- to intermediate-spreading mid-ocean ridge with a spreading rate increasing from 30 mm/year in full rate near the Equator to 49 mm/year in full rate at the RTJ. In the southern CIR near RTJ, the Kairei Hydrothermal Field (KHF) was discovered in August 2000 as the first directly observed hydrothermal vent site in the Indian Ocean. Recently, KH-10-06 cruise aboard R/V Hakuho-maru was organized for understanding the hydrothermal system and geological feature around KHF. In this study, we present the petrography of mafic and ultramafic rocks dredged from the vicinity of the KHF during KH-10-06 cruise. A total of 76 samples have been studied from 9 sites, including 24 ultramafic rocks and 38 mafic rocks and 14 other rocks. Most of them are remarkably altered and hydrated. We classified them into sub-groups based on their textures and mineral assemblies. The ultramafic rocks were classified into 5 sub-groups: 1 peridotite, 2 pyroxenites, 3 serpentinized peridotites, 9 olivine-bearing serpentinites and 9 serpentinites. The mafic rocks were classified into 8 sub-groups: 21 Fe-Ti oxide gabbros, 4 gabbros including 2 mylonites, 3 olivine gabbros, 7 gabbroic rocks with various textures and 8 amphibole-rich gabbros. The other rocks consist of 5 aragonites and 9 hydrothermally altered rocks.

Upper mantle electrical resistivity structure at the continental margin of East Antarctica

MATSUNO, Tetsuo[1*] ; NOGI, Yoshifumi[1] ; SEAMA, Nobukazu[2]

[1]National Institute of Polar Research, [2]Kobe University

The breakup of the Gondwana supercontinent is one of targets of the study on the plate tectonics and related mantle dynamics. The crust and the upper mantle structure under the western Cosmonauts Sea at the continental margin of East Antarctica, where a rifting of Gondwana and a subsequent seafloor spreading occurred, are anticipated to reflect the breakup process of Gondwana. We carried out a marine electromagnetic experiment to reveal an electrical resistivity structure at depth of the crust and the upper mantle under the western Cosmonauts Sea. Time variations of the electromagnetic field were acquired at two seafloor sites in the experiment. The time variations data were processed on the basis of the magnetotelluric (MT) method. The MT response function was obtained after considering influence of non-plane magnetic field sources at high geomagnetic co-latitude. The obtained MT response functions and polar diagrams imply that the MT responses involve topographic distortion and/or reflect a higher dimensional resistivity structure under the observational sites. Three dimensional forward modeling was conducted to examine influence on the observed MT responses from the topographic variation around the observational sites and a conductive layer just under the sites, which is mostly regarded as sediment. The results of the forward modeling clearly show that the topographic variation and the surface conductive layer have severe influence on the observed MT responses. A series of 3-D forward modeling with the topographic variation and the surface conductive layer was implemented to examine a resistivity structure at depth of the crust and the upper mantle. The results indicate that the resistivity structure is explained by a two-layer resistivity structure, in which the upper layer is resistive and the lower layer is conductive. The upper resistive and the lower conductive layers likely represent dry and water/melt rich oceanic upper mantle, respectively. The thickness of the upper resistive layer is thinner than that expected for a typical oceanic upper mantle of the seafloor age of the study area. The thin upper resistive layer may require high temperature and high water/melt anomalies that were generated through mantle convection, which was related to the breakup process of Gondwana at the continental margin of East Antarctica.

Geochemical characteristics of the peridotites from the southern Mariana forearc

SAKUYAMA, Tetsuya[1*] ; ISHII, Teruaki[4] ; MICHIBAYASHI, Katsuyoshi[2] ; OHARA, Yasuhiko[3] ; CHANG, Qing[1] ; HARAGUCHI, Satoru[5] ; KIMURA, Jun-ichi[1]

[1]JAMSTEC, [2]Shizuoka Univ., [3]Japan Coast Guard, [4]Fukada Geological Institute, [5]Faculty of Engineering, Univ. Tokyo

Dehydration of a subducting oceanic plate and infiltration of the fluid/melt released from the oceanic plate are thought to be the key processes to invoke melting of the wedge mantle. Although a number of studies on volcanic rocks in arcs have been conducted to reveal a material recycling process at subduction zone, understanding of geochemical development process within the wedge mantle is still not as far advanced. The southern Mariana forearc is one of the best locations on the Earth to investigate issues above, since serpentinized peridotites are widely exposed on the inner slope of the Mariana Trench. We have collected peridotite samples obtained by dredging and Shinkai diving from 3000 — 7000 mbsl at the southern Mariana Trench. The dredge and dive points are geographically grouped into three sites: site 1 (KH98-1-D1, KH98-1-D2, and 6K-973), 2 (KH03-3, KH98-1-D3, and 6K-1094), and 3 (6K-1095, 6K-1232, 6K-1233, and 6K-1234) from the east to the west. We conducted EPMA and LA-ICP-MS analyses on minerals in the recovered samples to reveal geochemical development process of the wedge mantle.

Peridotites from the easternmost site 1 consist of olivine (Fo# = 90 — 91), orthopyroxene (Mg# = 90 — 91), spinel (Cr# = 40 — 50), clinopyroxene (Mg# = 89 — 93), tremolite (TiO_2 = 0 — 0.4 wt%), pargasite (TiO_2 = 2.0 — 2.5 wt%), plagioclase, and serpentine. Clinopyroxene and pargasite exhibit LREE-depleted (type C1 and A1, respectively) and orthopyroxene LREE- and MREE-depleted patterns (type O1) in a chondrite-normalized diagram.

Peridotites from the westernmost site 3 consist of olivine (Fo# = 91 — 92.5), orthopyroxene (Mg# = 91 — 93.5), spinel (Cr# = 45 — 75), clinopyroxene (Mg# = 94 — 96), tremolite (TiO_2 = 0 — 0.2 wt%) and serpentine. Some clinopyroxene exhibits LREE-enriched convex upward pattern (type C2), others strong LREE- and MREE-enriched REE pattern (type C3). Tremolite and orthopyroxene exhibit LREE-enriched convex upward (type A3) and weakly LREE-enriched convex upward REE patterns (type O2), respectively. HREE, Ti, and Y abundances of type C3 clinopyroxene are higher and their LREE and Sr abundances lower than those of type C1 clinopyroxene.

Peridotites from the middle site 2 show intermediate characteristics between site 1 and 3. They consist of olivine (Fo# = 90 — 92), orthopyroxene (Mg# = 91 — 92.5), spinel (Cr# = 45 — 52), clinopyroxene (Mg# = ˜95), pargasite (TiO_2 = 0.8 — 1.7 wt%), tremolite (TiO_2 = 0 — 0.2 wt%), plagioclase and serpentine. Some clinopyroxene exhibits C1-type REE pattern and coexists with A1-type pargasite, while other clinopyroxene exhibits LREE- and MREE-depleted patterns (type C2) coexisting with LREE- and MREE-depleted tremolite with weak enrichment in LREE (type A2).

Compared to results of high-pressure melting experiments on peridotite, monotonous increase of Mg# of olivine, clinopyroxene, and orthopyroxene as well as Cr# of spinel from site 1 to 3 suggests increase of melting degree of the mantle peridotite from site 1 to 3. Monotonous decrease of HREEs, Ti, Y, Zr, and Hf abundance from C1- to C3-type clinopyroxene, from A1- to A3-type amphibole, and from O1- to O2-type orthopyroxene, is consistent with major element variations above. However, in contrast to the observation above, LREE and LILE abundance increase from C1- to C3-type clinopyroxene, from A1- to A3-type amphibole, and from O1- to O2-type orthopyroxene, suggesting involvement of melt/fluid enriched in such elements.

LREE-enriched clinopyroxene and amphibole have been found from mantle xenoliths and subaerial peridotite complex. Those clinopyroxene and amphibole have been interpreted as a product of melting and melt separation involving infiltration of LREE-enriched melt/fluid into the melting system. Similarity of geochemical characteristics of type C3 clinopyroxene and A3 amphibole to those in xenoliths or peridotite complexes may suggest involvement of LREE-enriched melt/fluid to the mantle beneath the southern Mariana forearc.

Petrological features of the peridotite xenoliths in the 1991 Pinatubo dacite and mantle metasomatism by subducted ocean

YOSHIKAWA, Masako[1*] ; TAMURA, Akihiro[2] ; ARAI, Shoji[2] ; KOBAYASHI, Tetsuo[3] ; KAWAMOTO, Tatsuhiko[1] ; OKUNO, Mitsuru[4] ; PAYOT, Betchaida[2] ; RIVERA, Danikko[5] ; BARISO, Ericson[5] ; MIRABUENO MA., Hannah T.[6]

[1]Institute for Geothermal Sciences, Kyoto Univ., [2]Department of Earth Sciences, Kanazawa Univ., [3]Department of Earth and Environmental Sciences, Kagoshima Univ., [4]Department of Earth System Science, Fukuoka Univ., [5]PHIVOLCS, [6]Institute of Volcanology and Seismology, University of the Philippines

We observed peridotite xenoliths in the dacite of the 1991 pyroclastic flow deposit of Pinatubo volcano, which is located at the volcanic front of the Luzon (Bataan) arc, Luzon island, the Philippines. The Luzon arc is associated with eastward subduction of the South China Sea plate along the Manila Trench. We also found olivine xenocrysts and xenoliths of amphibolite and granitic rocks in the dacitic deposits. The largest xenolith was up to 14 cm across among about 200 collected samples. Selvage of hornblendite, up to 5 mm width, is common between the peridotite and the dacite host.

Arai et al. (1996) classified peridotite xenoliths from Iraya volcano, Batan Island, the Philippines, into coarse grained (C) and fine grained (F) types depend in terms of olivine grain size. The C-type xenoliths are equivalent to ordinary mantle xenoliths from various localities and the F-type xenoliths are quite different in texture, its individual grains being hardly visible by the naked eye and the fine-grained ($\leq$ 0.1 mm) part occupying $>$10 % by volume (Arai and Kida, 2000). They interpreted that the F-type peridotite was possibly formed from the C-type one by recrystallization assisted by SiO_2-rich fluid or melt originated from subducting slab. Such peculiar F-type xenoliths can be observed in the peridotite xenoliths from Avacha volcano on the volcanic front of the Kamchatka arc, Russia (Ishimaru et al., 2007) and at Tubaf and Edison volcanos, Tabar-Lihir-Tang-Feni island arc, which occur in the fore-arc region of the New Ireland intra-oceanic island arc, Papua New Guinea (McInnes et al., 2001). According to their definition, the F-type peridotites occupy about 50 % of 40 Pinatubo samples. Almost all of the Pinatubo C-type xenoliths are spinel harzburgites (olivine + orthopyroxene + amphibole + spinel $\pm$ clinopyroxene $\pm$ phlogopite) except a wehrlite and a dunite samles. CO_2-bearing saline fluid inclusions were observed in all samples (Kawamoto et al., 2013).

The Sr-Nd isotopic compositions of amphibole from the primary C-type xenolith containing least amounts of fine-grained part are consistent with the most depleted values of the range of andesite and dacite ($^{87}Sr/^{86}Sr$ = 0.70419 - 0.70425, $^{143}Nd/^{144}Nd$ = 0.512863 - 0.512924; Castillo et al, 1991; Bernard et al, 1991). Their compositional variation is within a range of South China Sea oceanic basalt (Tu et al., 1992). Multi-element chondrite-normalized patterns of the amphiboles show depleted signatures with enrichment of Ba, Rb, U, in Pb. These enriching elements are considered as fluid mobile during dehydration of subducting mantle, oceanic crust and sediment (e.g. Tatsumi et al., 1986; McColloch & Gamble, 1991). The present Sr-Nd isotopic and geochemical signatures of the amphibole suggest that the Pinatubo C-type mantle xenoliths have also been metasomatized by aqueous fluids released from subducted oceanic crust beneath the volcanic front.

Petrology of mafic-ultramafic rocks in the East Taiwan Ophiolite, in the Lichi melange, Taiwan

KOMARU, Chihiro[1*] ; MORISHITA, Tomoaki[1] ; TAMURA, Akihiro[1] ; ARAI, Shoji[1]

[1]Graduate School of Natural Science, Kanazawa University

Taiwan is located on the border between the Philippine Sea Plate and the Eurasia Plate. The blocks of cherts, volcanic rocks, plutonic rocks (mafic-ultramafic rocks) are widely distributed as exotic blocks in the Lichi melange, southeastern Taiwan (Liou et al., 1977). These ophiolite-like rocks (cherts, volcanic rocks, plutonic rocks) are defined as the East Taiwan Ophiolite (Liou, 1977). The origin of the East Taiwan Ophiolite is still in debate. Three possible candidates are (1) Philippine Sea Plate (Liou, 1974), (2) the north extension of the Luzon volcanic arc (Ota and Kaneko, 2010), and (3) the South China Sea (Suppe et al., 1981). In this study, we focus on petrological characteristics of gabbros and peridotites in the East Taiwan Ophiolite.

In this research, we collected mafic-ultramafic rocks to cover a wide range of variations in terms of mineral variations at each outcrop. The gabbros are classified into troctolite, olivine gabbro, hornblende gabbro, and gabbronorite. Most of ultramafic rocks are extensively serpentinized, but have equigranular textures based on shape of relic and pseudomorph minerals except for a few serpentine mylonites. The serpentinized peridotites are classified into clinopyroxene-bearing harzburgite and dunite. The Cr# (Cr/(Cr+Al) atomic ratio) and Mg# (Mg/(Mg+Fe) atomic ratio) of spinels in the serpentinized peridotites are 0.3-0.6 and 0.3-0.5, respectively. It is well characterized that the high-Cr# spinel ($>$0.6) coupled with the formation of secondary orthopyroxene are commonly observed in ultramafic xenoliths in Luzon arcs (Arai et al., 2004). We conclude that the East Taiwan Ophiolite is similar with abyssal peridotites and gabbros collected from mid-ocean ridges or back arc basins.

Petrological evidence for arc-metasomatized peridotites beneath mid-ocean ridges

MORISHITA, Tomoaki[1*] ; SENDA, Ryoko[3] ; SUZUKI, Katsuhiko[3] ; NAKAMURA, Kentaro[3] ; SATO, Hiroshi[2] ; OKINO, Kyoko[4]

[1]Kanazawa University, [2]JAMSTEC, [3]Senshu University, [4]University of Tokyo

Here we report for the first time petrological evidence of recycled subduction-modified mantle materials beneath the Mid-Ocean Ridge. We conducted several cruises with submersible SHINKAI 6500 dives and dredges in the south end of the Central Indian Ridges (Phenix knoll). We recovered orthopyroxene-rich lithologies coupled with peridotites and gabbros from a small knoll along the present mid-ocean ridge. The orthopyroxene-rich lithologies can be formed by magmatic processes beneath the present mid-ocean ridges by crystallization from ultra-depleted primary melts (Sobolev and Shimizu, 1993, Nature) in the Mid-Ocean ridge system. Orthopyroxene-rich peridotites are also commonly observed in peridotite bodies of suprasubduction ophiolites (e.g., Morishita et al., 2011 Lithos) as well as in several sub-arc xenoliths (McInnes et al., 2001 EPSL; Arai and Kida, 2000 Island Arc; Arai et al., 2004 J. Petrol; Shimizu et al., 2004 Trans. Royal Soc. London; Ishimaru et al., 2007 J. Petrol). It is also well known that 30% of continental upper mantle samples are enriched in OPX/olivine relative to residual peridotite from partial melting of the primitive mantle (e.g., Boyd, 1989 EPSL; Kelemen et al., 1998 EPSL). Silica-enrichment in the uppermost mantle section under island-arcs is explained by infiltration of silica-rich hydrous fluids/melts derived from subducting slabs. The Re-Os system also supports subduction-metasomatized peridotite origins for orthopyroxene-rich lithologies. The Re-Os isotope system is used for a tracer of recycled crustal materials because oceanic/continental crust possess high Re/Os (parent/daughter) ratios, and develop radiogenic Os isotope compositions over time, which can be readily traced as recycled material if mixed back into the convective mantle. We examined the Os-isotopic compositions of the representative samples: dunite, one harzburgite and one olivine-orthopyroxenite, without signs of petrological and chemical modifications caused by the formation of gabbroic veins. The orthopyroxenite is characterized by a distinctively high in radiogenic Os (187Os/188Os) isotope signatures (0.1475-0.1499) with relatively high in Re contents (382-402 ppt) whereas the Os isotope of the harzburgite is slightly lower than the present-day depleted MORB mantle (0.123-0.126). High 187Os/188Os ratio coupled with high Os and Re contents of the olivine-orthopyroxenite cannot be accounted for by in situ 187Re decay after interaction between MORBs and peridotites for a million years. Radiogenic Os isotope compositions have been reported for MORB glass, and attributed to the presence of recycled oceanic crust in the upper mantle. Mixing of depleted mantle with exotic component that have an isotopic component with high 187Os/188Os ratios, i.e., radiogenic Os components, are required for the sample. We evaluate the effect of metasomatism of mantle by slab-derived fluids or melts on Os systematics observed in the samples. We conclude that ancient subduction-modified mantle domains, probably formed at continental margin of the Gondwanaland, now exists beneath the Central Indian Ridge.

An evaluation of the effect on 14C dating (AMS) by alkaline treatment of the ABA method on charcoal sample

ATSUMI, Shin[1*]

[1]Tokyo University of Sciences

Charcoal treatment by means of the Acid-Base-Acid (ABA) method (or Acid-Alkali-Acid; AAA method) has been widely used for radiocarbon (^{14}C) dating in the Earth Science and Archaeological field. Although the ABA method is a basic charcoal pretreatment method for ^{14}C dating, the evaluation of processing conditions of the ABA method based on any chemical indicator does exist few until today. This study aims to clarify the error of ^{14}C dating caused by the alkaline pretreatment which is not studied hitherto. The author performed 3 types of experiments for the purpose. The first experiment was performed for confirmation of the reproducibility of ges. The second experiment was performed for confirmation of optimal treatment time of an alkaline solution. The third experiment was performed for confirmation of the optimal concentration of alkaline solution for the ABA pretreatment.

The first experiment: X^2 test of the results shows T=0.45(df=3;5% risk rate T $>$12.59)for the treated samples which means high convergent validity, while T=10.74(df=4;5% risk rate T $>$9.49)for the untreated samples which means large scattering and significant variability.

The second experiment: even after the visual judgment of the completion of alkaline extraction, 3-DF detected humic acid in the retrieved NaOH solution, and Atsumi et. al. (2009) showed that radiocarbon (14C) dating was influenced the existence of humic acid. These results suggest that visual observation is inadequate for the judgment of the completion of alkaline extraction, and that 3-DF is more effective for monitoring the presence of dissolved organic contamination.

The third experiment: three charcoal samples from a single archaeological context were split into 8 aliquots respectively, and treated with 8 different concentrations of NaOH solutions ranging from 0.001 to 2.0 mol/l. Dating results and X^2 tests showed minimum convergence at 1.2 mol/l. This is supported by 3-dimensional fluorescent (3-DF) analysis, which clearly shows different leaching characteristics between 2.0-1.0 and 0.5-0.001 mol/l. 0.5-0.001 mol/l NaOH solutions were too weak in humic leaching capacity at low excitation ranges, which is thought to be the phenomenon that generates the scattering of dates. We recommend using from 1.0 to 1.5 mol/l NaOH for radiocarbon pretreatment.

These results show that the ^{14}C age is affected by difference of the residual of humic acid caused by the difference of chemical conditions of the pretreatment .

Dating of sea-floor hydrothermal barite collected at the Okinawa Trough by ESR and radioactive disequilibrium

FUJIWARA, Taisei[2*] ; TOYODA, Shin[1] ; UCHIDA, Ai[2] ; ISHIBASHI, Jun-ichiro[3] ; NAKAI, Shun'ichi[4] ; TAKAMASA, Asako[5]

[1]Faculty of Science, Okayama University of Science, [2]Graduate School of Science, Okayama University of Science, [3]Faculty of Science, Kyushu University, [4]Earthquake Research Institute, University of Tokyo, [5]National Institute of Radiological Sciences

The temporal change of submarine hydrothermal activities has been an important issue in the aspect of the evolution of hydrothermal systems which is related with ore formation (Urabe, 1995) and biological systems sustained by the chemical species arising from hydrothermal activities (Macdonald et al., 1980). Dating methods using disequilibrium between radioisotopes such as U-Th method (e.g. You and Bickle, 1998), ^{226}Ra-^{210}Pb and ^{228}Ra-^{228}Th method (e.g. Noguchi et al., 2011) have been employed for such studies.

Okumura et al., (2010) made the first practical application of ESR (electron spin resonance) dating technique to a sample of submarine hydrothermal barite to obtain preliminary ages, while Kasuya et al. (1991) first pointed out that barite can be used for ESR dating. Toyoda et al. (2011) determined the optimum ESR condition while Sato et al. (2011) confirmed that the signal is thermally stable enough for an age range of several thousand years. Takamasa et al. (2013) obtained U-Th and ESR ages which are roughly consistent with each other.

The samples were taken by research cruises operated by JAMSTEC. Barite (BaSO4) was extracted from hydrothermal sulfide chimney samples taken from two sites at the Okinawa Trough. Blocks of sulfide deposits were cut into pieces, and about 2.0g was crushed. The samples were soaked in 12M hydrochloric acid, left for approximately 24 hours. Then, 13M nitric acid was added. Finally, after rinsing in distilled water, the sample was filtered and dried. Impurities were removed by handpicking. An X-ray diffraction study was made to confirm that the grains are pure barite. After gamma-ray irradiation at Takasaki Advanced Radiation Research Institute, Japan Atomic Energy Agency, they were measured at room temperature with an ESR spectrometer (JES-PX2300) with a microwave power of 1mW, and the magnetic field modulation amplitude of 0.1mT. The bulk Ra concentration was measured by the low background pure Ge gamma ray spectrometer. Assuming that Ra is populated only in barite, the dose rate was calculated with the alpha effectiveness of 0.043 (Toyoda et al., 2012), where the decay of Ra (a half life of 1600 years) was also taken into account.

The obtained ages range from 4.1 to 16000 years, being consistent with detection of ^{228}Ra in younger samples and radioactive equilibrium/disequilibrium between radium and daughter nuclei. The variation of the ages within each sample is mostly within the statistical error range. The relative order of the ages is consistent with the result of ^{226}Ra-^{210}Pb method, where the difference in absolute ages would be explained by several hydrothermal events that form the chimney. It was found that Yoron Hole field is the youngest, then, Daiyon-Yonaguni Knoll field, Hatoma Knoll field, being nearly equal to Iheya North Knoll field, then Izena Hole field, which is consistent with the direct observation from the submersible.

Thermoluminescence property of calcite

OGATA, Manabu[1*] ; HASEBE, Noriko[1] ; FUKUSHI, Keisuke[1] ; FUJII, Naoki[2] ; SATO, Tsutomu[3] ; ITO, Kazumi[4]

[1]Kanazawa University, [2]RWMC, [3]Hokkaido University, [4]AIST

In earth science, the date of past event is very important. To determine accurate age, we have to select suitable dating method for an analyzed sample.

Thermoluminescence dating method calculates a date from equivalent dose estimated by emitted luminescence when mineral is heated. Thermoluminescence dating has been often applied to carbonate minerals because it emits strong luminescence and wider age range applicable than C14 dating method is an advantage of thermoluminescence dating.

However, thermoluminescence dating of calcite is sometimes problematic; e.g., sensitivity change of calcite occurred through repeated heating of samples, possible anomalous fading, difference in characteristics of luminescence response against different kinds of radiation (e.g., gamma-ray, beta-ray, alpha-ray, and x-ray), and so on.

In this study, calcite from Philippine, Mongol, and synthetic calcite are analysed to understand luminescence characteristics of calcite. Mgnesite is also analyzed to see the effect of chemistry. Luminescence was detected by Photon Multiplier (R649, HMA-MATSU) with filter of 600-650nm. Chemical composition, especially impurity concentration was measured by LA-ICP-MS.

First, we evaluate X-ray induced thermoluminescence property of each sample.

Second, we measured luminescence caused by alpha-ray, beta-ray and gamma-ray and compare it to the luminescence induced by the x-ray. .

Finally, the relationship between luminescence characteristics (namely a-x-value, b-x-value and c-x-value) and impurity concentration is examined.

As a result;

1. Most calcites have thermoluminescence peak at 80 and 230 degrees Celsius.
2. In thermoluminescence peak of calcite at 80 degrees Celsius, fading is detected, while at 230 degrees peak is stable.
3. Results show negative or positive relationship between luminescence efficiency factors (a-x-value, b-x-value and c-x-value) and Mg, Mn, Fe and Sr concentrations.
4. The concentration of Fe has a correlation with a luminescence emitting efficiency.

Fe plays an important role for thermoluminescence of calcite. Thermoluminescence property of calcite may be subject to multiple chemical factors (ex; Mg, Mn and Sr), therefore, further analyses on calcites with the variety of impurity is necessary to evaluate a relation between multiple impurity concentration and thermuluminescence properties quantitatively.

Zircon observation by atomic force microscope: Fission track or alpha recoil track?

HASEBE, Noriko[1*] ; ITO, Kentaro[1] ; OHISHI, Shinnosuke[1] ; HONDA, Chiaki[1] ; MATSUKI, Atsushi[1] ; FUKUMA, Takeshi[1]

[1]Kanazawa University

Fission track (FT) method is a dating technique based on the observation of damage (tracks) by spontaneous fission of 238U left in a mineral. The number of tracks is counted under an optical microscope after etching (chemical expansion of a track). However, as FT density per unit area rises, it becomes difficult to count the number of tracks. This is due to the fact that FTs overlap one another and are unable to be readily distinguished. The atomic force microscope has a potential to observe FT with high track density after a short time etching. However, when etching time is too short, the number of counted tracks were increased probably due to difficulties in recognizing the FT among structures other than FT (e.g., alpha recoil tracks). In the observation of young zircons collected from modern volcanic product, the surface structures found in old zircons do not exit, and a hole with the depth of ˜10nm can be found on the smooth surface. These countable holes may lead us to the alpha recoil track dating.

Excess argon in phengite from the Sanbagawa eclogites: Constraints on argon behavior during subduction zone metamorphism

ITAYA, Tetsumaru[1*] ; TSUJIMORI, Tatsuki[2]

[1]Okayama University of Science, [2]Okayama University

K-Ar system dating of phengitic mica is a powerful tool to determine cooling ages of HP?UHP metamorphic rocks. However, discordant ages in a same metamorphic unit have been often reported, particularly from rocks in Alpine-Himalayan type collisional metamorphic belts. For example, UHP-metamorphosed continental crust materials of the Dola Maira massif (western Alps, Italy) show the discrepancy due to the existence of excess argon in metamorphic minerals that has been inherited from the precursor rocks with polyphase metamorphic records. Over the last two decades, we have addressed an excess-argon free hypothesis in oceanic petrogenesis of Pacific-type convergent margins. According to the hypothesis, metamorphosed oceanic materials in Pacific-type HP metamorphic belts with only a monophase metamorphic records do not contain significant amount of excess 40Ar; in other words, the K-Ar system in syn-metamorphic phengitic mica is significantly reset during fluid-induced metamorphic recrystallization at a Pacific-type convergent margin. Well-documented geological examples are of schists from Sanbagawa, Suo and Renge metamorphic belts in SW Japan, and from Otago metamorphic belt in New Zealand. Ar-Ar phengite analyses of HP-UHP metamorphosed oceanic lithologies of the Lago di Cignana (western Alps, Italy) also show negligible excess 40Ar in eclogite-facies syn-metamorphic phengitic mica.

In the year 2000, as a preparation to guide participants for the IEC Conference in Japan, we have determined K-Ar ages of phengite and paragonite from the eclogite-facies Sanbagawa metamorphic rocks in Shikoku; the twenty-two results were obtained from four localities including Seba (84-89 Ma), Gongen (123-136 Ma) and Western Iratsu (78-80 Ma), and Kotsu/Bizan (82-88 Ma). Excepting for the quartz-rich kyanite eclogite from Gongen (GO), phengite and/or paragonite yields similar cooling-age ranges of metasedimentary rocks of the Sanbagawa metamorphic rocks in central Shikoku. Phengite K-Ar ages of GO eclogites are significantly older than syn-metamorphic zircon U-Pb ages at the same unit. These old ages are interpreted as the presence of excess 40Ar in phengitic mica. The bulk-rock compositions of GO eclogites suggest a sedimentary protolith such as greywacke. When, where and how has the excess argon been trapped in phengite crystals? Considering the geological fact that the GO eclogites are closely associated with the Higashi-Akaishi (HA) meta-peridotite body, the false age obtained from phengite were likely attributed to an interaction between the meta-sediment (GO eclogite) and the meta-peridotite (HA peridotite) at eclogite-facies depth. We postulate that the fluids exchange between deep-subducted sediments and mantle material enhanced a hydration of peridotite and mantle-derived noble gas (including extreme 40Ar) was diffused from mantle material to the sediments. During the exhumation of them, the rigid HA peridotite might have prevented a ductile deformation of GO eclogite and consequently mantle-derived argon gained from HA peridotite in GO eclogite might have been inherited by the limited-argon-depletion due to less deformation. This is not only very rare example of false K-Ar age of metamorphosed oceanic materials but also remarkable observation to explain argon behavior during sediments?peridotite interaction at a deep portion of subduction zone environment.

Deciphering early Earth's differentiation using short-lived isotope systematics

IIZUKA, Tsuyoshi[1*]

[1]Tsuyoshi IIZUKA

Knowledge of the timescale and nature of early Earth's differentiation is central to understanding the evolution of the young Earth. Here I discuss short-lived isotope systematics of terrestrial samples that extended our knowledge of early Earth's differentiation. Recent high-precision W isotopic studies revealed positive 182W anomalies of up to 0.15 epsilon unit in ca. 3.8 Ga Itsaq rocks from West Greenland and 2.8 Ga Kostomuksha komatiites from Russia. I explored the geologic significance of the 182W anomalies by combining with trace element and other isotopic data. In this context, the W isotopic data are interpreted to reflect early silicate differentiation events on Earth. Under the assumption that the bulk silicate Earth has a 5% higher Sm/Nd than the chondrite average, the 182W-142Nd-143Nd chronometry constrains the age of the source mantle differentiation for the Itsaq samples to 4.53-4.49 Ga. The age may reflect the timing of silicate differentiation during a sequence of magma ocean solidification.

Formation age of Fengtien Nephrite, Taiwan: Dating low-temperature thin (<20 um) zircon rims by NanoSIMS

YUI, Tzen-fu[1] ; USUKI, Tadashi[1*] ; CHEN, Chun-yen[1] ; ISHIDA, Akizumi[2] ; SANO, Yuji[2]

[1]Institute of Earth Sciences, Academia Sinica, Taiwan, [2]Atmosphere and Ocean Research Institute, The University of Tokyo

Nephrite in the Fengtien area is associated with serpentinites within the subduction-accretionary complex in eastern part of the Central Mountain Range, Taiwan. In addition to nephrite, there are also other metasomatic rocks, such as diopsidefels and epidotite, present between serpentinites and their country rocks (metapelites and metapsammites). Among these metasomatic rocks, diopsidefels is the most common one observed, while nephrite and epidotite are less frequently present in association with diopsidefels. When all these rocks are present at one outcrop, the common lithologic sequence is serpentinite-nephrite-diopsidefels-epidotite- metasedimentary rocks. Nephrite, diopsidefels and epidotite were interpreted resulting from fluid-rock (serpentinite+country rocks) interactions during subduction metamorphism. Field occurrence and petrographic observations clearly showed that while nephrite and diopsidefels are mainly metasomatic products after serpentinite, epidotite is after metapsammite. The formation temperature has been estimated to be 300 - 400 ℃ based on regional geology and thermodynamic calculations by previous studies. Timing of these metasomatic processes, however, has not been constrained, although the hosting subduction-accretionary complex was thought to be of late Cretaceous in age due to paleo-Pacific subduction beneath the Eurasia continent and to be correlated with the Sambagawa belt in Japan. Zircons were separated from one epidotite sample in this study. Most of these detrital zircons were shown to have a thin zircon rim, which is less than 15 - 20 μm in thickness. These zircon rims were considered to be newly formed during metasomatic interactions between serpentinite and country rocks, which also led to nephrite/diopsidefels/epidotite formation. The CAMECA NanoSIMS NS50 at AORI, the University of Tokyo was employed to date these low-temperature thin zircon rims with a ~5 nA O- primary beam confined to a ~15 μm diameter. Sample surface was pre-ablated for 5 minutes to remove the surface Au coating and any possible surface contaminants. Data acquisition time was 500 seconds. The resulting 238U/206Pb-204Pb/206Pb inverse isochron gave a young age of 3.3±1.7 Ma (MSWD = 2.1, n = 5). The date clearly showed that the Fengtien nephrite would have formed during the (initial) exhumation of the subduction-accretionary complex, which should be of late Cenozoic in age related to subduction of the South China Sea plate beneath the Luzon arc. The present study gave a good example that NanoSIMS is able to date zircon rims with a thickness about 15 μm formed under low temperature conditions only a few million years ago. The instrument has a great potential in future studies dating various low-temperature hydrothermal, metasomatic or metamorphic zircon overgrowths.

Significance of external morphology and zircon chemistry for precise U-Pb zircon dating

TAKEHARA, Mami[1*] ; HORIE, Kenji[2] ; TANI, Kenichiro[3] ; YOSHIDA, Takeyoshi[4] ; HOKADA, Tomokazu[2] ; KIYOKAWA, Shoichi[5]

[1]Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, [2]National Institute of Polar Research, [3]Institute for Research on Earth Evolution, Japan Agency for Marine-Earth Science and Technology, [4]Institute of Earth Sciences, Graduate School of Science, Tohoku University, [5]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

Improvement of U-Pb zircon dating by microbeam analysis has been provided opportunity of discussion about more detailed geological events. Recent analytical precision of less than 2% at Paleogene zircon allows us to investigate shorter period events such as crystallization differentiation in magma chamber. However, the highly precise U-Pb age data yield an importance of confirming their accuracy and assaying disturbance of U-Pb system and incorporation of exotic components. In this study, we introduce data processing method of the highly precise ages based on zircon morphology, trace element abundances as well as statistics.

The precise U-Pb zircon dating by using a sensitive high-resolution ion microprobe (SHRIMP II) at National Institute of Polar Research, Japan, was applied to igneous rocks of the Tertiary Ishizuchi Cauldron in the Setouchi volcanic belt of Miocene age in northwestern Shikoku. A primary ion beam of about 10 nA was used to sputter an analytical spot of about 40 μm diameter. A retardation lens system was utilized as a means to increase signal-to-noise ratio, and a secondary ion optics including slits of source and collector was adjusted to maximum transmission of the secondary ion under suitable mass resolution avoiding isobaric interferences on Pb isotopes. The surfaces of grain mounts were carefully washed with diluted HCl and ultra pure water to remove Pb contamination. A correction for common Pb was made on the basis of the measured ^{204}Pb and the model for common Pb composition.

Weighted mean ages were calculated from ^{206}Pb/^{238}U ratios corrected by ^{207}Pb. In order to ensure the accuracy of U-Pb age, age known zircon, OD-3, was analyzed together with unknown sample. Concentrations of Hf and rare earth element (REE) in zircons were also measured at the same analytical spot of U-Pb dating by SHRIMP.

Zircon grains from the Bansyodani-biotite-rhyolite were divided to two types based on the external morphology: sharply euhedral type and relatively rounded edge of prism and pyramid type. ^{206}Pb/^{238}U data of whole zircon grains were widely scattered beyond analytical uncertainty and show a weighted mean of 14.78 $\pm$ 0.18 Ma (mean square weighted deviation, MSWD: 3.4). On the other hand, the euhedral zircons yielded the weighted mean of 14.21 $\pm$ 0.19 Ma (MSWD: 1.0), whereas the relatively rounded zircons were older than the euhedral zircons, which suggests the incorporation of exotic components.

Zircon chemistry supported the classification by the morphology and the U-Pb dating. An average of Hf contents of the euhedral zircons were 9523 ppm ranging from 8883 to 10496 ppm and those of the relatively rounded zircons were 8475 ppm ranging from 7616 to 8803 ppm. Hf contents of the euhedral zircons were higher than those of relatively rounded zircons. C1 chondrite-normalized REE patterns of the euhedral zircons were characterized by a large fractionation between light REE and heavy REE, large positive Ce anomalies and large negative Eu anomalies. In contrast, those of the relatively rounded zircons were enrichment of light REE, weaker anomalies of Ce and Eu. Difference of the zircon chemistry between the euhedral zircons and the relatively rounded zircons reflects source melt composition. Therefore, the external morphology, Hf content, and REE abundance are useful criteria for the data processing of the highly precise U-Pb age data.

LA-ICP-MS U-Pb dating of Oki Dozen volcano using non-polished zircons

ITO, Hisatoshi[1*] ; BRENNA, Marco[2] ; MIURA, Daisuke[1] ; TOSHIDA, Kiyoshi[1] ; NAKADA, Setsuya[2]

[1]CRIEPI, [2]Univ. of Tokyo

LA-ICP-MS U-Pb dating using zircon is now widely used with great success. The normal dating process includes polishing zircons. This process is good in terms of avoiding surface contamination of common Pb and/or Pb loss and is essential for SHRIMP, in which only small fraction (drilling depth of 1-2 μm) is used for dating. Compared to SHRIMP, LA-ICP-MS ablates a much larger volume (drilling depth of $>$10 μm) of zircon. This means that it is easy to date zircons from the surface to the inner core of the crystal and examine the existence of inherited cores and potentially investigate the timespan of crystallization. Here we dated non-polished zircons for some reference samples (Fish Canyon Tuff and OD-3) and samples from Oki Dozen volcano. Zircons were ablated for 30 seconds using 213 nm Nd-YAG laser with 10 Hz repetition rate and 4-5 J/cm^2 energy density. Final drilling depth for 5 J/cm^2 was 27 μm and the ^{206}Pb/^{238}U ratio from 9-18μm depth were used to determine ages. It was found that non-polished zircons yield reliable ages because of agreement with reference ages. The Oki Dozen samples yielded 6-7 Ma ages, in agreement with or slightly older than K-Ar ages of 5.4-7.4 Ma.

Crustal noble gases anomaly associated with fault movement and aftershock the 3.11 Northeast Japan Earthquake

SATO, Keiko[1*] ; KUMAGAI, Hidenori[2] ; IWATA, Naoyoshi[3] ; HYODO, Hironobu[4] ; SUZUKI, Katsuhiko[2] ; TAKAOKA, Nobuo[5]

[1]JAMSTEC, SRRP, [2]JAMSTEC, IFREE, [3]Faculty of Science, Yamagata University, [4]Okayama University of Science, [5]Faculty of Science, Kyusyu University

Noble gases have unique characteristics that they are rarely combined with other chemicals as their very stable nature. Because its main reservoir is atmosphere, their isotopic composition is well defined and believed to be uniform all over the world insensitive to disturbance from anthropogenic and/or natural emission of geologically trapped noble gases in the earth interior. Based on our preliminary friction experiment, however, detectable amount of noble gases seem to be emitted accompanied with a fault motion (Sato et al., 2009). After the extreme Northeast Japan Earthquake occurred on March 11, 2011, extraordinary increase of seismic activity as numerous aftershocks e.g. over 4000 felt earthquakes in four months, which may be a source of non-atmospheric component preserved in the earth interior. In terms of anthropogenic component, Nuclear Power Plant) is a potential source, which is frequently monitored by radioactive species of noble gases.

We widely collected atmosphere samples all over Japan from Hokkaido, Honsyu, Chugoku and Kyusyu Is. The atmospheres have been sampled into vacuumed containers, Isotube@, at each sampling site to evaluate time-series changes. The elemental and isotopic compositions of the samples were analyzed mainly by quadrupole residual gas analyzers (RGA-200, SRS Co.) and partly confirmed by sector-type mass spectrometers (GVI-5400, GV instruments). In the duplicated analyses of the selected a few samples, the measured elemental and isotopic compositions were consistent within analytical uncertainties.

The relative elemental abundances were changed at least in heavier noble gases. Argon was enriched to pre-3.11 Earthquake atmospheres associating with a high $^{40}Ar/^{36}Ar$ ratio. It might be contributed by emission of crustal Ar at aftershock earthquakes, deformation and fault movements. In addition, a frictional melting was occurred in a >M5 earthquake as reported by Kanamori et al. (1998). Further, radioactive Ar isotopes (^{42}Ar and ^{39}Ar) were slightly abundant than those in "pre" 3.11 Earthquake atmospheres. These radioactive Ar isotopes were regarded to be detected limitedly in neutron irradiated geological samples especially in Ar - Ar dating. These altered atmospheric Argon isotopic composition in Eastern Japan area were observed until typhoon season.

Ultrahigh-sensitive simultaneous determination of halogens and noble gases by an extension of Ar-Ar and I-Xe methods

SUMINO, Hirochika[1*] ; KOBAYASHI, Masahiro[1] ; SAITO, Takehiko[1] ; NAGAO, Keisuke[1] ; TOYAMA, Chiaki[2] ; MURAMATSU, Yasuyuki[2]

[1]Geochemical Research Center, Graduate School of Science, University of Tokyo, [2]Department of Chemistry, Gakushuin University

Noble gas isotope ratios in various geochemical components in the Earth are significantly different, making them useful tracers to constrain origin of volatiles in the mantle. The development of noble gas mass spectrometry during the last two decades has enabled us to detect less than 10000 noble gas atoms (e.g., [1]).

An extension of Ar-Ar and I-Xe dating methods allows us to simultaneously determine trace amounts of noble gases, halogens, K, Ca, Ba, and U by use of ultrahigh-sensitive noble gas mass spectrometry on neutron-irradiated samples. This method has several advantages: (i) detection limits for halogens are three or four orders of magnitude lower than those of other conventional analytical methods, (ii) several components of different origin can be distinguished based on their relations with specific noble gas isotopes such as mantle-derived ^{3}He and by using various noble gas extraction methods such as laser microprobe [2], and (iii) in-situ production of radiogenic noble gas isotopes (such as ^{4}He and ^{40}Ar) after the entrapment of the noble gas component of interest in the sample can be corrected by the simultaneous determined their parent elements, such as U and K, when the age of the entrapment is known or can be assumed.

We have developed a new noble gas mass spectrometric system for this method based on an Ar-Ar and I-Xe dating system [3]. Accuracy and precision of our method were examined by analyzing GSJ and USGS reference materials, their original rocks, and scapolite standards [4] and by comparing the halogen data with those obtained with ion chromatography and ICP-MS followed by pyrohydrolysis extraction [5].

By using this method, we analyzed halogens and noble gases in exhumed mantle wedge peridotites and eclogites from the Sanbagawa-metamorphic belt, southwest Japan and those in mantle-derived xenoliths from Kamchatka and N. Philippines, in all of which relicts of slab-derived water are contained as hydrous mineral/fluid inclusions. The striking similarities of the observed noble gas and halogen compositions with marine pore fluids [6,7] challenge a popular concept, in which the water flux into the mantle wedge is controlled only by hydrous minerals in altered oceanic crust and sediment (e.g., [8]).

On the other hand, halogen ratios of olivines in lavas from the northern Izu-Ogasawara arc [9] indicate insignificant contribution to the mantle wedge of pore fluid-derived halogens. This implies a relatively small amount of the pore water subduction fluids would be released from the Izu slab at a sub-arc depth resulting in further subduction to great depths in the mantle, possibly resulting in the seawater-like heavy noble gas composition of the convecting mantle [10].

Based on the relation with ^{129}Xe produced from decay of short-lived nuclide ^{129}I during stepwise heating noble-gas extraction of the Allende and Shallowater meteorites, intrinsic I and U to the meteorites were distinguished from those of terrestrial contamination origin.

These results demonstrate that simultaneous determinations of noble gases, halogens, K, Ca, Ba, and U in mantle-derived rocks and meteorites provide important information about their origins.

Unspiked K-Ar dating for lavas from Zao volcano

YAMASAKI, Seiko[1*] ; OIKAWA, Teruki[1] ; BAN, Masao[2]

[1]Geological Survey of Japan, AIST, [2]Faculty of Science, Yamagata Univ.

Zao volcano is located in the central part on the volcanic front of the NE Japan arc. Previous study revealed that the onset of the volcanic activity is ca. 0.8 Ma, the main edifice-building stage is ca. 0.3-0.1 Ma, and the newest stage is from 0.03 Ma to the present. On this volcano, about 50 K-Ar age data are reported, but not all units are covered and some data contradict the stratigraphy probably because of low-K and/or excess Ar contamination. We report new unspiked K-Ar age data for the lavas collected also from unexplored units, in order to construct the detailed history of the volcano.

Diffusion experiment by stepwise heating and muscovite

HYODO, Hironobu[1*]

[1]RINS, Okayama Univ. of Sci.

It is generally recognized that diffusion experiment on micas in vacuum during stepwise heating for $^{40}Ar/^{39}Ar$ dating was unsuitable for diffusion studies because of the destruction of crystal structure from dehydration. However, we showed that estimates of closure temperature from single grain biotites during laser heating experiment gives reasonable values. The problem in case of muscovite is that it seems to have structural transition or significant destruction between 600 and 700^{o}C. The recent study using hydrothermal environment reported the activation energy E of 63 kcal/mole and an estimation of closure temperature exceeding 400^{o}C. The high E and closure temperature T_c are derived on the steep slope in Arrhenius plot. Without change in crystal structure, muscovite does not give high E and Tc. This is contradictory for samples with high E and T_c. It is necessary to separate diffusion phenomena from structural change, and even a hydrothermal experiment at high temperatures in a laboratory may not be suitable for such studies. Muscovite is known to have relatively high T_c in field. To make a practical estimate for T_c, it is necessary to consider both laboratory and field setting.

Luminescence dating and analysis of environmental change of fine grained sediments from Lake Yogo, Japan

ITO, Kazumi[1*]

[1]Geological Survey of Japan, AIST

We applied optically stimulated luminescence (OSL), infrared stimulated luminescence (IRSL), post-IR IRSL (pIRIR) and ^{14}C dating to the sediment core YG11-3 (294cm) from Lake Yogo, Japan. The fine grained quartz and polymineral sample are used for equivalent dose (D_e) estimation. As a result of several basically test, the preheat temperature of 200 ^{o}C for 10 s and a cut heat of 160 ^{o}C were suitable to all OSL measurements. The accepted aliquots are about 90 % per measurement discs and the range of D_e s are 0.3 ˜3.5 (Gy). The bulk ^{14}C ages are ca. 300 years older than these of plant residue. After subtracting this age difference from bulk ^{14}C ages, the corrected ages agree with the OSL ages except the ages of sediments from some depths. Two excepted OSL ages are older than the corrected bulk ^{14}C ages (YG11-3-245, YG11-3-343) and these layers include a lot of plant residue enough to analyze the plant residue ^{14}C ages. It seems that these sediments from two layers have been transported quickly in muddy stream based on a temporary environmental event. Additionally, the result of the $IRSL_{50/225}$ and $pIRIR_{225}$ age confirms the existence of this temporary event. By comparing the OSL ages with ^{14}C, IRSL and pIRIR ages, the quartz from the small catchment area can be applied to reconstruct the age model of sediment core in Japan.

Keywords: OSL dating, pIRIR dating, lake sediments

U-Pb dating of Eoarchaean zircon using a NanoSIMS -implication for the measurement of volatile in the inclusions

ISHIDA, Akizumi[1*] ; TAKAHATA, Naoto[1] ; SANO, Yuji[1] ; DAVID, Jean[2] ; PINTI L., Daniela[2]

[1]AORI the University of Tokyo, [2]University of Montreal

Volatiles, such as hydrogen or sulfur, trapped in the Eoarchaean igneous rocks, are one of the most important tracers of the evolution of the interior of the early Earth. Apatite or glass inclusions found in the zircon crystal, are expected to preserve such volatiles. However, because of their scarceness, high-sensitive, high-resolution analytical methods are required for quantify them and reveal their isotopic compositions. Furthermore, discriminating between pristine compositions and later alteration is problematic. We are trying to approach these issues carrying out analyses by NanoSIMS50.

Euhedral to subhedral zircons were separated from a tonalite which was from the Eoarchaean Nuvvuagittuq supracrustal belt, Surerior Craton, Canada. The reported U-Pb age of this tonalite is 3661±4 Ma by using LA-MC-ICP-MS [1]. The size distribution of zircons was from approximately 50 micrometers to 200 micrometers. Some of them have inclusions of apatite and glass whose size were 10 to 30 micrometers in diameter. Dating measurements were done avoiding such inclusions.

We performed ^{238}U-^{206}Pb and ^{207}Pb-^{206}Pb dating in the same analytical spot of zircon crystals. A 5 nA O^- primary beam, with spot size of approximately 10 micrometers in diameter, was used for ionizing the sample surface, and secondary positive ions were collected in a multicollector. The detector system was modified to measure $^{30}Si^+$, $^{90}Zr_2{}^{16}O^+$, $^{204}Pb^+$, $^{206}Pb^+$, $^{238}U^{16}O^+$, and $^{238}U^{16}O_2{}^+$ ions simultaneously in ^{238}U-^{206}Pb dating session. In ^{207}Pb-^{206}Pb dating session, $^{204}Pb^+$, $^{206}Pb^+$, and $^{207}Pb^+$ ions were collected in the same detector by changing the magnetic field. Detailed analytical procedure and standard calibration is described in Takahata et al.(2008) [2].

Measured ^{206}Pb/^{238}U ratios range from 0.4932 to 0.7993, and the ^{207}Pb/^{206}Pb ratios range from 0.3052 to 0.3443. After the correction of common Pb, those values were plotted on Tera-Wasserburg Concordia diagram, giving a corrected age of 3633±35 Ma, consistent with the previous value obtained by [1]. On the other hand, some samples showed a discordant age. Since such crystals are thought to have suffered metamorphism with subsequent loss of Pb, volatiles in the inclusions might have lost their initial information as well. Now we are proceeding to measure the volatile compositions of inclusions based on the results of U-Pb dating.

Geochronological-geochemical characterization of Proterozoic age, western part of the Napier Complex, East Antarctic

HORIE, Kenji[1*] ; HOKADA, Tomokazu[1] ; HIROI, Yoshikuni[2] ; MOTOYOSHI, Yoichi[1] ; SHIRAISHI, Kazuyuki[1]

[1]NIPR, [2]Chiba University

The Napier Complex in East Antarctica has attracted considerable interest from a viewpoint of long Archaean crustal history from 3800 Ma to 2500 Ma (e.g., Harley & Black 1997) and >1000 ℃ ultrahigh-temperature (UHT) metamorphism in a regional scale (e.g., Sheraton et al., 1987; Harley & Hensen 1990). The timing of ultrahigh-temperature metamorphism is in argument either >2550 Ma or <2480 Ma (Kelly and Harley, 2005). However, some previous works reported relatively younger ages, such as 2380 Ma, ˜2200 Ma, and ˜1820 Ma (e.g., Grew et al., 2001; Owada et al., 2001; Suzuki et al., 2001, 2006; Carson et al., 2002; Hokada and Motoyoshi, 2006). In addition, Horie et al. (2012) reported similar ages in felsic orthogneiss from Fyfe Hills and quartzite from Mt. Cronus via zircon U-Pb dating. In this study, we try to characterize the ”younger ages” in order to interpret thermal history after the UHT metamorphism in the Napier Complex.

A quartzo-feldspathic gneiss, YH05021606A, collected from Fyfe Hills by Y.H. during the field work at the 2004-2005 Japanese Antarctic Research Expedition was analyzed by using a high-resolution ion microprobe (SHRIMP II) at the National Institute of Polar Research, Japan. The zircon U-Pb ages of the YH05021606A sample are already reported in Horie et al. (2012). The sample shows multiple age peaks centered at ca. 3025, 2943, 2883, 2818, 2759, 2674, 2518, and 2437 Ma, and evidence of the ”younger ages” has never been reported. In this study, primary ion beam was focused up to 10 um in order to observe detailed zircon structure. The U-Pb analysis of zircon yielded similar age population to the previous work and revealed the ”younger ages” of ca. 2273, 2195, 2106, and 1980 Ma. Distribution of the ”younger ages” is consistent with those of a felsic orthogneiss, YH05021603A, in Fyfe Hills and those of a quartzo-feldspathic gneiss, YH05021701A, and a quartzite, YH05021701H, in Mt. Cronus (Horie et al., 2012). The ”younger ages” in this sample could be found in overgrowth rim and single grain, which indicates that both of Fyfe Hills and Mt. Cronus had been affected by any geological events after the UHT metamorphism. Previous workers suggested that the ca. 2200 Ma age that they obtained for beryllium syn-metamorphic pegmatites reflects post-emplacement deformation and metamorphism (Grew et al., 2001), and a ca. 1930-1800 Ma U-Pb upper intercept age for zircons were affected by aqueous fluid from Paleozoic pegmatite (Carson et al., 2002). Horie et al. (2012) only suggests that these 2380-820Ma ages represent local fluid infiltration or a local deformation events. We will discuss about character of the ”younger ages” zircon with trace element signature.

Sr and Nd isotope systematics of metacarbonate rocks as proxies for reconstructing extinct oceans: Mozambique Ocean

OTSUJI, Naho[1*] ; KAMEI, Atsushi[2] ; TSUCHIYA, Noriyoshi[3] ; G.H., Grantham[4] ; KAWAKAMI, Tetsuo[5] ; ISHIKAWA, Masahiro[6]

[1]Niigata University, [2]Shimane University, [3]Tohoku University, [4]Council for Geoscience, South Africa, [5]Kyoto University, [6]Yokahama National University

Geochemistry of sedimentary rocks is widely used for understanding the depositional environment and tectonic setting, including source rock composition and paleo-ocean signature. In particular, chemically deposited carbonate rocks are directly precipitated from saturated seawater are supposed to hold key information of extinct paleo-oceans. An important geochemical tool that can lead to the identification of contemporaneous seawater is isotopic composition of strontium and neodymium in carbonate rocks, because these elements have distinct residence and mixing time in seawater and also characterized by surrounding continents.

In the Sør Rondane Mountains (SRMs), East Antarctica, metasedimentary rocks including metacarbonate rocks are widely distributed. These rocks were supposed to have formed in the paleo-ocean called as "Mozambique Ocean". SRMs are divided into two terranes, the SW and NE terranes, by the Main Tectonic Boundary (MTB). In the SW terrane, metaigneous rock that were formed at ca. 1000 Ma and metasedimentary rocks occur as main lithological units, which underwent metamorphic evolution along a anticlockwise *P-T* path, whereas the NE terrane is dominated by metasedimentary rocks, with a characteristic clockwise of *P-T* path. Additionally, metapelitic rocks in the SW terrane have similar detrital age population with the nearby metaigneous rocks, in contrast to those in the NE terrane show older detrital ages (˜ca. 3300Ma)(Osanai *et al*., 2013). If it is possible to reveal the relationship between ocean and continents during depositional timing of carbonate rocks in both terranes, we will be able to put forward a model to explain the difference in depositional setting between SW and NE terranes. To achieve this, analyzed detailed study of Sr and Nd isotopic composition of metacarbonate and metamorphosed silicate rocks, such as pelitic, felsic, mafic and ultramafic rocks, from several important outcrops throughout SRMs were carried out. Based on these data, we discuss about the relationship with continent and depositional basin of carbonate sediments before the final amalgamation of Gondwana.

After geochemical screening for post-depositional alteration, using oxygen isotopes, trace elements and REE + Y patterns, strontium isotope chemostratigraphy was applied to the metacarbonate rocks from SRMs and depositional ages of 880-850 Ma and 820-790 Ma (late-Tonian and early-Cryogenian age) were estimated (Otsuji *et al*., 2013). Metacarbonate rocks in the Brattnipene and Tanngarden regions in the SW terrane are showing typical seawater-rock mixing relationship in a εSr vs. εNd cross-plot indicating the deposition of metacarbonate rocks nearby meta-tonalitic and orthogneiss dominated continental arc. By contrast, the Perlebandet region exhibits an extremely different depositional setting of a seamount based on Nd model and depositional age and REE and εNd compositions. Moreover, the Balchen metacarbonate rocks show a signature of depositional setting surrounding a continent, based on the comparison of metacarbonate rocks with continental and oceanic derived rock units. A comparison of isotopic characteristics of Balchen carbonate rocks with the basement rocks from neighboring Gondwana regions suggested the presence of an ancient continent that is different from Kalahari and Dharwar Craton.

Thus, the Sr and Nd isotopic compositions of carbonate rocks deposited in the Mozambique Ocean have preserved important information about depositional setting of sedimentary rocks and relationship with surrounding basement and continents. In summary, geochemical proxies such as Nd and Sr isotopes of metacarbonate rocks can yield key information not only of paleo-oceans but also about the surrounding rocks during depositional timing, which can lead to a better understanding of oceanic closure during the formation of supercontinents.

Geochemistry of Archaean Banded Iron Formations in the Chitradurga Schist Belt, Dharwar Craton, Southern India

KOINUMA, Kentaro[1*] ; MADHUSOODHAN, Satish-kumar[1] ; MISHIMA, Kaoru[2] ; UENO, Yuichiro[2] ; HOKADA, Tomokazu[3]

[1]Niigata University, [2]Tokyo Institute of Technology, [3]National Institute of Polar Research

Banded iron formations (BIF) are marine chemical sediment rocks precipitated mostly in Archaean and early Paleoproterozoic between 2.7Ga and 2.3Ga. This time interval record profound changes in the redox state of the oceans and atmosphere, such as the Great Oxidation Event (GOE). We present here the geochemical data obtained from 3.0 Ga banded iron formation (BIF) in the Chitradurga Schist Belt, Dharwar Craton, Southern India. This region exposes the Archaean strata predominated by supracrustal greenstone belts, stratigraphically overlying the Peninsular gneiss. Chitradurga schist belt comprises of three important BIF layers distributed in the Bababudan and Chitradurga groups. We present here the salient geochemical characteristics and strontium and neodymium isotope results of the BIFs and discuss the depositional environment.

BIF contain very low content of Al2O3 ($<$1wt.% except 1 sample) indicating less detrital components. The PAAS-normalized REY patterns shows positive La and Eu anomaly, low concentration of rare earth element, depletion of light rare earth elements (LREEs) relative to heavy rare earth elements (HREEs). These features differ with other Archaean BIFs in terms of lack of positive Y anomaly. The large positive Eu anomalies in Archean BIF of Chitradurga schist belt attribute to high-T hydrothermal fluid fluxes ($>$250 ^{0} C), while the negative Ce anomaly reflects the lack of significant oxidizing agents.

Sr isotopic composition of BIF shows large variations suggesting post depositional alterations, whereas Nd isotope rations gave consistent information. Most of the samples show εNd(3000Ma) in the range of +2 to +4 and T_{DM} model age in accordance with sedimentation age. The εNd(3000Ma) of depleted mantle is about +4, which suggests that most of the Chitradurga BIFs were deposited in an environment strongly affected by input from a depleted mantle. However samples with different REY pattern show higher εNd(3000Ma) between +6 and +14 and their T_{DM} model age are not equal to the sedimentation age. The geochemical results thus suggest that the BIFs in the Chitradurga schist belt were deposited near possible ridges affected by hydrothermal activities.

Tectonic evolution of Karwar and Coorg blocks, southern India

C, Ishwar-kumar[1*] ; K, Sajeev[1] ; B.F, Windley[2] ; M, Satish-kumar[3] ; T, Hokada[4] ; K, Horie[4] ; T, Itaya[5]

[1]Centre for Earth Sciences, Indian Institute of Science, Bangalore 560 012, India, [2]Department of Geology, University of Leicester, Leicester LE1 7RH, UK, [3]Department of Geology, Niigata University, 2-8050, Ikarashi, Nishi-ku, Niigata 950-2181, Japan, [4]National Institute of Polar Research, 10-3 Midori-cho, Tachikawa, Tokyo190-8518, Japan, [5]Institute of Natural Sciences, Okayama University of Science, 1-1 Ridai-cho, Kita-ku, Okayama 700-0

The Karwar and Coorg blocks in western India are important terranes in the point of paleogeographic study of India and Madagascar. The *c.* 1300 Ma Kumta suture separates the Karwar and Dharwar blocks within the western Dharwar craton of India (Ishwar-Kumar et al., 2013a). The major rock types are quartz phengite schist, chlorite schist, fuchsite schist, garnet biotite schist etc. Isochemical phase diagram estimates of the quartz phengite schist suggest peak metamorphic *P-T* conditions were *c.* 18 kbar and 550^o C. Towards the east of the suture Sirsi shelf contains weakly deformed sedimentary rocks, unconformable on high-grade gneisses of the Dharwar craton. The Karwar block to the west of the Kumta suture is mainly composed of undeformed tonalite-trondhjemite-granodiorite (TTG) with minor enclaves of amphibolite cut by later granites. Whole-rock major and trace element data suggest that the TTGs were derived from a volcanic arc, and that the granites have within-plate signatures. Amphibolites have a chemical composition comparable to basalts to basaltic andesites with MORB signatures. The TTGs from Karwar block shows a U-Pb zircon magmatic ages of *ca.* 3200 Ma (Ishwar-Kumar et al., 2013a). The K-Ar biotite age from the TTGs (1746 Ma and 1796 Ma) and amphibolite (*ca.* 1697 Ma) represents late-stage *c.* 1700 Ma uplift event of both TTGs and amphibolites. The Coorg block, which is about 100 km south of Karwar block, contains mainly granulite grade rocks (Chetty et al., 2012; Ishwar-Kumar et al., 2013b; Santosh et al., 2014). Major rocks types are charnockite, mafic granulites, hornblende-biotite gneiss, garnet-hornblende gabbro, anorthosite and granite. The Coorg (Mercara) suture which separates the Coorg block from the Dharwar craton to the east contains garnet-kyanite-sillimanite gneiss, mylonitic gneiss, calc-silicate granulite, mafic granulite, granite and syenite. Pseudosection calculations indicate that the constituent calc-silicate granulite and mafic granulite were re-equilibrated under high-pressure conditions of 15-20 kbar at a temperature of 800-900^o C (Ishwar-Kumar et al., 2013b). Santosh et al. (2014) recorded a metamorphic age of *c.*1200 Ma from metapelites from the Coorg (Mercara) suture zone. Integration of our structural, geological and geochronological results integrated with published data suggests the presence of a 1300-1200 Ma paleosubduction zone in western India. We propose that the Kumta and Coorg sutures are an eastern extension in western India of the northern and southern parts of the Betsimisaraka suture of north-eastern Madagascar.

Cambrian tonalite from Horei, Ofunato in southern Kitakami Mauntains, Japan

TSUCHIYA, Nobutaka[1*] ; TAKEDA, Tomoyo[1] ; SASAKI, Jun[1] ; ADACHI, Tatsuro[2] ; NAKANO, Nobuhiko[2] ; OSANAI, Yasuhito[2] ; ADACHI, Yoshiko[3]

[1]Iwate University, [2]Kyushu University, [3]Niigata University

The Lower Cretaceous volcanic rocks of Ofunato Group and plagioclase quartz diorite porphyry dikes are distributed in Ryori district, south Kitakami belt, Japan. The felsic volcaniclastic rocks and tonalite is discovered within the Ofunato Group in Horei, Ofunato, Japan. The felsic volcaniclastic rocks occur as blocks less than 10 m size, and tonalite are found as blocks less than 2 x 1 m in size. The tonalite composed mainly of plagioclase, quartz, biotite, and hornblende and is characterized by poverty of K-feldsper. The tonalite is rich in SiO_2 (73.1–73.4%), and is classified as volcanic arc granite after Pearce et al. (1984). However, it is characterized by low K_2O (0.72–1.27wt%), Rb (16–32ppm), and Ba (91–97ppm) concentrations. This rock is considered to be derived from arc magmatism in immature oceanic arc setting.

U-Pb dating of zircons were carried out using Agilent 7500cx quadrupole inductively coupled plasma mass spectrometer (ICP-MS) with a New Wave Research UP-213 Nd-YAG UV (213 nm) laser ablation system (LA) installed at the Kyushu University (Adachi et al., 2012). Zircon grains from tonalite concentrate around ca. 500 Ma, 8 analyses from 8 grains define a concordia age of 498 +/- 7 Ma. U-Pb zircon age obtained here correspond to latest Cambrian age, and is similar to U-Pb zircon SHRIMP age of the granitic rocks from the Daiouin granite in Hitachi metamorphic rocks (490.8 +/- 6.1 Ma) and the Hikawa granite in Higo metamorphic rocks, Kyushu (502.5 +/- 9.6 Ma) after Sakashima et al. (2003). In addition, Tagiri et al. (2010) described U-Pb zircon SHRIMP age of metamorphic porphyry (505.1 +/- 4.4 Ma) and metamorphic granite clast (499.6 +/- 5.6 Ma), and Tagiri et al. (2011) reported U-Pb zircon SHRIMP age of felsic schist (510.0 +/- 4.0 Ma) from the Hitachi metamorphic rocks. These rocks are considered to be resulted from Cambrian arc-trench system in proto-Japan (Isozaki et al., 2010). In south Kitakami Mountains, Shimojo et al. (2010) described U-Pb zircon SHRIMP age of trondjhemite in Hayachine complex (466 +/- 6 Ma), and Sasaki et al. (2013) reported that the solidification age of the Hikami granites is 450 Ma. In addition, Osanai et al. (in press) described U-Pb zircon LA-ICPMS age of granitic rocks in the Kurosegawa tectonic line in Kyushu (446–472 Ma). These data suggests that the granitic activity in early Paleozoic of proto-Japan arc occurs at ca. 500 Ma and ca. 450 Ma.

U-Pb ages of zircon in plutonic rocks within the southern Abukuma Mountains

TAKAHASHI, Yutaka[1*] ; MIKOSHIBA, Masumi[1] ; KUBO, Kazuya[1] ; DANHARA, Toru[2] ; IWANO, Hideki[2] ; HIRATA, Takefumi[3]

[1]Geological Survey of Japan, AIST, [2]Kyoto Fission Track Co., Ltd., [3]Kyoto University

Abukuma Plutonic and Metamorphic Rocks are widely distributed in the southern Abukuma Mountains. These rocks had been studied in detail (e.g. Miyashiro, 1958; Research Group of the Abukuma Plateau, 1969; Kano et al., 1974; Maruyama, 1979). Radiometric age datings of the Abukuma Plutonic Rocks were carried out by Kawano and Ueda (1965), Maruyama (1978), Shibata and Uchiumi (1983), Shibata (1987), Shibata and Tanaka (1987) and others. These studies indicated that radiometric ages of the Abukuma Plutonic Rocks are almost 90 to 120 Ma. Recently, Ar-Ar age dating of hornblende (Takagi and Kamei, 2008) and U-Pb age dating of zircon (Kon and Takagi, 2012) for plutonic rocks in northern Abukuma Mountains were carried out. They showed that the ages of gabbro and granitic rocks are similar. On the other hand, U-Pb age dating of zircon for plutonic rocks in southern Abukuma Mountains is not yet performed. Therefore, U-Pb age dating of zircon for major plutons of southern Abukuma Mountains was carried out, result of which is reported and tectonics of the Abukuma Mountains is discussed based on the cooling history of the plutons.

Plutonic rocks in the southern Abukuma Mountains are classified into gabbro and diorite, fine-grained diorite, hornblende-biotite granodiorite (Irishiken Pluton, Kamikimita Pluton, Tabito Pluton, Ishikawa Pluton, Miyamoto Pluton and Samegawa Pluton), biotite granodiorite (Torisone Pluton), biotite granite and fine-grained leucogranite, based on the geological relations. The U-Pb ages of zircon for gabbro are 102.7+/-0.8 Ma (Tabito Pluton), 109.0+/-1.1 Ma (Hanawa Pluton), 114.2+/-0.8 Ma (Miyamoto Pluton). As for the hornblende-biotite granodiorite, U-Pb ages are 105.3+/-0.8 Ma (IrishikenPluton), 105.2+/-0.8 Ma (Kamikimita Pluton), 113.8+/-0.7 Ma (Tabito Pluton), 104.4+/-0.7 Ma (Ishikawa Pluton) and 106.4+/-0.8 Ma (Miyamoto Pluton). Also for the biotite granodiorite (Hanawa Pluton), the biotite granite and fine-grained leucogranite U-Pb ages are 105.7+/-1.0 Ma, 104.5+/-0.5 Ma and 100.2+/-0.8 Ma, respectively. These data indicate that the intrusion ages of Gabbro and surrounding granitic rocks are similar to each other. Furthermore, K-Ar ages of biotite and or hornblende, and fission track ages of the same rock samples were measured. Accordingly, it is clear that these rocks had been cooled rapidly to 300 degree C (Ar blocking temperature of biotite) after their intrusion. This implies that the Abukuma Mountains were uplifted rapidly after the intrusion of the Abukuma Plutonic Rocks.

Structural trends and tectonic inversion in Miocene sedimentary basins in the Tsugawa-Aizu province, Niigata prefecture

NARISAWA, Sayaka[1*] ; KURITA, Hiroshi[2]

[1]Niigata University, [2]Niigata University

The Tsugawa and Mikawa Sedimentary Basins in the northeastern part of Niigata are composed mainly of Early to Middle Miocene formations that contain so-called ”Green Tuff” volcanic sediments. Previous studies emphasized the NW-SE trend in the basement during the genesis of the Tsugawa basin. This outcrop-based study intends to discuss structural trends in the development of the Miocene sedimentary basin in the Mikawa area, Aga Town, Niigata.

The Miocene in this study area are divided into the Kanose, Tsugawa, and Araya/Igashima Formations in ascending order. Sedimentary facies analysis showed that the Kanose and Tsugawa formations filled half graben or graben. N-S to NNE-SSW trending faults of a map-scale limited the extent of the formations. NW-SE trending faults formed minor steps on the basement as well as minor, syn-sedimentary faults in the Miocene. They also affected the dyke intrusion trend. In short, the genesis of the Tsugawa basin involved 2 structural trends in this study area, while more significant is the N-S to NNE-SSW trend.

At present, the extent of the Miocene in this study area is, in many places, limited by thrust faults. Thrust faults locate at the position where rift-border faults are suggested. This indicates that tectonic inversion occurred with reactivation of N-S to NNE-SSW trending faults of the two. The trend of fault reactivation suggests that development of the basin in this study area is influenced by the Shibata-Koide tectonic line.

K-Ar whole rock dating of the metamorphic rocks in the Yorii-Ogawa area of the north-eastern part of the Kanto Mountains

ONO, Akira[1*]

[1]none

Atokura Nappe is widely exposed in the Yorii-Ogawa area. It is mainly composed of Permian granitic rocks, Cretaceous Atokura Formation, Cretaceous pyroclastic rocks, Paleogene Yorii Formation and Paleogene Kiroko greenstone melange (Figure 1). Mid-Cretaceous metamorphic and granitic rocks are also distributed as small tectonic blocks. Kiroko greenstone melange mainly consists of high-pressure-type metamorphic rocks (Kiroko metamorphic rocks), meta-gabbro, meta-tonalite, serpentinite, epidote amphibolite and amphibolite. The Atokura Nappe tectonically overlies on the Mikabu greenstones and Chichibu Complex.

K-Ar whole rock ages of the Kiroko metamorphic rocks were determined on three slates and one mafic rock. The results for the slates are 127Ma, 117Ma and 115Ma. Whereas the K-Ar whole rock age of the mafic rock is 57.4Ma. The older ages of the slates are due to the presence of detrital white mica [1]. Based on the results of the K-Ar ages, the Kiroko metamorphic rocks are regarded as members of Sanbagawa metamorphic rocks. This conclusion reveals that nappe tectonics took place even in the region where Sanbagawa metamorphic rocks were exhumed.

The nappe tectonics occurred at many times in Cretaceous and Paleogene forearcs of Southwest Japan. In the northeastern part of the Kanto Mountains weakly metamorphosed Chichibu complex lie on the Mikabu greenstones by thrust faults [2, 3]. The existence of unconsolidated fault gouges suggests the formation of the thrust faults in a surface part of the crust. The thrust faults were formed by Cretaceous nappe tectonics before the formation of the Atokura Nappe.

Radiometric dating of the metamorphic rocks of the Chichibu and Mikabu belts is lack in the surveyed area. Hence, K-Ar whole rock dating was performed on a muscovite-chlorite schist from the Mikabu belt and a slate from the Chichibu belt. The results are presented on the left side of Figure 1. Locations of the samples are described below and are shown by star signs in the geological map.

The sample Yorii-Mikabu is a pelitic schist of the Mikabu belt exposed near the River Arakawa, Yorii town. The sample Sekisonzan is a weakly metamorphosed slate of the Chichibu belt which was exposed near Mt. Sekisonzan, Ogawa town. The sample Suguro-P2 is a black slate rich in carbonaceous materials and fine white mica. The location of the slate is loc. d of Ref. [1]. It is a member of the Kiroko metamorphic rocks.

Particle sizes of white micas vary considerably for each slate specimen studied. This is an evidence for insufficient recrystallization of white mica during regional metamorphism. Therefore, K-Ar whole rock ages of all the studied slates are older than the assumed metamorphic ages.

Detrital zircon geochronology of the Tetori Group in the Arimine and Itoshiro areas, central Japan

KAWAGOE, Yuta[1] ; SANO, Shin-ichi[2] ; ORIHASHI, Yuji[3] ; KOUCHI, Yoshikazu[1*] ; UEDA, Tetsuya[1] ; YAMAMOTO, Koshi[4] ; OTOH, Shigeru[1]

[1]Grad. School Sci. Eng., Univ. Toyama, [2]Fukui Prefectural Dinosaur Museum, [3]ERI, Univ. Tokyo, [4]Grad. School Env. Stu., Nagoya Univ.

Introduction Provenance of the Tetori Group in the Arimine (Toyama-Gifu prefs.) and Itoshiro (Fukui Pref.) areas was analyzed using detrital zircon age distribution. In the course of the study, zircon ages of the Hida gneiss and granitoid were also determined.

Geologic Setting The Tetori Group consists of Middle Jurassic to Early Cretaceous shallow marine to terrestrial deposits. The group is divided, in ascending order, into the Kuzuryu, Itoshiro, and Akaiwa subgroups in the Itoshiro area (Maeda, 1961), and into the Higashisakamori, Nagatogawa, and Atotsugawa formations in the Arimine area (Kawai & Nozawa, 1958); the lower, middle, and upper units of the two areas have been correlated with each other. The lower members of the Nagatogawa-Atotsugawa formations consist of gravelly deposits of eastward running braided rivers, whereas the upper members consist of sandstone and mudstone of southward running meandering rivers. The U-Pb age of a tuff bed in the upper member of the Atotsugawa Formation is 120.0 +/- 1.2 Ma.

Zircon ages from surrounding areas The Hida Gneiss to the west of the Arimine area contains abundant 250-220-Ma zircons (Sano et al., 2000). The Korean Peninsula is mainly occupied by Archean-Paleoproterozoic basements of the Nangnim and Yeongnam massifs, covered with Cambrian-Jurassic deposits and cut by 250-160-Ma granitic rocks (e.g. Zhao et al., 2005). On the other hand, Northeast China between the Jiamusi Massif and the Songliao Basin, famous for " Phanerozoic crustal growth " (Wu et al., 2000), is composed primarily of 250-160-Ma granitic rocks and virtually no Precambrian rocks.

Samples and method of study U-Pb ages of zircons from (1) sandstone and sandy siltstone samples from six formations (members) of the Tetori Group from each area, (2) the Shimonomoto, Funatsu and Utsubo bodies of the Hida granite around the Arimine area, and (3) the Hida meta-granite on the north of the Arimine area were determined with laser ablation inductively coupled mass spectrometers (LA-ICP-MS) equipped in the Earthquake Research Institute of the University of Tokyo and Graduate School of Environmental Studies, Nagoya University.

Results There was marked difference in the percentage of Precambrian zircons (%Pc) between the Itoshiro-Akaiwa subgroups and the Nagatogawa-Atotsugawa formations: i.e. the %Pc of the former is 80 or more whereas that of the latter is less than 10. The samples of the Itoshiro-Akaiwa subgroups contained abundant 2500-1500-Ma zircons and a couple of Archean zircons. Age peaks of 190-170-Ma and 250-220-Ma were commonly seen for all samples of the Tetori Group. Among them, the peak of 250-220-Ma was higher in the braided river deposits and that of 190-170-Ma was higher in the meandering river deposits in the Arimine area. The Shimonomoto, Funatsu, Utsubo, and meta-granite bodies mainly contained 200-180-Ma, 250-190-Ma, 205-185-Ma, and 280-220-Ma zircons, respectively, and 180-170-Ma zircons were rare in the Hida Belt.

Discussion The meandering-river deposits in the Arimine area contain abundant 180-170-Ma zircons, which are virtually absent in the Hida Belt, and very few Precambrian zircons (%Pc $<$10). The catchment of the meandering rivers must have been occupied by Triassic-Jurassic igneous rocks with narrow exposures of Precambrian rocks. Considering the geology of eastern margin of Asia, the meandering rivers most likely passed through Northeast China (Jiamusi-Songliao). On the other hand, the braided river deposits of the area contain many 250-220 Ma zircons, suggesting that they were likely supplied at the time of uplifting of the Hida gneiss to the west. On the other hand, the Itoshiro-Akaiwa subgroups have abundant Precambrian zircons (%Pc $>$80). Possible candidates of the Precambrian exposure that could supply the sediments of these subgroups are the Yeongnam-Nangnim massifs. Hence the sediments of the Itoshiro-Akaiwa subgroups were likely carried by rivers that passed through the massifs.

Quaternary Tectonic Environments in North-Central Japan

TAKEUCHI, Akira[1*]

[1]Graduate school of Science and Engineering for Research, University of Toyama

The present-day central Japan is located at the convergent junction area among four tectonic plates, Amur, Okhotsk, Philippine Sea and Pacific plates. The Toyama Trough - Fossa Magna region is a major tectonic depression bounding the contrasting, tectonic provinces, i.e. the Northeast Japan (NEJ) arc on the Okhotsk plate and the Southwest Japan (SWJ) arc on the Amur plate. The north-central Japan on the Japan Sea side of Honshu Island is characterized by the latest Cenozoic thrust/fold belts, which are considered as the results of a series of inversion/conversion tectonics in relation to the Quaternary changes in relative motion between Eurasia/Amur and Philippine Sea plates.

This paper aims at describing these changes in crustal movements including active tectonics, and evaluates the existing hypotheses on the plate tectonic framework.

At the end of Pliocene in the NEJ arc, typical basin inversion has been occurred along the NE-SW trending, boundary faults of the Miocene sedimentary basins. While, on the side of SWJ arc, boundary faults of the Miocene basins were not reactivated, but other preexisting fractures have been reused to form the reverse fault and strike-slip fault provinces in response to N-S compression due to the Early Pleistocene northward subduction of the Philippine Sea plate, and to E-W compression due to the eastward motion of Amur plate, although the Present tectonic zone of strain concentration is probably related to the subduction of Pacific plate. In order to account for the Quaternary tectonic environment with a widespread stress field of strike-slip faulting in the basement as inferred from focal mechanism solutions, an accommodation mechanism is likely to have been worked in the asthenospheric mantle of the present arc-arc collision zone.

Considering the above neotectonic circumstances from the existence of the tectonic inversion of north-central Japan and stress field of the seismogenic layer, the hypotheses on eastward motion of Amur plate and on the nascent plate-boundary along the eastern margin of Japan Sea were positively evaluated.

Fracture system in the Sawara Granite at the area beside the Hinatatoge-Okasagitoge Fault, northern Kyushu

YUHARA, Masaki[1*] ; MIYAZAKI, Sotaro[1] ; AIZAWA, Jun[1]

[1]Department of Earth System Science, Faculty of Science, Fukuoka University

The Hinatatoge-Okasagitoge Fault has been identified by recent research. This fault continues to the Maebaru and Itoshima-hanto-oki Faults Group, and forms a single fault zone (Shimoyama et al., 2013). Activity rank of this fault is estimated C class. We recorded fractures in the Sawara Granite at the area beside the Hinatatoge-Okasagitoge Fault, and examined formation history of fracture system.

The fractures in the surveyed area are classified by their orientations into three types: NNW-SSE to NW-SE-oriented high-angle fractures, ENE-WSW-oriented high-angle fractures, and low-angle fractures. The fractures are further divided into three groups: minor faults associated with cataclasite, minor faults associated with fault gouge, and joints.

Based on the crosscut relationships of these fractures and the mineralization along joints, the formation process of the fractures related to activity of the Hinatatoge-Okasagitoge Fault involves five stages.

The minor faults associated with cataclasite were formed at the first stage. The laumontite veins were precipitated in spaces formed by the opening of joints at next stage. At the third stage, the minor faults associated with fault gouge were formed. The stilbite veins were precipitated in spaces formed by the opening of joints at next stage. At the last stage, the minor faults associated with fault gouge were formed.

Keywords: Hinatatoge-Okasagitoge Fault, Sawara Granite, fracture system, hydrothermal activity

Bouguer gravity anomaly related to Cretaceous volcanic rocks in the Yanahara area, Okayama prefecture, SW Japan

ISHIKAWA, Nobuyo[1*] ; KOMURO, Hiroaki[1] ; YAMAMOTO, Akihiko[2]

[1]Dept. of Geoscience, Shimane Univ., [2]Dept. of Earth's Evolution Environment, Division of Mathematics, Physics, Earth Science, Ehime Univ.

Cretaceous volcanic rocks (volcanic, pyroclastic and lesser sedimentary rocks) unconformably overlying the basement rocks composed of the Maizuru Group and the Yakuno complex are widely distributed in the region from Okayama to Hyogo Prefectures, central Chugoku, SW Japan. Remarkable low gravity anomalous areas observed in the region of these volcanic rocks suggest some cauldrons. Total 610 observation points including 411 new points and 199 published points (GSJ, 2000; Shichi and Yamamoto, 2001) depict a detailed Bouguer gravity anomaly map of the Yanahara district through the band-pass filter between 1 to 30 km after the terrane and Bouguer corrections with a density of 2670kg/m3.

The Bouguer gravity anomaly map reveals low gravity anomalous areas corresponding with the Cretaceous volcanic rocks and the related granitic intrusive rocks; whereas high gravity anomalous areas corresponding with the Maizuru Group and the Yakuno complex.

The low gravity anomalous areas of the Yanahara district are observed in two parts: western and northeastern areas. The western low gravity anomalous area, measuring 20×7km in size, shows a flat-floor type anomaly surrounded with high gradient margins. The relative anomaly value is 8mgal less than that of the peripheral area. This suggests a flat-floor caldera (cauldron) filled up with thick rhyolitic volcanic rocks. This inferred caldera was possibly produced 80Ma, because quartz diorite intruded into this caldera has been dated as 79.8±1.8Ma by biotite K-Ar method.

Another area northeast of Yanahara shows an elongated funnel floor surrounded with high gradient margin. The anomaly value is 7mgal less than that of the peripheral area. This value is nearly equivalent to the gravity anomaly in the above mentioned western area. Accordingly, another lesser cauldron possibly lies in this area.

Distribution of stratigraphic units of Middle Pleistocene Izumiyatsu Formation and their arsenic concentrations

YOSHIDA, Takeshi[1*] ; KUSUDA, Takashi[2] ; NIREI, Hisashi[3]

[1]Research Institute of Enviornmental Geology, Chiba, [2]Foremer Research Institute of Enviornmental Geology, Chiba, [3]Institute of medical geology

We identified the strata units of the Pleistocene Izumiyatsu Formation, which extends from the central part of Chiba Prefecture to the northeast, and the distribution of arsenic in these strata. In our summary of the geology, we refer to the Shimofusa Group.

It is possible to divide the facies of the Izumiyatsu Formation, a type locality, into five beds ? a muddy sand layer (facies 1: an estuarine sediment), an interbed of fine sand and mud (facies 2: a tidal flat sediment), a sand layer (facies 3: a tidal channel sediment), a silt layer (facies 4: a freshwater?seawater marsh sediment), and a medium sandy mud layer (facies 5: a inner bay marine sediment). The Izumiyatsu Formation, with changing facies, exhibits the following distribution pattern: facies 1, 2, 3, 4, and 5 in the southwest area, facies 5 only in the central area, and facies 4 and 5 in the northeast area. Only facies 5 is continuously distributed throughout the research areas.

Silt layer(Facies 4), the freshwater?seawater marsh sediment, has lower arsenic concentrations in sediment and in leachate than the other facies. Facies 5, the inner bay sediment, has higher arsenic concentrations in sediment and in than the other facies.

Chronology of Brunhes-Matuyama geomagnetic polarity transition recoreded in sediments and climate change

ODA, Hirokuni[1*]

[1]National Institute of Advanced Industrial Science and Technology

Channell et al. (2010) suggested that the midpoint of the M-B boundary lies at 773.1 ka, ~7 kyr younger than the previously accepted astrochronological age for this polarity reversal (780-781 ka). Their results are based on the five high-resolution Matuyama-Brunhes polarity transition records from the North Atlantic placed on isotope age models produced by correlation of the d18O record to an ice volume model. They further inferred that the 40Ar/39Ar Fish Canyon sanidine (FCs) standard age that best fits the astrochronological ages is 27.93 Ma, which is younger than the two recently proposed FCs ages of 28.201 +-0.046 Ma (Kuiper et al., 2008) and 28.305 +- 0.036 Ma (Rene et al., 2010). However, recent study by Ganerod et al. (2011) suggested an age of 28.393+-0.194 Ma for FCs based on paired 40Ar/39Ar and 206Pb-238U radiometric dating supporting the calibrations of Kuiper et al. (2008) and Renne et al. (2010). Furthermore, recent study by Rivera et al. (2011) suggested an age of 28.172+-0.028 Ma for FCs based on cross-calibration with an astronomically tuned age of A1 tephra sanidines in the studied sequence of Faneromeni section in Crete. The discrepancy is significant that needs to be investigated carefully especially in terms of climate system involved.

On the other hand, the age model for relative paleointensity stack PISO-1500 (Channell et al., 2009) is based on IODP U1308 from North Atlantic. Channell et al. (2008) developed the age model for U1308 by correlating the benthic oxygen isotope curve with LR04 oxygen isotope stack (Lisiecki&Raymo, 2005). LR04 stack is known as oxygen isotope stack for benthic foraminifarra, whose age model is dependent on ice volume model with a certain time lag. Caballero-Gill et al. (2012) developed an absolute age model based on U-Th dating for stalagmites from China and correlated the oxygen isotope curve with that on planctonic foraminiferra for a deep-sea core from South China Sea. On the basis of the radiometrically calibrated chronology, they estimated that the time constant of the ice sheet is 5.4 kyr at the precession band and 10.4 kyr at the obliquity band. These values are significantly shorter than the single 17 kyr time constant originally estimated by Imbrie et al. (1984), based primarily on the timing of terminations I and II and the 15 kyr time constant used by Lisiecki and Raymo (2005) for LR04 stack.

In the presentation, the chronology of Brunhes-Matuyama geomagnetic polarity transition will be further discussed in relation to the chronology of 10Be records of EPICA Dome C (Dreyfus et al., 2008).

SHRIMP U-Pb zircon dating for Byakubi tephra: implication for refined chronology for the Matuyama-Brunhes boundary

SUGANUMA, Yusuke[1*] ; OKADA, Makoto[2] ; HORIE, Kenji[1] ; KAIDEN, Hiroshi[1] ; TAKEHARA, Mami[3] ; SENDA, Ryoko[4] ; KIMURA, Jun-ichi[4] ; KAZAOKA, Osamu[5]

[1]National Institute of Polar Research, [2]Ibaraki University, [3]Kyushu University, [4]JAMSTEC, [5]Research Institute of Environmental Geology, Chiba

Paleomagnetic records from marine sediments have contributed to improved understanding of variations in the Earth's magnetic field and have helped to establish age models for marine sediments. However, lock-in of the paleomagnetic signal at some depth below the sediment-water interface in marine sediments through acquisition of a post-depositional remanent magnetization (PDRM) adds uncertainty to synchronization of marine sedimentary records (e.g., Roberts and 2004; Suganuma et al., 2011; Roberts et al., 2013). Recently, Suganuma et al. (2010) presents clear evidence for a downward offset of the paleointensity minimum relative to the ^{10}Be flux anomaly at the Matuyama-Brunhes (M-B) geomagnetic polarity boundary, which they interpret to result from a 16 cm PDRM lock-in depth. This indicates that a certain age offset probably occurs when a paleomagnetic record is used for dating marine sediments. This phenomenon also suggests that the accepted ages for the geomagnetic polarity boundaries, including the M-B boundary, should be revised (ca. 10 kyr younger in case of the M-B boundary). Contrary, two recently proposed revisions of the age of the ^{40}Ar/^{39}Ar Fish Canyon sanidine (FCs) standard (Kuiper et al., 2008; Renne et al., 2010) would adjust ^{40}Ar/^{39}Ar ages of the M-B boundary from Maui (Singer et al., 2005) to 781 $\pm$ 2 ka and 784 $\pm$ 2 ka, respectively.

Plio-Pleistocene marine sedimentary sequences are widely distributed in the Boso and Miura Peninsula, central Japan. Because these sequences have a significantly high sedimentation rate with well-preserved platonic and benthic foraminifera fossils, it is possible to reconstruct a detailed geomagnetic behavior along the polarity boundaries such as M-B with high resolution oxygen isotope records. In addition, a number of tephra layers are accompanied with these sedimentary sequences, which make it possible to provide absolute age constrains for the boundaries. The Byakubi tephra, located few tens of cm above the M-B boundary, has been investigated based on SHRIMP (Sensitive High Resolution Ion Microprobe) U-Pb dating of single zircon crystals from the tephra. The initial U-Th ratio is also corrected by using ICP-MS (Inductively Coupled Plasma Mass Spectrometer) analysis of volcanic glasses of the tephra. The ^{206}Pb/^{238}U ratio corrected by ^{207}Pb assuming ^{206}Pb/^{238}U-^{207}Pb/^{235}U age concordance from 20 grains are equivalent with a weighted mean of 761.1 $\pm$ 7.6 ka. Although this M?B boundary age is ˜23 kyr younger than previously accepted ^{40}Ar/^{39}Ar ages, this is almost consistent with a younger ice core derived age of 770 $\pm$ 6 ka (Dreyfus et al., 2008), marine sediments age of 770 ka based on ^{10}Be anomaly (Suganuma et al., 2010), and ^{40}Ar/^{39}Ar age of 761 $\pm$ 2 ka adjusted by the K-Ar based FCs standard ages (27.5 Ma: Mochizuki et al., 2010).

Rockmagnetic and Paleomagnetic examinations for the Matuyama-Brunhes polarity transition recorded in the Kazusa Group

OKADA, Makoto[1*] ; SUGANUMA, Yusuke[2] ; MARUOKA, Toru[1] ; HANEDA, Yuki[1] ; KAZAOKA, Osamu[3]

[1]Ibaraki University, [2]National Institute of Polar Research, [3]Research Institute of Environmental Geology, Chiba Pref.

We report results of rockmagnetic and paleomagnetic examinations for the Matuyama-Brunhes polarity transition recorded a marine sequence of the Kokumoto Formation, Kazusa Group in the Boso Peninsula. We have taken 130 oriented mini-cores from a 13 meters interval of sandy-siltstones spanning across the TNTT bed (Byakubi-ash layer) at the Tabuchi section along to the Yoro River and at the Yanagawa section. Results from thermal magnetic experiments suggested that the samples include iron sulfide, magnetite as a primary remanence carrier and no hematite. Measurements of magnetic hysteresis indicated that a domain state of the samples was PSD. Results of progressive alternating field demagnetization indicated a reversed to normal polarity transition boundary was observed at around 1.5 meter below the TNTT bed as well as previous studies, however the transition boundary was observed at around the TNTT bed in thermal demagnetization results. In the samples showing this discrepancy, a magnetite derived reversed polarity component was observed after a normal polarity component completely demagnetized at around 300-400 ℃. This phenomenon would be due to that the magnetite derived primary component was slightly acquired under a weak magnetic field condition just before the M-B boundary, and then chemically yielded iron sulfide magnetic minerals acquired a much stronger normal polarity component under a strong filed condition after the polarity transition. Those results exhibited that the M-B boundary situated at around the TNTT bed where about 1.5 metes above the position reported in previous studies.

High-resolution magnetostratigraphy across the Matuyama-Brunhes polarity transition from the Chiba Section

HYODO, Masayuki[1*] ; TAKASAKI, Kenta[2] ; MATSUSHITA, Hayato[2] ; KITABA, Ikuko[1] ; KATOH, Shigehiro[3] ; KITAMURA, Akihisa[4] ; OKADA, Makoto[5]

[1]Research Center for Inland Seas, Kobe University, [2]Department of Earth and Planetary Sciences, Kobe University, [3]Division of Natural History, Hyogo Museum of Nature and Human Activities, [4]Institute of Geosciences, Faculty of Science, Shizuoka University, [5]Department of Earth Sciences, Faculty of Science, Ibaraki University

An oriented 54-m core was collected from the Kokumoto Formation of the Kazusa Group, near the Chiba Section, a candidate for the GSSP of the Early-Middle Pleistocene boundary. The core spans in stratigraphy from a thick sand layer below a mud clast layer up to just below the Ku-2B tuff. A detailed Matuyama-Brunhes (MB) geomagnetic reversal record was obtained, using u-channel samples of 1 m long cut out from 1-m core section. Magnetization components were separated by stepwise alternating field demagnetization (AFD). Low field magnetic susceptibility and anhysteretic remanent magnetization show the core consists of magnetically homogeneous sediments. Magnetizations of discrete samples of 2.2cm x 2.2cm x 2.2cm were also measured, being subjected to progressive thermal demagnetizations (THD) and AFD. The declinations of characteristic remanent magnetization (ChRM) well agree across the boundary of 1m-sections, indicating that orientation of each 1m-core section was successful. Magnetic hysteresis measurements show magnetic grains are of PSD size. THD shows that hematite is included besides magnetite, a main magnetic carrier. Thermomagnetic measurements and THD suggest that the sediments include greigite, ferrimagnetic iron sulfide, which may cause a false reversal due to self-reversal of magnetic minerals. The paleomagnetic results show that the upper boundary of the MB transition lies above the Byakubi volcanic ash layer, which is much higher than the previous result. Our data show normal polarity continues from a depth of about 1m below the Byakubi, but several polarity swings exist above it. From about 70cm above the Byakubi to the top of the core, normal polarity continues. Relative paleointensity data show the lower end of the MB transition lies below the base of the core. The relative paleointensity keeps low values in the lower part below the Byakubi, and gradually increases upward above it, reaching a maximum value at about 39 m above the Byakubi. This linear increase feature is similar to the post-MB reversal intensity pattern observed in the paleointensity stack Sint-2000 (Valet et al., 2005). The low paleointensity kept throughout the basal part suggests the beginning of the MB transition lies much below the base of the core.

Identification of Pleistocene tephra layers in marine sediment core C9001C, offshore Shimokita Peninsula, NE Japan

HASEGAWA, Takeshi[1*] ; SUGAYA, Manami[1] ; OKADA, Makoto[1] ; MOCHIZUKI, Nobutatsu[2] ; FUJII, Satomu[2] ; SHIBUYA, Hidetoshi[2]

[1]Faculty of Science, Ibaraki University, [2]Kumamoto University

Correlations for Pleistocene tephra layers in marine sediment core C9001C was investigated. The core was obtained from near the Shimokita Peninsula, Japan by the CK06-06 D/V CHIKYU Shakedown Cruise in 2006. The stratigraphy of the Hole C9001C (365 m long) has been well established based on the correlation of the benthic d18O curve with the LR04 stack (Domitsu et al., 2011). Tephra layers, a few millimeters to centimeters in thickness, can be often recognized in this sediment core that is mainly composed of dark olive-gray, diatomaceous silty clay. Two tephra layers at 30.3 mbsf and 54.3 mbsf were already correlated with the Spfa-1 and Aso-4, respectively. In this study, we focus on relatively thick and coarse tephra samples from 20 mbsf to 150 mbsf (30 - 240 ka, LR04 age). As the result, seven tephra layers were newly identified on the basis of tephro-stratigraphy and petrology, such as glass chemistry and mineralogy.

We identified the To-Of (BP1) at 19.6 mbsf, To-GP at 24.8 mbsf, Ko-i at 25.5 mbsf, Toya at 61.4 mbsf, Aso-3 at 73.9 mbsf, Mb-1 at 115.6 mbsf and Tn-C at 145.9 mbsf based on tephra databases (e.g. Okumura, 1991; Machida and Arai, 2003; Aoki and Machida, 2005). Descriptions of each tephra layer are as follows: The tephra layer at 19.6 mbsf is 6 cm thick, medium-sand sized, crystal vitric ash, including Cpx and Opx crystals. Chemical composition of glass shards is SiO2=77.5%, K2O=1.2% (100% normalized). The tephra layer at 24.6 mbsf is 3 cm thick, medium-sand sized, vitric crystal (Cpx, Opx) ash, showing Low-K glass composition (SiO2=75.4%, K2O=1.1%). The tephra at 25.5 mbsf is patchy (5 mm in maximum thickness), fine-sand sized, vitric ash, showing the Medium-K composition (SiO2=76.2%, K2O=2.1%). The tephra at 61.4 mbsf is 1.5 m thick, fine-sand sized, vitric ash, containing trace amount of Opx. Glass shards have Medium-K composition (SiO2=79.0%, K2O=2.7%). The tephra layer at 73.9 mbsf is 2 cm thick, medium-sand sized, vitric crystal (Cpx, Opx) ash, characteristically showing High-K glass composition (SiO2=70.3%, K2O=4.6%). The tephra layer at 115.6 mbsf is 4 cm thick, medium-sand sized, vitric crystal ash, characteristically including Bt, Hb crystals in addition to pyroxenes. The glass chemistry is: SiO2=78.1%, K2O=3.9%. The tephra layer at 145.9 mbsf is 20 cm thick, medium to coarse-sand sized, vitric crystal (Cpx, Opx) ash, showing relatively Low-K glass composition (SiO2=78.4%, K2O=1.5%).

We can re-examine the correlations for tephras with marine isotope stages (MIS) based on LR04 age. The To-Of tephra from Towada volcano can be newly correlated with early MIS 2 (<29 ka). The Aso-3 can be correlated with late MIS 6. It is also needed to revise the estimations of eruption volume and distribution of Aso-3. The Tn-C tephra from Osore volcano can be correlated with MIS 7 (<240 ka). Detailed identification of these seven tephras and further correlations for other tephra samples are now in progress, and will be presented elsewhere.

Overview of tephrochronological study on Kazusa Group, the standard Quaternary marine sediments, central Japan

SUZUKI, Takehiko[1*]

[1]Tokyo Metropolitan University

The author will review tephrochronological study on Kazusa Group, the standard Quaternary marine sediments, central Japan, and will point out issues to study in future. The former will be carried out by referring to previous works by each area such as Boso, Tama Hills, Yokohama, Choshi, and underground of central Kanto Plain. Recent studies have focused on description of characteristic properties of tephras and correlation between areas in Kanto district. Moreover, studies for correlation with proximal tephras around source volcanoes had been carried out.

The Kazusa Group as a standard tephrostratigraphy of Japanese Lower to Middle Pleistocene formations

SATOGUCHI, Yasufumi[1*]

[1]Lake Biwa Museum

Tephrostratigraphy of the Pliocene to Pleistocene formations at Kyushu and Honshu Island are established (Satoguchi and Nagahashi, 2012). Establishment of stratigraphy and chronological model needs integrative interpretation of biostratigraphy, paleo-magnetostratigraphy and other stratigraphic and chronological studies. In the early stages of the work like this, decision of standard stratigraphy for is valid. Satoguchi and Nagahashi (2012) adopted the Kazusa Group as a standard formation of the Pleistocene stratigraphy of Japan.

The Kazusa Group, which is composed of marine deposits, is investigated about magnetostratigraphy, biostratigraphy, correlated with MIS and other stratigraphical studies. Many tephra beds in this group have been described, and data of characteristic properties of these tephras for correlations are accumulated (e.g. Satoguchi, 1995). Some of these tephras are examined for correlations with widespread tephras, are revealed about their volcanic source area. For example, the Ss-Pnk, the Ss-Az and the Kb-Ks tephras are from Kyushu Island (Hayashida et al., 1996; Kamata et al., 1994; Kikkawa et al., 1991). The Ho-Kd39, Eb-Fukuda, Om-SK110 tephras are from the Chubu Mountains (Nagahashi et al., 2000). The JA-O18L tephra is from north of the Kanto district (Nakamura and Arai, 1998). The As-Kd8 and the Hkd-Ku tephras are from the Tohoku district (Murata and Suzuki, 2011; Suzuki et al., 2005). The Kazusa Group contains tephras from various areas. This thing is important for being standard tephrostratigraphy. Tephras mentioned above are widespread tephras that are distributed over 500km. Some tephras in this group are revealed that they distributed relatively small area. Volcanic source of the Byakubi tephra, which is intercalated around boundary of the Lower-Middle Pleistocene, is the Older Ontake Volcano (Takeshita et al., 2005). The Ks12 tephra above the Byakubi tephra is also from the Older Ontake Volcano. These tephras are important for investigation of volcanic history about the Older Ontake Volcano. Therefore, the Kazusa Group is important formation for Japanese stratigraphic studies and investigation of explosive volcanism in the Pleistocene.

Reconstruction of paleogeography of Kanto district about 1.6 Ma based on tephrostratigraphy

NAKAJIMA, Eri[1*] ; SUZUKI, Takehiko[2]

[1]Graduate student, Tokyo Metropolitan University, [2]Tokyo Metropolitan University

First Horinouchi Tuff (HU_1) in the Oyamada Formation of the Kazusa Group, erupted about 1.63 Ma, had been found in and around Kanto Plain by previous studies. We examined the correlation of HU_1 and tephras stratigraphically near to HU_1 to reconstruct paleogeography of Kanto district in Early Pleistocene. The tephras collected from the river bed of the Tama River (Tachikawa city), the Sayama Hills, the Yokohama area, the Choshi area, Enoki Trench Core, Tachikawa Core, and Higashiyamato Core were analyzed. The tephras were correlated based on their mineral contents, refractive indices of volcanic glass shards and minerals, chemical compositions of volcanic glass shards and titanomagnetite. As a result, it was newly revealed that three tephra layers (Sayama Gomashio Volcanic Ash in Sayama Formation, pumice fall deposit in the Tachikawa Core Fujimi of Tachikawa, HY-1.1-HY1-6 in the Higashiyamato Core Narabashi of Higashiyamato) are correlated with HU_1. Also, We analyzed Tobiratoge Pyroclastic Rocks and Sanjiro Pyroclastic Rocks occured in the south part of the Utsukushigahara Plateau in order to detect the source volcano of HU_1. As a result, both Tobiratoge Pyroclastic Rocks and Sanjiro Pyroclastic Rocks are not correlated because of difference refractive indices and chemical compositions of volcanic glass shards and refractive indices of hornblende. Thus, it was revealed that HU_1 has not been erupted from the volcano vicinity of Utsukushigahara Plateau. We estimated the accumulation rates of sedimentation based on correlated tephras. The accumulation rates of sediments are 46.3 cm/kyr in the Yokohama area, 59.0 cm/kyr at Tachikawa Core, 2.5-10.3 cm/kyr at Haginaka Core, 3.8-6.7 cm/kyr in the Choshi area. These differences of the accumulation rates of sediments reflect the difference of the sedimental environment. Moreover, in Tachikawa Core and Sayama Hills, HU_1 are accumulated thicker than other areas. It is expected that HU_1had reworked again and again after its primal deposition by the effect of wave action in shallow sea.

Stratigraphy of the L-M Pleistocene boundary section in the Kokumoto Formation with re-definition of the Byk-TNTT tephra

KAZAOKA, Osamu[1*] ; OKADA, Makoto[2] ; KAMEYAMA, Shun[1] ; SUGANUMA, Yusuke[3] ; AIDA, Nobuyuki[4] ; MORISAKI, Masaaki[1] ; KAGAWA, Atsushi[1] ; KUMAI, Hisao[5] ; NIREI, Hisashi[6]

[1]Research Institute of Environmental Geology, Chiba, [2]Ibaraki University, [3]National Institute of Polar Research, [4]Shumei University, [5]Osaka City University, [6]Officer of IUGS-GEM

Detailed stratigraphy of the Kazusa Group was surveyed for development of water-soluble natural gas on many marker tephra in Boso peninsula (Kanehara et al.,1949; Shinada et al.,1951; Mitsunashi et al.,1959; Mitsunashi et al.,1961; Ishiwada et al.,1971; Mitsunashi et al.,1979). Magnetostratigraphy (Nakagawa et al., 1969; Niitsuma, 1976; Okada & Niitsuma, 1989), planktonic foraminifera (Oda,1977), nannofossils (Takayama,1967; Sato et al., 1988) and diatom (Cherepanova et al.,2002) were studied on the detailed stratigraphy for international correlation.

The Early-Middle Pleistocene boundary is in the middle part of the Kokumoto Formation in Kazusa Group (Kumai, 1996). Many marker tephra are interbeded in Kiwada F., Otadai F., Umegase F. and Kakinokidai F. Only 5 marker tephra are intercalated in Kokumoto F. Over twenty thin tephra, pumice bed, scoria bed and vitric fine tuff were fined out in the middle silty part of the Kokumoto F. for detailed stratigraphy around the Early-Middle Pleistocene boundary in Yoro river route, type route of the Kazusa G. (WQSB, 1996). Byakubi(Byk) tephra, 1-3cm thick vitric fine tuff under 27m thick from Ku2 distribute in Byakubi district along Yoro river. Matuyama?Brunhes magnetic reversal was fined out in the middle silty part under Ku2 tephra (Nakagawa et al.,1969). Aida(1997) showed that the magnetic reversal distribute just below the Byk tephra. TNTT tephra and the Matuyama?Brunhes magnetic reversal just below the TNTT tephra were fined under Ku2 on Yanagawa route (Niitsuma,1976). Same tephra and the magnetic reversal were fined on Heizo rute and Chonan route (Okada & Niitsuma, 1989). White vitric tephra are interbeded often in the Kazusa G. So marker tephra is necessary tephra association with over 2 tephra. 4 tephra, 3 scoria bed and 1 vitric fine tuff, were fine out just above Byk tephra on Yoro river route for detailed stratigraphy around the magnetic reversal by this study. And same tephra association were recognized just above the TNTT tephra in Yanagawa route, too.

Byk tephra zone is defined as follows. Byk tephra zone is composed of 5 tephra which in ascending order are Byk-E, Byk-D, Byk-C, Byk-B and Byk-A. Byk-B, Byk-C and Byk-D are medium sand grain scoria lenticular beds. Byk-A is 9 cm thick reddish gray vitric fine tuff. Byk-E is 1-3cm thick white vitric fine tuff. Byk-E tephra is correlated with TNTT tephra.

Lower - Middle Pleistocene Boundary at Chiba Section and istribution situation of Byakubi Ash, central Japan

KIMURA, Hideto[1*] ; KAZAOKA, Osamu[2] ; NIREI, Hisashi[3]

[1]Toho Chisui Co., Ltd. Kanto office, [2]Research Institude of Environmental Geology, Chiba, [3]International Union of Geological Science for Environmental Management(IUGS-GEM)

The Byakubi Ash is distributed over the Ichihara City southern part and is located in the vicinity of a base of the middle-upper member of Kokumoto formation, Kazusa Group. Kokumoto formation is sorted four member by facies, is upper member (sandy alternation), middle-upper member (mussive mud), middle-lower member (sandy alternation) , and lower member (mussive mud). The Matsuyama / Brunhes chron boundary as the Lower - Middle Pleistocene Boundary is attracted by the lower base of the Byakubi Ash, it was confirmed that the Byakubi Ash was distributed from the Yoro River(Tabuchi) , Tabuchi River(Tabuchi), Nishi River(Tsukide), to the Koshikiya River (Koshikiya).

The future follow-up survey comes to need a careful survey, but it is thought that it is to the important clue of the chase because the distribution situation of Ku2(Ku2B' and Ku2B) inserted between the high rank of the Buakubi Ash is considerably confirmed.

Tephras of the Kokumoto Formation in the Mobara area

NAKAZATO, Hiroomi[1*] ; NANAYAMA, Futoshi[2]

[1]NARO, [2]AIST

Authors are examining the tephra stratigraphy of the Kazusa Group as part of the geologic map investigation in 1/50,000 Mobara district. The tephras of Ku0.6-Ku6E were confirmed from the Kokumoto Formation. The TNTT tephra (Niitsuma, 1971) which is just above the B/M boundary is pursued to Obota, Chonan town by Okada and Niitsuma (1989). The TNTT is a fine vitric volcanic ash with abundant hornblende (n_2=1.680-1.703) and the pumice type volcanic glass (n=1.505-1.510). This tephra was correlated with the tephras from the Older Ontake Volcano (Takeshita et al., 2005). The distribution of the TNTT was confirmed to Baba, Mutsuzawa town in the authors' investigations. Tephras of Ku0.6, Ku0.9 and Ku2.5 were confirmed in Terasaki, Mobara city where is the northeast limit of distribution of the Kokumoto Formation. The TNTT and the B/M boundary horizon are able to trace to this region.

The source volcano and age of the Byakubi tephra in the Kazusa Group in Boso Peninsula, central Japan

UCHIYAMA, Takashi[1*] ; TAKESHITA, Yoshihiro[2] ; KUMAI, Hisao[3]

[1]Yamanashi Institute of Environmental Sciences, [2]Shinshu University, [3]Prof. Emeritus, Osaka City University

Introdution

The Kazusa Group in the Boso Peninsula, central Japan is composed of Lower- Middle Pleistocene marine sediments that contain numerous tephra layers (Mitsunashi et al.1959; Machida et al. 1980; Satoguchi 1995; Satoguchi 1996 and so on). One of numerous tephra layers, Byakubi tephra (BYK; Takeshita et al. 2005) is intercalated just above Brunhes/ Matuyama (B/M) boundary in middle part of the Kokumoto Formation (Okada and Niitsuma 1989; Aida et al. 1996). BYK was correlated with YUT4 or 5 from the Older Ontake Volcano, which provide a datum plane of the Lower-Middle Pleistocene boundary in central Japan (Takeshita et al. 2005).

Correlation of the tephra beds in the Kazusa Group with those from the Older Ontake Volcano

Heavy mineral assemblage and chemical compositions of hornblende of nine Lower-Middle Pleistocene tephra beds (Ku6E, Ku5C, BYK, Ka2.4A, Ka2.4B, Ch3, Ch1.5, Ks18, Ks12) from the Kazusa Group, in Boso Peninsula were examined in order to correlate with the tephra from the Older Ontake Volcano in central Japan by Takeshita et al. (2005). Conclusively, hornblende compositions from the nine tephra beds were distinguishable. Two of the nine beds, BYK and Ks12 tephra, were correlated with two tephras from the Older Ontake Volcano, YUT4 or 5 and KZT, respectively . The age of these tephra beds of the Kazusa Group could be inferred from the stratigraphic relationships with 47 dated lava flows on the foot of the Older Ontake Volcano, and from presence of well-known widespread tephras and magnetostratigraphy in the Boso Peninsula. Correlated these two tephra beds became valuable marker tephra for geochronological studies in inland and marine sediments from central Japan. It was also emphasized that the BYK and YUT4 or 5 could provide a datum plane of the Lower-Middle Pleistocene boundary in this region.

Concentration of Elements Related to Redox Evolution in Oceanic Environments

OTAKE, Tsubasa[1*]

[1]Faculty of Engineering, Hokkaido University

Chemical sedimentary rocks, which are precipitates from ancient seawater, not only concentrate useful elements (e.g., Fe, Mn, Co, Ni, Rare Earth Elements (REEs)), but may also reflect changes in Earth ' s surface environments (e.g., pH, redox conditions, surface temperature). The temporal distribution of Banded Iron Formations (BIFs), the main economic Fe source, has been proposed to indicate changes in atmospheric and ocean chemistry in early Earth related to the evolution of the biosphere. However, to acquire a better understanding of the surface environments, BIFs deposited in various sedimentary setting need to be investigated. In this study, geological and geochemical investigations of BIFs that were deposited in a shallow ocean in the Archean Barberton Greenstone Belt, South Africa, show that the Cr/Ti and U/Th ratios are higher in the BIFs compared with the underlying and overlying clastic sedimentary rocks. Oxygen isotope compositions in each chromite grain, a host mineral of Cr, were determined by SIMS. The results show the chromite has lower δ^{18}O values compared with igneous and metamorphosed chromites, indicating that they were formed under hydrothermal conditions. The results suggest that dissolved Cr and U species in ocean were coprecipitated with ferric (hydr)oxides during the formation of the BIFs, and that chromite was formed by later hydrothermal alteration. Therefore, the results of the study indicate that enrichments of redox-sensitive elements (e.g., Cr, U) in BIFs have already occurred through chemical processes as early as 3.2 billion years ago due to the oxygenation of a shallow part of the ocean.

Volcanogenic Massive Sulfide (VMS) deposits such as Kuroko deposits in the Hokuroku district, Akita Prefecture were formed by ancient submarine hydrothermal activity, and are also associated with Fe-rich chemical sedimentary rocks. Because VMS deposits are primarily composed of sulfide minerals that are unstable in an oxic environment, such as pyrite and chalcopyrite, an anoxic environment in the Hokuroku basin may play an important role in the preservation of sulfide ores. Therefore, REE patterns and Fe isotope compositions of the Fe-rich chemical sedimentary rocks were investigated since geochemical evidence of such an environment being present in the Hokuroku basin is currently lacking. The results of these analyses show that the δ^{56}Fe values of samples occurring directly on and above Kuroko deposits were -1.5 to 0.5 ‰. These values are largely fractionated from the δ^{56}Fe value of the standard (i.e., 0 ‰), which is a similar to that of igneous rocks. The samples that have a large negative value also bears negative Ce anomaly. These signatures indicate that partial oxidation of dissolved ferrous iron occurred by mixing ferrous iron-bearing anoxic water with oxygen-bearing seawater, and therefore that the seafloor of the Hokuroku Basin was anoxic. On the other hand, δ^{56}Fe values of chemical sedimentary rocks formed 2 - 3 Ma after the Kuroko deposits formed ranges from -0.8 to -0.3 ‰. These values are similar to those of dissolved ferrous ion in a modern seafloor hydrothermal fluid. Therefore, the δ^{56}Fe values of the samples indicate near complete oxidation of dissolved ferrous iron in an oxic environment. Therefore, these results suggest that the depositional environment in the Hokuroku basin shifted from anoxic to oxic after the formation of Kuroko deposits.

Sedimentation age determination by using an Os isotope stratigraphy is one of the effective dating methods for a ferromanganese crust. This dating method is applicable to the almost whole sedimentation age of a ferromanganese crust from the Late Cretaceous to present. So far, we have applied the Os isotope dating method to various ferromanganese crust samples collected from Northwestern Pacific, South Atlantic Oceans and Philippine Sea. In this presentation, we introduce the principles and applications of the Os isotope dating method, and discuss our recent results especially focusing on the growth hiatus of a ferromanganese crust.

Occurrence of hydrothermal alteration minerals at the Jade hydrothermal field, in the Izena Hole, mid-Okinawa Trough

MIYOSHI, Youko[1*] ; ISHIBASHI, Jun-ichiro[2] ; YOKOYAMA, Yuka[3] ; TAKAHASHI, Yoshio[3]

[1]National institute of Advanced Industrial Science and Technology (AIST), [2]Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, [3]Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University

Mineralization at the Jade hydrothermal field, in the Izena Hole, mid-Okinawa Trough, resembles in many aspects the Kuroko type ore mineralization. In the Kuroko type ore deposits, zonal distribution of hydrothermal clay minerals was recognized around the deposit. This study aims to reveal occurrence of hydrothermal clay minerals below the seafloor in the Jade hydrothermal field. We report mineralogy and geochemistry of hydrothermal clay minerals identified in surface sediments in the Jade field and compare with those in the Kuroko type ore deposits.

Surface sediment cores (˜30 cmbsf (centimeters below the seafloor)) were collected by an acrylic push corer (MBARI-type corer) attached to remotely operated vehicle (ROV) Hyper-Dolphin. The core sampling was conducted during the NT10-17 cruise of R/V Natsushima (Japan Agency for Marine-Earth Science and Technology (JAMSTEC)) in September 2010. Minerals in the sediment were identified by X-ray diffraction (XRD), at the Department of Earth and Planetary Sciences, Kyushu University. For some sediment samples, clay fractions ($<2\mu$m) were collected from suspending particles in the distilled water according to the Stokes' law. Clay minerals in the clay fraction samples were identified by the XRD and analyzed chemically using a transmission electron microscope (TEM) equipped with an energy dispersive spectrometer (EDS) in the Research Laboratory for High Voltage Electron Microscopy (HVEM), Kyushu University.

A surface sediment core collected near the sulfide chimney venting high temperature fluid up to 320^{o}C was characterized by occurrence of kaolinite, with sulfide minerals such as sphalerite and galena. The kaolinite would be related to be formed under acidic condition caused by oxidation and dissolution of the sulfide minerals by penetrating seawater. Surface sediment cores collected near clear hydrothermal fluid venting of about 100^{o}C, which is located in 400 m distant from the sulfide chimney, were characterized by assemblage of chlorite and smectite. The chlorite had chemical composition close to Al-rich chlorite (sudoite) which was found around a few Kuroko type ore deposits. In the Kuroko type ore deposits, sudoite was considered to be stable under acidic condition because of the associated clay minerals. This study revealed occurrence of acidic alteration minerals in surface sediment at the Jade hydrothermal field, in the Izena Hole, mid-Okinawa Trough.

Geochemistry of hydrothermal fluids collected from submarine volcanoes in the Izu-Bonin Arc

ISHIBASHI, Jun-ichiro[1*] ; NAGATOMI, Kentaro[1] ; TAKAHASHI, Minoru[1] ; KODAMATANI, Hitoshi[2] ; TOMIYASU, Takashi[2] ; TAKEUCHI, Akinori[3] ; YAMANAKA, Toshiro[4]

[1]Graduate School of Science, Kyushu University, [2]Graduate School of Science and Engineering, Kagoshima University, [3]National Institute for Environmental Studies, [4]Graduate School of Natural Science and Technology, Okayama University

The Izu-Bonin Arc is an intraoceanic arc related to subduction of the Pacific Plate beneath the Philippine Sea Plate. At some submarine volcanoes on the volcanic front, active hydrothermal fields have been located. Hydrothermal fluids were collected from two active fields, the Suiyo Seamount and Myojin Knoll, and analyzed. Geochemical characteristics of hydrothermal fluids collected from the Izu-Bonin Arc hydrothermal fields will be presented, comparing with those of Okinawa Trough hydrothermal fields.

Hydrothermal fluid samples were collected from the Suiyo Seamount during the NT07-08 cruise in 2007, and from the Myojin Knoll during the NT12-10 cruise in 2012. Fluid samples were collected with ROCS (Rotary Clean Seawater Sampler) installed on ROV Hyper Dolphin (JAMSTEC). Temperature monitored during the fluid sampling showed up to 296 degC at the Suiyo Seamount, and 235 degC at the Myojin Knoll.

Fluid chemistry was characterized as 1) Depletion in Mg and SO_4, 2) Enrichment in K and Ca compared with seawater; especially Ca enrichment is notable, and 3) Low concentration of organic derived species such as NH_4. The fluid chemistry is explained by high-temperature water-rock interactions. Notable enrichment in Ca would be in accordance with low- and Mid-K series chmiecal composition of volcanic rocks. Low NH_4 concentration would be related to depletion in organic-rich terrestrial sediment around the volcanoes.Concentration of minor elements including metal elements will be present, to discuss linkage with mineralogy of hydrothermal deposits in these hydrothermal fields.

Relationship between the formation of mercury deposits and the occurrences of organic minerals in subduction zones

ECHIGO, Takuya[1*]

[1]Faculty of Education, Shiga University

Karpatite and idrialite occur in mercury deposits in the West Coast in the USA. In addition, organic matter was also found in mercury deposit in Hokkaido. Both mercury deposits are epithermal type and formed in subducting zone. The relationship between organic minerals and mercury deposits in subducting zone will be discussed.

A pilot magnetotelluric survey for geothermal exploration in northern Thailand

AMATYAKUL, Puwis[1*] ; RUNG-ARUNWAN, Tawat[1] ; OGAWA, Yasuo[2] ; SIRIPUNVARAPORN, Weerachai[1]

[1]Geophysics Research Group, Department of Physics, Faculty of Science, Mahidol University, [2]Volcanic Fluid Research Center, Tokyo Institute of Technology

One of Thailand's most prominent geothermal field is located in Maechan district, Chiangrai province, along the active Maechan fault which is East-West left-lateral strike-slip fault. Its surface temperature is 99.5 degree Celsius with the flow rate of 3 l/s. Magnetotelluric (MT) survey is proposed to help delineating geothermal fluid and controlling features of the hydrothermal system. In July 2013, 7 magnetotelluric stations were deployed covering the area of Maechan geothermal field. Horizontal magnetic and electric fields (H_x, H_y, E_x and E_y) were collected with the remote reference site located 70 km away in Fang district, Chiangmai province. To obtain 3-D resistivity model, 18 periods of off-diagonal (Z_{xy} and Z_{yx}) elements ranging from 0.003 to 300 second were applied with WSINV3DMT, a 3-D MT inversion widely used among many authors. The obtained resistivity model shows the shallow conductive zones which their locations coincide with the hot springs manifestation. These conductive zone locates from the surface to not more than 500 m and referred as the reservoir of hot geothermal fluid heated by the deeper resistive batholith granite basement. The resistivity contrast in the obtained model up to 2 km northward is corresponding to the lineament of Maechan fault. This also confirms the hypothesis from previous studies that the hot fluid is being stored in fractures of weathered granite which is the damage zone of Maechan fault and reaches the surface where the springs are located through shallow fractures and faults.

Development of in-situ Cu isotope ratio measurement by femtosecond-LA-MC-ICP-MS and its applications to ore minerals

IKEHATA, Kei[1*]

[1]Faculty of Life and Environmental Sciences, University of Tsukuba

A new method for determining copper isotope compositions of copper-rich minerals (native copper, cuprite, chalcocite, chalcopyrite, cubanite and malachite) using a femtosecond LA-MC-ICP-MS has been developed. The standard-sample-standard bracketing technique was applied to correct the instrumental mass fractionation. Matrix effects found in chalcocite, chalcopyrite, cubanite and malachite can be corrected using the matrix-matched calibration standard. The analytical precision ($<$0.14 ‰, 2σ) and accuracy were significantly improved compared with those of previous works using a nanosecond-LA-MC-ICP-MS.

The developed LA-MC-ICP-MS method was applied to the measurements of copper isotope ratios of minute copper ore minerals in igneous rocks (e.g., Horoman peridotite complex) and seafloor hydrothermal deposits (modern: Mariana Trough; ancient: Besshi-type and Kuroko-type volcanogenic massive sulfide deposits) in order to investigate variability of copper isotopic compositions in these samples.

The δ^{65}Cu (where δ^{65}Cu = [(^{65}Cu/^{63}Cu)$_{sample}$/ (^{65}Cu/^{63}Cu)$_{NIST-SRM976}$-1] $\times$ 1000) values of copper-rich sulfide minerals of the active seafloor hydrothermal deposits are significantly large (δ^{65}Cu = -0.7 to 4.0 ‰) compared to those of the ancient submarine hydrothermal deposits (δ^{65}Cu = -0.3 to 0.4 ‰) and the igneous rocks (δ^{65}Cu = -0.3 to 0.3 ‰). These large copper isotope variations in the modern active seafloor hydrothermal deposits are most likely explained in terms of a redox-controlled isotope fractionation during hydrothermal reworking or alteration of precipitated copper-rich minerals. These results also suggest that sub-seafloor and metamorphic recrystallization effects probably have reduced the original range of copper isotopes.

Secondary malachite (δ^{65}Cu = 2.6 to 3.0 ‰) and native copper (δ^{65}Cu = 1.4 to 1.7 ‰) in the Besshi-type deposit have heavier copper isotope values compared to precursor copper-rich minerals. These variations are mainly due to isotope fractionation during redox reactions (weathering) at low temperatures involving the preferential incorporation of heavy copper isotope in secondary Cu(II) solutions. Therefore, copper isotope geochemistry could be a useful tool for understanding geochemical processes of copper transport and deposition in ore-forming systems.

Origin of Heavy-REE-rich apatite in deep-sea mud from Minami-Torishima area, south-eastern Japan

KON, Yoshiaki[1*] ; SHIN, Ki-cheoul[2] ; HOSHINO, Mihoko[1] ; SANEMATSU, Kenzo[1] ; OKAMOTO, Nobuyuki[3] ; YANO, Nobuhiko[3] ; TANAKA, Mikiya[4] ; TAKAGI, Tetsuichi[1]

[1]Geological Survey of Japan, AIST, [2]Research Institute for Humanity and Nature, [3]JOGMEC, [4]Research Institute for Environmental Management Technology, AIST

We have conducted geochemical and mineralogical investigations of the rare earth and yttrium (REY)-rich mud from Minami-Torishima area in the Pacific in order to clarify the concentration of REY and their host-phase in the mud. X-ray diffraction analysis shows that the mud is mainly composed of phillipsite, fluorapatite, quartz, albite, illite and montmorillonite. Whole-rock CaO, P2O5 and total REY contents of the mud are positively correlated. Relative abundance of apatite is also positively correlated to P2O5 and total REY contents. These correlations suggest that apatite is the main host of the P2O5 and REY in the mud. In order to quantitatively estimate the REY-host phase, we make in-situ compositional analyses of constituent minerals in the REY-mud. The result shows that the apatite is abundant in REY (9300 to 32000 ppm) and characterized by negative Ce-anomaly. In contrast, phillipsite is less abundant in REY (60 to 170 ppm). We conclude that the main REY host phase of the mud is apatite.

Upgradation of silica rich fluvial sands of Bangladesh: Proposals for alternate uses

RAJIB, Mohammad[1*]

[1]Bangladesh Atomic Energy Commission / Graduate Student, Grad. Sch. Sc. Eng., Saitama University

Major rivers of Bangladesh are carrying billions of tons of sediments from the Himalayan mountain range from the north, forming bars almost on every river. These bars inundate in floodwater every year, eroding some sediments as well as depositing more. Thus, almost all the rivers are getting filled with the sediment in course of time. The government of Bangladesh has undertaken a mega plan for Capital Dredging, for raising navigability of the main and important rivers across the country. But there is not enough space to keep those dredged materials. Hence, most of the time, the dredged materials are thrown only in the vicinity of dredging area. In course of very short time, those materials eventually return back to river bed with the precipitation and surface runoff. This makes wastage of time and money.

The river sediments are rich in silicate mineral, mainly quartz and feldspar, along with others, like heavy and micaceous minerals. Quartz (SiO_2) is the raw material for glass production. River sands of Bangladesh also contain some heavy minerals like magnetite, ilmenite, rutile, zircon, garnet, leucoxene, pyroxene etc., and some Mica group minerals like muscovite, biotite, chlorite etc. Industrial use of these minerals are widely accepted. Upgradation of river silica by some physical separation procedures like density, magnetic and electric separators, and chemical composition revealed from X-ray fluorescence analysis shows that 60-70% silica of river sediment can be easily enriched up to 94%. Very low amount of Fe, Al, Ca, Mg and absence of Cr and Ti indicates the probable use of this upgraded silica as glass producing sand.

For industrial use, advance research is necessary for potential use of such silica for silicon extraction or other silicon products e.g. silicon chip, if the upgradation can be reached more than 99%. The heavy and magnetic minerals associated with silica also can be used economically as by-products of the process. Mining of this sediment from the rivers will increase the navigability of the rivers. As dredging is a must in almost every river of Bangladesh, the mining will work as alternative work of dredging, saving huge amount of money to be spent for dredging. This will also lessen the risk of dangerous flood problem of the country.

Moreover, since fluvial sands has been used as earth filling materials for long time and is suitable in many technical aspects, potentiality of using such sediments for artificial islands can be thought. Japan has been implementing several artificial islands where materials like solid waste, soil from mountains are mostly used as filling materials which are not always environment friendly. Feasibility study for using bulk fluvial sand from Bangladesh as earth filling materials for future artificial islands of Japan can a better alternative. This will decrease the risk of potential environmental hazards that can be created from solid waste or hill-cutting. Use of dredged materials from Bangladesh will help decreasing environmental hazards like floods too. Economical sustainability can be achieved through such reduction of hazard risk.

Iron isotopic composition of the Palaeoproterozoic Hotazel Formation in the Kalahari Manganese Field, South Africa

ASAKURA, Jun[1*] ; YAMAOKA, Kyoko[2] ; BORROK, David[3] ; WATANABE, Yasushi[2] ; KAWAHATA, Hodaka[1]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, [2]National Institute of Advanced Industrial Science and Technology, [3]University of Louisiana

Kalahari manganese deposit in the Palaeoproterozoic Hotazel Formation of Transvaal Supergroup of South Africa is the world's largest layered manganese deposit. It has alternating layers structure of three manganese rich layers and banded iron formation. This banded iron formation and manganese deposits of Hotazel Formation were formed at approximately the same time as Global Oxidation Event, which was the period of explosive growth of oxygen in Earth ' s atmosphere. In addition, the relevance of the snowball Earth event of Huronian glaciation has also been suggested from its formation age. Iron isotopes are sensitive indicators of the redox state, and it is suitable for estimating the marine environment when the banded iron formation was formed. Although a prior study on the iron isotope analysis of manganese deposits and banded iron formation of Hotazel Formation has been reported by Tsikos et al. in 2010, it is hard to say enough data is gathered.

In this study, drill core that was collected from the Kalahari manganese deposit in South Africa was subjected to iron isotope analysis with MC-ICP-MS and XRD analysis, and the results were compared with those of Tsikos et al.(2010). In isotopic analysis, δ56Fe values of drill core samples for the standard sample IRMM-14 were measured.

From the results, low δ56Fe values (not higher than -0.70 ‰) throughout the all samples were measured. When limited to manganese-rich layers, δ56Fe values are between -1.66 and -2.86 ‰. Relationship between Fe-Mn ratio and δ56Fe value showed that δ56Fe value have a tendency to drop to a lower value with the increasing abundance ratio of manganese to iron in a formation. This results are consistent with those of Tsikos et al.(2010). In other words, this results support their theory that banded iron formation has a role as a sink of heavy iron isotopes, and manganese are deposited in an environment that was rich in light iron isotopes.

Hydrogen transport into the bottom of the lower mantle by phase H- phase delta solid solution MgSiO2(OH)2-AlOOH

OHTANI, Eiji[1*] ; AMAIKE, Yohei[1] ; OHIRA, Itaru[1] ; KAMADA, Seiji[1] ; SAKAMAKI, Tatsuya[1] ; HIRAO, Naohisa[2]

[1]Tohoku University, [2]SPring-8

Water circulation in a global scale is a key for understanding dynamics and evolution of the Earth. Subducting slabs transport water into the Earth's deep interior. There are many studies on the stability of hydrous phases under the deep mantle conditions, and several hydrous minerals such as phase D and superhydrous phase B have been reported to be stable to the top of the lower mantle. It has been reported that hydrous phase δ-AlOOH is stable up to the bottom of the lower mantle (Ohtani et al., 2005; Sano et al., 2008). Tsuchiya (2013) theoretically predicted that Phase H, $MgSiO_2(OH)_2$, which is the iso-structure with δ-AlOOH, is stable from 45 GPa to 55 GPa. This phase was experimentally confirmed at around 50 GPa (Nishi et al., 2014). Here, we present our recent results on synthesis experiments of hydrous phase H and a solid solution of phase H and phase δ up to the base of the lower mantle along the normal mantle geotherm. The high pressure and high temperature in situ X-ray diffraction experiments were performed by using a double-sided laser heated diamond anvil cell at BL10XU, SPring-8. We observed that the stability field of this new candidate of water reservoir, hydrous phase H, under the lower mantle conditions up to 75 GPa and 2000 K in the MgO-SiO_2-H_2O system, although the previous studies claimed that phase H is broken down at pressures above 55 GPa. Thus, hydrous phase H is a host phase of water in the lower mantle at least up to the depth of 2000 km along both slab and normal mantle geotherms. Our experiments also revealed that the solid solution of phase H and phase δ, AlOOH-$MgSiO_2(OH)_2$, containing 15 mol % of $MgSiO_2(OH)_2$ can coexist with Mg-perovskite and/or Mg-post perovskite up to 135 GPa and 2000 K. If this hydrous phase contacts with the metallic outer core, hydrogen could be dissolved into the core by forming iron hydride, FeH (Terasaki et al., 2012).

Influence of H2 fluid on the stability of MgSiO3 enstatite in the upper mantle condition

SHINOZAKI, Ayako[1*] ; KAGI, Hiroyuki[1] ; HIRAI, Hisako[2] ; OHFUJI, Hiroaki[2] ; OKADA, Taku[3] ; NAKANO, Satoshi[4] ; YAGI, Takehiko[2]

[1]GCRC, The university of Tokyo, [2]GRC, Ehime university, [3]ISSP, The university of Tokyo, [4]NIMS

C-O-H fluids affect the phase relation and melting of silicate minerals in the mantle of the Earth. The mantle is expected to become progressively reduced with increasing depth, so that H_2 fluid is considered to exist in the deep mantle with H_2O fluids. In this study, influence of H_2 fluid on stability and phase relation of enstatite, which was the secondary most abundant mineral in the upper mantle, was examined using a laser heated diamond anvil cell.

In this presentation, we will report the results of $MgSiO_3$-H_2 system, which is non-iron-bearing system. After heating at 3.1-13.8 GPa and about 1500-2000 K, decomposition of enstatite and formation of forsterite (Mg_2SiO_4), periclase (MgO) and coesite/stishovite (SiO_2) were observed from XRD measurements. The presence of H_2 fluid were observed from Raman spectra even after the heating. Since the studied P-T range is in the stability field of orthoenstatite and high pressure clinoenstatite under dry condition, the decomposition reaction observed in the present study was presumably induced by H_2 fluid. Formation process of these silicate phases were evaluated by observation of quench texture of the recovered samples using SEM and TEM.

Dehydration boundary and the EoS of chlorite under high pressure and temperature

SUENAMI, Hideki[1] ; INOUE, Toru[1*] ; KAKIZAWA, Sho[1] ; KIKEGAWA, Takumi[2]

[1]Geodynamics Research Center, Ehime University, [2]High Energy Accelerator Research Organization

Water in hydrous minerals has been transported to deep Earth's interior by subducting slab, which dehydrate at certain pressure and temperature. The existence of deep Earth's water affects the physical properties of Earth's mantle minerals, such as melting point, viscosity, elastic velocity, and so on. Therefore it is important to study the effect of water for the subducting slab materials. Serpentine ($(Mg,Fe)_6Si_4O_{10}(OH)_8$) is major hydrous mineral in subducting slab, and chlorite ($(Mg,Fe,Al)_6(Si,Al)_4O_{10}(OH)_8$) should be also important hydrous mineral in the subducting slab because Al is included in slab materials. In this study, the dehydration reactions of chlorite were determined by time-resolved X-ray diffraction analysis under high pressure and temperature using MAX80, PF-AR, KEK. In addition, P-V-T experiments of chlorite have also been conducted under HPHT. We found that chlorite was quickly dehydrated to forsterite + pyrope + fluid within 1 hour at 3 - 7 GPa when across the phase equilibrium boundary. On the other hand, the kinetic boundary was observed above 7 GPa because of low temperature phase equilibrium boundary, and the dehydration product was Mg-sursassite + unknown + fluid, The result of P-V-T experiments will be also reported.

Composition and nature of melts, supercritical fluids and liquids formed by dehydration of subducted oceanic lithosphere

ULMER, Peter[1*] ; SCHMIDT, Max W.[1] ; PETTKE, Thomas[2] ; LUGINBUEHL, Stefanie[1]

[1]Department of Earth Sciences, ETH Zurich, [2]Inst. Geol. Sciences, University of Bern

At crustal pressures, phase relations in natural rock-H_2O systems involve low density aqueous fluids and/or high density hydrous melts. The wide miscibility gap between these two liquid phases leads to a dichotomy of mobile phases with quite distinct major element solubilities and trace element geochemical signatures. With increasing pressure, the fluid-melt miscibility gap closes until the crest of the miscibility gap intersects the fluid-saturated solidus, leaving a single supercritical liquid that has chemical and physical properties continuously evolving with temperature. The question is if the endpoint of the solidus is relevant for natural rock compositions. We have experimentally determined these endpoints in a variety of systems ranging from MOR basalt, to pelitic systems and to the simplified mantle systems MgO-SiO_2-H_2O (MSH) using different experimental techniques in the P-T range from 2.0 GPa/700 ℃ to 13.5 GPa/1300 ℃. Supercriticality occurs over a wide range of P-T conditions ranging from 1 GPa/1100 ℃ for the SiO_2-H_2O system to 12-13 GPa in the SiO_2-poor part of the MSH system.

In the MORB system, major element compositions of the fluid/melt phase evolve from peralkaline, H_2O-rich, granite-like compositions to metaluminous, andesitic to basaltic compositions with increasing temperature. The endpoint of the fluid-saturated solidus occurs around 5 GPa and 1000 ℃; thus, the dichotomy of fluid versus melt ceases to exist in the oceanic crust. Similar conditions were determined for pelitic to greywacke systems representing deep-sea sediments. In the mantle-like system MSH critical endpoints for fluid/melt solvi along the solidus are located between 12 and 13.5 GPa at 1100 ℃. Melt compositions buffered by olivine and opx remain enstatite - olivine normative below the critical endpoint; in contrast, fluids below the endpoint become progressively enriched in MgO and are silica undersaturated (Mg/Si ratios $>$2) at pressures exceeding 6 GPa. Supercritical liquids coexisting with forsterite and enstatite or dense hydrous silicates are strongly silica undersaturated. The P-T evolution of fluids and liquids in the MSH system allows drawing conclusions regarding the effects of Mg-Si metasomatism in the overlying mantle wedge of a subduction system.

The consequences of the various nature of hydrous mobile phases emanating from hydrated subducted oceanic lithosphere were investigated in the MORB system by determining trace element partitioning between cpx, gar, amphibole, epidote, rutile, titanite, staurolite and phengite and liquid, the latter either being an aqueous fluid, a hydrous melt, or a supercritical liquid. Hydrous melts and supercritical liquids have almost identical trace element pattern. Thus, recycling rates of these elements are not indicative of melting, and in the fast and steep circum-pacific subduction zones, they most likely testify for production of a mobile phase from the subducting crust in the supercritical liquid regime (i.e. at pressure in excess of 4-5 GPa).

Modeling of trace element signatures of fluids, melts and supercritical liquids generated in or passing through eclogitic crustal lithologies during their ascent into the overlying mantle wedge indicate that (1) the mode of fluid advection - porous flow or - focused fluid flow - produces rather contrasting trace element signatures and (2) the presence or absence of accessory phases such as epidote, staurolite, rutile/titanite controls to a large extent the concentrations of high field strength, light REE elements and Th, U. Thus, inversion of geochemical compositions of igneous products in arc settings used to constrain the nature and composition of metasomatizing agents released from the subducted oceanic lithosphere is not straightforward and it is unlikely that an unequivocal solution is obtained.

Trace element mass balance in hydrous adiabatic mantle melting: The HAMMS1 model

KIMURA, Jun-ichi[1*] ; KAWABATA, Hiroshi[2]

[1]JAMSTEC, [2]Kochi University

A numerical mass balance calculation model for the adiabatic melting of a hydrous metasomatized peridotite source was programmed in order to simulate trace element compositions of mid ocean ridge basalt, back arc basin basalt, ocean island basalt, and large igneous province basalt. The Excel spreadsheet-based calculator, Hydrous Adiabatic Mantle Melting Simulator ver.1 (HAMMS1) uses: (1) a thermodynamic adiabatic melting model of mantle peridotite; with (2) experimentally parameterized melting relationships in terms of pressure, temperature, water content, and degree of partial melting. The trace element composition of the model basalt is calculated from the accumulated incremental melts within adiabatic melting, with consideration of source mantle depletion. The mineralogic mode in the mantle in adiabat is calculated using experimental parameterization, and is incorporated into the program. Partition coefficients of the residual mantle minerals are from lattice strain model based parameterization tested by the latest compilations of experimental results. The parameters that control the trace element composition in the model are: (1) mantle potential temperature, (2) water content in the source mantle, (3) depth of termination of adiabatic melting, and (4) source mantle depletion. It is possible to obtain the above controlling parameters by using Monte Carlo fitting calculations and comparing the calculated basalt compositions with primary basalt compositions. Additionally, HAMMS1 compares those melting parameters with its major element model. HAMMS1 provides a unique estimate of the source conditions of basalt genesis using an incompatible trace element mass balance.

Very Large Intramolecular D-H Partitioning in Hydrated Silicate Melts Synthesized at Upper Mantle P and T

CODY, George[1*] ; WANG, Ying[1] ; CODY, Samantha[1] ; FOUSTOUKOS, Dionysis[1] ; MYSEN, Bjorn[1] ; LE LOSQ, Charles[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington

Hydrogen isotope fractionation during magnetic processes is key to understanding the deep Earth hydrological cycle and may place constraints on the origin of Earth ' s oceans. It is well established that the D/H content of water in hydrated nominally anhydrous mantle minerals is systematically lower (<-100 ‰) than the standard mean ocean water (SMOW, D/H = 1.5576 x 10^{-4}, defined as 0 ‰). Experiments have revealed significant hydrogen isotope partitioning between melts and fluids or vapors at magmatic temperatures. The origin of such fractionation, given the high temperatures of magmatic processes, is not likely due to classical isotope effects as described by bond energies via statistical mechanics.

It is well known that water has a very high affinity for silicate melts, it both dissolves in the melt as molecular water and hydrolyzes Si-O-Si linkages forming Si-OH. Whereas the molecular forms of water in melts are limited to H_2O and OH, the variety of environments available for water to reside in the melt structure is surprizing large. In order to study water in silicate melts one is restricted to molecular spectroscopy, e.g. Raman spectroscopy in the mid infrared regime, in windowed high pressure devices, e.g. the hydrothermal diamond anvil cell. Alternatively, one can study melts quenched to glass, where the structure of the glass corresponds to the structure of the melt at the glass transition temperature. The advantage of glasses is that one can use Solid State Nuclear Magnetic Resonance (NMR) Spectroscopy. The hydrogen isotopes conveniently provide two stable nuclei with spin, ^{1}H (H) and ^{2}H (D), thus we can use D and H solid state NMR to analyze the nature of water in silicate melts quenched to glass. Given that glass transition temperatures for silicate melts are high (500-600 ∘C), one does not expect H and D to behave differently. D-NMR can, however, be useful in characterizing the molecular dynamics of water in various sites in the glass.

We studied hydrated (with D_2O and H_2O) sodium tetrasilicate glasses, quenched from melts at 1400∘C and 1.5 GPa, using ^{1}H, ^{2}H and ^{29}Si solid state NMR. Whereas D_2O and H_2O depolymerize the silicate melt to similar degrees, as would be expected, we surprisingly find that protium (H) and deuterium (D) intramolecular partitioning between different molecular sites within the glasses is very large and controlled by a strong preferential association of deuterons to sites with short O D O distances. This preference is independent of total water content and D/H ratio. Substantial intramolecular D-H partitioning is also observed in a glass with a model hydrous basalt composition. Such large isotope partitioning cannot result from classic fractionation effects because of the high synthesis temperatures. Potential kinetic isotope effects are excluded via a slow quench experiment. The partitioning is likely governed by density/molar volume isotope effects, where deuterium prefers sites with smaller molar volume. Large intramolecular site partitioning in melts could lead to significant D-H partitioning between water saturated melt and exsolved aqueous fluid (where $D/H_{W,Melt} \neq D/H_{W,Fluid}$) during crystallization of Earth ' s magma ocean, potentially controlling the D/H content of the Earth ' s oceans.

Chemical dependence of the speciation and structural position of water in silicate melts

LE LOSQ, Charles[1*] ; CODY, George[1] ; MYSEN, Bjorn[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington

Water is the main volatile component affecting the thermodynamic, structural and rheological properties of magmatic liquids in the Earth's interior resulting in major influence on past history and present magmatic activity of the Earth. Previous experiments and modelling have shown that water can be dissolved as H_2O molecules (H_2O_{mol}) and OH^- groups, with the OH^- groups bonded to the silicate network to form Si-OH or Al-OH bonds and perhaps alkali-OH and alkaline earth-OH complexes. However, important questions remain as to how bulk chemistry governs the link between the different OH groups and the silicate network, and the global H_2O_{mol}/OH ratio.

It is now widely accepted that dissolved water reacts with the O^{2-} oxygen composing the silicate network following:

$H_2O_{mol} + O^{2-} \Leftrightarrow 2OH^-$. (1)

As O^{2-} from the silicate network is involved in this reaction, its equilibrium constant must depend on the activities of bridging (BO), non-bridging (NBO), and free oxygen species potentially present in silicate melts, and hence on their global chemistry. Even if Al-OH and Si-OH bonding were the only variables (and, therefore, the Al/Si ratio of a melt), reaction (1) implies that the H_2O_{mol}/OH should depend on silicate melt composition. However, as the activity of NBO species is also affected by the ionic field strength of alkali and alkaline earth cations, we expect the equilibrium of reaction (1) to be affected by those cations.

To test and to quantify the occurrence and the impact of chemical effects on the speciation of water in quenched, hydrous silicate melt (glass), we analysed $M_2Si_4O_9$ glasses (M = Li, Na or K) containing different amounts of water (from 3.3 up to 17.6 mol%) with the help of ^1H and ^{29}Si MAS NRM, Raman and Infrared spectroscopy. Glasses were formed by temperature quenching (∼100 ℃/s) at 1.5 GPa. Raman and infrared spectroscopy show three different bands close to 2300, 2800 and 3600 cm^{-1}. These are assigned to O-H stretching from OH groups bonded to silicate components and from H_2O molecules. Correlation of those frequencies with the O ⋯ O distances in minerals suggest that those three bands arise from OH stretching in two main different environments: one with a mean O ⋯ O distance close to ∼0.26 nm and another one with a ∼0.29 nm O ⋯ O distance. In the ^1H MAS NMR spectra, we retrieved signals near 15 and 5 ppm arising from the ∼0.26 and ∼0.29 nm environments respectively. Increasing the alkali radius tends to increase the intensities of the 15 ppm ^1H MAS NMR peak and of the 2000-2900 cm^{-1} Raman region, indicating an increase of the population of OH groups in the ∼0.26 nm environment. In addition, the higher the alkali radius the higher the effect of water on the polymerization degree is, as testified by changes of the ^{29}Si NMR and Raman signals.

Those NMR and Raman observations suggest that the H_2O_{mol}/OH ratio in quenched hydrous silicate melts decreases in the order Li, Na, K. The greater the radius of alkali, the higher the proportion of OH^- the smaller the mean O ⋯ O distance in their environment, and hence the more extensive hydrogen bonding. We propose that this structural evolution arises from a combination of steric hindrance and electron distribution around alkali elements that affects both equilibrium reaction (1), which will decrease in the order K >Na >Li, and the local environment of the formed OH^- groups. This interplay between the nature of the alkali modifier, the speciation of water and the polymerization of the silicate network must result in non-negligible differences in viscosity of Li, Na and K silicate melts. Therefore, following this study, variation of the concentration of alkali and alkaline-earth elements in natural hydrous magmas, following their origin, will result in changes of their rheological properties, not only because of the different effects of alkali/alkaline earth elements on Si-O bonds, but also because of differences in the water speciation and OH^- environments.

Large ion lithophile elements delivered by saline fluids to sub-arc mantle

KAWAMOTO, Tatsuhiko[1*] ; MIBE, Kenji[2]

[1]Inst Geotherm Sci, Grad School Sci, Kyoto Univ, [2]Earth Research Institute, Univ of Tokyo

Geochemical signatures of arc basalts are explained by addition of aqueous fluids, melts, and/or supercritical fluids from subducting slab to sub-arc mantle. Partitioning of large ion lithophile elements between aqueous fluids and melts is crucial as these two liquid phases are present in the sub-arc pressure-temperature conditions. Using synchrotron x-ray beams, in-situ x-ray fluorescence (XRF) spectra are obtained from aqueous fluids and silicate melts at high-temperature and high-pressure conditions under varied concentrations of (Na, K)Cl (0-25 wt.%). There is a positive correlation between partition coefficients and pressure, as well as partition coefficients and salinity. In the systems with 13-25 wt.% (Na, K)Cl, partition coefficients of Rb, Cs, and Pb are greater than unity, indicating the capacity of such highly saline fluids to effectively transfer those elements. Enrichment of large ion lithophile elements in arc basalts relative to mid oceanic ridge basalts has been attributed to the mantle source fertilization by aqueous fluids from dehydrating oceanic plate. Such aqueous fluids are likely to contain Cl, although their amount remains to be quantified.

In-situ characterization of carbon-speciation in silicate-C-O-H fluid and melt with temperature, pressure, and redox con

MYSEN, Bjorn[1*]

[1]Geophysical Laboratory, CIW, USA

Speciation and partitioning of C-bearing volatiles species in and between silicate-saturated C-O-H fluids and (C-O-H)-saturated melts have been determined in-situ with the samples to pressures and temperatures of ~2GPa and 900^{o}C, respectively. Structural characterization was conducted with vibrational spectroscopy of samples contained in externally-heated, hydrothermal diamond anvil cells. The redox conditions were controlled near that of the Fe+H_2O=FeO+H_2 (reducing, RED) and Ni+H_2O=NiO+H_2 (oxidizing, OX) equilibria, respectively. Melts are, therefore saturated in H_2O, H_2, and C-bearing species (redox dependent) and coexisting fluids saturated in silicate components. Solubility of volatile and silicate components depend on both temperature and pressure.

The melt/fluid partition coefficients of the C-bearing species vary with redox conditions and temperature with the $\triangle H_{RED}{}^{melt/fluid}$ = 44(7) kJ/mol and $\triangle H_{OX}{}^{melt/fluid}$ = -70(32) kJ/mol. Pressure is a dependent variable and increases with increasing temperature. It is assumed no pressure effect of the partition coefficients.

The solution equilibria under reducing and oxidizing conditions, respectively, were; (1) $2CH_3{}^- + H_2O + Q^{n+1} = 2CH_4 + Q^n$ and (2) $2CO_3{}^{2-} + H_2O + 2Q^{n+1} = HCO_3{}^- + 2Q^n$, where the superscript, n, in the Q-species denotes number of bridging oxygen in the silicate species (Q-species). In the absence of H_2O equilibrium (1) changes to $CH_3{}^- + Q^n = CH_4 + Q^{n+1}$. For oxidized carbon, there is an analogous expression expressing equilibrium between molecular CO_2 and structurally bound $CO_3{}^{2-}$-groups. Under both oxidizing and reducing conditions, the abundance ratios, $CH_4/CH_3{}^-$ and $HCO_3{}^-/CO_3{}^{2-}$ increase with temperature. The enthalpy change associated with the species transformation does, however, differ for fluids and melts and also for oxidized and reduced carbon ($\triangle H_{(1)}{}^{fluid}$ = -16(5) kJ/mol, $\triangle H_{(1)}{}^{melt}$ = -49(5) kJ/mol, $\triangle H_{(2)}{}^{fluid}$=81(14) kJ/mol). For the exchange equilibrium of CH_4 and CH_3 species, the temperature-dependent equilibrium constant yields $\triangle$H=34(3) kJ/mol.

Reactions (1) and (2) involve changes in silicate polymerization where increasing abundance ratios, $CH_4/CH_3{}^-$ and $CO_3{}^{2-}/HCO_3{}^-$lead to increased silicate melt polymerization. As a result of the relations between speciation of C-bearing species and melt and fluid structure, stable isotope (C and H) and element partition coefficients between melts and fluids, which depend on and silicate polymerization and silicate speciation, also vary with speciation of C-bearing species in silicate-C-O-H systems. Pressure, temperature, and redox control on the C-speciation also govern those (and other) properties.

Effect of CO2 content on melting phase relations in kimberlite group I at 6.5 GPa and 1200-1600oC

SHATSKIY, Anton[1] ; LITASOV, Konstantin[1*] ; SHARYGIN, Igor[1] ; OHTANI, Eiji[2]

[1]V.S. Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk 630090, Russia, [2]Department of Earth and Planetary Material Science, Graduate School of Science, Tohoku University

Our understanding of kimberlite petrogenesis is significantly hampered by uncertainty about the compositions of kimberlite magma. It is generally accepted that the last equilibration of kimberlite magma with surrounding mantle (garnet lherzolite) occurred beneath cratons at 6-7 GPa prior its rapid ascent (about 70 km/h) to the surface. This conclusion is based on the following facts. The deepest (170-220 km depths) and hottest (1200-1500^{o}C) xenoliths entrapped by kimberlites are sheared garnet lherzolites originating from the lower part of lithospheric mantle. The preservation of deformation features in sheared lherzolites indicates that the rock was undergoing dynamic recrystallization just before it was picked up by the magma and that it reached the surface after less than a few days or even hours in magma rising by crack propagation (Green and Gueguen, 1983; Meyer, 1985; Sparks et al., 2006). Based on our resent study (Sharygin et al., 2013) of melting phase relations in an exceptionally fresh kimberlite group I from Udachnaya-East kimberlite (UEK) pipe at 3.0-6.5 GPa and 900-1500^{o}C, the kimberlite melt had essentially Na-K-Ca carbonatite composition <15 wt.% SiO_2, Na_2O + K_2O = 5-18 wt%, Na/K = 2, Cl >1.5 wt%, and Ca/(Ca+Mg) >0.5. However, the mineral assemblages obtained in these experiments differ from known mantle parageneses. This may be due to unaccounted CO_2 budget missed at shallow depth as a result of decarbonation reactions at 1.5-2.5 GPa. Therefore, in present study we examined the effect of additional CO_2 on melting phase relations in synthetic UEK kimberlite system at 6.5 GPa and 1200-1600^{o}C.

Based on obtained results mineral assemblage equilibrated with kimberlite partial melt gradually changes from peridotite to eclogite paragenesis with increasing its CO_2 content from 13 to 35 mol %. As can be seen at 6.5 GPa kimberlite partial melt (i.e. Na-K-Ca carbonatite melt) becomes equilibrium with garnet lherzolite (i.e. olivine + enstatite + diopside + garnet + FeS + ilmenite assembly) at 1500^{o}C and 23 mol % (20 wt%) CO_2. This value is 10 mol% more than natural abundance of CO_2 in the Udachnaya-East kimberlite rock (group I kimberlite). In other words, the kimberlite magma lost almost half of the CO_2 budget during the eruption.

We greatly thank the Global Center-of-Excellence program at Tohoku University (Sendai, Japan) for the technical and financial support of this study.

Figure. Melting phase relations in Udachnaya-East kimberlite (kimberlite group I) versus temperature and CO_2 content at 6.5 GPa. 13 mol % CO_2 corresponds to the natural abundance of CO_2 in UEK rock.

Carbon dioxide in granitic magma under lower crustal conditions

YOSHIMURA, Shumpei[1*] ; NAKAMURA, Michihiko[2] ; YURIMOTO, Hisayoshi[3]

[1]Department of Earth and Environmental Sciences, Yamagata University, [2]Department of Earth Science, Tohoku University, [3]Department of Natural History Sciences, Hokkaido University

<Introduction>

Carbon dioxide is a major volatile component in the crust and mantle. Its solubility and speciation in silicate melts are important in understanding of mechanisms of magmatism and volcanism. However, they are not well constrained under lower-crustal conditions, especially in granitic magma, which is common in the crustal magmatism. In this study, we carried out equilibrium experiments in the CO_2-H_2O-granitic melt system to investigate the solubility and speciation of CO_2.

<Experimental procedure>

High-PT experiments were performed using a piston cylinder apparatus and a cold-seal pressure vessel. Obsidian flakes of a granitic composition and oxalic acid dehydrate (fluid source) were put in a gold or platinum capsule and run at 1123 and 1473 K and 0.1-1.5 GPa. Oxygen fugacity was estimated to be close to NNO. After quench, volatiles dissolved in the glass were analysed with FTIR spectroscopy. The composition of the coexisting fluid was quantified either by manometric analysis or based on the low-pressure solubility law and volatile contents of the glass.

<Results>

FTIR spectra showed that both CO_2 molecules (CO_{2mol}) and carbonate anions (CO_3^{2-}) were present in all of the glass samples. The concentrations of CO_{2mol}, CO_3^{2-} and total H_2O increased generally with increasing pressure; they were 9200 ppm, 2100 ppm and 6.1 wt%, respectively, at 1.5 GPa and 1473 K. Here, we used new molar absorption coefficients of 2350 cm^{-1} (1192 $\pm$ 130 L cm^{-1} mol^{-1}; CO_{2mol}) and 1410 cm^{-1} (91 $\pm$ 28 L cm^{-1} mol^{-1}; CO_3^{2-}) determined in this study. The fraction of CO_3^2 to total CO2 in the granitic melt increased with increasing total CO2 content, from 0.09 (total CO_2 = 260 ppm) to 0.19 (11300 ppm). The molar fractions of CO_2 in the fluids (X_{CO2}^{fluid}) were 0.25-0.48 for the cold-seal experiments and 0.73-0.79 for the piston cylinder experiments.

<Discussion>

We formulated the solubility law of CO_{2mol} based on a vapour-liquid equilibrium equation. On the basis of the reaction CO_2 (vapour) $\rightleftharpoons$ CO_{2mol} (melt), we calculated the partial molar volume of CO_{2mol} in the granitic melt and the reaction enthalpy to be 24.9 $\pm$ 2.0 cm^3/mol and -22.2 $\pm$ 6.3 kJ/mol, respectively. These values are similar to those in previous experiments carried out at <6.6 kbar (Fogel and Rutherford, 1989; Behrens et al., 2004), indicating that the low-pressure solubility law can be extrapolated to 1.5 GPa. As for the formation of CO_3^{2-}, we assumed a reaction CO_{2mol} + O^{2-} (non-bridging oxygen) $\rightleftharpoons$ CO_3^{2-}. Possible factors shifting the equilibrium to the right-hand side include the total pressure (e.g., Fine and Stolper, 1985; Guillot and Sator, 2011) and water content (King and Holloway, 1992; Behrens et al., 2004). In this study, it was difficult to evaluate these parameters separately, since the water content increased simultaneously with total pressure. If we assume that the effect of water is small enough to be neglected, the change of the partial molar volume of CO_2 in the melt and the reaction enthalpy can be calculated to be -8.6 $\pm$ 6.0 cm^3/mol and -0.4 $\pm$ 3.1 kJ/mol, respectively.

<Application>

Recently, unusually CO_2-rich rhyolitic melt inclusions (up to 1.7 wt% total CO_2) were reported by Blundy et al. (2010). The saturation pressure of this CO_2 content is estimated to be 1.4 GPa when CO_2 dissolved only as CO_{2mol} (X_{CO2}^{fluid} = 1; T=1173 K). If we consider the formation of CO_3^{2-}, the saturation pressure is estimated to 1.2 GPa.

Hydrogen positions in hydrous ringwoodite determined by pulsed neutron powder diffraction

PUREVJAV, Narangoo[1*] ; OKUCHI, Takuo[1] ; TOMIOKA, Naotaka[1] ; ABE, Jun[2] ; HARJO, Stefanus[3] ; AIZAWA, Kazuya[3]

[1]Institute for Study of the Earth's Interior, Okayama University, [2]CROSS-Tokai, [3]J-PARC Center, Japan Atomic Energy Agency

The transition zone in the Earth's mantle has been considered potentially large water reservoir. It was experimentally evidenced that its main constituent minerals can uptake significant amount of water as hydroxyl groups in their crystal structures. The ringwoodite [(γ-Mg,Fe)$_2$SiO$_4$] is one of the high pressure polymorph of olivine, which is the most major phase in the lower part of the transition zone, between 525 to 660 km in depth. It was reported that ringwoodite can incorporate up to 2.6 wt.% of water (Kohlstedt et al., 1996). The hydration of ringwoodite strongly affects its physical and chemical properties such as electrical conductivity, compressibility and seismic velocities. However, crystallographic sites of hydrogen and its incorporation mechanism are still unclear mainly due to insensitiveness of X-ray probe for hydrogen. The previous studies of its structure refinement by X-ray diffraction demonstrated that hydrous ringwoodite has cubic spinel structure with Fd-3m space group (Kudoh et al., 2000; Smyth et al., 2003). Here we applied neutron diffraction for hydrous ringwoodite for the first time to analyze its hydrogen positions.

Deuterated ringwoodite powder samples were synthesized at 1300 ^{o}C and 18 GPa for 5 minutes using a scaled-up Kawai-type multi anvil apparatus. The run products were evaluated by micro-focused X-ray, Raman spectroscopy and powder X-ray diffractometer to confirm their purity.

Neutron powder diffraction patterns were taken at BL-19 (TAKUMI) at Materials and Life Science Experimental Facility, J-PARC. The two representative deuterated ringwoodite samples were with identical composition mixed and measured together in a sample holder made of TiZr "null" alloy. The obtained diffraction pattern has been analyzed by Rietveld refinement using the "Z-Rietveld" code in order to determine positions and site occupancies of deuterium atoms in the ringwoodite structure.

We can propose two possible models for the deuterium atomic positions, 96g and 192i. These refined models were given with almost identical R factors. They also gave similar site occupancies and temperature factors for the elements except for the deuterium. However, in terms of deuterium temperature factor, the 192i model is more preferable than the 96g model. The refinement results also showed that the (Mg+Fe)/Si ratio is lower than the ideal ratio of dry ringwoodite [(Mg+Fe)/Si = 2.0] while Si in T sites are fully occupied, which demonstrates that deuterium only substitutes Mg and Fe in M sites and Si in T sites is not affected.

Stability of Hydrous phase H MgSiO2(OH)2 in the lower mantle

AMAIKE, Yohei[1*] ; OHTANI, Eiji[1] ; KAMADA, Seiji[1] ; SAKAMAKI, Tatsuya[1] ; TAKAHASHI, Suguru[1] ; HIRAO, Naohisa[2] ; OHISHI, Yasuo[2]

[1]Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University, [2]Japan Synchrotron Radiation Research Institute

Subducting slabs transport water to Earth's deep interior and its circulation on a global scale is the key to understanding the evolution of the planet. However, it is still a matter of debate how deep water can be transported. Therefore, there are many studies on phase relationships in hydrous minerals or MORB-H2O systems. Most dense hydrous magnesium silicates (DHMS) are stable up to 50 GPa (e.g., Komabayashi et al., 2004). Recently, the synthesis of Mg- and Si- bearing δ-AlOOH, which is a solid solution between 2AlOOH-MgSiO2(OH)2, was reported and it might be transported with Mg-perovskite or Mg-post perovskite up to 135 GPa (Ohira et al., 2012, AGU). Tsuchiya (2013) theoretically reported Phase H, the end member of the system, was stable above 45 GPa and up to 55 GPa. And also it was experimentally synthesized at 50 GPa (Nishi et al., 2014). Although the previous studies claimed that Phase H was broken down above 55 GPa, it may be a host phase of water in the deep Earth interior. Here, we report the stability field of a new candidate phase of water reservoir at the lower mantle conditions by investigating the MgO-SiO2-H2O system up to 75 GPa and 2000 K.

A mixture of quartz and brucite (molar ratio 1 : 1) powders were used as starting materials. The high pressure and high temperature experiments were performed by using a double-sided Laser heated diamond anvil cell. A pellet with thickness of about 15 μm was made by a cold compression technique. In situ XRD experiments in the MgO-SiO2-H2O system were performed at BL10XU, SPring-8. In this study we confirmed that hydrous phase H does exist in the MgO-SiO2-H2O system and its stability fields expands at least up to 75 GPa and above 2000 K in contrary with previous reports (Tsuchiya, 2013; Nishi et al., 2014).

If Phase H exists under high pressure conditions corresponding to the pressure of CMB, it may transport water to CMB and thus the core may contains hydrogen as a light element.

Partitioning of carbon between metallic- and silicate-liquids in carbonaceous chondrite compositions at high pressure

ASAHARA, Yuki[1*] ; OHTANI, Eiji[1]

[1]Tohoku University

Major volatile elements in the terrestrial planets are oxygen, sulfur, carbon, hydrogen, and nitrogen. They are also candidates for light components in the earth's core which were incorporated into the core at terrestrial magmaocean stage. Partitioning behavior of carbon has not been determined well though it is one of the strong candidates for light elements in the earth's core. We investigated partitioning of carbon with sulfur and oxygen between metallic- and silicate liquids at 6 GPa and 2073 K in carbonaceous chondrite composition (Allende meteorite; CV3). Effect of nitrogen and water as accessory components were also examined. High pressure experiments were conducted with multi-anvil high pressure apparatus. Graphite was used as capsule material. Composition of coexisting metallic- and silicate liquids were measured by electron microprobe with wavelength dispersion type spectrometer except for carbon in silicate liquid. Carbon concentration of bulk recovered sample was measured by elemental analyzer. Then, carbon concentration in silicate liquid was obtained by subtraction of carbon amounts in metallic phase which obtained by electron microprobe and SEM image analyses. Present result suggests that in oxidized carbonaceous chondrite composition, partitioning coefficient of carbon [$D^{Metallicliquid/Silicateliquid} = C^{Metallicliquid}/C^{Silicateliquid}$; C is concentration of carbon in wt.%] is close to 1, and it may increase with increasing the Fe^{metal}/Fe^{oxide} ratio in the carbonaceous chondrite composition.

Microanalysis of H2O and CO2 in silicate melt using laser Raman spectroscopy

YOSHIMURA, Shumpei[1*] ; KAGASHIMA, Shin-ichi[1] ; NAKASHIMA, Kazuo[1]

[1]Department of Earth and Environmental Sciences, Yamagata University

<Introduction>

Water and carbon dioxide are the major volatile components in the crust and mantle. Development of microanalytical techniques of these volatiles has made it possible to investigate mechanisms of igneous and volcanic processes. FTIR has been used as a fundamental tool for this purpose, but its spatial resolution is too large ($\sim$30 μm) to analyse small melt inclusions and micro-scale volatile distribution within a high-pressure experimental sample. In this study, we developed a new technique for volatile analysis in silicate glasses with $\sim$1 μm spatial resolution using laser Raman spectroscopy.

<Experimental and analytical procedure>

Standard glasses were synthesized by using a piston-cylinder apparatus in M. Nakamura's laboratory. Basaltic glass power was loaded into a platinum-sleeved nickel capsule together with oxalic acid and run at 1473 K and 0.5-1.2 GPa. After quench, the H_2O and CO_2 (dissolved as CO_3^{2-}) contents of the glasses were measured by using FTIR. The same glasses were then analysed with a Thermofisher DXR laser-Raman spectrometer. Wave length, power and diameter of the laser beam were 532 nm, 10 mw and 0.7 μm, respectively. We normalized the Raman spectra by the intensity of a peak at 500 cm^{-1} (T-O-T bond) and subtracted the spectrum of the volatile-free glass. The intensities of peaks at 3550 cm^{-1} (H_2O) and 1080 cm^{-1} (CO_3^{2-}) in the resulting spectra were compared with the H_2O and CO_2 contents determined by FTIR spectroscopy.

<Results>

The H_2O and CO_2 contents were determined to be 0.7-2.1 wt% and 0.05-0.82 wt%, respectively. Raman spectroscopy showed that the intensities of peaks at 3550 and 1080 cm^{-1} increased with increasing H_2O and CO_2 contents, respectively. We fitted a linear equation to the data and obtained H_2O (wt%) = $(3.58\pm0.14)\times I_{3550}$ and CO_2(wt%) = $(4.61\pm0.21)\times I_{1080}$.

<Application>

We applied this technique to volatile analysis of an experimentally-produced bubble-bearing basaltic glass. In the experiment, basaltic melt was first equilibrated with H_2O-CO_2 mixture fluid at 1473 K and 1 GPa, and then decompressed to 0.5 GPa and kept for 10 minutes. After quench, the H_2O and CO_2 contents around bubbles were measured along the radial direction at 2-μm intervals for a total of 50 μm. The CO_2 contents decreased on moving towards the bubble, indicating that CO_2 was diffusing into the bubble. Fitting the diffusion equation to this profile, we estimated the diffusivity of CO_2 to be 1.2×10^{-12} m^2/s. This value is consistent with that reported by Zhang et al. (2007). In contrast to CO_2, H_2O showed a flat profile, suggesting that H_2O was already equilibrated with the fluid in the bubble. This is because the diffusivity of H_2O is one order of magnitude greater than that of CO_2. Such a diffusive fractionation was observed also in rhyolitic melt (Yoshimura and Nakamura, 2010).

Dynamic and cyclic process of carbon-bearing phases of the terrestrial interior

MIURA, Yasunori[1*]

[1]In & Out Universities

The results of the present study are summarized as follows:

1) Carbon-bearing mineral phases of the terrestrial interior are discussed to elucidate dynamic change of material states (air, liquid and solid) on active Earth planet.

2) Samples used in this study are diamond (Congo,Africa), limestone (Akiyoshi, Japan), carbonatite (Lengai, Tanzania,Africa and Europe-North America), and shungite (Shunga, Russia) together with carbonate grains of Libyan glass (Africa) to observe micro nano-grains of carbon-bearing materials with the FE analytical SEM etc.

3) The present data indicate that micro carbon-bearing grains are easily changed and remained as the three materials states mainly as solidified glasses by high pressure shock waves of earthquake, volcano and impact events to the surface to the interior.

4) Local fluid-bearing depositions irregularly distributed on the surface and interior of active Earth are based on storages on the interior formed by solidified mixtures of multiple carbon-bearing material states originally triggered by impact process on primordial Earth and ocean floors of evolved Earth.

5) The primordial planet Earth with remained heterogeneous surface by original impact-related process is considered to produce dynamic cyclic system of three material states (air, liquid and solid) of carbon-bearing materials with macro-life activity which is formed by huge production from the interior triggered by huge collision process of the giant impact and followed inner movement of active Earth with complicate local reservoir.

Placing time constraints on a P-T-D evolution: insights from Lu-Hf garnet and U-Th-Pb monazite dating

SKRZYPEK, Etienne[1*] ; SZCZEPANSKI, Jacek[2] ; ANCZKIEWICZ, Robert[3] ; STIPSKA, Pavla[4] ; KRONER, Alfred[5]

[1]Kyoto University, [2]University of Wroclaw, [3]Polish Academy of Sciences, Krakow, [4]Universite de Strasbourg, [5]Universitat Mainz

The best approach for understanding the tectono-thermal evolution of a crustal level is through reconstructing its pressure-temperature-deformation-time (*P-T-D-t*) evolution. Whereas *P-T-D* paths can be inferred from crystallization-deformation relationships, placing absolute time constraints on such paths remains challenging, especially because a link between major element-bearing index minerals and trace element-bearing geochronometers needs to be established.

We present the example of medium-grade metasedimentary rocks (Orlica-Snieznik Dome, EuropeanVariscan Belt) for which results of Lu-Hf garnet and U-Th-Pb monazite dating are linked with prograde and retrograde stages of the *P-T-D* evolution, respectively. On the macroscopic scale, a succession of three metamorphic foliations is recognized: initial subhorizontal S1, intermediate subvertical S2, and late subhorizontal S3. A garnet±staurolite assemblage is ascribed to the S1 foliation, whereas the S2 fabric is associated with staurolite demise producing a garnet-biotite-sillimanite/andalusite assemblage. Post-S2 garnet and cordierite blastesis is followed by chlorite growth during and after the formation of the S3 foliation. Garnet porphyroblasts show a peculiar zoning pattern with a linear Mn-Ca decrease in the allanite-bearing core, an inner rim of alternating Ca-Y- and P-rich annuli, and a Ca-poor outer rim. Monazite is found as subhedral aggregates at garnet rim, and lone matrix grains close to partially resorbed garnet, staurolite or apatite. Textural observations and modelling of the garnet composition suggest that the inner rim with Ca-Y-rich annuli reflects the allanite-to-monazite transition which occurred close to the staurolite isograd. In this inner rim, a Lu oscillatory zoning pattern coincides with the zone of Ca-Y-rich annuli. Since the inner rim dominates the Lu budget of garnet, the associated Lu-Hf garnet-whole-rock isochron age of 344±3 Ma is ascribed to *P-T* conditions of the staurolite isograd, i.e. ∼5 kbar/575 ℃ in the S1 fabric. A subsequent temperature increase to peak conditions of ∼5 kbar/580-625 ℃ in the S2 fabric is indicated by the Ca-poor garnet outer rim that reflects staurolite breakdown. LA-ICP-MS monazite dating yields $^{208}Pb/^{232}Th$ ages defining a dominant group at 313±2 Ma and a secondary peak at 328±2 Ma. Based on monazite textures, these relatively young ages are ascribed to fluid influx during retrograde chloritization.

The short time span between prograde garnet growth (∼344 Ma) and existing Ar-Ar cooling ages on micas (∼335 Ma) points to a tectono-thermal event of about 10 Ma. Assumed high heating and cooling rates during this event are explained by the synchronous intrusion of granitoid sheets. Nevertheless, monazite ages indicate that a low-grade overprint occurred more than 20 Ma after peak conditions.

Microdiamond - bearing UHP chromitite from the Higo Metamorphic Rcoks, Central Kyushu, Japan

NISHIYAMA, Tadao[1*] ; SHIOSAKI, Dai[1] ; EGUCHI, Hibiki[1] ; YOSHIASA, Akira[1]

[1]Graduate School of Science and technology, Kumamoto University

Microdiamond-bearing ultrahigh-pressure (UHP) chomitite was newly found from a spinifex-textured metaperidotite in the Higo Metamorphic Rocks (HMR) , Central Kyushu, Japan. This is the first finding of microdiamond from Japanese metamorphic rocks and the second finding in Japan following the first one from a mantle xenolith in a Cenozoic lamprophyre dyke in Shikoku[1]. The HMR represents a low P/T metamorphism of Cretaceous in age, however, the precursor HP or UHP metamorphism of ca. 250Ma has been inferred[2]. A great deal of debate has been done on whether or how the Dabie-Sulu UHP terrane extends eastward to the Korean Peninsula and also to Japan. The HMR is one of the candidates[3] for the eastern extension in Japan, but no definitive evidence has been given yet.

Metaperidotites occur in two localities in the HMR: one at Yamato Town in the biotite zone and the other in Matsubase Town in the garnet-cordierite I zone[4]. The metaperidotites from Matsubase Town show distinct spinifex-texture with decimeter-sized elongated olivine (mostly serpentinized) and enstatite. Those from Yamato Town shows either spinifex-texture or granular texture of finer grains (several mm to 1 cm across), and is strongly serpentinized. The metaperidotite bodies occur in mostly pelitic gneisses as small lenticular bodies about several ten meters in size, which are concordant to the gneissosity. The mineral assemblage of the metaperidotite is olivine (mostly serpentinized) + enstatite with secondary tremolite and antigorite. Talc occurs locally along the cleavage of enstatite. A podiform chromitite occurs in such a strongly serpentinized metaperidotite at Yamato Town as a nodular form of about 10 cm in diameter, in which we found many inclusions of microdiamond 1 to 10 μm in size. We have made four thin sections, polished with colloidal silica, from one chromitite sample, and found many microdiamond inclusions in all thin sections. Microdiamonds occur both in chromite and in nickeline, and they are all monocrystalline. Many euhedral to subhedral grains (mostly 1 μm in size) of microdiamond occurs in chromite, making several lines of aligned grains. Identification of diamond was carried out with an energy dispersive X-ray spectroscopy (EDS) analysis (carbon peak) and Raman spectroscopy with a He-Ne laser. We observed a Raman peak at 1333.5 cm^{-1}, which is comparable to the peak (1332 cm^{-1}) characteristic of diamond. They show no evidence of partial or total graphitization. The occurrence suggests that the striations represent healed cracks and that microdiamonds precipitated from a reduced C-O-H fluid[5,6]. Our finding presents a convincing evidence for the hypothesis that the Higo Metamorphic Rocks is an eastern extension of the Dabie-Sulu UHP terrane in Japan. The second implication of our finding is on the nature of UHP chromitite. Microdiamonds are found from several UHP metamorphic terranes[5,6,7], however, microdiamond-bearing UHP chromitite has been found from ophiolites in non-UHP metamorphic terrane[8], making the occurrence of UHP chromitite as an enigma[9]. The Higo UHP chromitite represents a deep subduction product as indicated by spinifex-texture in the host metaperidotite due to high pressure breakdown of antigorite (serpentine), instead of a product of mantle migration10. Therefore the origin of the UHP chromitite requires a specific interpretation in each case.

Grain Size Grading of Garnet in the Liesegang Metamorphism

TORIUMI, Mitsuhiro[1*] ; FUKUYAMA, Mayuko[2]

[1]JAMSTEC, [2]Akita univ.

The very puzzling phenomena is that the grain size of metamorphic garnet shows apparently gradational in both basic and politic schists, for bulk chemistries of large grain and small - grain layers are not different with each other and for chemical zonings of large and small grains of garnet display very similar pattern. These facts suggest that the domain structure by diffusion and growth of garnet should be formed in the layer and the spacing of the domain changes gradually across the grain - size layering in the metamorphism.

The layering shows parallel to subparallel against the schistosity plane, suggesting the parameter changes uniaxialy along the normal direction against the schistosity. The length scales of the grain size layering ranges from several to several ten cm, being likely to those of the compositional banding derived from metasomatism. Judging from these facts, it seems that the size grading process in the plate boundary metamorphism is governed by the diffusion, reaction and grain growth mechanism, that is the precipitation mechanism in the Liesegang bands. The precipitation in the Liesegang band is considered as the Cahn - Hillert - Cook process (1), which is characterized by the relation of average grain size, size distribution, width of the layer, and spacing distribution among grains.

In this paper, we would like to investigate these relations of the size grading of garnet in the subduction zone metamorphism.

Metamorphism of sodic pyroxene-bearing quartz schists from the Bizan area, Sambagawa belt, eastern Shikoku, Japan

KABIR, Md fazle[1*] ; TAKASU, Akira[1] ; KAINUMA, Masaaki[1]

[1]Department of Geoscience, Shimane University, Japan

The Bizan area of the Sambagawa metamorphic belt is occurs in easternmost Shikoku, southwest Japan. The Bizan and Kotsu areas are located in the same tectonostratigraphic horizon, i.e. the Kotsu Formation in eastern Shikoku. The Kotsu Formation in the Kotsu-Bizan area is structurally overlying and underlying by the Kawata Formation and the Kawatayama Formation, respectively. The main rock types in the Bizan area include pelitic, basic and siliceous schists, with minor amounts of psammitic and calcareous schists (Iwasaki, 1963). Faure (1983) suggested a melange zone containing tectonic blocks of serpentinite, metagabbro and garnet-amphibolite (garnet-glaucophane schist) occurs along a ductile shear zone between spotted and non-spotted schist zones. Sodic pyroxene-bearing quartz schists consist mainly of quartz and phengite, with minor amounts of amphibole (Fgl, Mrbk, Rbk, Mkt, Wnc, Brs, Fbrs), garnet, Na-Ca pyroxene (hereafter sodic pyroxene) (aegirine, aegirine-augite and omphacite) and albite. Hematite, chlorite, and epidote occur occasionally. A schistosity is defined by preferred orientation of phengite and quartz.

Garnets are spessartine-rich in composition, show a growth zoning with decreasing spessartine (X_{Sps} 0.82-0.35) and increasing almandine (X_{Alm} 0.01-0.41) and pyrope (X_{Prp} 0.03-0.09) from core to the rim and contain inclusions of phengite (6.84 pfu), epidote, hematite and quartz. The garnets are occasionally replaced by chlorite and biotite along cracks and at the rims. Amphiboles occurring as inclusions in porphyroblastic albite are compositionally zoned, with Fbrs and Brs cores and Rbk rims. Matrix amphiboles are Brs and Mkt core, Fgl mantle and Rbk and Mrbk rims, and contain inclusions of phengite (6.50-6.51 pfu), hematite and quartz. Sodic pyroxenes occurring as inclusions in porphyroblastic albite are aegirine, aegirine-augite and omphacite with X_{Jd} 0.08-0.37 contents. Some of them are compositionally zoned, with aegirine-augite and omphacite cores (X_{Jd} 0.34-0.37) to aegirine-augite and aegirine rims (X_{Jd} 0.34-0.21). Matrix sodic pyroxenes are aegirine-augite (X_{Jd} 0.09-0.27), decreasing X_{Jd} from cores (0.22-0.25) to the rims (0.22-0.17). Some other sodic pyroxenes in the matrix display increasing X_{Jd} from core to the mantle (0.13-0.19) and decreasing towards the rim (0.19-0.12). They contain inclusions of amphibole (Brs, Fbrs, Rbk), phengite (6.66-6.82 pfu), hematite and quartz, and are partially replaced by chlorite along their cleavages. Porphyroblastic albite crystals up to 2 mm across contain inclusions of garnet, amphibole (Brs, Fbrs, Rbk), sodic pyroxene (X_{Jd} 0.10-0.37), phengite (6.57-6.76 pfu) and quartz. Matrix phengites show relatively higher in Si (6.33-6.98 pfu) contents than inclusions.

According to the occurrence of mineral assemblage the Kwata, Kotsu and Kawatayama Formation probably correlate with the albite-biotite zone of the Besshi area (Enami *et al*., 1994). Jadeite content in the sodic pyroxenes are significantly higher in sodic pyroxene-bearing quartz schists (X_{Jd} 0.08-0.37) than those of garnet-aegirine augite-alkali amphibole-quartz schist (X_{Jd} 0.30) in the Bizan area (Iwasaki, 1963) and Asemigawa (X_{Jd} 0.15-0.19), Besshi (X_{Jd} 0.14-0.23) and the Sarutagawa area (X_{Jd} 0.17-0.30) in the central Shikoku (Enami *et al*., 1994). This higher jadeite content in sodic pyroxenes suggests metamorphic conditions in the Bizan sodic pyroxene-bearing quartz schists might be higher in pressure than those of the metamorphic zonation in the albite-biotite zone of the Sambagawa belt central Shikoku by Enami *et al*. (1994).

Application of the Raman carbonaceous material thermometer to the Chichibu-Sanbagawa belt in the Kanto Mountains, Japan

KOUKETSU, Yui[1*] ; SHIMIZU, Ichiko[2]

[1]Geochemical Research Center, Graduate School of Science, The University of Tokyo, [2]Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo

The structure and tectonic history of the Chichibu-Sanbagawa belt have been investigated by the lithological structure, radiolarian age, radiometric age, deformation microstructural analysis, and X-ray diffraction analysis of carbonaceous material (CM). The structural discontinuities (nappe boundaries) within the Chichibu-Sanbagawa belt are proposed in several studies (e.g., Shimizu 1988, *J.Geol. Soc. Japan*; Isozaki & Maruyama 1991, *J. Geogr.*; Hirajima *et al*. 1992, *J.Geol. Soc. Japan*). However, the boundary between the Chichibu and Sanbagawa belts and their structural relationship are still under debate. In addition, the thermal structure was not well investigated because the geothermometer that can be applied over the temperature range of the Chichibu and Sanbagawa belts was not available. Recently, several studies proposed the geothermometers applying the Raman spectroscopy. Kouketsu *et al*. (2014, *Island Arc*) analyzed the CMs with a wide range of crystallinity, from amorphous carbon to well-crystallized graphite, in sedimentary and metamorphic rocks and proposed a new Raman CM geothermometer. By using this technique, we evaluate the peak temperatures of the rocks in the Chichibu and Sanbagawa belts in the Kanto Mountains, which is the type locality of these belts.

We investigated the mudstone, sandstone, and pelitic schist taken from the Kannagawa, Sanbagawa, and Ayukawa River districts in the Kanto Mountains, Gunma Prefecture. In the studied area, the accretionary complexes of the Northern Chichibu belt are distributed in the south, crystalline schists of the Sanbagawa belt are distributed in the north, and the Mikabu greenstones are exposed between them. The Chichibu belt is divided into three units: Kamiyoshida, Manba, and Kashiwagi units, in descending structural order (Shimizu & Yoshida 2004, *Island Arc*). The Sanbagawa belt is divided into three metamorphic zones: chlorite, garnet, and biotite zones, in order of ascending metamorphic grade (Yano & Tagiri 1998, *J.Geol. Soc. Japan*). The strata gently dip to the north and the metamorphic grade monotonously increases towards the lower structural level.

The Raman spectra of CM in mudstone and sandstone taken from the Chichibu belt include broad peaks that are characteristic of the amorphous carbon structure. The temperatures of most samples estimated by full width and half maximum (FWHM) of the D1-band are around 260-300 ℃. Several CMs in the rocks near the Mt. Nishi-Mikabo show the temperature higher than 300 ℃.

The intensities of Raman spectra of CM in the Sanbagawa schists are one order weaker than those in the rocks taken from the Chichibu belt. The D4-band, which is the characteristic peak in amorphous carbon, is not observed. Instead, G-band, which is the characteristic peak in well-crystallized graphite, becomes the most prominent peak at higher-grade zone. The metamorphic temperatures are estimated by using the FWHM of D1- and D2-bands and area ratio (R2) of CM Raman spectra. The metamorphic temperatures of the samples are estimated around 360-400 ℃, 420-450 ℃, and 460-510 ℃ in the chlorite, garnet, and biotite zones, respectively.

The temperatures estimated from CM show the gap of several tens of degrees or more between the Chichibu and the Sanbagawa belts. Further sampling and analysis will be proceeded.

Fission track and U-Pb zircon ages of psammitic rocks from the Harushinai unit of the Kamuikotan belt, Hokkaido

OKAMOTO, Ayumi S.[1*] ; TAKESHITA, Toru[1] ; IWANO, Hideki[2] ; DANHARA, Tohru[2] ; HIRATA, Takafumi[3] ; NISHIDO, Hirotsugu[4]

[1]Hokkaido University, [2]Kyoto Fission-Track Co., Ltd., [3]Kyoto University, [4]Okayama University of Science

In order to discuss exhumation processes and mechanisms for high-*P/T* type metamorphic rocks, it is necessary to obtain correct informations on pressure-temperature-time paths of these rocks from sedimentation to exhumation through maximum burial. We conducted coupled fission-track (FT) and U-Pb dating on detrital zircon grains in two psammitic rock samples collected from the Harushinai unit of the Kamuikotan metamorphic rocks using a Laser Ablation-Inductively Coupled Plasma-Mass Spectrometry (LA-ICP-MS). The results indicate that the concordant zircon U-Pb ages greatly vary between 1980-90 Ma. Among them, the youngest U-Pb age cluster (*c.* 110-90 Ma) is dominant, yielding the weighted mean ages of Albian (100.8±1.1 and 99.3±1.0 Ma with 2σ errors) for both samples. According to an oscillatory zoning of igneous origin without any overgrown rims in the analyzed zircon, the zircon U-Pb ages were not reset by the high-*P/T* type metamorphism, and hence the youngest U-Pb ages indicate the upper bound of sedimentary ages. On the other hand, the zircon FT data show the spectra with a single peak age at 100-90 Ma, which are comparable with the youngest U-Pb age cluster. The fact indicates that these zircon FT ages were once reset at *c.* 100 Ma due to an intense igneous activity at the provenance, but have not been essentially reset since the sedimentation. The scenario is supported by the temperature conditions slightly less than those of brittle-ductile transition of quartz (*c.* 300 ℃, also closure temperature of zircon FT) estimated from the microstructures in deformed quartz detrital grains constituting the psammitic rocks. Combining these results with the previously reported K-Ar ages of white mica, it is inferred that Harushinai unit was deposited after *c.* 100 Ma, dragged down to the maximum depth, and further affected by a localized thermal overprint during exhumation (*c.* 58 Ma).

Shape evolution of spinel grains in the Horoman Peridotite Complex, Hokkaido

KOIDE, Satoko[1*] ; SHIBATA, Tomoki[2] ; MICHIBAYASHI, Katsuyoshi[1]

[1]Institute of Geosciences, Shizuoka University, [2]Institute of Geosciences, Shizuoka University

We present the evolution of spinel grains in the Horoman Peridotite Complex, Hokkaido. For deformation under differential stresses at high temperature conditions, both diffusion processes including diffusion creep and annealing process and dislocation creep will affect shape change of a crystal inclusion (Okamoto and Michibayashi, 2005 JGR). Grain size and grain shape are related to the shape change of the crystal with respect to given temperature and differential stress conditions. We applied this theory to spinel grains in the Horoman Peridotite Complex, Hokkaido. As a result, grain shapes of coarser spinel grains more than 100 micron are dominantly controlled by dislocation creep, whereas those of smaller spinel grains less than 100 micron are influenced by both diffusion processes and dislocation creep. Moreover, we found that grain shapes of the smaller spinel grains can be only explained by post-tectonic annealing process after their intense deformation. Our result will provide a new insight to understand the deformation processes in mantle.

Verification of ultra-low strain rate effect from microstructural observation on naturally deformed olivine

YAMAMOTO, Takafumi[1*] ; ANDO, Jun-ichi[1] ; OHFUJI, Hiroaki[2] ; MORISHITA, Tomoaki[3] ; TOMIOKA, Naotaka[4]

[1]Department of Earth and Planetary Systems Science, Hiroshima University, [2]Geodynamics Research Center, Ehime University, [3]School of Natural System, Colleage of Science and Technology, Kanazawa University, [4]Institute for Study of the Earth's Interior, Okayama University

Kitamura et al. (1986) and Ando et al. (2001) reported Fe concentration on dislocation core in naturally deformed olivine. They suggested that compositional heterogeneity is formed by Cottrell atmosphere of solute atoms. This phenomenon is well known in the realm of metallurgical science, and only occurs during dislocation creep at very low strain rate condition. The presence of Cottrell atmosphere has a pinning effect on dislocations and prohibits their movements. As a consequence, plastic behavior of materials is drastically changed in the presence of Cottrell atmosphere. On the basis of this compositional heterogeneity, they demonstrate that the study of ultra-low strain rate effect on olivine plasticity is very important to understand the dynamics of the upper mantle.

With this background, the purposes of the present research are: (1) to confirm whether the Fe concentration on dislocation core is a common phenomenon in deformed olivine grains of mantle-derived peridotite, (2) to verify the deformation condition at which Fe concentration was occurred, from the microstructural observation of each studied peridotite samples, (3) to clarify the exact mechanism of Fe concentration, namely Cottrell atmosphere or pipe diffusion. The studied peridotite samples are xenoliths from basalt (Takashima, Megata, Kurose and Salt Lake), and alpine rocks (Uenzaru and Horoman). The techniques employed for the present study include optical microscopy, EPMA, SEM-EBSD, TEM and ATEM.

The main results are as follows:

1) Fe concentration on dislocation core in all olivine samples is detected, which suggests that it is common phenomenon in mantle peridotite.

2) The mechanism of Fe concentration on dislocation core in olivine grains is preferably Cottrell atmosphere than other phenomena such as pipe diffusion. However we need to carry out more careful and detailed observations to confirm it.

3) The microstructural observations indicate that the all peridotites preserve the deformation characteristics developed at the upper mantle. This fact suggests strongly that the Fe concentration on dislocation core in olivine grains occurred in the upper mantle condition.

The relationship between microstructures and metasomatism preserved within coarse granular peridotites derived from Kaap

TOMITA, Daiki[1*] ; MICHIBAYASHI, Katsuyoshi[1] ; KATAYAMA, Ikuo[2] ; KOMIYA, Tsuyoshi[3]

[1]Institute of Geosciences, Shizuoka University, [2]Department of Earth and Planetary Systems Science, Hiroshima University, [3]Department of Earth Science & Astronomy Graduate School of Arts and Sciences The University of Tokyo

Kimberlite was generated in deep upper mantle (70-250km) beneath craton and subsequently ascended to surface rapidly. Peridotite xenoliths, which were entrained by kimberlite, record composition and texture formed in upper mantle beneath the craton. We studied coarse granular peridotites obtained from Kimberley pipe, South Africa, as they have a few studies in terms of microstructural development, presumably because of very coarser grains. We performed mineral crystal-fabric analyses of the coarse granular peridotites in order to understand the structure of the cratonic lithosphere. The peridotites consist mostly of olivine and orthopyroxene with clinopyroxene, garnet and a minor amount of spinel and phlogopite. The crystallization of clinopyroxene appears to be associated with melt metasomatism, whereas that of phlogopite could be associated with hydration metasomatism. Garnet grains occur commonly with kelyphite consisting of fine-grained orthopyroxene, clinopyroxene and spinel, indicating that these peridotites could have been uplifted above the phase boundary between garnet peridotite and spinel peridotite stability fields. Although both foliation and lineation are not commonly identified because of coarse granular texture, olivine crystal fabrics are characterized by a single maximum of [010] with single maxima or weak girdles of [100] and [001]. We found that the intensities of olivine and orthopyroxene crystal-fabrics are correlated to the modal composition of clinopyroxene and phlogopite. It suggests that the melt metasomatism weakened crystal-fabrics, whereas the hydration metasomatism intensified crystal-fabrics. As a consequence, the metasomatism could result in the development of different types of microstructures in the peridotites and may weaken the craton lithosphere.

Corona-forming reaction in the Lutzow-Holm Complex, East Antarctica at Ongul Island

SHIMADA, Asami[1*] ; IKEDA, Takeshi[1]

[1]Kyushu University

[Introduction]

Corona is a microstructure that aggregate of one or several species of mineral surrounds another mineral. This suggests that corona was formed by the reaction between the interior mineral and the matrix minerals (Passchier and Trouw 1996). Estimating this reaction enables us to know which component transferred and how temperature and pressure changed. In this study, we estimated corona-forming reaction by describing the microstructure and chemical composition of a corona in the Lutzow-Holm Complex at Ongul Island.

[Geological Outline]

In the Lutzow-Holm Complex, metamorphic grade increases from amphibolites facies in the northeast to granulite facies in southwest (Hiroi et al., 2006). The granulite facies metamorphic rocks are widely distributed throughout East Ongul Island. The rock types are mainly garnet gneiss and hornblende gneiss (Shiraishi et al., 1994). Ultramafic rocks occur as thin layers in the garnet gneiss. The ultramafic rocks analyzed in this study are composed mainly of hornblende and porphyroblasts of garnet. Corona structure forms around the garnet.

[Microstructure]

In the ultramafic rocks, hornblende-rich domain and plagioclase-rich domain occur. Both domains consist of hornblende, plagioclase, brown biotite and orthopyroxene. The corona consists mainly of green biotite and plagioclase, and occurs around the garnet. Plagioclase in the matrix and the corona has twin and chemical zoning. Garnet porphyroblast (about 15mm diameter) shows concavo-convex shape. In the embayed part of garnet, biotite tends to occur with long axis is at right angles to garnet surface.

[Chemical Composition]

Garnet; Rim shows higher Fe and lower Mg than the interior.

Plagioclase; Ca/(Ca+Na) increases in the order of Pl-rich domain, Hbl-rich domain and corona. Ca/(Ca+Na) in every domain increases from core to rim.

Biotite; Mg/(Fe+Mg) decreases in the order of Hbl-rich domain, Pl-rich domain and corona. Rim in every domain shows lower Al than the core.

Hornblende; Hbl-rich domain shows higher Al and Mg/(Fe+Mg) than Pl-rich domain. The rim of both domains shows higher Al than the core.

Orthopyroxene; Composition is almost homogeneous within the domain.

[Discussion]

The compositional difference between core and rim of each mineral in the matrix can be regarded as growth zoning. We used the rim-composition in each domain to estimate the corona-forming reaction. The average of analyses was used for plagioclase and biotite in the corona and for garnet. The corona-forming reaction employing the compositions of Hbl-rich domain was given as follows.

Grt + 1.10Bt + 3.25Pl + 0.76K + 0.81H2O = 1.91Bt + 3.62Pl

On the other hand, the reaction using the compositions of Pl-rich domain expects garnet as products, which is inconsistent with the observation that garnet was consumed. This suggests that K is supplied from the outside through fluid during corona formation. We also compared volume of left side minerals, that is,

Grt : Bt : Pl = 1 : 1.4 : 2.8

Garnet is minimum in amount. Nevertheless, corona formed around garnet. This suggests that diffusion of component from garnet controlled the rate of the reaction.

Possible tectonic models before, during and after mylonitization in the Sor Rondane Mountains, East Antarctica

TOYOSHIMA, Tsuyoshi[1*] ; KANEYA, Akiko[1] ; OSANAI, Yasuhito[2] ; BABA, Sotaro[3] ; HOKADA, Tomokazu[4] ; NAKANO, Nobuhiko[2] ; ADACHI, Tatsuro[2]

[1]Niigata University, [2]Kyusyu University, [3]University of the Ryukyus, [4]National Institute of Polar Research

The deformational history in the Sor Rondane Mountains (SRMs), eastern Dronning Maud Land (DML), East Antarctica, is divided into 13 stages (D1?D13). The tectonic regime varied frequently from extension (D3?D4) to layer-normal compression and layer-parallel extension (D5), to compression (D6), top-to-the S shearing (D7), top-to-the SE shearing and sinistral strike-slip (D8), compression (D9?D11), and ?nally extension related to dextral shearing (D12?D13). In this paper we discuss change in deformation and P-T conditions before, during and after the D7-D8 mylonitization, using mineral textures, assemblage, compositions and microstructures of D7 and D8 mylonites.

Garnet porphyroclasts of the D7-D8 mylonites include high-Ca mantles and crenulation microfolds defined by sillimanite fibrolites. The high-Ca mantles of garnets and their plagioclase inclusions in the mylonites imply an increase in pressure before the D7-D8 mylonitization. S-tectonites having a dominant planar fabric were formed before the D7-D8 mylonites and after the high-Ca mantles of the garnets. The planar fabric (foliation) of the S-tectonites is produced by fan-shaped arrangement of sillimanite and biotite grains. The sillimanite and biotite grains were formed by breakdown of garnet. Most of the sillimanite and biotite grains have been rotated and folded by the D7-D8 mylonitization. The D7-D8 mylonite foliations are parallel to the planar fabric of the S-tectonites. The S-tectonites indicate a flattening type of strain and resulted from the layer-normal shortening after the increase in pressure and before the D7-D8 mylonitization. kyanite-quartz porphyroblasts and randomly oriented crystals of sillimanite/kyanite and biotite were formed after the D7-D8 mulonitization. The randomly oriented crystals of sillimanite/kyanite and biotite resulted from the breakdown of garnet porphyroclasts of the D7-D8 mylonites. The kyanite-quartz porphyroblasts accompany leucogranite veins cutting the D7-D8 mylonite foliations. The randomly oriented crystals and porphyroblasts imply non-deformational conditions after the D7-D8 mylnitization and D9 folding.

Three possible tectonic models for D7 and D8 mylonite-forming events before the D9 deformation can be considered as follows: extensional tectonic model, positive flower structure model and rotated mylonite model. In the former model, D7 and D8 indicate major extensional tectonic activity in the southern part of the East African and Antarctic Orogen (EAAO) before the Pan-African compressional event, and after the 650-600 Ma peak of metamorphism. In the latter two models, D7 and D8 mylonites may have resulted from the compressional events. In the positive flower structure model, the SRMs are the southern half of the E-trending positive flower structure. The flower structure model needs top-to-the N shear zones to the north of the SRMs. In the rotated mylonite model, the present S-dip of the D7 and D8 mylonites results from the rotation and folding of originally N-dipping reverse (top-to-the S-SE, normal-sinistral shear, present day coordinates) mylonites. The Pan-African compressional event resulted in the formation of upright folds with horizontal axes that curve along the coastline in central to eastern DML during the D9 deformation that took place between 600 and 560 Ma. The coastline-parallel fold axes and subvertical axial-planes correspond to the X-axes and the XY-planes, respectively, of strain ellipsoids that were progressively rotated counterclockwise toward the central parts of a sinistral shear zone. Therefore, the curved fold axes and axial-planes suggest the EAAO acted as a zone of sinistral transpression during the collision of parts of East and West Gondwana.

Significance of multi-stage chloride brine activity- An example from Sor Rondane Mountains, East Antarctica

HIGASHINO, Fumiko[1*] ; KAWAKAMI, Tetsuo[1] ; TSUCHIYA, Noriyoshi[2] ; MADHUSOODHAN, Satish-kumar[3] ; ISHIKAWA, Masahiro[4] ; GRANTHAM, Geoffrey H.[5]

[1]Kyoto University, [2]Tohoku University, [3]Niigata University, [4]Yokohama National University, [5]Council for Groscience, South Africa

It has been gradually recognized chloride brine potentially plays an important role in large-scale mass transfer during high-grade metamorphism without partial melting. This is because brine is a powerful solvent, can coexist with CO_2-rich fluid under the granulite facies conditions and has low-H_2O activity (Newton & Manning, 2010; Heinrich et al., 2004). In natural observation, evidence for the presence of brine is often found as fluid inclusions. In metamorphic rocks under granulite facies conditions, however, brine inclusions are only rarely found (Markl & Bucher, 1998). This is partly because brines have a high mobility due to their low viscosity and low wetting angle (Watson & Brenan, 1987; Holness, 1997).

On the other hand, hydrous minerals such as biotite (Bt), hornblende (Hb) and apatite can record the f_{H2O}/f_{HCl} of the last equilibrated Cl-rich fluid as their mineral compositions. In order to understand the metamorphic fluid activity using these minerals, *P-T* condition under which these minerals equilibrated with a fluid as well as the crystallographic requirements for these minerals to record the fluid composition should be known (e.g., Makino, 2000). However, there still are a lot of unsolved issues about brines, for example, cations transported in the fluid, *P-T* condition and areal scale of brine activity, and its origin (Newton et al., 1998).

In order to understand the multiple brine activities and the cation composition in brines, two meta-mafic gneisses are studied in detail in Brattnipene, Sør Rondane Mountains (SRM), East Antarctica.

In a Grt-Bt-Hb gneiss, Cl-rich Bt is exclusively included in garnet (Grt). Bt, Hb, and cummingtonite (Cum) in the matrix are Cl-poor. These compositional differences imply that Bt included in the Grt formed under the presence of chloride brine and Cl-poor fluid infiltrated after Grt formation. Grt is enveloped by the gneissosity defined by the arrangement of Cum overgrown by Hb, and Bt. Therefore, chloride brine activity predated or was simultaneous with the penetrative gneissosity formation in this area. After considering the effect of Mg-Cl avoidance rule and compositional change during retrogression, the geothermobarometry (Holdaway, 2000; Wu et al., 2004) gave 650 $<T<$800 ℃ and 0.96 GPa for the peak *P-T* condition of this sample. The Cl-rich Bt entrapment was probably predated or simultaneous with the attainment of this *P-T* condition.

In a Grt-Opx-Hb gneiss, ca. 1cm-thick Grt-Hb vein cut the penetrative gneissosity in this area. Cl-content of Hb and Bt, and K-content of Hb decrease with the distance from the vein center and become constant at ca. 1.6 cm from the vein center. Plagioclase present next to the vein has a core (An_{55}) and mantle (An_{68}) which is sharply overgrown by Na-richer rim (An_{51}). Plagioclase in the vein is An_{51} without zoning, and development of Na-richer rim gets thinner with a distance from the vein. Therefore, the Grt-Hb vein was probably formed by NaCl-KCl brine infiltration. This is also supported by the isocon analysis of whole-rock chemistry determined for wall rock of the vein. *P-T* condition of the vein formation is estimated as 720 ℃ and 0.70 GPa (Holdaway, 2000; Wu et al., 2004).

P-T conditions of multi-stage chloride brine activity, cation composition of the brine, and outcrop-scale pathways of the brine are constrained in SRM from these two gneisses. From the pelitic gneisses in SRM, Cl-rich fluid or melt activity with a linear distribution over 200 km has been reported (Higashino et al., 2013). Additionally, this study revealed that the brine activity in SRM is not controlled by the lithology or specific deformational stages. It is clear that chloride brine in SRM was not a result of *in situ* fractionation through the selective consumption of H_2O in the fluid (Kullerud, 1995), but substantial amount of brine was actually moving, and was playing an important role in mass transfer.

Rate-limiting process and degree of disequilibrium of garnet-forming reaction

MIYAZAKI, Kazuhiro[1*]

[1]GSJ AIST

Water released by dehydration reaction in metamorphic rocks will take a major role in rheology, mass transport, and reactivity of metamorphic rocks. Rate-limiting process of the dehydration reaction can be divided into the following three steps, such as reaction at interface, diffusion, and heat-flow. Garnet is one of the common minerals produced by dehydration reaction in metamorphic rocks. The rate-limiting process of garnet-forming reaction is usually assumed to be diffusion-controlled reaction. However, there are few cases where clear evidences for diffusion-controlled reaction were proposed. In addition, degree of disequilibrium of the diffusion-controlled reaction is not well known. Here, I report evidence of diffusion-controlled reaction and estimation of degree of disequilibrium of garnet-forming reaction in the Tsukuba Metamorphic Rocks.

Garnets in the Tsukuba Metamorphic Rocks are formed by the dehydration reaction of biotite + sillimanite + quartz = garnet + cordierite + K-feldspar + water. Biotite-depleted region surround the irregular shaped garnet. The depleted region of reactant is typically expected for diffusion-controlled reaction, but is rare for natural garnet-forming reaction. Irregular shape of garnet is also expected for diffusional instability of growing interface (Mullins & Sekerka, 1963). These sets of observations strongly suggest that the garnets were formed by diffusion-controlled reaction.

Spherical shape of growing particle under diffusion-controlled reaction becomes unstable due to diffusional instability, but interfacial energy will reduce the instability. Using spherical harmonics function, instability of small perturbation from spherical shape can be evaluated. Assuming interfacial energy of garnet, dominant wavelength in unstable regime is predicted with degree of super-saturation under diffusion-limited reaction. Dominant wavelength of the irregular garnet suggests that degree of super-saturation is less than 0.1. This value can be translated to degree of disequilibrium temperature with entropy change of the garnet-forming reaction. The disequilibrium temperature $\triangle T$ is less than 5 ℃, and is very small. This small value of disequilibrium temperature suggests that spherical or euhedral garnets that are more common than irregular garnets, should be produced near equilibrium condition. Otherwise, such common spherical or euhedral garnets should be produced by interface-controlled reaction associated with influent fluid.

FLUID RELATED ORIGIN OF SILLIMANITE VEINS IN POLYMETAMORPHIC ROCKS FROM THE RYOKE BELT, JAPAN

AMANO, Saori[1*] ; KAWAKAMI, Tetsuo[1]

[1]Graduate School of Science, Kyoto University

In the polymetamorphic area, it is important to distinguish the effect of each metamorphism in order to appreciate the evolution of thermal structure of the area. Some authors have successfully distinguished the regional metamorphism from the postdating contact metamorphism (e.g. Miyake et al., 1992), but studies dealing with a fluid activity during polymetamorphism is not sufficiently available. Veins consisting of fibrous sillimanite (Sil) in a contact metamorphic aureole have been previously interpreted as a result of fluid activity (e.g. Johnson et al., 2003).

In Kasagi area (Kyoto, Japan), Ryoke metamorphic rocks are widely exposed and main lithology is pelitic and psammitic schists and gneisses. Younger Ryoke granites discordantly intrude to the metamorphic rocks and, therefore, the regional metamorphic rocks are overprinted by the heat (Ozaki et al., 2000) and fluid flux from the granites. This area belongs to the Sil zone that is defined by the presence of Sil in the pelitic lithology (Ozaki et al., 2000) whose origin has not been discussed in detail.

However in this area, fibrolite bundles are often observed to cross-cut the gneissosity formed by the regional metamorphism and it seems difficult to explain their formation during the regional metamorphism. In this study, we report the mode of occurrence of Sil veins emanating from the granite into psammitic gneiss and discuss the fluid-related origin of them.

The studied psammitic gneiss containing Sil veins is collected from the Sil zone near the granite intrusion contact. Ryoke granite intrudes discordantly to the gneissosity of this sample, and the Sil vein subparallel to the gneissosity emanate from it. The Sil vein consists of fibrolite and retrograde muscovite (Ms) replacing it. Quartz (Qtz) in the matrix near the vein are coarser-grained and they include fibrolite grains. The amount of fibrolite included in the Qtz decreases as a distance from the Sil vein increases. Fibrolite is present in veins and Qtz grains. Fine, retrograde Ms after fibrolite is present along grain boundaries in the matrix. Although plagioclase (Pl) is a common constituent mineral in the matrix, it is almost completely absent near and in the Sil veins. K-feldspar is absent in the studied sample, but instead, retrograde Ms cutting the schistosity is abundant in the matrix.

Cathodoluminescence (CL) observation of the microstructures around the Sil veins revealed that the brightness of CL signal of Qtz grains increases as the distance from the Sil vein increases. That is, Qtz grains near the vein or including Sil are dark under CL observation. In particular, part of a single Qtz grain including more fibrolite grains appears dark under CL image.

From the observation of microstructural relationships described above, we consider that Sil veins were formed by the fluid released from the Ryoke granite. Formation of fibrous Sil by the action of mobile hydrogen ions on pre-existing minerals has been previously discussed (Vernon, 1979). Moreover, experimental work has shown that Al2SiO5 minerals and Ms can be produced by the action of acidic, aqueous solutions on various common silicate minerals (Burnham, 1967). In this study, fibrolite is present in veins and Qtz grains and the amount of fibrolite crystals included in the Qtz crystals decreases as a distance from the vein increases. Pl is absent in and at the vicinity of the veins. From these pieces of observation, a fluid from the granite would have reacted with the matrix to dissolve Pl and to form coarser-grained Qtz and fibrolite bundles simultaneously. Thermodynamic calculation using SUPCRT92 (Johnson et al. 1992) has revealed that infiltration of the aqueous fluid with low Na+/H+ and K+/H+ ratio can destabilize Pl and stabilize Sil under the presence of Qtz at 3 kbar, 600oC. Therefore, Sil in this study is not regional metamorphic in origin, but is probably a result of fluid infiltration during a contact metamorphism by the Ryoke granite.

Comparison of UHP chromitites from the Higo and Nishisonogi Metamorphic Rocks, Kyushu, Japan.

SHIOSAKI, Dai[1*] ; MORIBE, Yosuke[1] ; EGUCHI, Hibiki[1] ; NISHIYAMA, Tadao[1]

[1]Department of Earth and Environmental Sciences, School of Science and Technology Kumamoto University

We have found microdiamond - bearing ultrahigh-pressure (UHP) chromitites from two metamorphic terranes in Kyushu: the Higo (HMR)[1] and Nishisonogi (NMR)[2] Metamorphic Rocks. This paper describes the similarity and difference between the two UHP chromitites. The HMR are located in west-central Kyushu with an E-W trend. They have undergone low P /T metamorphism, however, precursor HP or UHP metamorphism of ca. 250 Ma has been inferred[3]. The protoliths have affinity to continental shelf deposits[4], consisting mainly of pelitic gneisses and meta-carbonates with minor metabasites and metaperidotites (partly serpentinite). Chromitite occurs very rarely as a nodular form in serpentinized metaperidotites which shows spinifex-texture. The NMR is located in western Kyushu with a N-S trend. They have undergone high P /T metamorphism of epidote-blueschist subfacies. They consists mainly of pelitic and psammitic schists with minor basic schists and serpentinites, some of which show a character of serpentinite melange[5]. Detrital zircon from the pelitic schists show the age of 89-86 Ma[6], whereas zircon from jadeitites in a serpentinite melange does 136 -126 Ma in the core and 84 - 80 Ma in the rim[7,8]. Chromitite occurs as a deformed schlieren-like layer in serpentinite with no reilc minerals. The P-T condition of the HMR has been estimated to be 200 - 600 MPa and 600 - 800 ℃ [3,9,10,11,12,13]. Higher pressure and temperature conditions are reported from the following two samples: a sapphirine-bearing granulite[3,10] as a tectonic block in the spinifex-textured metaperidotite (900 MPa and 950 ℃) and a calc-silicate granulite[13] (900 MPa and 820 ℃) intercalating with garnet - biotite gneiss. We newly estimated the peak P-T condition of Al-spinel and chlorite -bearing metaperidotite as 2.0 GPa and 780 - 990 ℃. In the case of the NMR, the peak metamorphic condition of the crystalline schists is 1.4 GPa and 520 ℃ for a garnet galucophanite[14]. Jadeitites[15] as tectonic blocks in the serpentinite melange shows the peak condition of 1.5 GPa and 500 ℃. Chromite from the HMR has the composition $(Mg_{0.34}Fe^{2+}{}_{0.75}Mn_{0.02})(Cr_{0.81}Al_{0.06}Fe^{3+}{}_{0.04}Si_{0.05)2}O_4$, whereas that from the NMR has similar composition $(Mg_{0.33}Fe^{2+}{}_{0.65}Mn_{0.03})(Cr_{0.84}Al_{0.12}Fe^{3+}{}_{0.04})_2O_4$ in the core and Fe-rich composition $(Mg_{0.06}Fe^{2+}{}_{0.89}Zn_{0.02}Mn_{0.03})(Cr_{0.85}Al_{0.12}Fe^{3+}{}_{0.04})_2O_4$ in the rim. Microdiamonds occur as i*n situ* inclusions in chromite in both chromitites. They are 1 to 10 μm in size in HMR chromite, and those in NMR chromite is much smaller, mostly <1 μm with small number of larger grains. In both chromitites microdiamonds occur in some cases as numerous aligned grains, making diamond - rich zones. Both microdiamonds are identified with Raman spectra. HMR microdiamonds show a broad peak at 1333 cm^{-1}. NMR microdiamond, also shows a broad peak at 1331 cm^{-1} with graphite peak at around 1600 cm^{-1}, suggesting partial graphitization. Both UHP chromitites will be deep subduction origin. HMR can be an eastern extension of the Dabie-Sulu UHP terrane in China, however, NMR is more problematic. No corresponding UHP terrane of ca. 80Ma is found around Kyushu. Our findings of UHP chromitites require reexamination of micro-tectonics in Kyushu, a peculiar location of an arc-arc junction at the continental margin.

3D imaging of the Mn-caldera shaped zoning of the garnet found from the Sanbagawa metamorphic belt and its origin.

YOSHIDA, Kenta[1*] ; HIRAJIMA, Takao[1]

[1]Graduate School of Science, Kyoto University

Garnets with a complex compositional zoning were found from the northern proximal area of the Western Iratsu body of the Sanbagawa metamorphic belt of the Besshi district, southwest Japan. The studied garnet shows incipient Mn-reverse (increasing) zoning part (defined as core) and subsequent Mn-bell shape (decreasing) zoning part (defined as mantle), which is almost identical to the " Mn-caldera shaped zoning " described by Banno et al. (2004) in the Asemigawa region of the central Shikoku. In order to describe the chemical characteristic sterically, X-ray chemical mapping were performed by each 0.2-0.3 mm depth step, for one very-coarse-grained garnet with ca. 11 mm in diameter. The result clearly shows that the core/mantle boundary has the highest Mn content with euhedral shape, and that the chemical composition continuously changes through the grain. Internal schistosity defined by sigmoidal inclusion arrays cross-cuts the core/mantle boundary. This fact also suggests the continuous growth of garnet from the central part to the outer part. In the same sample, garnets with Mn-bell shape type zoning are also observed, which are relatively fine-grained up to 5 mm. Raman barometry and thermodynamic modeling suggest the climax *P-T* conditions of the studied sample did not reach the eclogite facies, which are consistent with the conditions of the oligoclase-biotite zone of the Sanbagawa metamorphic belt (610 ℃ and 1.0 GPa, Enami, 1994).

Contrary to the simple Mn-bell shape type zoning which grown up with progressive regional metamorphism, " Mn-caldera shaped zoning " could be generated from the crystal nucleation under oversaturated environment (Matsumoto and Kitamura, 2004). Such oversaturation is expected in a rapid increase of temperature. Recently, Aoya et al. (2013) proposed the eclogite nappe covering the large part of the Besshi district. However, the exact boundary between the eclogite nappe and lower grade surrounding rocks is still under the debate. The conjunction of the eclogite nappe and the lower-grade surrounding rocks are thought to have taken place near the peak metamorphic stage of the surrounding rocks (500-600 ℃ and ca. 1 GPa, Aoya et al., 2013). Mn-caldera shaped zoning garnet found in the Besshi district (this study; Xu et al., 1994) are both found from the northern proximal of the hypothesized eclogite nappe. Those Mn-caldera shaped zonings are possibly originated from the conjunction of the eclogite nappe and surrounding crystalline schist, and corresponding rapid heating. Such features of garnet can help to determine the boundary of the eclogite nappe in the Besshi district.

Widespread analyses of pressure-temperature trajectory and timing in the Altai Range, Mongolia

NAKANO, Nobuhiko[1*] ; OSANAI, Yasuhito[1] ; OWADA, Masaaki[2] ; SATISH-KUMAR, M.[3] ; ADACHI, Tatsuro[1] ; JARGALAN, Sereenen[4] ; YOSHIMOTO, Aya[1] ; KUNDYZ, Syeryekhan[4] ; BOLDBAATAR, Chimedtseie[5]

[1]Kyushu University, [2]Yamaguchi University, [3]Niigata University, [4]Mongolian University of Science and Technology, [5]Mongolian Exploration Partners, LLC

This study performed large-scale petrographical and geochronological investigation in the Altai Range, Mongolia distributed in the Central Asian Orogenic Belt, which is the typical subduction-accretion-collision orogeny on the Earth. Based on the petrographical observation, clockwise and anti-clockwise pressure-temperature trajectories were identified in whole of the studied area (400 km long). U-Th-Pb monazite dating yields c. 350 Ma and c. 260 Ma. Samples with clockwise pressure-temperature path, containing kyanite in garnet and sillimanite in the matrix, commonly have c. 350 Ma monazite in garnet and c. 260 Ma monazite in the matrix. In contrast, samples with anti-clockwise pressure-temperature path containing sillimanite in garnet and kyanite in the matrix have monazites showing (i) c. 350 Ma both in garnet and the matrix, (ii) c. 260 Ma both in garnet and the matrix, and (iii) c. 350 Ma in garnet and c. 260 Ma in the matrix. Ca zoning pattern in garnet shows either continuous or discontinuous zoning. Samples containing single monazite age cluster (either c. 350 Ma or c. 260 Ma) have continuously zoned garnet, in which samples with anti-clockwise pressure-temperature trajectory at both periods show Ca zoning increasing from core to rim or mantle, whereas some samples with unknown pressure-temperature path at both periods show opposite zoning. These features strongly suggest both clockwise and anti-clockwise evolutions occurred at both periods. Discontinuous Ca zoning in garnet is observed in samples that contain c. 350 Ma monazite inclusions in garnet and c. 260 Ma monazite grains in the matrix, and the zoning patterns show a decrease in Ca at the rim for samples with clockwise paths and an increase in Ca at the rim for those with counterclockwise paths. In some cases, c. 350 Ma monazite grains are included in the large garnet cores but c. 260 Ma monazite grains are found in the garnet rims as well as in the matrix. These rocks might be metamorphosed at c. 350 Ma, whereas they did not exhume to the surface and have remained deep crustal level. Subsequent compression and decompression event formed garnet rim and monazite at c. 260 Ma, which should be caused by same tectonic regime to clockwise and anti-clockwise pressure-temperature path at the period. The presence of the regional-scale clockwise and anti-clockwise trajectories and their repetition during less than 100 My have never reported from any other orogenic belts in the world. Further studies may allow to realize the complex tectonic evolution of the Altai Range.

Temporal change of modal abundance of minerals during formation of arrested charnockite from Sri Lanka

YAMASAKI, Yukiko[1*] ; IKEDA, Takeshi[1] ; MOTOYOSHI, Yoichi[2] ; HIROI, Yoshikuni[3] ; PRAME, Bernard[4]

[1]Kyushu University, [2]National Institute of Polar Research, [3]Chiba University, [4]Geological Survey of Sri Lanka

Charnockite occurs as a number of several-decimeters patches in hornblende-biotite gneiss in central Sri Lanka. This type of charnockite has been called arrested charnockite. Local condition of low-H_2O activity or low-oxygen fugacity could explain the difference of mineral assemblage in local scale. They might be caused by fluid influx and/or partial melting (e.g. Newton et al., 1980; Hiroi et al., 1990; Burton and O'Nions, 1990; Ravindra Kumar, 2004; Endo et al., 2012). The temporal and spatial development of charnockite has been unclear. This study describes variation in modal abundance of hornblende, biotite and orthopyroxene in melanocratic and leucocratic parts from surrounding gneiss to charnockite.

Charnockite and surrounding gneiss have layer structure composed of melanocratic and leucocratic parts. Each part can be traced continuously between the two rock types. Melanocratic parts consist mainly of hornblende and biotite in gneiss, and orthopyroxene added in charnockite. Leucocratic parts are composed of biotite and colorless minerals in gneiss, while biotite is absent in charnockite. Modal abundances of hornblende and biotite have no systematic trend in melanocratic parts of gneiss. Hornblende and biotite decrease drastically and gradually, respectively, while orthopyroxene increases gradually in melanocratic parts of charnockite. Biotite decreases gradually toward charnockite in leucocratic parts in gneiss.

Biotite of leucocratic parts breaks down within gneiss. Orthopyroxene appears in the location of dehydration reaction of biotite and hornblende in melanocratic parts. This suggests that the element released due to break down of biotite in leucocratic layer diffused from leucocratic part to melanocratic part to produce orthopyroxene. It is a possible that hornblende broke down first to produce significant amount of orthopyroxene in melanocratic part. The element released due to break down of biotite in leucocratic part transported to the location of preexisting orthopyroxene in order to grow the crystals. Biotite in leucocratic layers is enriched in Fe as compared with that in melanocratic part. Fe-rich biotite breaks down under lower temperature (or higher activity of H_2O) than Mg-rich biotite. This could explain the decrease of biotite in leucocratic layer in gneiss.

Thermal structure and water transportation in subduction zones: a comparison between NE and SW Japan

ISHII, Kazuhiko[1*] ; OKUNO, Masashi[1]

[1]Graduate School of Sciences, Osaka Prefecture University

Northeastern and southwestern Japan are considered to be typical examples of cold and hot subduction zones, respectively. The old Pacifc plate subducts beneath northeastern Japan at high rate and the young Philippine Sea plate subducts beneath southwestern Japan at low rate. These contrasts in the subduction conditions reveals in several aspects including higher activity of arc volcanism and deeper down dip limit of inter-plate earthquake in northeastern Japan, and deep low-frequency tremors at plate boundary of southwestern Japan. We have investigated thermal structure and geophysical and geochemical processes in these subduction zones using a numerical model. The model includes hydration and dehydration of the slab and mantle wedge, melting and solidification of mantle peridotites, permeable flow of melt and aqueous fluids, and temperature-dependent solid flow of mantle peridotites with water- and melt-induced weakening. We will discuss effects of the subduction conditions on the volcanic and seismic activities through the processes, especially water transportation.

Stress and strain history during the microboudinage for granite intrusion: Mt. Edger granite complex, East Pilbara

MATUMURA, Taroujirou[1*] ; KIMURA, Nozomi[2] ; OKAMOTO, Atsushi[3] ; MASUDA, Toshiaki[2]

[1]Graduate school of science and Technology, Shizuoka University, [2]Institute of Geoscience, Shizuoka University, [3]Graduate school of Environmental studies, Tohoku University

Stress and strain analysis is essential to improving the understanding of deformation process. Microboudinaged columnar minerals can be used as an indicator of stress and strain during the microboudinage for quartzose and calcareous metamorphic tectonites. In this presentation, we discuss the stress and strain history during the microboudinage deduced by the microboudin method with a collaboration of the strain reversal method.

We collected samples of metachert from the Archean Warrawoona greenstone belt around Mt. Edger granite complex, East Pilbara, Western Australia, and identified microboudinaged tourmaline grains embedded within quartz matrix in 10 samples. The result revealed that the samples experienced extensional strain at least -0.56 and differential stress in the range from 3.9 to 11.9 MPa. We obtained stress-strain curves which show increase in differential stress with increasing inverse natural strain (ε_{inv}). The frequency distribution of interboudine gaps between separated grains with respect to ε_{inv} for boudinaged tourmaline grains shows that end of microboudinage occurred immediately after the peak frequency of fracturing. This occurrence commonly appeared in all the 10 samples. These results provided us with keys to discuss a stress-strain history during the microboudinage in relation to evolution of the granite complex. The spectacular implication would be a drop or relaxation in increased differential stress at the end of the microboudinage.

Time scale for formation of diffusion zoning in response to breakdown reaction

IKEDA, Takeshi[1*]

[1]Kyushu University

In high-grade metamorphic rocks, garnet commonly represents an increase in Mn or Fe toward margin. This feature has been interpreted as diffusion zoning owing to garnet-consuming reactions during retrograde metamorphism. In this process, the zoned thickness can be described in terms of distances of internal diffusion and surface retreating. This study preliminaly formulated to express these distances as a function of time and retreating velocity of the surface. Applying the formulation to some high-temperature metamorphic belts yielded that the diffusion zoning with zoned thickness of 0.04 to 0.1 mm was formed by 1 to several million years. This result may be applied to estimate cooling rate provided that the surface equilibrium was mainetained during the formation of diffusion zoning.

Integrated radiometric dating of schist clasts from the Eocene and Miocene conglomerates in Shikoku

IIZUKA, Ryota[1*] ; TAKAGI, Hideo[1] ; HONDA, Emi[1] ; IWANO, Hideki[2] ; ISHIDA, Akizumi[3] ; SANO, Yuji[3]

[1]Waseda University, [2]Kyota Fission-Track Co. Ltd., [3]AORI, the University of Tokyo

The age that the high P/T type Sanbagawa metamorphic rocks reached at erosion level gives an important constraints for considering exhumation processes of the Sanbagawa metamorphic rocks. It is shown by the oldest age of the conglomerate containing schist clasts derived from the Sanbagawa Belt. Integrated radiometric dating has been carried out for schist clasts from the Paleogene and Neogene conglomerates in Shikoku. The results of K-Ar and fission-track (FT) ages for the schist clasts from the Eocene Hiwadatoge Formation and the Miocene Furuiwaya Formation (Kuma Group) were already reported (Takagi and Sakisaka, 2012; Takagi et al., 2013). We have been doing U-Pb dating of zircon grains from the same clasts for the FT dating using NanoSIMS 50 ion microprobe of AORI. The youngest U-Pb age of zircon grains approximates the sedimentary age of the protoliths of the schist, because the zircon grains in the low-grade metamorphic rocks are detrital origin. The tentative results shown by the youngest peak yield around 110 Ma in all samples. We will report on details of the U-Pb ages at the meeting. FT dating was also carried out for the schist clasts from Eocene Oyamamisaki Formation in the Shimanto Belt where K-Ar ages (78.2-71.4 Ma) of the clasts have been already reported by Yoshikura et al (1991). The FT ages were 67.3 +/- 9.0 Ma and 68.4 +/- 8.2 Ma. From the results of K-Ar phengite ages and FT zircon ages for schist clasts (Table 1), it is suggested that the exhumation rate of the schist eroded at Eocene time is faster than that eroded at Miocene time.

The metamorphic evolution from PrP to LBS facies in a late Paleozoic cold subduction system in Kurosegawa belt

SATO, Eitaro[1*] ; HIRAJIMA, Takao[1]

[1]Graduate School of Science, Kyoto University

Introduction: Recent progress of thermal modeling and thermodynamic calculation can help the general understanding of the thermal structure of subducting plate and the total movement of H2O stored in high-pressure type metamorphic rocks from the trench to the upper mantle depth in various subduction settings (e.g., Peacock & Wang, 1999; Hacker et al., 2003). For example, Peacock (2009) indicated that the oceanic plate in the Philippine Sea plate subducting below the Kii Peninsula would suffer the cold HP/LT type metamorphism represented by zeolite facies, prehnite-pumpellyite facies, pumpellyite-actinolite facies, lawsonite-blueschist facies to jadeite-lawsonite-blueschist to 2GPa. However, the natural example recording abovementioned progressive metamorphic evolution has not been recognized yet.

Recently prehnite-pumpellyite facies and lawsonite-blueschist facies units have been recognized in the Otao unit of Kurosegawa belt in Yatsushiro area, Kyushu, Japan (Kamimura et al., 2012). However, the relationship of two metamorphic units has not been verified yet.

In this paper, we propose the progressive change of metamorphic grade from the prehnite-pumpellyite facies to lawsonite-blueschist facies based on petrography and thermodynamic phase analysis in metabasite system.

Petrography and Mineralogy: We confirmed that the prehnite-pumpellyite facies assemblage is predominant in the Tobiishi subunit of (Kamimura et al., 2012), but we newly found pumpellyite-actinolite facies from the western end of this subunit.

In the lawsonite-blueschist facies unit, Hakoishi-subunit of (Kamimura et al., 2012), located to the west of the Tobiishi-subunit, following mineral assemblage with excess chlorite, quartz, albite and phengite are systematically distributed from the east to the west in the subunit:

lawsonite + pumpellyite + aegirine-augite,pumpellyite + Na-amphibole,lawsonite + pumpellyite + Na-amphibole, lawsonite + Na-amphibole + aegirine-augite.

The compositions of sodic pyroxene, pumpellyite and Na-amphibole also show the following systematic trend westwards in the subunit; jadeite component of sodic pyroxene generally increases from XJd=0.12 to XJd=0.50 with XAeg= up to 0.5. Al content of pumpellyite increases from 3.7 to 4.6 p.f.u. for O=24.5 Fe3+/(Al+Fe3+) in Na-amphibole decreases from 0.8 (riebeckite) to 0.15 (glaucophane).

Thermodynamic phase analysis: To evaluate stability relationship among abovementioned mineral assemblages, the phase diagram was construct-ed in the NCFMASH system with PERPLE_X soft-ware package (Connolly, 2005) for 1-10 kbar and 100-400 C. The considered minerals are stilbite, laumontite, prehnite, pumpellyite, ferro pumpellyite, tremolite, ferro tremolite, diopside, hednbargite, clinochlore, daphnite, lawsonite, glaucophane, ferro graucophane, clinozoisite and albite with excess, quartz and water. As the first order approximation, solid solution in each mineral was ignored. The new-ly constructed phase diagram predicts following representative mineral assemblages appear with the increase of the pressure along the high HP/LT path.

lawsonite + pumpellyite + clinopyroxene,pumpellyite + glaucophane,lawsonite + pumpellyite + glaucophane,lawsonite + glaucophane + clinopyroxene.

This metamorphic evolution in the model system is coincident well with the natural observation in the Hakoishi subunits.

Conclusion: Mineral assemblages observed in metabasites of the Tobiishi and Hakoishi subunits and the newly constructed petrogenetic grid suggest the metamorphic grade increases from prehnite-pumpellyite facies to lawsonite-blueschist facies westward ca. 20km in the Otao unit of Kurosegawa belt. The westward increase of Al content in pumpellyite, Na-amphibole, and Na- clinopyroxene also suggest the metamorphic grade increases westward. Thus, this area would become a type locality of a cold subduction system as proposed by the Peacock (2009)s thermal modeling.

Morphological change of zircon under high temperature metamorphism: Example of the Kiso Ryoke metamorphic rocks

IKAWA, Chiaki[1*] ; MOTOYOSHI, Yoichi[2] ; HOKADA, Tomokazu[2] ; HORIE, Kenji[2]

[1]Department of Polar Science, the Graduate University for Advanced Studies, [2]National Institute of Polar Research

Zircon is an important key mineral to obtain the age of rocks, however zircon newly grew at each metamorphic cycle and its timing of crystallization should have been recorded as U-Pb age. It is not always fully understood how zircon crystal grows at different metamorphic grade. Williams (2001) demonstrated that the behavior of zircon has been changed accompanying with metamorphic grade in Cooma complex, SE Australia. In low grade, there are detrital zircons but in high grade, overgrown or newly formed zircons are observed. Kawakami et al (2013) reported the behavior of zircon in the upper-amphibolite to granulite facies schist/migmatite transition, Aoyama area, Ryoke metamorphic belt. They concluded that the recrystallization of zircon has been controlled by partial melt. Thus, crystal morphology is quite important for understanding the U-Pb age of zircon.

This study reports morphological change of zircon crystal at different metamorphic grades in the Kiso area, Ryoke metamorphic belt in Central Japan, where metamorphic grade continuously increases from non-metamorphic (Mino belt) to migmatite facies, similar with Cooma complex. The district is located in northeastern part of Mt. Kisokomagatake and the study area is about 43km from north to south, and about 22km west to east. In this district, regional metamorphic rocks (metasediments, quartz schist, basic schist, and carbonate rocks, etc.) and non-metamorphic rocks widely occur. Morikiyo (1984) classified the district into nine mineral zones (I to VII) based on the mineral assemblages.

We have studied total 46 samples from all zones. Mineral assembles of the studied samples indicate the following characteristics features: biotite appears in zone II, albite disappears in zone IIIa, chlorite disappears in zone IIIb and sillimanite appears in zone VIa.

On the basis of the optical microscope and SEM observations, morphology of zircon is divided into 3 groups, such as zones I-II, zones IIIa-V and zones VIa-VII.

Zones I-II: Under the optical microscope, each zircon grain shows different color (purple, pale-pink and colourless). Zircon grains are essentially euhedral, and show variable range of grain size (40-220 um). In SEM observation, the abrasion and cracks are notable in zircon crystal surface. The above observations are consistent that the zircons in these zones are detrital origin that were derived from a variety of different source rocks.

Zones IIIa-V: Surface of zircon in these zones are irregular and rough with small holes which are likely to reflect resorption during the metamorphism. In contrast with the zircons from zones I-II, zircon crystal surface is relatively rough and shows no abrasion and cracks. But, even in the same zircon grain, both resorption surface and non-resorption surface can also be observed. Non-resorption surface is considered to preserve detrital surface (same with zone I-II), and resorption surface possibly reflects metamorphic dissolution or recrystallization (similar to zone VIa-VII). According to BSE images, no obvious new growth zone can be observed in many of zircon grains, but a few grains show sign of new overgrowth zone. Grain size of newly growing zircon is relatively small about 30um.

Zones VIa-VII: Surface of zircon in these zones is relatively smooth, which differs from rough crystal surface in zones IIIa-V. It is assumed that the irregular surface of zone IIIa-V zircons are overgrown and filled by smooth surface as temperature increases to zones VIa-VII. In the highest-grade zone VII, the rough surface is disappeared, and smooth zircon grains are dominated.

Thus in the Ryoke metamorphic rocks from Kiso area, crystal morphology of zircons changes from the dominant detrital signature in the lowest-grade zone through irregular and rough resorption and recrystallization features in the middle-grade zone to the more smooth overgrowth recrystallization in the higher-grade. New zircon grain growth can be found in the middle to higher-grade zone.

P-T estimates of a metapelite containig garnet zoning from Mefjell, Sr Rondane Mountain, East Antarctica

TSUBOKAWA, Yumiko[1*] ; ISHIKAWA, Masahiro[1] ; ICHIKI, Takashi[1] ; KAWAKAMI, Tetsuo[2] ; MADHUSOODHAN, Satishkumar[3] ; TSUCHIYA, Noriyoshi[4] ; GEOFF, Grantham[5]

[1]Yokohama National University, [2]Kyoto University, [3]Niigata University, [4]Tohoku University, [5]Council for geoscience, South Africa

The Sør Rondane Mountains, East Antarctica have been considered to be situated in the Gondwana suture zones. Therefore the mountains have attracted interest as a key area for understanding amalgamation process of the supercontinent. The mountains consist of amphibolite- to granulite-facies metamorphic rocks with granitic intrusions, and the timings of the main metamorphism are interpreted as *c*. 640-600 Ma and *c*. 550-500 Ma. Metamorphic rocks from northern and eastern part of the mountains (Balchenfjella and northern part of Austkampane) record a clockwise *P-T* path, on the other hand, metamorphic rocks from central part of the mountains (Brattnipene and eastern Menipa) record anti-clockwise *P-T* path. This suggests each area records a different *P-T* path. However, pre-peak *P-T* conditions of southwestern part of the mountain such as Mefjell have been still not clear.

In this study, we report a garnet porphyroblast with a prograde zoning in a metapelite from Mefjell. The St-bearing Grt-Sil-Bt gneiss mainly consists of garnet, biotite, sillimanite, quartz and plagioclase, with minor K-feldspar, staurolite, apatite, monazite, ilmenite and magnetite. The garnet grain is 12 mm in diameter, with the change of color from reddish in the core to transparent in the rim. The garnet has core-rim boundary defined by Mn-zoning. The garnet is typically almandine-rich, and shows compositional zoning with decrease in spessartine content from the core ($Alm_{63}Sps_{24}Prp_{14}Grs_{6}$) to the rim ($Alm_{74}Sps_{2}Prp_{20}Grs_{4}$), and spessartine content increase again towards the outer-rim ($Alm_{73}Sps_{11}Prp_{20}Grs_{6}$). The garnet includes staurolite, sillimanite, biotite, chlorite, plagioclase, K-feldspar, quartz, apatite and ilmenite. Garnet-ilmenite and staurolite-garnet geothermometers yield a temperature increase towards rim from 350-400 to 630-700 ℃. Garnet-Al_2SiO_5-quartz-plagioclase geobarometer applied to rim inclusions yields 7.2kbar±0.9kbar for an assumed temperature of 650 ℃.

Syn-metamorphic fluid infiltration and petrogenesis of leucogranites in the MCT zone in Eastern Nepal

KAWAKAMI, Tetsuo[1*] ; SAKAI, Harutaka[1] ; SATO, Katsushi[1]

[1]Graduate School of Science, Kyoto University

Syn-metamorphic fluid activity in the continental collision zone is of great importance especially for the petrogenesis of leucogranites and mass transfer through the fluid/melt extraction. Tourmaline (Tur) is a common accessory mineral in the crust having a wide stability field [1]. It is the most important sink of B in metapelites [2, 3, 4]. Although B behaves incompatibly under the absence of its sink minerals and is transported in fluid, once the *P-T-X* condition permits, it can be precipitated as Tur and other borosilicates in the site of fluid/rock interaction. Therefore, Tur can be a good tracer of B-bearing fluid [4]. Since Tur is a polar mineral, different concentrations of cations are incorporated at opposite poles of the crystal as a function of temperature up to 650^{o}C, and this interpolar element partitioning in Tur can be used as a geothermometer [2, 5].

We have investigated the mode of occurrence of Qtz veins and Tur-rich veins in the MCT zone around Dhankuta, Eastern Nepal. In this area, pelitic schists are widely exposed and subordinate amounts of metamorphosed dolostone, quartzite and mafic rocks are intercalated with them. The metamorphic grade decreases from the Ky zone through the St zone to the Grt zone as the distance from the MCT increases toward the south.

Qtz veins are abundant in metapelites of this area. They are mostly deformed by the ductile deformation with top-to-S sense of shear during the activity of the MCT, and are found as lenses. In the Ky zone, Qtz veins contain mm- to cm-sized crystals of Ky and minor Pl. Grt and Ky are coarse-grained only at the vicinity of the Qtz veins, and Ky tends to be formed exclusively around the Qtz veins. This suggests that the fluid activity that formed the Qtz veins took place around the peak metamorphism of the Ky zone, and Si, Al, Na and Ca were mobile in the fluid. Preliminary *P-T* estimate of this fluid activity using Grt-Ky-Pl-Bt-Qtz assemblage gave ca. 8kbar and ca. 600^{o}C. In the St and Grt zones as well, Grt tends to be coarser grained around the Qtz veins. Therefore, these veins are the evidence for the externally derived fluid that infiltrated during the prograde to peak metamorphism of each zone.

Unusually abundant Tur is locally found in metapelites of the MCT zone. It is localized in aluminous, Ms-rich layers and can be formed through the input of external B into the appropriate whole-rock composition for Tur growth. Such a B-bearing fluid infiltration continued from the prograde stage because Grt with prograde chemical zoning includes abundant Tur crystals. B-bearing fluid infiltration continued in the post-peak stage as suggested by the presence of Tur-rich vein cross-cutting the schistosity. Interpolar Ca/Na partitioning of Tur [5] gives 530-590^{o}C for the temperature of the Tur-rich vein formation. A potential source of external fluid could be lower grade metasediments underlying these metamorphic zones, because syn-metamorphic dehydration reactions of hydrous minerals can supply not only H_2O but also B in the fluid.

B-bearing fluid infiltration during the prograde to post-peak metamorphism in the MCT zone is important for the petrogenesis of the Higher Himalayan (HH) and North Himalayan leucogranites whose source region and petrogenesis remain highly controversial [6]. Observation in this study supports the fluid-fluxed melting of the MCT zone or Higher Himalayan Crystallines (HHC) [7]. Tur-bearing leucogranite veins in the HHC just above the MCT could be a potential product of such a fluid fluxed partial melting that took place near the MCT.

Geochronology of the metamorphic rocks from the Masora, Antananarivo and Betsimisaraka domains, east-central Madagascar

ICHIKI, Takashi[1*] ; ISHIKAWA, Masahiro[1] ; OSANAI, Yasuhito[2] ; NAKANO, Nobuhiko[2] ; ADACHI, Tatsuro[2]

[1]Yokohama National University, [2]Kyushu University

In a previous reconstruction of Gondwana supercontinent, Madagascar is located within the interior of the supercontinent (e.g. Jacobs and Thomas, 2004). Therefore, Madagascar is one of the most significant areas to understand the process of Gondwana supercontinent formation. However, it is still controversial whether the central part of Gondwana supercontinent was formed by young arc-arc collision and amalgamation (Stern, 1994), or was reworked of old continent (e.g. Collins and Pisarevsky, 2005; Tucker et al., 2012). In this study we estimated the age of protolith formation by applying LA-ICP-MS zircon dating method to metaigneous rocks and the age of metamorphism by applying EPMA monazite dating method to metasedimentary rocks, to understand the geochronological characteristics of the composed domains in east-central Madagascar.

East-central Madagascar is divided into Masora, Betsimisaraka and Antananarivo domains from east to west based on the geology and geochronology (Tucker et al., 2011). The Masora domain is mainly composed of the felsic metamorphic rocks with subordinate amounts of the metasedimentary rocks. Two metasedimentary rocks gave ages ranging from ca. 520 to 510 Ma. This age range is consistent with the age obtained from the meta-granitoid (ca. 530 to 510 Ma, Smith et al., 2008) and from quartzite (ca. 540 to 520 Ma, De Waele et al., 2011) by U-Pb zircon dating method. The felsic metamorphic rock gave igneous age at ca. 3300 Ma. This age is consistent with the age obtained from the migmatized gneiss (Tucker et al., 2011).

The Antananarivo domain is mainly composed of the felsic metamorphic rocks with subordinate amounts of the metasedimentary rocks. This domain is divided into east and west on the basis of the metamorphic condition and structural geology. The east and west areas are bounded by the low-angle ductile shear zone of top-to-west sense. Monazites from the metasedimentary rock in the east gave ages ranging from ca. 500 to 480 Ma. In the west monazites from the two types of the metasedimentary rocks gave ages ranging from ca. 540 to 500 Ma (Martelat et al., 2000) and ca. 630 to 540 Ma (Jöns and Schenk, 2011) and from the meta-granitoid gave age ranging from ca. 560 to 540 Ma (Grégoire et al., 2009). Therefore, the metamorphic age in the east is relatively younger than in the west. The felsic metamorphic rocks are geochemically classified into two types, which gave individual igneous ages of ca. 2700 Ma in the east and ca. 760 Ma in the west, respectively. The intermediate metamorphic rocks are exposed in the west and gave igneous age at ca. 550 Ma.

The Betsimisaraka domain is mainly composed of the metasedimentary rocks. Monazites from the metasedimentary rocks gave ages of ca. 500 Ma. This age is younger than the ages reported from the quartzite at ca. 550-520 Ma (Tucker et al., 2011) and rim ages from the metasedimentary rock at ca. 550 Ma (Collins et al., 2003) by U-Pb zircon dating method.

As a consequence east-central Madagascar was metamorphosed between ca. 550 and 500 Ma. Both the east of the Antananarivo and Betsimisaraka domains was metamorphosed at the youngest age around ca. 500 Ma. In previously reported geochronological results the oldest igneous activity was at ca. 2500 Ma in the Antananarivo domain (e.g. Kröner et al., 2000) Therefore the ca. 2700 Ma igneous age is new and the oldest igneous age in this domain. The east of the Antananarivo domain was older than the west and the oldest part of this domain. The age transition zone was possibly exposed between the Masora, Betsimisaraka and the west of the Antananarivo domains. The age and geological relationship in Archean domain was recently reported from the Dhawar Craton in southern India (Peucat et al., 2013). The existence of the ca. 2700 Ma igneous activity in the east of the Antananarivo domain could be the significant evidence of the continuity between India and Madagascar since Archean.

Deformation microstructures of a Kamila amphibolite mylonite and their formative temperatures

ARAI, Tomoyuki[1*] ; KANAGAWA, Kyuichi[1] ; YOSHINO, Takashi[2]

[1]Graduate School of Science, Chiba University, [2]Institute for Study of the Earth's Interior, Okayama University

The Kohistan complex and the Kamila amphibolite belt in the northern Pakistan are considered to represent a Cretaceous island arc crust and a part of its lower crust, respectively. Here we report deformation microstructures of a Kamila amphibolite mylonite sample and their formative temperatures.

The amphibolite mylonite sample studied is composed of 100 μm to 1 mm thick alternating layers of hornblende + pyroxene, plagioclase, and hornblende + plagioclase + quartz, intercalating a 3 mm thick layer of garnet + quartz + plagioclase. Composite planar fabrics of a top-to-south sense of shear are developed in this sample; C plane defined by compositional layering (= foliation), S plane defined by lenticular domains of plagioclase aggregate clockwise oblique to the C plane, and C $'$ plane anticlockwise oblique to the C plane.

Hornblende + pyroxene layers contain pyroxene porphyroclasts of grain sizes $\approx$ 200 μm scattered in matrix mainly composed of hornblende grains with grain sizes $\approx$ 30 μm. Hornblende exhibits a strong crystallographic preferred orientation with (100) and [001] subparallel to foliation and lineation, respectively. Orthopyroxene porphyroclasts are elongated subparallel to foliation, and are accompanied by asymmetric tails mainly composed of hornblende indicating a top-to-south sense of shear. In addition, pyroxene porphyroclasts are surrounded by fine-grained ($\approx$ 10 μm) hornblende and quartz, suggesting a breakdown reaction of pyroxenes (orthopyroxene + clinopyroxene + H2O = hornblende + quartz), which is a retrograde reaction from granulite facies to amphibolite facies.

Plagioclase layers are composed of dynamically recrystallized plagioclase grains of An_{47-54} in composition. Lenticular domains of plagioclase are likely porphyroclasts in origin. Plagioclase grains are polygonal in shape, and weakly aligned clockwise oblique to foliation, which also suggests a top-to-south sense of shear. Plagioclase exhibits a distinct crystallographic preferred orientation with {131} and <1-12>clockwise oblique to foliation and lineation, respectively by $\approx$ 20 degrees. But {131} and <1-12>are aligned subparallel to the S plane, suggesting the dominance of {131}<1-12>during the dynamic recrystallization of plagioclase.

We applied three pyroxene geothermometers to the chemical compositions of orthopyroxene and clinopyroxene porphyroclasts, which yielded temperatures around 850 degrees C. We also applied a hornblende-plagioclase geothermometer to the average chemical compositions of hornblende and plagioclase in hornblende + plagioclase + quartz layers, and obtained a temperature of $\approx$ 610 degrees C. Thus, the amphibolite mylonite studied likely experienced a peak metamorphism of granulite facies at $\approx$ 850 degrees C, and subsequently a retrograde metamorphism of amphibolite facies at $\approx$ 610 degrees C, during which it was sheared by top-to-south thrusting.

The tectonics evolution of metamorphic and igneous rocks embedded in the serpentinite melange from the Kurosegawa Tecton

YOSHIMOTO, Aya[1*] ; OSANAI, Yasuhito[1] ; NAKANO, Nobuhiko[1] ; ADACHI, Tatsuro[1] ; KITANO, Ippei[1] ; YONEMURA, Kazuhiro[2] ; ISHIZUKA, Hideo[3]

[1]Kyushu Univ., [2]JOGMEC, [3]Kochi Univ.

This study focuses petrology of the Kurosegawa Tectonic Zone, which is characterized by serpentinite melange in the Jurassic Chichibu Belt, in SW Japan. The serpentinite melange contains several blocks including high-pressure/low-temperature metamorphic rocks, high-temperature metamorphic rocks and granites. A small amount of age data obtained in previous study suggests that all rock types were formed before the Jurassic. However, detailed petrological and geochronological works on the blocks have been never performed so far. In this study, we carried out regional-scale geological, geochemical and geochronological analyses on the blocks in serpentinite from the western part of Kyushu to the eastern part of Kii peninsula.

Metamorphism of the NE side of the Seba eclogitic basic schist in the Sambagawa metamorphic belt, central Shikoku, Japan

KISHIRA, Naohito[1*] ; TAKASU, Akira[1] ; KABIR, Md fazle[1]

[1]Department of Geoscience, Shimane University, Japan

The Sebadani area belongs to the albite-biotite zone and is located in the central part of the Besshi district. The Sebadani area is composed of the Sebadani metagabbro mass and surrounding Seba basic schists, pelitic and siliceous schists occur as intercalation within the Seba basic schists (Takasu and Makino, 1980; Takasu, 1984). Eclogitic mineral assemblages are sporadically preserved in both the Sebadani metagabbro and the Seba basic schists (Seba eclogitic basic schists) (e.g. Takasu, 1984; Naohara and Aoya, 1997; Aoya, 2001). The Onodani eclogites preserved within the Seba basic schists have a complex metamorphic history, undergoing three different metamorphic episodes (Kabir and Takasu, 2010). The first and second eclogite facies metamorphism is estimated as 530-590 ℃ and 19-21 kbar and 630-680 ℃ and 20-22 kbar, respectively. The second metamorphic event is similar to that of the Seba eclogitic basic schist of Aoya (2001) (610-640 ℃ and 12-24 kbar). The pelitic schists intercalated within the Seba eclogitic basic schists also underwent eclogite facies metamorphism of 520-550 ℃ and *c*. 18 kbar (Zaw Win Ko *et al*., 2005; Kouketsu *et al*., 2010).

The eclogite in the northeastern part of the Seba eclogitic basic schists consist mainly of garnet, epidote, amphibole (glaucophane, barroisite, taramite, Mg-taramite, Mg-katophorite, edinite), omphacite (X_{Jd} 0.27-0.41), phengite (Si 6.5-6.9 pfu). Minor amounts of albite, dolomite, rutile, titanite, biotite, chlorite and quartz. The schistsity is defined by preferred orientation of phengite, amphibole and epidote. Garnets are almandine-rich in composition, increasing almandine (X_{Alm} 0.54-0.60), pyrope (X_{Prp} 0.07-0.13) and decreasing spessartine (X_{Sps} 0.10-0.03) from core to the rim and contain inclusions of epidote, omphacite (X_{Jd} 0.27-0.41), dolomite, quartz and titanite. They also contain inclusions of barroisite/Mg-katophorite and albite symprectite. Amphibole in the matrix are zoned, barroisite/Mg-katophorite cores to edinite rims. Some other amphiboles in the matrix are parallel to the schistosity and occasionally occur as randomly oriented. The cores of these amphiboles are resorbed barroisite, glaucophane in the mantle and barroisite/edenite in the rim.

Based on the mineral paragenesis of the eclogites the metamorphism is divided into three events. The first eclogitic metamorphic event is deduced from symprectites of barroisite/ Mg-katophorite and albite after omphacite inclusions in garnet. The prograde stage of the second eclogitic metamorphic event is represented by the inclusions minerals within the mantle and rim of garnets consisting of epidote, barrosite and dolomite. The peak eclogite facies stage is defined by garnet rim and omphacite inclusins within the garnets with schistosity forming minerals of barroisite, omphacite and phengite. Garnet and omphacite rim-rim pairs yielded 530-570 ℃ and >11-14 kbar, and garnet and omphacite inclusion within garnet yields 520-560 ℃, >11-12 kbar (Ellis & Green, 1979 ; Bannno, 1986). THEMOCALC (Holland & Powell, 1998) average *P-T* calculation for garnet + omphacite + barroisite + phengite assemblage obtained 590-610 ℃ and 19-20 kbar. The retrograde stage is defined by symprectite of barrosite and albite after omphacite. The third metamorphic event is defined by zoned amphibole in the matrix.

The estimated matamorphic temperatures of the eclogites are lower than that of the second high-pressure metamorphic event of the Onodani eclogite and similar to that of the omphacite-bearing metapelites from the NW part of the Seba eclogitic basic schists (Kouketsu *et al*., 2010). This suggests a metamorphic thermal gradient existed within the Seba eclogitic basic schists.

Metamorphic history of garnet amphibolite from the Neldy Formation, Makbal district in the Kyrgyz Northern Tien-Shan

KASYMBEKOV, Adil[1*] ; TAKASU, Akira[1] ; KABIR, Md fazle[1] ; BAKIROV, Apas[2] ; SAKIEV, Kadyrbek[2]

[1]Department of Geoscience, Shimane University, Japan, [2]Institute of Geology, Academy of Science, Kyrgyz Republic

The Kyrgyz Tien-Shan Mountains extend from east to west, separating the Kazakhstan plate to the north and the Tarim plate to the south. They are divided into three tectonic units; the Northern Tien-Shan, the Central (or Middle) Tien-Shan and the Southern Tien-Shan. In the Northern Tien-Shan there are two HP and UHP metamorphic complexes, Makbal HP and UHP in the western part, and Aktyuz HP in the eastern part of the complexes. The Makbal complex in the Kyrgyz Northern Tien-Shan is located in the western segment of the CAOB.

The metamorphic rocks exposed in the Makbal district are divided into the Akdzhon and the Scharkyrak Groups based on their metamorphic conditions. The Akdzhon Group contains rocks of the HP and UHP metamorphic conditions, whereas the Scharkyrak Group underwent greenschists facies metamorphism. The Akdzhon Group is divided into two contrasting metamorphic formations, the structurally lower Makbal Formation and the upper Neldy Formation.

The Neldy Formation is mainly composed of garnet-phengite schists and chlorite-carbonate rocks, along with minor metaquartzites and marbles. Amphibolites and garnet amphibolites occur in the garnet-phengite schists as lenses or blocks up to 50 m across. Eclogites preserved in the cores of the garnet amphibolite bodies. Garnet amphibolite consists mainly of amphibole (magnesiohornblende, ferropargasite, ferrotschermakite, tschermakite, barroisite, actinolite), garnet and chlorite, with minor amounts of quartz, epidote and albite. Accessory minerals are paragonite, titanite and calcite. A schistosity is defined by preferred orientation of amphibole.

Garnets in the garnet amphibolite are rich in almandine (X_{Alm} 0.35-0.64), with variable amounts of spessartine (X_{Sps} 0.00-0.20), grossular (X_{Grs} 0.27-0.61) and pyrope (X_{Prp} 0.01-0.07) compositions. Garnet displays a compositional zoning, in which decrease X_{Sps} (0.20-0.04), increases X_{Alm} (0.35-0.60), X_{Grs} (0.31-0.62) and slightly increase X_{Prp} (0.01-0.03) from the core to the rim and contain inclusion of paragonite, titanite, chlorite, epidote and amphibole (actinolite, magnesiohornblende). The garnets are partly replaced by chlorite and aggregates of amphibole (ferrotschermakite, barroisite), chlorite and quartz along the cracks. Amphiboles in the matrix are zoned with magnesiohornblende and barroisite cores to ferrotschermakite and tschermakite rims and contain inclusions of titanite and quartz.

Based on the texture and mineral composition, we consider that the prograde stage probably stable in the epidote-amphibolite facies condition due to the existing of barroisitic amphibole and epidote along with garnet, paragonite, albite and chlorite. The tschermakitic rim of matrix amphibole suggests that the peak stage probably stable in the amphibolite facies conditions. The expecting metamorphic condition of the garnet amphibolite from the Neldy Formation corresponding with peak *P-T* conditions of 610-620 ℃ and 14-16 kbar for the garnet amphibolite from the Makbal complex (Rojas-Agramonte *et al*., 2013).

The stress-strain history of metamorphic sole: the case study of Greece, Turkey, Oman and Andaman islands

HOSHINO, Kenta[1*]

[1]Shizuoka University, Graduate School of Science

Metamorphic sole is formed by intra-oceanic thrusting and is found in some locations around the world. Greece, Turkey, Oman and Andaman islands are Tethys type ophiolite exposured area. The microboudin method, which is palaeostress analysis, is based on the proportion of boudinaged mineral grains with respect to applied differential stress. In this study, we used columnar minerals bearing metacherts from four areas and examined the value of palaeodifferential stress. The microboudin method revealed the value of palaeodifferential stress is 3.3˜24.8 MPa and we got stress-strain curve by using strain reversal method. The stress-strain curve indicate the stress history. Palaeodifferencial stress increased until the end of deformation in all samples. This result show that peak P-T condition and peak differencial stress are not simultaneous.

Late Cretaceous and Paleogene nappe tectonics in the forearc regions of Southwest Japan

ONO, Akira[1*]

[1]none

Nappe tectonics occurred at many times in the Paleogene and late Cretaceous forearcs of Southwest Japan. Upper parts of the crust moved toward trench by the nappe tectonics (Figures A and B). Actually the Atokura and Ryoke Nappes are observed in the northern margin of the Kanto Mountains although most of the nappes were eroded. The Atokura Nappe is mainly composed of Permian granites, mid-Cretaceous granitic and metamorphic rocks, late Cretaceous Atokura Formation, early Paleogene Yorii Formation and late Cretaceous pyroclastic rocks. The Ryoke Nappe mainly consists of late Cretaceous granitic and metamorphic rocks. The Permian granitoids are geological bodies of the Kinshozan-South Kitakami Belt. The mid-Cretaceous granitic and metamorphic rocks were geological members of the Higo-Abukuma Belt. The late Cretaceous granitic and metamorphic rocks were distributed in or near the Ryoke Belt. These various rocks were located in the early Paleogene forearc (Figure B) and were removed by nappe tectonics (Ono, 2011, Abs. Geol. Soc. Japan, Meeting, p. 196).

It is important to reveal the tectonics of the lower crust when the upper crust of about 5km in thickness was moved as a nappe toward trench. The author postulates that the lower crust moved toward mantle. The surface layer of the crust moves as a nappe and the lower crust flows towards the mantle. A thrust is assumed near the base of the lower crust. Figure C shows directions of the movements of crustal materials. Tectonics like this has been repeated in late Cretaceous and Paleogene and almost all the mid-Cretaceous Higo-Abukuma metamorphic rocks were eliminated. The Ryoke Belt was also partly removed after the nappe tectonics.

The tectonics described above is consistent with the geological structure near the Median tectonic Line where the Ryoke Belt is directly in contact with the Shimanto Belt in the central part of the Kii Mountains. In this context, Ryoke granitic and metamorphic rocks are in contact with Sanbagawa metamorphic rocks from surface to lower crust according to the crustal section of Southwest Japan (Ito and Sato, 2010, Journal of Geography, 119, p.235). It is difficult to find a crustal layer which was situated in the deep parts of the Higo-Abukuma and Kinshozan-South Kitakami Belts in the crustal section.

First-principles calculations of the structure of MgSiO3 melt at high temperature and high pressure

MATSUI, Masanori[1*]

[1]School of Sci., Univ. of Hyogo

Crystals and melts with MgSiO3 composition are important constituents of the Earth's lower crust and mantle. Therefore an accurate knowledge of their structural and elastic properties at high temperatures and high pressures is crucial to investigate the chemical and physical structures, and the conditions of formation and evolution of the Earth. However, reliable experimental data under geophysically relevant conditions are generally lacking for MgSiO3 melt, mainly due to the difficulty in obtaining such data at the combined high temperature and high pressure found in the Earth's interior. Here we use the first-principles molecular dynamics (FPMD) method to study the structures and elastic properties of MgSiO3 melt at high temperatures and high pressures.

All calculations were performed with the Vienna Ab Initio Simulation Package VASP (Kresse and Furthmuller, 1996). The projector-augmented wave (PAW) method was used in the local density approximation (LDA) for the exchange-correlation functional (Blochl, 1994; Kresse and Joubert, 1999). FPMD calculations were carried out in the canonical ensemble (constant temperature T, constant volume V, and constant number of atoms N in the system) using cubic basic cells. N was taken to be 160 (32 MgSiO3) throughout this study. After annealing the system sufficiently at 4000 K, and then 3000 K, we fixed V at 38.54 cm3/mol and T at 2000 K to calculate the interference function S(Q), where Q is the length of scattering vector, and the radial distribution function (RDF) for each atom pair. We found FPMD calculated S(Q) compares reasonably well with the observed data from X-ray analyses at 1973 K by Waseda and Toguri(1990). The FPMD predicted average nearest neighbor bond distances r(ij), and coordination numbers n(ij) between atoms i and j are also compared well with the data by Waseda and Toguri(1990), except the r(MgO) distance, in which the FPMD value of 1.97 A is much shorter than the value [2.12(1) A] by the X-ray analyses. We further apply the FPMD technique to investigate the temperature and pressure dependencies of the structure of MgSiO3 melt.

Forsterite-$MgSiO_3$ liquid interface : molecular dynamics perspective

NORITAKE, Fumiya[1*] ; KAWAMURA, Katsuyuki[1]

[1]Okayama University

Knowledge about the viscosity and permeability of partial molten rocks is important to understand the thermal history of the Earth and volcanisms. For understanding those obtained by experiments and estimating the physical properties at extreme conditions those are difficult to reproduce in laboratory experiments, the knowledge about structure and properties of silicate crystal-liquid interfaces is necessary. The properties of melt as sandwiched thin films are considered as being different with ones in bulk melts by the effect of crystal surface. For instance, lateral self-diffusivity of water to crystal surfaces shows different from bulk one in the case of water-brucite surface (Sakuma et al. 2003), water-muscovite mica surface (Sakuma and Kawamura, 2009). The dynamic property anomalies on solid - liquid surfaces affect properties of bulk rock such as permeability (Ichikawa et al. 2001).

In this study, structure and properties of the forsterite-$MgSiO_3$ liquid interfaces are investigated by using molecular dynamics simulations. It is essential to know the structure and physical properties of forsterite-$MgSiO_3$ liquid interfaces since forsterite is the liquidus mineral of primordial magmas.

Molecular dynamics simulations were performed with NPT ensemble using MXDORTO code (Sakuma and Kawamura, 2009). The initial structure is a 21440 atom system in which a sheet of MgSiO3 liquid consist of 8000 atoms (˜5 nm) is sandwiched between (010) surfaces of forsterite(Pbnm) and 43440 atom system in which a sheet of MgSiO3 liquid consist of 30000 atoms (˜20 nm) is sandwiched between (010) surfaces of forsterite. Firstly we calculated equilibrated MgSiO3 liquid film in vacuum starting with a randomly generated structure and randomly generated velocities of atoms through 0.5 ns (1,000,000 steps) at 1973 K and quench to 300 K. Secondly we calculated a bulk forsterite crystal with 13440 atoms ($11*5*8$ unit cells of forsterite(Pbnm)) starting with a given experimental crystal structure which was obtained by the experiment [5] and with randomly generated velocities of atoms and then cut along (010) surface. Finally we combined forsterite cut along (010) surface and MgSiO3 liquid film. Under maintaining isobaric and isothermal conditions, we performed the relaxation of 0.5˜1.5 ns. Then the statistical averages of the structure and physical properties were obtained from the velocities and coordinates of each atom in the simulations through 500 ps. The function of inter-atomic potential model was same as used in our previous work (Noritake et al. 2012).

By these simulations, characteristic structures in the forsterite-$MgSiO_3$ liquid interface are observed. The layered structure of alternated crystal surface, Si-rich and Mg-rich layers in the crystal-liquid interface was observed. The layered structure was formed by energy difference between Si-O semi-covalent bonds and Mg-O ionic bonds. Si-O-Si bridging and free oxygen atoms are excessively formed and in the near surface since the energy of Si-O bonding is much lower than that of Mg-O bonding. The difference of layered structure by thickness of MgSiO3 liquid film might be caused by the difference of the degree of freedom of configuration in liquid film. The two-dimensional diffusivity of oxygen atoms is controlled by two factors. The one is the thickness of liquid film that decreases oxygen diffusivity with decreasing the film thickness because of decrease of degree of freedom of configuration in liquid film. The other is composition of sliced layer where oxygen diffusivity increases with increasing the Mg/Si ratio since Si-O bonding is much stronger than Mg-O ones.

Phase transitions in Zn_2SiO_4: first-principles study

KANZAKI, Masami[1*]

[1]Inst. Study Earth's Interior, Okayama University

Recent experimental study (Liu et al., PCM, 40, 467, 2013) suggested that high-pressure phases of III and IV in Zn_2SiO_4 could be retrograde phases transformed during decompression. In order to check stabilities of these phases under pressure, and to find original high-pressure phases, density functional theory total energy calculations of 12 phases at 0 K have been conducted.

Three pressure-induced "phase transitions" during structural optimization were observed: phase II to spinel structure, phase III to a new high-pressure phase, and phase IV to Na_2SO_4 III-type structure. Phase III, having tetrahedral olivine structure, exhibited extraordinary high compressibility, which is due to large volume reductions in vacant octahedral sites corresponding M1 and M2 sites in olivine structure. Calculated enthalpies of the phases at 0 K confirmed that phase III and IV are not stable at any pressure. It also suggested that Na_2SO_4 III and II phases will be stable phases replacing phase III and IV, respectively.

A new high pressure phase of Fe2SiO4 and the relationship between spin and structural transitions

YAMANAKA, Takamitsu[1*] ; KYONO, Atsushi[2] ; NAKAMOTO, Yuki[3] ; KHARLAMOVA, Svetlana[1] ; STRUZKIN, Viktor[1] ; MAO, Ho-kwang[1] ; HEMLY, Russell[1]

[1]Carnegie Institution of Washington Geophysical Laboratory, [2]Division of Earth Evolution Sciences, Life and Environment Sciences, University of Tsukuba, [3]Center for Quantum Science and Technology Under Extreme Conditions, Osaka University

A structural change in Fe_2SiO_4 spinel (ringwoodite) has been found by synchrotron powder diffraction study and the structure of a new high-pressure phase was determined by Monte-Carlo simulation method and Rietveld profile fitting of x-ray diffraction data up to 64 GPa at ambient temperature. A transition from the cubic spinel structure to a body centered orthorhombic phase (I-Fe_2SiO_4) with space group Imma and Z=4 was observed at approximately 34 GPa. The structure of I-Fe_2SiO_4 has two crystallographically independent FeO_6 octahedra. Iron resides in two different sites of six-fold coordination: Fe1 and Fe2, which are arranged in layers parallel to (101) and (011), and very similar to the layers of FeO_6 octahedra in the spinel structure. Silicon is located in the six-fold coordination in I-Fe_2SiO_4. The transformation to the new high-pressure phase is reversible under decompression at ambient temperature. A martensitic transformation of each slab of the spinel structure with transition vector $<$1/8 1/8 1/8 $>$generates the I-Fe_2SiO_4 structure. Laser heating of I-Fe_2SiO_4 at 1500 K results in a decomposition of the material to rhombohedral FeO and SiO_2 stishovite.

Fe K beta x-ray emission measurements at high pressure up to 65GPa show that the transition from a high spin (HS) to an intermediate spin (IS) state begins at 17 GPa in the spinel phase. The IS electron spin state is gradually enhanced with pressure. The Fe2+ ion at the octahedral site changes the iron radius under compression from 0.78 A at the high-spin state to 0.61 A at the low spin, which results in the changes of the lattice parameter and the deformation of the octahedra of the spinel structure. The compression curve of the lattice parameter of the spinel is discontinuous at approximately 20 GPa. The spin transition induces an isostructural change.

Synchrotron Mössbauer spectroscopy on Fe_3S, FeO and natural almandine

KAMADA, Seiji[1*] ; HIRAO, Naohisa[2] ; HAMADA, Maki[3] ; SUZUKI, Nanami[1] ; OHTANI, Eiji[1] ; OHISHI, Yasuo[2] ; MASUDA, Ryo[4] ; MITSUI, Takaya[5]

[1]Tohoku Univ., [2]JASRI, [3]School of Nature system, College of Science and Engineering, Kanazawa University, [4]Research Reactor Institute, Kyoto Univ., [5]JAEA

The Earth's core is considered to be composed of an iron alloy with light elements since its density is smaller than that of pure iron under core conditions (e.g., Birch, 1964; Dubrovinsky et al., 2000). Although there are many candidates for these elements, such as H, C, O, Si, and S, sulfur in particular has been considered as one of the most plausible candidates. This is because it is depleted in the mantle, suggesting that it exists in the Earth's core (Murthy and Hall, 1970), and iron sulfides are found universally in iron meteorites, i.e., analogues of the Earth's core. Although the content of sulfur in the Earth's core is not known precisely, the sulfur content in the core is estimated to be at least a few wt% based on cosmic element abundances (McDonough, 2003) and high pressure partitioning experiments (e.g., Hillgren et al., 2000).

Since sulfur is one of the most plausible light elements, a compressibility and phase diagram in the Fe-FeS system has been studied (e.g., Campbell et al., 2007; Chen et al., 2007; Fei et al., 2000; Kamada et al., 2010; Li et al., 2001; Seagle et al., 2006). According to previous studies, Fe_3S is stable from 21 GPa and at least up to 200 GPa. Therefore, Fe_3S can be one of a candidate of the inner core materials. In addition, a synchrotron Mössbauer spectroscopy (SMS) and X-ray emission spectroscopic studies on Fe_3S revealed a spin transition and magnetic transition between 20 and 25 GPa (Lin et al., 2004; Shen et al., 2003). It also showed an abnormal evolution of a and c axes with increasing pressure (Chen et al., 2007).

Synchrotron Mössbauer spectroscopy is a good probe of a small sample under high pressure to investigate magnetic properties and electronic states of Fe of core and mantle minerals. An energy domain Mössbauer spectroscopic system has been recently developed at the BL10XU, SPring-8. We have measured Mössbauer spectra from Fe_3S and FeO under high pressure and a natural almandine at ambient pressure.

A powder mixture was made from ^{57}Fe (96.63%, ISOFLEX) and FeS (99.9%, RAREMETALLIC co., LTD.) with a ratio of Fe:S=75.0:25.0 (in at%). A foil was made from the mixture by a cold compression using a diamond anvil cell (DAC) and loaded into a sample chamber. ^{57}Fe enriched Fe_3S was synthesized from the powder mixture in a DAC at 30 GPa and 1350 K. The synthesis of Fe_3S was confirmed by X-ray diffraction patterns at BL10XU, SPring-8. ^{57}FeO was made by reducing from $^{57}Fe_2O_3$ (ISOFLEX) at ambient pressure and high temperature. A pellet was made from ^{57}FeO powder and loaded into a sample chamber of a DAC. We also measured Mössbauer spectra of a natural almandine ($Py_{15.7}Alm_{78.6}Gros_{4.4}Sp_{1.3}$, Idaho, USA). The energy of used X-ray for Mössbauer spectroscopy was 14.4125 keV.

We have measured Mössbauer spectra of Fe_3S during decompression at 5, 15, 20, 25, and 30 GPa and room temperature at BL10XU and BL11XU. At BL10XU, those of FeO and the almandine were obtained at 200 GPa and ambient pressure, respectively. The magnetic transition in Fe_3S was observed between 20 and 25 GPa, which is consistent with Lin et al. (2004). We observed doublet peaks from FeO. An evidence of Fe^{3+} in the almandine was not detected in this study. We will report the results of the Mössbauer spectra based on the newly developed system at BL10XU, SPring-8.

Temperature dependence of Fe^{3+}, Al and Ga distributions and local domain structure in synthetic Ca-clinopyroxene

AKASAKA, Masahide[1*] ; HAMADA, Maki[2] ; NAGASHIMA, Mariko[3] ; EJIMA, Terumi[4]

[1]Dep. Geoscience, Shimane Univ., [2]School of Nature system, Kanazawa Univ., [3]Dept. Earth Sci., Yamaguchi Univ., [4]AIST

Distribution of Fe^{3+}, Al^{3+} and Ga^{3+} among octahedral and tetrahedral sites in synthetic esseneite ($CaFeAlSiO_6$)- and $(CaFe^{3+}GaSiO_6)_{90}(CaGa_2SiO_6)_{10}$-clinopyroxenes at 800 and 1200 ℃ were investigated using ^{57}Fe Mössbauer and X-ray Rietveld methods to find a relation between site occupancies of trivalent cations at the octahedral and tetrahedral sites and ionic sizes of trivalent cations. The esseneite was synthesized from oxide mixture using sintering technique at 1200 ℃ in air. The $FeGaTs_{90}GaTs_{10}$-Cpx was crystallized from glass starting material at 1200 ℃ in air. The Cpxs synthesized and those annealed at 800 ℃ were analyzed using ^{57}Fe Mössbauer spectroscopic and X-ray Rietveld methods. In the synthetic esseneite, $^{VI}Fe^{3+}$:$^{IV}Fe^{3+}$-ratio at 800 ℃ was determined as 82(1):18(1) by Mössbauer method and 78.2(5):21.8(5) by Rietveld method, whereas, at 1200 ℃, 79(1):21(1) by Mössbauer method and 77(1):23(1) by Rietveld analysis. The resulting Fe^{3+} populations at octahedral M1 and tetrahedral T sites in the synthetic esseneite are Fe^{3+}0.782(5)-0.82(1) apfu and 0.218(5)-0.18(1) apfu, respectively. In the synthetic Fe^{3+}-Ga-Cpx, $^{VI}Fe^{3+}$:$^{IV}Fe^{3+}$-ratio at 800 ℃ was 74(3):26(2) (Mössbauer analysis data) and 78(1):22(1) (Rietveld analysis data), while, at 1200 ℃, 71(3):29(1) (Mössbauer analysis data) and 67(1):33(1) (Rietveld analysis), which results in populations at the octahedral M1 and tetrahedral T sites of $[Fe^{3+}_{0.67(1)-0.70(1)}Ga_{0.33-0.30}]^{M1}[Si_{1.0}Fe^{3+}_{0.23-0.20}Ga_{0.77-0.80}]^{T}$ (O = 6) at 800 ℃, and $[Fe^{3+}_{0.64(1)-0.60(1)}Ga_{0.36-0.40}]^{M1}[Si_{1.0}Fe^{3+}_{0.26-0.30}Ga_{0.74-0.70}]^{T}$ at 1200 ℃. This result indicates the temperature dependence of Fe^{3+}, Al^{3+} and Ga^{3+} distributions between M1 and T sites. However, it is evident that, even at different temperatures, distributions of Fe^{3+}, Al^{3+} and Ga^{3+} between M1 and T sites are well correlated with the ratio of ionic radius of larger Fe^{3+}-cation against smaller Al^{3+} and Ga^{3+}, as Akasaka et al. (1997) indicated. Another finding in this study is the splitting of a ^{57}Fe Mössbauer doublet by Fe^{3+} at M1 site into two doublets. This indicates existence of short-range domain structure by two kinds of M1 sites with slightly different distortions, which cannot be detected by X-ray diffraction.

Phase Transformation of Zirconium under High P-T Conditions

ONO, Shigeaki[1*]

[1]JAMSTEC

The behavior of zirconium metal under high pressures is important in the community of the high-pressure study, because changes in resistivity due to the phase transformations of zirconium (Zr) are used as pressure calibration points in the high-pressure experiments. Zirconium metal, which shows the hcp structure at ambient conditions, is known to transform to the bcc structure (beta phase) above 1135 K at ambiant pressure. With increasing pressure, phase transformations to a hexagonal structure (omega phase), at the pressure around 5 GPa and to a bcc structure around 30 GPa have been observed at room temperature. The formation of the high-pressure phases is concerned with changes in the electronic structure. Recent investigations for the phase transformation from the hexagonal to the bcc structures at high temperatures (Zhang et al. 2005 and 2007) were inconsistent with previous study at temperatures around the room-T (Xia et al. 1991). Therefore, we reinvestigated the transformation pressure in zirconium metal.

The starting material used in this study was polycrystalline Zr. High-pressure X-ray diffraction experiments were carried out in an external heated diamond anvil cell. The small sample sandwiched between pellets of NaCl powder was loaded into a hole that had predrilled into a rhenium gasket. The heating temperature was up to 800 K, and was recorded using the R-type of thermocouples. The sample was probed using angle-dispersive X-ray diffraction, located on the synchrotron beam lines, at NE1A of the Photon Factory. Details of the synchrotron X-ray experiments have been described elsewhere (e.g., Ono et al. 2005). The angle-dispersive X-ray diffraction patterns were obtained on the imaging plate of an X-ray data collection system (Rigaku, RAXIS). The pressure was calculated from the NaCl unit cell volume using the equation of state (EOS) for NaCl, as developed by Ono (2010).

The boundary from the omega phase to the bcc phase was determined at high temperatures (300 - 800 K). Our results were in good agreement with those reported in previous room-temperature study. The gradient of dP/dT of the boundary was negative. However, the gradient observed in our experiments was 2-3 times more negative than that reported by previous high-temperature experiments (Zhang et al. 2005 and 2007). Our new data indicated that the difference in the stress conditions of the sample led to the discrepancy of the gradient of dP/dT slope in previous studies.

Crystal structure analysis of a new high-pressure strontium silicate

SEKINE, Keisuke[1] ; ISHII, Takayuki[1] ; KOJITANI, Hiroshi[1*] ; AKAOGI, Masaki[1]

[1]Dept. of Chemistry, Gakushuin University

$SrSiO_3$ is an analog material to $CaSiO_3$ which is an important component of the Earth's crust- and mantle-constituting minerals. High-pressure phase relation experiments in $SrSiO_3$ showed that δ'-$SrSiO_3$ is stable up to about 10 GPa and decomposes into $BaGe_2O_5$-III -type $SrSi_2O_5$ + larnite-type Sr_2SiO_4 between 14 and 20 GPa (Kojitani et al., 2005). Then, hexagonal perovskite-type $SrSiO_3$ becomes stable above about 20 GPa (Yusa et al., 2005). However, phases except for larnite-type Sr_2SiO_4 appearing in the pressure range between 10 and 14 GPa have been unclear. In this study, crystal structure and composition of one of the unknown phases were determined.

A sample for single-crystal structure analysis was synthesized by heating a mixture of pseudowollastonite-type $CaSiO_3$ and SiO_2 cristobalite (mole ratio of 1:1) with a little amount of water at 12 GPa and 1200 ℃ for 90 min using a Kawai-type multi-anvil high-pressure apparatus. A single-crystal sample with 120x80x60 μm was used for the single-crystal X-ray diffraction measurement. 953 reflection data were analyzed using the SHELX-97 software. Composition analysis of the high-pressure phase was performed using SEM-EDS.

The composition analysis showed that the new high-pressure phase had a composition of $Sr_4Si_9O_{22}$. The single-crystal structure analysis suggests the monoclinic crystal system with the space group of $C2/m$. Lattice parameters were determined to be a = 13.3765(4) $\AA$, b = 5.2321(2) $\AA$, c = 11.6193(6) $\AA$, β = 113.976(4)deg. R factor was 1.25%. The framework of the obtained crystal structure consists of two layers by corner-sharing single chains of edge-shared SiO_6 octahedra or SiO_5 rhombic pyramid polyhedra and by corner-shared SiO_4 tetrahedra and SiO_6 octahedra. It should be mentioned that this structure includes the SiO_5 rhombic pyramids which are very rare in silicates. Strontium ions in the structure are arranged between the two layers and are coordinated by seven oxygens. The structure of δ'-$SrSiO_3$ consists of four-membered rings of SiO_4 tetrahedra and strontium ions coordinated by seven oxygens. On the other hand, $BaGe_2O_5$-III type $SrSi_2O_5$ has a framework by corner-shared SiO_6 octahedra and SiO_4 octahedra and coordination number of Si^{2+} is 12. The crystal structure determined in this study is consistent with the fact that its density would be between those of the lower-pressure and higher-pressure phases.

Heat capacity and entropy measurements by PPMS for high-pressure phases in TiO2 and MnSiO3

AKAOGI, Masaki[1*] ; KOJIMA, Meiko[1] ; FUKAI, Aya[1] ; KOJITANI, Hiroshi[1]

[1]Dept. of Chemistry, Gakushuin University

Thermodynamic properties of high-pressure minerals are widely used to calculate phase relations at high pressures and high temperatures and to compare with the properties by the first-principles calculations. Standard entropy, S298.15, is determined by integrating Cp/T in the temperature range between 0 and 298.15 K, where Cp is isobaric heat capacity and T is absolute temperature. To measure Cp at the temperature range, adiabatic calorimetry has been widely used with the highest precision. However, Cp of only a few high-pressure minerals have been measured so far, because a sample of more than several gram is required for the adiabatic calorimetry. Recently, low-temperature Cp measurement with thermal relaxation method using the Physical Properties Measurement System (PPMS) has been developed for samples of about ten milligram quantity. In this method, the sample is cooled with liquid helium and Cp is measured at about 2-310 K. By measuring the sample temperature change associated with applied heat pulse, thermal relaxation process is analyzed to obtain Cp. By this method, we measured Cp and determined S298.15 for Mg2SiO4 wadsleyite and ringwoodite, MgSiO3 akimotoite and perovskite, and SiO2 stishovite, in collaboration with Atake-Kawaji laboratory, Tokyo Institute of Technology. Very recently, we have installed the PPMS apparatus in the laboratory in Gakushuin University, and have investigated Cp and S of rutile-type and α-PbO2-type TiO2 and garnet-type MnSiO3.

Using a multianvil apparatus, rutile- and α-PbO2-type TiO2 phases were synthesized at 3 and 8 GPa, respectively, at 600-700 oC, and MnSiO3 garnet was made at 15 GPa and 1000 oC. All the cylindrical samples were polished and fixed with grease on the stage in the PPMS. The Cp measurements in this study were performed at 2-308 K using the polycrystalline samples of 10-21 mg. The Cp measured for α-Al2O3 (NBS SRM-720) by the PPMS apparatus were consistent within experimental errors with those measured by adiabatic calorimetry by Ditmars et al. (1982).

The measured Cp of rutile-type TiO2 were in good agreement with those by previous studies, and the obtained S298.15 was 50.10 J/molK. Our Cp data of α-PbO2-type TiO2 were almost consistent with those with PPMS measurement by Yong et al. (2014), but substantially smaller than those with DSC measurement by Manon (2008). The S298.15 of α-PbO2-type TiO2 was determined as 46.50 J/molK in this study. The Cp data of MnSiO3 garnet indicated an anomaly at 15 K probably due to magnetic transition, and S298.15 of 90.92 J/molK. High-pressure phase relations calculated using the above data are also reported.

Mechanisms of phase transitions of methane hydrate under high pressure

KADOBAYASHI, Hirokazu[1*] ; HIRAI, Hisako[1] ; HIRAO, Naohisa[2] ; OHISHI, Yasuo[2] ; OHTAKE, Michika[3] ; YAMAMOTO, Yoshitaka[3] ; KOJIMA, Yohei[1]

[1]Geodynamics Research Center, Ehime University, [2]Japan Association of Synchrotron Radiation Institute, [3]National Institute of Advanced Industrial Science and Technology

Methane hydrate (MH), called as " burning ice " , is expected to be a fruitful natural resource, at the same time, methane is rather effective greenhouse gas than carbon dioxide. It is also thought to be a major constituent of icy bodies in and outside the solar system. MH is composed of hydrogen-bonded host water molecules forming cages or frameworks that include guest methane molecules. Three phases of MH have been known so far. The low-pressure phase, sI, is stable below 0.8 GPa and it transforms into a hexagonal structure, sH, at 0.8 GPa and further transforms to a filled ice Ih (FIIhS) at 1.8 GPa at room temperature. At these phase transitions, release of water content is accompanied. As described above, the existence of phase transitions and the structures of transformed high-pressure phases have been clarified by the previous studies. However, transition mechanisms from the lower-pressure phase to individual high-pressure phases have been unresolved issue. In this study, high-pressure experiments were performed to investigate mechanisms of the phase transitions of MH at high pressures.

Clamp type and lever-spring type diamond anvil cells were used in this study. The pressure and temperature conditions were from 0.2 to 3.0 GPa and 300 K, respectively. Pressure measurements were made via a ruby fluorescence method. The initial samples of MH were prepared by ice-gas interface method. The samples were characterized via time-resolved X-ray diffractometry using synchrotron radiation at BL-10XU, SPring-8, and time-resolved Raman spectroscopy at GRC, Ehime University.

As for sI-sH phase transition, Raman spectroscopy revealed that 5^{12} cages of sI survived during the transition and that the 5^{12} cages remained as same 5^{12} cages of sH structure. And, $5^{12}6^2$ cages of sI changed to $4^3 5^6 6^3$ and $5^{12}6^8$ cages of sH. The results suggested that the sI-sH transition may follow a martensitic-like mechanism because of being maintaining 5^{12} cages unchanged in sH structure. On the other hand, at sH-FIIhS transitions, Raman spectroscopy detected abrupt collapse of all constituent cages in sH and release of fluid or solid methane molecules. And then, the framework of FIIhS was gradually reconstructed, absorbing the released methane molecules into the FIIhS structure. The results indicated that the sH-FIIhS transition follows reconstructive mechanism. The explanations may be reasonable, because the former transition is from a cage to another cage structure, and the latter one is from a cage structure to different framework of a filled ice structure.

Incorporation of NaCl into ice VI and ice VII under high pressure.

HIRAI, Hisako[1*] ; YAMASHITA, Fukunori[1] ; KAGAWA, Shingo[1] ; KADOBAYASHI, Hirokazu[1] ; OHISHI, Yasuo[2] ; YAMAMOTO, Yoshitaka[3]

[1]Geodynamics Research Center, Ehime University, [2]JASRI, [3]AIST

Icy satellites have been thought to contain a large amount of salts besides water ices. Ice exhibits a wide variety of forms consisting of hydrogen-bonded water molecules. More than sixteen stable and metastable forms have been reported so far. Liquid water can dissolve various kinds of solutes. Whereas, in the previous idea, when water crystallizes, the dissolved solutes are excluded, which results in formation of pure water ices. Recently, Frank et al. [1] and Komatsu et al. [2] reported that NaCl or other salts was incorporated into ice VI and/or ice VII. In these studies, however, it has been still unclear which ice can incorporate NaCl, and amount of salts incorporated and states of the salt in the ice structure have not yet been clarified. In this study, in order to understand possible incorporation of salts in to ice VI and VII structures, high-pressure experiments were performed with a system of H_2O-NaCl, a typical salt, at room temperature.

Lever-and-spring type diamond anvil cell was used. Pressure range examined was from 0.2 to 10 GPa. NaCl aqueous solutions with three concentrations, 1.5, 2.5, and 5.0 w%, were prepared as starting samples. Characterization was made by optical microscopy, X-ray diffractometry (XRD), and Raman spectroscopy.

Similar phase changes were observed for the samples with three different concentrations. The NaCl aqueous solutions finally crystallized to form iceVI above 1.6 GPa, although in case of pure water ice VI is formed at 1.0 GPa at room temperature. At the pressure range from 2.1 to 3.2 GPa, a new high-pressure phase, of which diffraction pattern was not explained by ice VI, ice VII, and solid NaCl, was observed. Above 3.2 GPa, ice VII and solid NaCl appeared. The high-pressure phase observed may correspond to a phase having a modified structure of NaCl-dihydrate reported by Nakayama et al. [3]. Unit cell volumes of ice VII calculated expanded larger than those of pure ice VII. The result was opposite sense to those by Frank et al, where the volumes decreased smaller than those of pure ice VII. The amounts of the volume expansion for 2.5 and 5.0 w% samples were larger than those of 1.5 w% samples. The volume expansions of the former two samples were almost similar. The results suggested that limitation of incorporation into ice VII is less than 2.5 w%. The O-H vibrational modes shifted to higher frequencies by 10 to 20 cm^{-1} and 5 to 10 cm^{-1} from those of pure ices for ice VI and ice VII, respectively.

All experimental results indicated that NaCl is incorporated both into ice VI and ice VII at room temperature. The amounts of incorporation were estimated to be up to 2.5 w%. Such large amount of incorporation of salt is expected to effect on physical properties of ices, which is important in inferring the interiors of icy bodies.

Legrandite, $Zn_2AsO_4(OH)H_2O$ and paradamite, $Zn_2AsO_4(OH)$, are zinc arsenate minerals and have a color between pale yellow and yellowish brown. Related minerals of legrandite and paradamite are adamite, $Zn_2AsO_4(OH)$, and so on with different structures. We performed the structure refinement of legrandite and paradamite Oujela Mine, Mapimi, Durango, Mexico, by (RAPID) RIGAKU single-crystal structure analysis system. We determined the hydrogen position by difference Fourier method. We revealed the detail hydrogen bond using bond valence calculation and hydrogen positions and compared crystal structures of these. The structure of legrandite is constituted by two AsO_4 tetrahedrons, ZnO_6 octahedron and three ZnO_5 trigonal dipyramids that have large unique distortion. AsO_4 tetrahedron, ZnO_5 trigonal dipyramid and ZnO_6 octahedron constitutes the unique framework. The structure of paradamite is constituted by AsO_4 tetrahedron and two ZnO_5 trigonal dipyramid that have large unique distortion. In legrandite, 5 coordination of trigonal dipyrmids have a distance to be expected from ionic radii but interatomic distance of Zn(3)-O(1) has extraordinary distance. Two OH groups bond to Zn1 and Zn2, Zn3 and Zn4 make the $ZnO_3(H_2O)_2$ trigonal dipyramid that is bonded to two H_2O group in legrandite. In paradamite, Zn1 and Zn2 make $ZnO_3(OH)_2$ and $ZnO_4(OH)$ trigonal dipyramid. Hydrogen atoms make a lot of hydrogen bonding in legrandite and paradamite. Crystal structure of legrandite has a tunnel structure continuous that is only parallel to c axis and similar structure is observed in paradamite only parallel to a axis. There are path of proton-conduction in these direction and we conjecture that these proton-conductivity have large anisotropy of one dimension.

Structure analysis of deuterated brucite at pressures to 3 GPa by pulsed neutron powder diffraction

OKUCHI, Takuo[1*] ; TOMIOKA, Naotaka[1] ; PUREVJAV, Narangoo[1] ; HARJO, Stefanus[2] ; ABE, Jun[3] ; WU, Gong[2]

[1]Institute for Study of the Earth's Interior, Okayama University, [2]Japan Atomic Energy Agency, [3]CROSS Tokai

Atomic-scale structures around hydrogen atoms in hydrous minerals may significantly change with increasing pressure, which affect thermodynamic stability, optical properties (Raman, IR, etc.), and transport phenomena of the relevant minerals. To directly observe such structure change around hydrogen atoms, we have conducted neutron diffraction experiments of deuterated brucite at high pressures to 2.8 GPa, using a high-resolution neutron powder diffractometer recently installed at J-PARC Materials and Life Science Experimental Facility. To discriminate subtle structure change of deuterium site positions with increasing pressure, the quality of observed diffraction patterns has been considerably improved from the corresponding previous studies by adopting a new-type experimental apparatus and facility. A newly-designed opposed anvil cell apparatus optimized for the pulsed neutron beam (Okuchi et al., High Pressure Research, 33, 777, 2013) was effectively coupled with the time of flight diffractometer TAKUMI, which was designed to have the resolution of delta-d / d ˜0.3% along with moderately-intense beam and low background (Harjo et al., Materials Science Forum, 524, 199). We used single crystal diamond anvls with culet diameter of 2 mm for sample compression along with deuterated glycerine pressure medium. The combination gives very high neutron transparency as well as high resolution to enable acurate structure refinements of tiny sample volume of the order of less than 1 mm^3. Through Rietveld refinements of the observed patterns, tilting of all OD dipoles in the compressed brucite toward one the three nearest-neighbor oxygen anions in the brucite structure was confirmed to be substantial at the observed pressure regime, suggesting the formation of pressure-induced hydrogen bonding. Therefore, at lower crust and mantle wedge conditions, this pressure-induced bonding may play an important role to constrain hydrogen into the relevant hydrous minerals.

Factors controlling barite-water distribution of selenium oxyanion

TOKUNAGA, Kouhei[1*] ; YOKOYAMA, Yuka[1] ; TAKAHASHI, Yoshio[1]

[1]Department of Earth and Planetary Systems Science, Graduated School of Science, Hiroshima University

Geochemical behavior of trace elements is controlled by their interaction with major minerals through ion exchange, sorption/desorption, and coprecipitation/dissolution processes, which govern the concentrations of trace elements in natural water. Especially, the coprecipitation process with mineral is potentially important because trace elements can be incorporated and immobilized in the crystal lattice at least until the minerals are dissolved. Previous studies showed that the partitioning behaviors of trace elements to minerals were controlled by many complex factors, such as crystal constraints of ion substitution, effects of complexation in the aqueous phase, rate of crystallization, and changes in temperature or pressure. For instance, Yokoyama [2011, 2012] demonstrated that, in the case of arsenic (As) and selenium (Se) incorporation into calcite, arsenate rather than arsenite is selectively incorporated into calcite, whereas selenite (Se(IV)) rather than selenate (Se(VI)) into calctite because of the high stabilities of calcium arsenate and calcium selenate complexes compared with those for arsenite and selenite. In this study, we focused on the distribution behavior of Se into barite to determine the factors controlling the partitioning behaviors of the trace elements to minerals at the molecular scale by X-ray absorption fine structure (XAFS). Our previous results suggested that the distribution behavior of Se into barite was controlled by two factors: the stability of the surface complex between barite and Se species (=chemical affinity) at the initial process and the stability of the ion substitution in the crystal structure (=structural affinity) for the subsequent process. In this presentation, the barite-water distributions of Se controlled by the structural affinity are highlighted.

The coprecipitation experiments were conducted to examine the influence of ion substitution structure on the distribution behavior of Se into barite as a function of the reaction time in term of the variation of barite morphology, total concentration, oxidation states, and coordination structure of Se in barite. The results showed that both total Se concentration and the Se(VI)/Se(IV) ratio in barite increased abruptly within first 24 hour and almost reached equilibrium after 24 hours. EXAFS analysis for the initial and aged samples showed that the coordination number of Se-Ba in the aged sample is larger than that in the initial stage. The results indicates that a larger amount of Se(VI) than Se(IV) was incorporated from adsorption site on the surface into the barite crystal by substituting sulfate site because of their high crystallinity that can excludes Se(IV) to a larger degree than Se(VI) due to the similar structure of sulfate ion and sulfate. Based on these results, it is considered that the Se(VI) was preferentially incorporated into barite due to its high structural affinity than Se(IV), thus, the Se(VI)/Se(IV) ratios in barite relatively increased through crystallization. These results suggest that structural affinity is an important factor for controlling the distribution behavior of Se between barite and water.

Mid- and far-infrared spectroscopy for Li-Al-Mg micas

MAKIO, Masato[1*] ; ISHIDA, Kiyotaka[1]

[1]Graduate School of Social and Cultural Studies

Mica is a one of the major rock forming minerals and widely spread in the earth crust. The hydrothermal synthetic Li-Al-Mg trioctahedral mica series were measured by mid- and far-infrared spectroscopy and X-ray powder diffraction Rietveld refinement: (a)Trilithionite: $K(Li_{1.5}Al_{1.5})$ $(AlSi_3)O_{10}F_2$- Phlogopite: $KMg_3(AlSi_3)O_{10}F_2$, (b)Polylithionite: $K(Li_2Al)Si_4O_{10}F_2$- Tainiolite: $K(LiMg_2)Si_4O_{10}F_2$, (c)Polylithionite- Eastonite: $K(Mg_2Al)(Al_2Si_2)O_{10}F_2$ and OD- F Mg- Masutomilite: $K(LiAlMg)AlSi_3O_{10}(F, OD)_2$.

The Li-Al-Mg micas synthesized hydrothermally at 600- 650 ^{o}C and 150- 200MPa in cold-seal externally heated Tuttle-type vessels. The starting materials were mixed and then sealed in Pt/Au capsules with 20 wt % D_2O (99.9 % in purity). X-ray Rietveld analysis was done using Rietan- 2000 (Izumi and Ikeda 2000). Mid- and far-infrared spectra were measured with JASCO FTIR- 620 spectrometer. Each sample was scanned 256 times in an evacuated sample-chamber.

All samples could refine monoclinic, C2/m (1M polytype). In the 250- 50cm^{-1} far-infrared region , three kinds of bands are observed: these bands due to an in- plane tetrahedral torsional band between 170- 150cm^{-1}, an interlayer K- O_{inner} stretching band between 120- 140 cm^{-1} and K- O_{outer} stretching band between 90- 100 cm^{-1}. With increasing<K- O_{inner}>, K- O_{inner} stretching band shifts higher frequency, while with increasing <K- O_{outer}>, K- O_{outer} stretching band shifts lower frequency. In the 650- 250cm^{-1} mid- and far-infrared region, two parts of bands are observed. With increasing $^{[4]}$Si→Al, (Si,Al)- O deformational band in the range of 600- 400cm^{-1} became broad and merged.

Cesium (Cs) Sorption Experiments into Weathered Biotite in Fukushima

KIKUCHI, Ryosuke[1*] ; KOGURE, Toshihiro[1]

[1]Earth and Planetary Sci., Univ. Tokyo

After the accident of Fukushima Daiichi nuclear power plant in March 2011, radioactive contamination of the soil around the plant has become an urgent problem in Japan. Previous studies proposed that weathered micaceous minerals present favorable sorption environments for Cs^+. Because the contaminated areas in Fukushima are mainly covered with weathered granite soil, weathered biotite with hydrated (vermiculite) interlayers is abundant. Hence basic understanding of Cs^+ sorption process into the biotite is important to find the recipe for decontamination of radiation. Some of previous studies reported that Cs^+ is adsorbed mainly at the frayed-edge sites of such micaceous crystals. However, other studies indicated that Cs^+ penetrates deeply inside the crystals, along the interlayer regions by ion-exchange. In this study, we performed Cs^+ sorption experiments using single-crystals of Fukushima weathered biotite with well-regulated edge surfaces, and considered the relationship between the weathering state of biotite and Cs^+ sorption property.

Fresh and two kinds of weathered biotite were collected from granodiolite of Abukuma granite body in Fukushima prefecture. For each sample, cross sections of $<$1 mm thick perpendicular to the basal planes were prepared. Surface damage formed by the mechanical grinding/polishing was removed by Ar^+ ion sputtering. These sections were immersed in 30 mL of CsCl aqueous solution of 2000 / 200 / 20 / 0 ppm for 24 hours at room temperature to incorporate Cs^+.

After the reaction, the surfaces of the sections were investigated using scanning electron microscopy (SEM) with energy dispersive X-ray spectroscopy (EDS). SEM-EDS with various acceleration voltage indicated that the concentration of the sorbed Cs^+ does not change in the depth direction of ˜several microns range. Cs^+ was apparently sorbed at 2000 ppm but not at 200 ppm for fresh biotite, whereas Cs^+ was sorbed at both concentrations in the weathered biotite. Back-scattered electron (BSE) images and EDS analysis showed preferred sorption of Cs^+ at the regions probably with dense vermiculite interlayers in the weathered biotite. Moreover, some specimens were processed into this foils using focused ion beam (FIB) and examined using scanning transmission electron microscopy (STEM). High-angle annular dark field (HAADF) imaging in STEM has visualized Cs^+-incorporated interlayer regions individually in the weathered biotite.

Pressure-induced phase transitions of vaterite, a metastable phase of calcium carbonate

MARUYAMA, Koji[1*] ; KOMATSU, Kazuki[1] ; KAGI, Hiroyuki[1] ; YOSHINO, Toru[2] ; NAKANO, Satoshi[3]

[1]Geochemical Research Center, Univ. Tokyo, [2]TIRI, [3]National Institute for Materials Science

1. Introduction

Calcium carbonate is one of the most common and ubiquitous minerals on the Earth's surface and plays an important role in global carbon cycle. There are many studies about high-pressure behavior of calcite and aragonite. At ambient temperature, calcite transforms to calcite II at about 1.5 GPa and to calcite III at about 2.0 GPa. The transition from aragonite to post-aragonite phase was observed at about 40 GPa. In contrast, no study has been reported on the high-pressure behavior of vaterite, which is a metastable phase of $CaCO_3$, and is known as a precursor material of more stable $CaCO_3$ polymorphs, calcite and aragonite. In this study, the high-pressure behavior of vaterite was investigated by in situ synchrotron X-ray diffraction (XRD) experiments using a diamond anvil cell.

2. Experimental method

In this study, vaterite was synthesized by mixing two aqueous solutions, 60 mM $CaCl_2$ aq. and 60 mM $NaHCO_3$ aq., kept at 30 degree C. The mixed solution was sealed in a plastic bottle and stirred for 10 min at 30 degree C, and then filtered using an aspirator, washed by pure water, and dried at about 130oC. The obtained white powder was identified as pure vaterite using powder XRD method.

High-pressure experiments were carried out using a diamond anvil cell (DAC). The synthesized vaterite and several tiny ruby crystals were loaded into a gasket hole together with helium as a pressure transmitting medium. The pressure was changed between 0-14 GPa, which was measured by the ruby fluorescence method. XRD patterns were measured at each pressure at room temperature. X-ray diffraction observations were carried out at room temperature using the synchrotron beam line of BL18C in the Photon Factory, Japan.

3. Results and discussion

XRD patterns recorded at pressures lower than 4.7 GPa indicated that the sample consists of vaterite only. At 4.7 GPa, main three peaks of vaterite were split and a peak assignable to calcite III appeared. The discontinuous changes in axial lengths were observed by refinement of lattice constants using a crystal structure model proposed by Le Bail et al. (2011). This change suggests a pressure-induced phase transition from vaterite to a high-pressure form (hereafter vaterite II). Change in the diffraction intensities suggested that vaterite II transformed to calcite III with increasing pressure up to about 9 GPa. At 12.9 GPa, new diffraction spots were observed. These spots were not explainable with the diffraction peaks from any polymorphs of $CaCO_3$. This implies that the new spots are derived from another high-pressure phase of vaterite (vaterite III). After decompression, the recovered sample was identified as a mixture of calcite and vaterite. These results indicate that the transition from vaterite II to calcite III is irreversible. In this study, new high-pressure phases of $CaCO_3$ (vaterite II and III) were discovered by high-pressure experiments of vaterite at ambient temperature.

Huge plastic deformation of SiO_2 glass at room temperature

WAKABAYASHI, Daisuke[1*] ; FUNAMORI, Nobumasa[1] ; SATO, Tomoko[2]

[1]Department of Earth and Planetary Science, University of Tokyo, [2]Department of Earth and Planetary Systems Science, Hiroshima University

Covalent solids are known to be hard but brittle. Moreover, glasses do not deform plastically by dislocation movement seen in crystals due to the lack of long-range order. However, SiO_2 glass, a highly covalent glass, has long been known to be densified up to about 20% by applying high pressure. This phenomenon is called permanent densification, which is some kind of phase transformation caused by the reconstruction of the network structure consisting of SiO_4 tetrahedra [e.g., Wakabayashi et al., 2011], and could be considered as plastic deformation in a broad sense. Recently, the differential strain of SiO_2 glass in its intermediate-range structure, corresponding to the first sharp diffraction peak, was measured under uniaxial compression by a radial X-ray diffraction method, in which X-rays irradiate the sample from a direction perpendicular to the compression axis (i.e., from a radial direction) [Sato et al., 2013]. In those measurements, very large differential strains were observed under pressure and surprisingly also after decompression. This residual strain may be attributable to the anisotropic reconstruction of the network structure (i.e., anisotropic permanent densification).

In this study, the change in size of bulk samples was measured for uniaxially-compressed SiO_2 glass to clarify whether SiO_2 glass undergoes plastic deformation in a narrow sense, i.e., without density change. X-ray diffraction measurements were also conducted in a wide Q-range with 50 keV monochromatic X-rays by irradiating the recovered sample from the radial direction to clarify whether a differential strain remains only in the intermediate-range network structure or also in the short-range SiO_4 tetrahedral structure. Pressures were generated by using a diamond-anvil cell. The starting material was in the form of a disk, and was adjusted to have an appropriate initial thickness to be compressed under uniaxial conditions, i.e., pinched directly by the two anvils, above a certain pressure. Three independent experiments were conducted with an argon pressure medium up to 20 GPa in run 1, 12 GPa in run 2, and 6 GPa in run 3. The change in size of sample was measured with an optical microscope. X-ray diffraction measurements were carried out at PF AR-NE1. All the experiments were conducted at room temperature.

In runs 1 and 2, the diameter of sample was found to increase significantly with pressure from 6-8 GPa, where uniaxial conditions were achieved, to the maximum pressure of each run without fracturing, and it became about 15% larger at 20 GPa than at 0 GPa. The macroscopic differential strain was about an order of magnitude larger than the microscopic differential strain reported in the previous study [Sato et al., 2013], suggesting that SiO_2 glass deformed plastically at room temperature. The X-ray diffraction measurements clarified that the recovered samples were in the fully densified state (about 20% densified). It was also revealed that a residual differential strain was observed only in the intermediate-range network structure and its magnitude was consistent with the previous study [Sato et al., 2013]. On the other hand, in run 3, the sample did not deform plastically by uniaxial compression from 2-3 GPa to 6 GPa. The X-ray diffraction pattern of the recovered sample was the same as that of the ordinary SiO2 glass. Permanent densification is known to begin at about 9 GPa under hydrostatic conditions [e.g., Wakabayashi et al., 2011], and it is suggested that permanently densified SiO_2 glass easily undergoes plastic deformation even at room temperature.

Shock compression of synthetic amino acid - silica gel complex modeling for comet nucreus

MURAI, Takuro[1] ; OKUNO, Masayuki[2*] ; OKUDERA, Hiroki[2] ; ARASUNA, Akane[1] ; MASHIMO, Tsutomu[3] ; CHEN, Liliang[3] ; MIZUKAMI, Tomoyuki[2] ; ARAI, Shoji[2]

[1]Graduate School of Kanazawa University, [2]Kanazawa University, [3]Kumamoto University

Some amino acids were found in comet coma particle and Murchison meteorite [1,2]. These reports may suggest a possibility that basic materials of primitive life on the earth were formed in the space and delivered to the earth.

Greenberg et al. (1997)[3] reported the almost comets are made of organic compounds, silicates and ice. On the other hand, silica gel contains a non crystalline SiO_4-$_n(OH)_n$ framework with water molecules. So, silica gel is a suitable model material for comet. In this study, in order to investigate the stability of amino acid (L-serine) in the comet nucleus during the impact to the earth, synthetic amino L-serine - silica gel complex materials were shock compressed and the structure change of the recovered samples were analyzed by X-ray diffraction measurements, IR and Raman spectroscopies. Shock compression experiments were performed at 8.2, 10.9, 19.7 and 26.9 GPa.

By Raman spectroscopic analyses, it was indicated that synthetic complex materials include two types of L-serine such as crystalline L-serine and hydrated L-serine. Obtained Raman spectra of shocked materials show the L-serine crystal was disappeared and hydrated L-serine molecules survived at 19.7 GPa of shock pressure. Therefore, the sample at 19.7 GPa includes only hydrated L-serine molecules. This may indicate that intermolecular hydrogen bonds of L-serine molecules may be broken by shock compression with water molecule.

The shock pressure of 19.7 GPa is consistent with the estimated impact pressure of about 19% comets to the earth reported by Blank et al. (1999) [4]. This fact may indicate that a possibility for the basic materials of primitive life on the earth were formed in the space and delivered to the earth.

Microtexture and formation mechanism of impact diamonds from the Popigai crater, Russia

OHFUJI, Hiroaki[1*] ; YAMASHITA, Tomoharu[1] ; LITASOV, Konstantin[2] ; AFANASIEV, Valentin[2] ; POKHILENKO, Nikolai[2]

[1]Geodynamics Research Center, Ehime University, [2]Siberian Branch of the Russian Academy of Sciences

Large meteoritic impact occasionally produces an extensive amount of diamond on the surface of the Earth [1, 2]. Popigai crater located in the north central Siberia is a typical example of such diamond-forming shock events and has recently been brought back into the spotlight due to its vast estimated reserves of the impact diamonds [2-4]. Authigenic impact diamonds occur in shocked graphite-bearing garnet-biotite gneisses that are found as inclusions in impact melt rocks, so-called tagamites and suevites. Popigai diamonds occur as irregular to tabular grains of 0.5-2 mm size (up to 10 mm) and usually show yellow, gray or black colors [3]. Electron microscopic (SEM and TEM) observations in previous studies described that they are polycrystalline aggregates of 0.1-1 μm grains and show a distinct preferred orientation along the [111], which is in a coaxial relation to the [001] of the original graphite source [2-4]. This crystallographic feature as well as the occasional coexistence of lonsdaleite, a metastable carbon polymorph, suggest the Martensitic phase transformation for the potential formation process of the impact diamonds from Popigai crater. However, the textural feature of the impact diamonds and its variation has not fully been examined. Here, we present the result of detailed microtextural observations of impact diamonds from the Popigai crater by transmission electron microscopy (TEM) and discuss the formation mechanism and condition in comparison with those of synthetic diamonds obtained by high pressure and high temperature experiments.

In total 10 diamond grains (7 transparent yellowish and 3 black samples) from the Popigai crater were studied. Each sample was first analyzed by a micro-focus XRD equipped with a Mo target and an IP detector. The results showed that transparent samples consist mostly of diamond and occasionally contain lonsdaleite, while black ones are a mixture of graphite, lonsdaleite and diamond, which are all in a coaxial relation as shown by 2D diffraction patterns collected in transmission geometry. Each sample was then transferred to a focused ion beam (FIB) system to cut out TEM foil sections perpendicular to the surface (of the tabular grains). TEM observation revealed that although all the samples commonly possess layered structures and preferred orientation (mostly along [111] of diamond), there are varieties in crystallite (grain) size (down to 10-20 nm) and degree of preferred orientation. Taking into account the similarity in texture and preferred orientation feature between the Popigai diamonds and synthetic diamond, the variation is likely derived from the small difference in crystallinity of the starting graphite sources and perhaps more significantly from the difference in shock temperature.

According to the shock features recorded in the silicate minerals of the diamond-bearing impactites, the threshold pressure for the onset of the graphite-diamond transformation is estimated to be 34-36 GPa [3]. However, our recent experimental synthesis [5] demonstrated that a similar phase assembly (mostly diamond + traces of lonsdaleite) and microtexture can be produced at much lower pressures of 15-25 GPa at $>$2000 ℃. The shock pressure as well as shock- and post-shock temperature accompanied with the formation of the Popigai crater might be needed to be reevaluated carefully to understand the real nature of the giant impact.

Melting and crystal growth textures developed in rapid heating and cooling of olivine fine particles

ISOBE, Hiroshi[1*] ; GONDO, Takaaki[1]

[1]Grad. Sch. Sci. Tech., Kumamoto Univ.

Olivine is one of the most common mineral in the solid Earth and chondritic meteorites. Olivine crystals show characteristic textures in chondrules depending on heating and cooling histories in chondrule formation processes at the early solar system. In this study, quick heating and cooling experiments of mixed olivine particles were carried out with a fine particles free falling apparatus (Isobe and Gondo, 2013). In the run products, characteristic melting and crystal growth textures controlled by phase relations, diffusion, and nucleation and growth behavior of olivine can be seen.

Starting material is mixed powder of natural olivine (Fo90), fayalite and an artificial olivine (Fo55). The typical diameter of the starting material particles is approximately 100 micron meters. Each particle is single crystal of olivine or mixture of two or three kinds of raw materials. Heating and cooling experiments are carried out in a high temperature furnace with mass flow controllers to regulate oxygen fugacity and total gas flow rate. Particles can be heated to 1400 degrees C within two seconds, are kept over 1400 degrees C approximately one second and quenched within a second. Maximum temperature has negative correlation to diameter of the particles, and cooling rate has positive correlation to the diameter depending on the falling velocity of the particles. Run products show spherical shape when the particles mostly melted, and are crystal fragments when the particles did not melt. The outside shape of the retrieved run products are observed with a scanning electron microscope. Inner textures of the particles are observed on polished section of the particles. Chemical compositions are also analyzed on the sections.

Fayalite grains are completely melted and Fo90 olivine grains are not melted by themselves concordantly with the phase relation of olivine. Internal textures of Fo55 olivine crystals show quick partial melting when the temperature reach solidus temperature. In the mixed olivine particles, relict crystals of Fo90 and Fo55 olivines dissolve to iron-rich melt derived from melting of fayalite. The dissolution of relict crystals produce steep chemical gradient at interface between crystals and melt.

Run products like barred olivine chondrules or melted cosmic spherules are produced from completely melted particles. In the particles including relict crystals, overgrowth textures from the relict crystals can be seen. Dendritic olivine crystals with regulated crystallographic orientation are developed in melted particles. Surface texture of melted particles may be affected by the dendritic olivine crystals. Oriented magnetite dendrites may also occur between olivine crystals when oxygen fugacity was in the magnetite stability field. Melting, nucleation and crystal growth processes in a few seconds can be discussed from the textures in the run products.

Temperature-dependent thermal expansivities of aluminum-free silicate melts and borosilicate melts

SUGAWARA, Toru[1*] ; KATSUKI, Junki[2] ; YOSHIDA, Satoshi[2] ; MATSUOKA, Jun[2] ; MINAMI, Kazuhiro[3] ; OCHI, Eiji[3]

[1]Akita University, [2]The University of Shiga Prefecture, [3]Japan Nuclear Fuel Limited

Thermal expansivities (dV/dT) of silicate melts are essential in a thermodynamic calculation of phase equilibira in magmatic system as a function of pressure and temperature and in a numerical simulation of flow and thermal structures in glass melting furnace. Previous studies have been suggested that the dV/dT of alumino-silicate melts (Lange, 1996; Potuzak et al., 2006) and magmatic silicate melts (Lange, 1997; Ghiorso and Kress, 2004) is a function of composition, but independent of temperature. On the other hand, it has been reported that the dV/dT of SiO_2-TiO_2-Na_2O melt (Liu and Lange, 2001) and 50SiO_2-25CaO-25MgO melt (Gottsmann and Dingwell, 2000) decrease with increasing temperature. Recently, we found that simulated-radioactive waste glass melt which has sodium-borosilicate composition also shows negative temperature-dependent dV/dT (Sugawara et al., 2013). We carried out density measurements for sodium-silicate melts ((100-x)SiO2-xNa2O, x=23 or 32.3 mol%), commercial soda-lime silicate melt (71SiO_2-6MgO-9CaO-14Na_2O, mol%) and borosilicate melts (66.6SiO_2-yB_2O_3-(33.33-y)Na_2O where y=8.3, 16.6, 25; 66.6SiO_2-(12.5+z)B_2O_3-(4.2-z)Al_2O_3-zCaO-(16.7-z)Na_2O where z=0 or 4.2 mol%). The temperature and compositional dependences of the dV/dT are discussed based on the new density data and the literature data.

The high-temperature density (dHT) measurement has been made by double-bob Archimedean method between 1173K and 1665K. The glass samples were annealed around glass transition temperature (Tg) for 6-396 hours and quenched. Then the density of annealed glasses at 298K (d298) and linear thermal expansivity (dL/L) were determined by Archimedean method and TMA. respectively. The densities of supercooled melt around Tg (dTg) were calculated from the d298 and the dL/L of glasses. Then, molar volume as a function of temperature and the dV/dT of melts were obtained by combining the dTg and the dHT.

The dV/dT values of all samples examined in this study show negative temperature dependence. In the sodium silicate melts, the temperature dependence of the dV/dT is remarkable when the SiO2 content increases from 50 to 67 mol%, while the dV/dT becomes close to zero as further increase in the SiO2 content. The negative temperature-dependent dV/dT observed in the 71SiO_2-6MgO-9CaO-14Na_2O melt can be reproduced by an additive sum of the dV/dT of 67.8SiO_2-32.2Na_2O, diopside (Gottsmann and Dingwell, 2000) and wollastonite (Potuzak et al., 2006) melts. High-temperature Raman spectroscopy for the SiO_2-Na_2O and SiO_2-Na_2O-MgO melts has been indicated that amount of Q4 species increases with increasing temperature and SiO_2 and MgO contents (Maehara et al., 2004, 2005). Therefore, the temperature dependent dV/dT for the sodium-silicate, commercial soda-lime silicate and diopside melts can be rationalized by an increase of rigid Q4 species at high temperature. The temperature dependence of the dV/dT is most remarkable in the 66.6SiO_2-8.3B_2O_3-25Na_2O melt among the borosilicate melts. The dV/dT decreases with replacement of Na_2O by B_2O_3 or CaO and of B_2O_3 by Al_2O_3, suggesting that partial molar dV/dT of B_2O_3 depends on temperature-induced coordination change of boron and their composition dependence (Wu and Stebbins, 2010).

Thermodynamic properties of Mg-postperovskite with Fe^{3+} and Al^{3+} dopant: an internally consistent LSDA+U study

WANG, Xianlong[1*] ; TSUCHIYA, Taku[1]

[1]GRC, Ehime University and ELSI, Tokyo Institute of Technology

Thermodynamic properties of $MgSiO_3$ perovskite (Pv) and postperovskite (PPv) with Fe and Al incorporation at high pressure and high temperature are important to understand the Earth's lower mantle (LM). The thermodynamic properties of Fe^{2+}, Fe^{3+}, and Al^{3+}-bearing Pv[1,2,3] and Fe^{2+}-bearing PPv[4] have been investigated in our previous works uniformally based on first-principles method combined with the internally consistent LSDA+U method and quasi-harmonic approximation (QHA). However, to date, effects of trivalent ions, Fe^{3+} and Al^{3+}, on the thermodynamic properties of PPv are still unclear. In this work, by using the same methods with previous works, the structural, electronic, magnetic, and thermodynamic properties of $(Mg,Fe^{3+})(Si,Fe^{3+})O_3$ and $(Mg,Fe^{3+})(Si,Al^{3+})O_3$ PPv at several pressures, from 0 GPa to 180 GPa, are investigated. Our results show that for $(Mg,Fe^{3+})(Si,Fe^{3+})O_3$ PPv, Fe^{3+} ions substituted at Mg and Si site respectively have the high and low spin state within the deep LM pressure range, while Fe^{3+} in $(Mg,Fe^{3+})(Si,Al^{3+})O_3$ PPv remains in the high spin state. Furthermore, separated phase between Fe_2O_3 and Al_2O_3 in PPv is found unfavorable.

Thermal expansion of $Ca(OD)_2$ at high pressure

NAGAI, Takaya[1*] ; SANO, Asami[2] ; IIZUKA, Riko[3] ; KAGI, Hiroyuki[3] ; HATTORI, Takanori[4]

[1]Faculty of Science, Hokkaido Universuty, [2]Japan Atomic Energy Agency, [3]Graduate School of Science, The University of Tokyo, [4]Materials and Life Science Division, J-PARC Center

$Ca(OH)_2$ is one of the important hydrous minerals to understand structural behavior at high pressure and high temperature, because this type of structure is a building unit in more complex hydrous phases such as chondrodite. It is surprising that only a few previous researches can be found on crystallography of $Ca(OH)_2$ in the conditions of simultaneously high pressure and high temperature. We gave an oral presentation about some preliminary results in this conference last year. We have continued to analyze the data carefully and will add some new information.

Deuterated samples were prepared via hydrothermal treatment with CaO fine powders and excess D_2O water in a Teflon lined stainless steel autoclave at 493 K for 4 days. After the hydrothermal treatment was completed, precipitates were filtered out, washed with D_2O water, and then dried at 383 K under vacuum for 3 hours. The products were confirmed to have the CdI2-type structure by conventional powder X-ray diffraction measurements and were checked to be deuterated by IR absorption spectra. Synchrotron X-ray diffraction experiments were performed at the beamline AR-NE5C, KEK, Japan in order to obtain cell parameters of $Ca(OD)_2$ at various P-T conditions from 2-4 GPa and 300-800 K. TOF neutron powder diffraction measurements of $Ca(OD)_2$ were carried out from 300 to 773 K at high pressure at the PLANET beamline in J-PARC, Japan. Pressure was estimated by comparing unit cell parameters with those obtained by synchrotron experiments.

All our TOF data obtained include only $Ca(OD)_2$ peaks and no peaks from sample surrounding materials such as ZrO_2 pressure medium, graphite furnace and WC anvils could be detected owing to radial collimators equipped with the 6-ram pressure apparatus (Atsuhime). The detailed structure parameters such as lattice parameters and atomic coordinates could be reasonably refined by the Rietveld method by using a program GSAS. It is an interesting result that thermal expansion along the *c*-axis seems to be suppressed at high pressure comparing to that at ambient pressure. Mechanism of the thermal expansion of $Ca(OD)_2$ at high pressure will be discussed.

High-temperature heat capacity of SiO2-Al2O3-RO (R=Mg, Ca, Sr, Ba) melts

SUGAWARA, Toru[1*]

[1]Akita University

Heat capacity (Cp) of silicate melts is an important property in consideration of phase equilibria in magmatic system and a numerical simulation of flow and thermal structures in glass melting furnace. Heat capacity of aluminum-free melts can be expressed by an additive function of partial molar heat capacities for components (Richet and Bottinga, 1985). On the other hand, it has been reported that the heat capacities of alumino-silicate melts show complicated dependence on both temperature and composition (Richet and Mysen, 2005). However, they are still poorly understood due to the lack of calorimetric data. This study provides new experimental data for the high-temperature heat capacities of Ca, Sr and Ba-bearing alumino-silicate melts.

Drop calorimetry measurements were performed for $50SiO_2$-$25Al_2O_3$-25CaO (An), $36.5SiO_2$-$27Al_2O_3$-36.5CaO (Ca36.5), $8SiO_2$-$30Al_2O_3$-62CaO (Ca62) and $75SiO_2$-$12.5Al_2O_3$-12.5SrO or 12.5BaO (Sr12.5, Ba12.5) melts between 873K and 1889K using a Bunsen ice calorimeter. Heat capacity of melts was determined from the differential of measured relative enthalpy. The heat capacity of anorthite melt is 1.356+0.0001151T(K) (J/K-g), which is consistent with the value reported by Richet and Bottinga (1985). The heat capacities for Ca36.5, Ca62, Sr12.5 and Ba12.5 are 1.532, 1.508, 1.313 and 1.160 (J/K-g), respectively, and they are independent of temperature.

The temperature and compositional dependence of the Cp for SiO_2-Al_2O_3-RO (R=Mg, Ca, Sr, Ba) melts are considered by combining new calorimetric data and literature data by drop calorimetry (n=11, Richet and Bottinga, 1984; Courtial and Richet,1993; Neuville and Richet, 1991; Richet and Neuville, 1992) and by differential scanning calorimetry (n=22, Webb, 2008, 2011). The positive temperature dependence is observed in the SiO_2-Al_2O_3-MgO melts as reported by Courtial and Richet (1993). In the system SiO_2-Al_2O_3-CaO, temperature dependence of the Cp is only observed at anorthite composition. The heat capacity of alkaline-earth aluminosilicate melts can be expressed by a symmetric solution model. The derived heat capacity of mixing is negative value in all of the systems. At constant temperature and oxide ratio, the heat capacity decreases with decreasing field strength of alkaline-earth elements (Ba <Sr <Ca <Mg), suggesting that configurational freedom is restricted in the cations with lower field strength due to the charge compentation effect of aluminum. Further experimental data for Sr and Ba-bearing melts are required to generalize temperature dependence of the heat capacity.

Viscosity of titanium-bearing silicate melts at high pressure

SUZUKI, Akio[1*]

[1]Tohoku University

Knowledge about viscosity of silicate melt is valuable for understanding the activity of magma in the planetary interiors. The high-Ti magmas erupted on the lunar surface. These magmas contains TiO2 up to 16 wt%. Because the viscosity change at high pressure is affected by the structural change of TO4-network, it is very interesting to know the influence of Ti on the pressure dependence of viscosity. We performed viscosity measurement of K2TiSi4O11 melt as an analogue of the lunar high-Ti magmas. Viscosity was measured by the falling sphere method using an X-ray radiography system. Experiments were performed at the NE7A station of the PF-AR synchrotron radiation facility in KEK, Tsukuba, Japan. We found that the viscosity of K2TiSi4O11 melt has a viscosity minimum at 3 GPa. Paris et al. (1994) reported that the coordination number of titanium increases with increasing pressure on the basis of the XANES spectra of glasses synthesized under high pressure. Our results suggest that the viscosity minimum of K2TiSi4O11 is strongly related to the coordination change of titanium. The viscosity minimum is also found in the terrestrial MORB magma. Recently, Sakamaki et al. (2013) proposed that the viscosity minimum causes the low velocity zone of seismic wave in the upper mantle. The present study suggests that the high-Ti melt causes an attenuating zone in the deep lunar mantle.

Study of physical properties of Fe-Si alloy at high pressureusing using synchrotron radiation Mossbauer spectroscopy

SUZUKI, Nanami[1*] ; OHTANI, Eiji[1] ; HIRAO, Naohisa[2] ; KAMADA, Seiji[1] ; HAMADA, Maki[3] ; SAKAMAKI, Tatsuya[1] ; OHISHI, Yasuo[2] ; MASUDA, Ryo[4] ; MITSUI, Takaya[5]

[1]Department of Earth and planetary materials science, Graduate School of Science, [2]Japan Synchrotron Radiation Research Institute, Hyogo, 679-5198, Japan, [3]School of Natural System, College of Science and Engineering, Kanazawa University, Kanazawa, 920-119, [4]Research Reactor Institute, Kyoto University, Osaka, 590-0494, Japan, [5]Japan Atomic Energy Agency, Hyogo, 679-5148, Japan

The Earth's core is divided into the liquid outer core and solid inner core based on seismological observations. The Earth's core has been geochemically and cosmochemically thought to be mainly composed of Fe. The density of the core is smaller than that of pure iron under the core conditions. Therefore, the core has been considered to contain light elements, such as H, S, Si, C, and O. Si is one of the most important light elements in the core. Although the phase relations and compression behaviors in the Fe-Si alloy have been studied at high pressure and temperature in order to investigate properties of the inner core, magnetic properties of the alloys have not been studied well. In order to clarify the relationship between the magnetic transition and the structural transition of the Fe-Si alloy, we made simultaneous measurements of X-ray diffraction and synchrotron M*ö*ssbauer spectroscopy of the Fe-Si alloy up to 40 GPa at room temperature.

The Fe-Si alloy used for the measurements has a composition of $Fe_{0.95}Si_{0.05}$ enriched with ^{57}Fe. The starting material was synthesized by melting the mixture of ^{57}Fe and Fe-Si alloys under the Ar-H_2 atmosphere by laser heating. M*ö*ssbauer spectra and XRD patterns were obtained at the beamlines, BL10XU and BL11XU of SPring-8 up to 40 GPa at room temperature. Our M*ö*ssbauer data together with X-ray diffraction data revealed that the magnetic transition from magnetic to non-magnetic phase occurs at 18 GPa simultaneously with the bcc to hcp transition. The change in the sound velocity and compression behavior of the Fe-Si alloy has been reported associated with the structural transformation of the alloy from bcc to hcp. The present results imply that the change in these physical properties is caused not only by the structural change but also by the magnetic transition.

Experimental determination of post-spinel transition boundary in Fe_2SiO_4

MATSUZAWA, Taisuke[1*] ; KOJITANI, Hiroshi[1] ; AKAOGI, Masaki[1]

[1]Department of Chemistry, Gakushuin University

It is widely accepted that $(Mg,Fe)_2SiO_4$ ringwoodite is the most abundant mineral in the mantle transition zone. Because spinel-type Fe_2SiO_4 is the endmember of $(Mg,Fe)_2SiO_4$ ringwoodite, many investigators have been studied on phase transitions of Fe_2SiO_4 spinel (Kawada 1977, Ohtani 1979, Morooka 1992, Katsura et al. 1998). Spinel-type Fe_2SiO_4 decomposes into $2Fe_xO+SiO_2$(stishovite)+2(1-x)Fe above about 18GPa. However, the dissociation boundary has not yet been established well due in part to difficulty in oxygen fugacity control. In this study, we determined the post-spinel phase boundary in Fe_2SiO_4 by high-pressure experiments controlling oxygen fugacity with the Fe-FeO buffer.

A starting material of high-pressure experiments was a mixture of Fe_2SiO_4 (fayalite), Fe_xO and Fe with molar ratios of 10:2:1, and it was packed in a Fe capsule. Oxygen fugacity of the sample at high pressure and high temperature was controlled by the Fe-FeO buffer. The high-pressure experiments were performed using a Kawai-type 6-8-type multi-anvil apparatus at 16-20GPa and 1000-1400 ℃. The starting samples were heated at the desired conditions for 3-6 hours, and then quenched and decompressed to ambient conditions. Recovered samples were identified by using powder XRD method and SEM-EDS, and then lattice parameters of FexO were determined by using powder XRD. The x values in Fe_xO were estimated from the composition-lattice parameter relationship of Fe_xO by McCammon (1993).

The post-spinel transition boundary in Fe_2SiO_4 was determined to be P(GPa) = -0.0021T(℃) + 20.0 in the temperature range of 1000-1400 ℃. The phase boundary has a negative slope. Our boundary is almost consistent with those of Ohtani (1979) and Katsura et al. (1998). Katsura et al. (1998) interpreted that the negative slope of the boundary in the previous studies was apparent which was caused by slow kinetics of spinel decomposition. Because our study indicated that the decomposition of Fe_2SiO_4 spinel completed in the runs for 3 hours at 1000 ℃ and that x values of Fe_xO in the run products for 3 and 6 hours at the 1000 ℃ were approximately equal, we conclude that heating at 1000 ℃ for at least 3 hours was enough to reach the equilibrium. Because our transition boundary was determined by the runs for 6 hours at 1000 ℃, 3 hours at 1200 ℃, and 3 hours at 1400 ℃, we suggest that the negative slope of the post-spinel transition boundary in Fe_2SiO_4 is not apparent but the essential feature.

Relationship between Raman spectral pattern and crystal orientation of cordierite

ABE, Miyako[1*] ; MADHUSOODHAN, Satish-kumar[1] ; KAGI, Hiroyuki[2]

[1]Niigata University, [2]Tokyo University

In the crystal structure of cordierite, six-membered rings of (Al, Si) O_4 are stacked along the *c*-axis and form a channel structure. This channel structure can trap volatiles such as H_2O and CO_2, and makes cordierite an important mineral for preserving the information of past fluid conditions during metamorphism. Earlier studies have shown that the intensity of CO_2 Raman band represents the contents of CO_2 inside the channel (e.g. Kaindl et al., 2006). Carbon dioxide is aligned linearly along the *a*-axis in the channel (Aines and Rossman, 1984), and therefore the peak intensity of CO_2 at 1383cm^{-1} in the Raman spectra varies considerably depending on the crystal orientation of cordierite (Kolesov and Geiger, 2000). Thus, it is necessary to correct the effect of crystal orientation for the determination of true contents of CO_2 in randomly oriented cordierite grains in metamorphic rocks. As a first step to accurately quantify the CO_2 content in cordierite using Raman spectroscopy, we analyzed euhedral crystals of cordierite for revealing the relationship between Raman spectral patterns and crystal orientation.

In this study, euhedral cordierite crystals collected from the volcanic ash deposit in the Takiga swamp, Gunma Prefecture, Japan were examined in detail using micro-Raman spectroscopy. Raman spectra were observed with different conditions for each analytical point to check the effect of polarization and crystal orientation. Mineral chemical analyses of cordierite crystals indicate homogeneity in its composition (X_{Mg} = 0.735 $\pm$ 0.14). However, different Raman spectral patterns were obtained for (001) plane and (100) plane; the (001) plane show only one pattern, but the (100) plane showed three different patterns. Peak splitting between 554 and 575 cm^{-1}, the peaks of 970 cm^{-1} and 1180 cm^{-1} changed its intensity drastically, whereas the peak at 670 cm^{-1} remained constant. We selected five Raman peaks at 554 cm^{-1}, 575 cm^{-1}, 670 cm^{-1}, 970 cm^{-1}, and 1180 cm^{-1} attributable to the cordierite (Al, Si)O_4 structure and analyzed the intensity ratio of these five peaks in different orientations. A parameter of Δintensity was defined, where the intensity ratios of (001) plane were concentrated around 0, and those of (100) plane deviates from 0. This parameter can be used to identify the crystal orientation of cordierite. The spectral variations observed in cordierite and its relationship with crystal orientation are interpreted based on the stretching and/or bending vibrations of cordierite unit cell structure

The low-temperature Moessbauer spectroscopy of an M3’ epidote from Osayama, Okayama prefecture, Japan

YAMAKAWA, Junji[1*] ; KAWASE, Masaya[2] ; KUROKUZU, Masayuki[3] ; MORIMOTO, Shotaro[4] ; SAITO, Tadashi[5]

[1]Graduate School of Natural Science and Technology, Okayama University, [2]Nagahama Institute of Bio-Science and Technology, [3]Research Reactor Institute, Kyoto University, [4]Faculty of Pharmacy, Osaka Ohtani University, [5]Radioisotope Center, Osaka University

Epidote, $Ca_2(Al,Fe^{3+},Fe^{2+})Al_2SiO_4Si_2O_7(O,OH)$ is a common rock forming mineral found low-grade metamorphic rocks. The chemical compositions of the epidote vary with the formation conditions and make some complex zoning textures. The distribution of Fe^{2+}-Fe^{3+} ions in the crystal structure will be able to analyze by the Mössbauer spectrometry and the stability/unstability of the sample can be estimated from the distribution.

Moreover, in some sample, the Fe ions are distributed in the characteristic M3′ site that can be detected by the Mössbauer spectroscopy. The distribution ratio of the Fe ions in the M3′ site can not be estimated by the X-ray structure analysis, so the M3′ sites are making a small ordering structures and distribute homogeneously in the crystal. Distribution ratio of Fe in the site of M1/M3/M3′ corresponds to the formation conditions of the sample.

In this study, the low-temperature Mössbauer spectrum and Magnetic susceptibility of the M3′ epidote sample was measured and the characteristics of the M3′ site were analysed.

Structural change in ikaite ($CaCO_3 \cdot 6H_2O$) near the freezing point temperature of water

TATENO, Natsuki[1] ; KYONO, Atsushi[1*]

[1]Div of Earth Evolution Sciences, Grad Sch of Life & Environmental Sciences, Univ of Tsukuba

Ikaite, one of the calcium carbonate minerals, is thermodynamically stable only at near-freezing temperature and transformed rapidly into calcite and vaterite at ambient temperature. During the phase transformation with dehydration, its crystal shape is preserved as pseudomorphs, termed glendonite, thinolite, and gennoishi. This study aims to clarify the structure change and dehydration mechanisms by using low-temperature single-crystal X-ray diffraction study. At -50 ^{o}C, the crystal structure of ikaite is monoclinic, space group $C2/c$ with the unit cell parameter a = 8.8134 (1), b = 8.3108 (1), c = 11.0183 (1) $\AA$, β = 110.418 (1) ^{o}. It is composed of four $CaCO_3 \cdot 6H_2O$ molecules in the cell. With increasing temperature, the unit cell volume is increased monotonously from 756.3 to 758.0 $\AA^3$ between -50 and -20 ^{o}C, and then jumped to 771.0 $\AA^3$ at -10 ^{o}C. The unit cell lattice anisotropically expands mainly along the c-axis, followed by the a-axis. The intramolecular Ca-O(5) bond distance is drastically elongated at -10 ^{o}C, which is associated with elongations of the intermolecular O(2)-O(3), O(2)-O(5), O(4)-O(5) distances. The a unit cell expansion is directly due to the elongation of the O(2)-O(5) aligned parallel to the a-axis. The drastic elongation of the Ca-O(5) bond distance gives rise to an initial dehydration of the $CaCO_3 \cdot 6H_2O$ molecule. The intermolecular Ca-O(3)-O(2) angle is constantly increased with temperature, leading to rotational motion of the $CaCO_3 \cdot 6H_2O$ molecule along b-axis. This is responsible for the highest expansion coefficient of the c lattice parameter.

Synchrotron powder X-ray diffraction study of the structural thermal properties on hydrogrossular

KATO, Masato[1*] ; KYONO, Atsushi[2]

[1]Graduate School of Life and Environmental Science, [2]Graduate School of Life and Environmental Science

Synchrotron powder X-ray diffraction study on synthetic Si-free hydrogrossular, katoite $Ca_3Al_2(O_4H_4)_3$, were performed at temperature range from 300 to 10 K. The temperature dependence of structure parameters was refined by Rietveld analysis. Since structural contraction with decreasing temperature would directly cause a phase transition on the hydrogrossular structure, three candidates for space group: *Ia*-3*d* (katoite at ambient), *I*-43*d* (katoite at high pressure), and $I4_1/acd$ (majorite), were applied to the X-ray diffraction profile fitting collected at 10 K. The final Rw with the *Ia*-3*d* space group consequently results in the smallest value, which suggests that the katoite structure remains unchanged up to the lowest temperature of 10 K. However, the temperature dependence of the unit cell volume shows two different expansion coefficients at temperatures above and below 100 K. It can be accounted for by the effect of the repulsion between atoms of the same species. Whereas the unit cell of katoite is monotonously contracted with decreasing temperature, the O_4H_4 tetrahedron and AlO_6 octahedron are alternatively expanded and contracted. Compared with the phase transition in katoite under high pressure, moreover, the unit cell volume contraction up to 5 GPa is about eight times larger than that under low temperature. The structural characteristics could therefore explain the reason why no phase transition occurs in katoite at low temperature condition.

Structural study on the phase transformation of natural scolecite with increasing temperature

UCHIDA, Takahiro[1*] ; KURIBAYASHI, Takahiro[1] ; NAGASE, Toshiro[2]

[1]Department of Earth Science, graduate school of science, Tohoku University, [2]The Tohoku University Museum, Tohoku University

Scolecite, $CaAl_2Si_3O_{10}\cdot 3H_2O$ is classified to fibrous zeolite group. The sequence of general phase transformation with increasing temperature has been reported for natural scolecite: scolecite→ meta-scolecite → amorphous phase and decomposes to An + Qtz (Rykl *et al.* 1986; Gottardi and Galli 1985).

In this study, the high-T evolution of the structure of natural scolecite from Poona, India were studied up to 573 K to reevaluate the dehydration process of scolecite using TG-DTA and in situ single crystal X-ray diffraction experiments.

As the results from structual refinement at room temperature, the lattice constants of the sample are determined as follows : a= 18.504(3)A, b= 18.971(2) A, c= 6.5262(9) A and β = 90.558(5) ^{0} . The crystal structure of scolecite, $CaAl_2Si_3O_{10}\cdot 3H_2O$, was refined with the space group $F1d1$ from 3567 reflections with Io $>2\sigma(I)$, yielding R= 4.62%, wR= 11.41%. At ∼423 K, the space group was changed to Fdll from $F1d1$, and scolecite underwent a phase transformation to meta-scolecite phase.

As the results from structual refinement at 523 K , the lattice constants of the sample are determined as follows : a= 18.122(3)A, b = 18.847(3) A, c = 6.5408(11) A and α = 88.948(7) ^{0} . The crystal structure of scolecite, $CaAl_2Si_3O_{10}\cdot 2H_2O$, was refined with the space group $Fd11$ from 2782 reflections with Io $>2\sigma(I)$, yielding R= 10.72%, wR= 28.85%. When phase transformation occurs, OW2 in scolecite is expelled and then the half of Ca ions move by ∼1/2c. At 573 K, the number of ovserved reflections was decreased dramatically.

Under high-T experiments from 423 to 523 K, two reciprocal lattices were observed, each lattice is corresponding to twin component with the [00-1] twin law. The [00-1] twinning could be associated with the dehydration mechanism. The X-ray diffraction data suggest the possibility of exist of a new H_2O site in meta-scolecite phase. This may be a key to solve the dehydration process of scolecite.

Near-infrared spectra of ice under high pressure and high temperature

NOGUCHI, Naoki[1*] ; KOMATSU, Kazuki[2] ; SHINOZAKI, Ayako[2] ; SHINODA, Keiji[3] ; KAGI, Hiroyuki[2]

[1]Graduate School of Engineering, Hiroshima University, [2]Geochemical Laboratory, Graduate School of Science, The University of Tokyo, [3]Department of Geosciences, Faculty of Science, Osaka City University

The physical properties of ice VII under high pressure and high temperature (HP-HT) conditions are important to planetary science. Ice VII is considered a primary constituent of the interior of giant icy satellites and planets (e.g., Podolak et al. 1998). Thus, understanding the physical properties of ice VII will contribute to better knowledge about the structure and dynamics of other satellite and planetary interiors. In particular, the ionic conductivity of ice VII, which affects the magnetic fields of these bodies (Stevenson 2003), is controlled by ionic and rotational defects in the ices (Jaccard 1959); moreover, ionic defects have two types: OH^- and H_3O^+. The probability of forming defects in ice VII under the HP - HT conditions that typify the interiors of icy satellites and planets is surely increased by thermal activation.

In the near-infrared (NIR) region, the spectrum of ice VII shows absorption bands of the bending-stretching combination (ν_2 + ν_3) and stretching overtone ($2\nu_3$) modes of the normal vibration of water molecules (Larsen and Williams 1998). These modes correspond to the high vibrational energy level of the potential well, and provide information regarding the potential barrier along the O...O axis. To determine the probability of forming ionic defects in the ice VII structure at elevated temperatures, the NIR spectra of ice VII must be measured. The aim of this study is to investigate the state of protons in ice VII under HP-HT conditions. Thus, we measured the NIR absorption spectra of water at pressures up to 16 GPa and temperatures up to 368 ℃ using an external heating diamond anvil cell and synchrotron NIR radiation of BL43IR at SPring-8.

The absorption band of the first OH stretching overtone mode divided into doublet peaks above 5 GPa at room temperature, suggesting that proton tunneling occurs at the overtone level. As the temperature increased, the doublet peaks gradually reduced to a singlet. This result implies that thermally activated protons hop between the two potential minima along the oxygen-oxygen axis. A P-T diagram for the proton state was constructed from the changing band shape of the overtone mode.

Phase changes of filled ice Ih methane hydrate induced by the orientational ordering of the guest molecules

TANAKA, Takehiko[1*] ; HIRAI, Hisako[1] ; MATSUOKA, Takahiro[2] ; OHISHI, Yasuo[3] ; YAGI, Takehiko[1] ; OHTAKE, Michika[4] ; YAMAMOTO, Yoshitaka[4] ; NAKANO, Satoshi[5]

[1]Geodynamics Research Center, Ehime University, [2]Gifu University, [3]Japan Synchrotron Radiation Research Institute, [4]The National Institute of Advanced Industrial Science and Technology, [5]National Institute for Materials Science

Orientational ordering of guest methane molecules in a filled ice Ih structure of methane hydrate (MH) was observed above 15 to 20 GPa at room temperature in a previous Raman study. However, the change in the fundamental structure was not observed at the pressure region by X-ray diffractometry. In this study, low-temperature and high-pressure experiments were performed with filled ice Ih structure of methane hydrate under pressure and temperature conditions of 2.0 to 77.0 GPa and 30 to 300 K, respectively, using diamond anvil cells and a helium-refrigeration cryostat. Distinct changes in the axial ratios of the host framework were revealed by In-situ X-ray diffractometry. Splitting in the CH vibration modes of the guest methane molecules, which was previously explained by the orientational ordering of the guest molecules, was observed by Raman spectroscopy. The pressure and temperature conditions at the split of the vibration modes agreed well with those of the axial ratio changes. The results indicated that orientational ordering of the guest methane molecules from orientational disordered-state occurred at high pressures and low temperatures, and that this guest ordering led to the axial ratio changes in the host framework. Existing regions of the guest disordered-phase and the guest ordered-phase were roughly estimated by the X-ray data. In addition, above the pressure of the guest-ordered phase, another high pressure phase was developed at a low-temperature region.

Zirconium local structure in tektite and impact-related natural glasses probed by XAFS

TOBASE, Tsubasa[1*] ; YOSHIASA, Akira[1] ; WANG, Ring[1] ; HIRATOKO, Tatsuya[1]

[1]Graduate School of Science, Kumamoto University, [2]Materials and Structures Laboratory, Tokyo Institute of Technology

The local structures of tektite and natural glasses were studied by Zr K-edge X-ray absorption near edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) in order to provide quantitative data on bonding distances and coordination numbers. The XAFS measurements were performed at the beam line BL-NW10A of the PF-AR in National Laboratory for High Energy Physics (KEK), Tsukuba, Japan. Zr4+ ion in tektite has different kinds of coordination environment. Various natural glasses are formed under different physical conditions. Impact-related glass, fulgurite and volcanic glasses are typical natural glasses. Glass structure is affected by the pressure and temperature conditions during the glass formation and annealing process. This study indicated that different formation process of natural glasses gives different local structure of zirconium ions.

The Zr K-edge XANES spectra of tektite have the double post-edge peaks with different heights. All tektites are classified in same types. Zr-O distances in tektite are 2.198-2.215$\AA$ and XANES spectra of tektite have similar shape. It indicates that tektites have similar Zr local structure with 7-fold coordination Zr ions. Volcanic glasses are classified same type. Impact-related glasses are classified to different types. Impact glasses are formed under different geological process at impact event and are experienced different physical environments.

Light element quantification using electron microprobe and Os surface coating

OHFUJI, Hiroaki[1*] ; YAMAMOTO, Masashi[1] ; KOJIMA, Yohei[1]

[1]Geodynamics Research Center, Ehime University

Electron microprobe analysis is a non-destructive method widely used for determining the chemical composition of solid materials such as not only minerals and rocks but also industrial and biological materials. Recent advances of solid-state detectors for energy dispersive spectroscopy (EDS) analysis allow us to readily collect precise quantitative data. For SEM and EDS analysis of non-conductive (insulating) materials such as minerals and rocks, surface coating of a thin conductive layer is a prerequisite for sample preparation. For this purpose, carbon and gold are most commonly used; the former with low atomic (Z) number is suitable for microprobe chemical analysis, while the latter is preferable for textural observation of samples with rough, uneven surfaces and/or with high porosity. Recently, osmium coating prepared by chemical vapor deposition (CVD) has been a focus of attention and found to be effective for high-resolution SEM observation of samples with uneven surfaces. In the present study, we applied the sample preparation technique using very thin osmium surface coating for chemical quantification of various mineral samples by EDS.

The SEM-EDS analysis was performed by using FE-SEM (JEOL, JSM-7000F) equipped with a silicon-drift-type EDS detector (Oxford Instruments, X-Max 20). Accelerating voltage and probe current were 15 kV and 1 nA, respectively. Osmium coating of 5 nm thick was carefully made by using a Neoc-ST osmium coater (Meiwafosis). Quantification analyses were conducted on a variety of mineral samples, silicate (including hydrous silicates), carbonate and oxide minerals.

The results showed that the quantification data obtained from samples with osmium coating are as accurate as those from samples with conventional carbon coating for principle elements such as Na, Mg, Al, Si, K, Ca and Fe. With respect to the quantification of light elements such as C, N and O, the results from osmium-coated samples are found to be closer to their stoichiometric values than those from carbon-coated samples. This is likely caused by the absorption correction of the X-rays passing though each coating layer. The thickness of the surface coating layer can be precisely controlled in the case of osmium coating prepared by the CVD technique, but not readily adjusted in carbon coating. As the result, the deviation of the estimated thickness of the coating layer from the actual thickness over/underestimates the effect of X-ray absorption correction, in which low-energy X-rays from light elements are more significantly influenced by the correction. We found that the precise quantification of oxygen as a separate element (not as oxide forms of cations) using osmium surface coating might be helpful and effective in estimation of the valence state of iron in iron-bearing minerals and water (hydrogen) content in hydrous minerals. We also confirmed that the present technique is also useful for precise quantification of carbonate minerals such as $CaCO_3$.

Cathodoluminescence characterization of terrestrial and extraterrestrial alkali-halide minerals

YOSHIDA, Eisuke[1*] ; NISHIDO, Hirotsugu[1] ; NINAGAWA, Kiyotaka[1]

[1]Okayama University of Science

Luminescence of natural alkali halides such as halite and sylvite is characterized by structural defects related to F-center (+p) and V-center (+e). On their CL (cathdoluminescence), however, scarcely has been reported so far. Since asteroidal water was discovered as fluid inclusion in halite from H5 chondrite, Monahans (1998), alkali halides in meteorites have been extensively investigated for understandings of aqueous alteration and thermal metamorphism on the parent body. Therefore, luminescence features of halides can provide valuable information on such issues. In this study we have measured CL spectra of terrestrial and extraterrestrial halite samples to clarify luminescence centers in various types of halite.

Halite crystals of terrestrial origin and small halite particles in ureilite meteorites were selected for CL measurements. All samples were prepared using oil while cutting and polishing without water. Also cleavage fragments of terrestrial samples were used for CL spectral measurements after carbon coating.

All samples exhibit weak blue to greenish blue CL with broad band emissions from 350 to 650 nm. CL spectra corrected for total instrumental response were converted into energy units for spectral deconvolution using a Gaussian curve fitting, because Gaussian curve in energy units can be assigned to one specific type of emission center (Stevens-Kalceff, 2009). The deconvoluted components can be assigned to the emission centers related to V_k (+e), F (+p), V_F (+e), Mn^{2+} (Na^{+}) and Mn^{2+} (interstitial) by referring to Gorobets and Rogojine (2002).

The CL spectra of terrestrial halite at room temperature are consisted of five components at 3.34 eV, 3.05 eV, 2.46 eV, and 2.28 eV and at 2.00 eV. At low temperature the emission of Mn2+ impurity center is enhanced due to an increase in the probability of radiation transition. In the case of high-energy emission, a decrease in sample temperature reduces the intensity of F-center emission, but sensitizes the intensity of V_k-center emission, suggesting the energy transfer from F-center to V_k-center. The CL spectral analysis of terrestrial sylvite at room temperature confirms four emission components at 3.32 eV, 2.97 eV, 2.53 eV and 1.89 eV.

Halite in the meteorite of polymict ureilite (Dar al Gani 319) gives a broad emission band in blue region, which is deconvoluted into two components at 2.70 eV for unknown center and at 3.11 eV for F-center. However, no emission in red region associated with Mn impurity center has not recognized in ureilite halite. It implies that high-energy radiation in cosmic space might break up the crystal fields around Mn ions.

Effects of Mn activator and site occupancy on cathodoluminescence of dolomite

KUSANO, Nobuhiro[1*] ; NISHIDO, Hirotsugu[1] ; NINAGAWA, Kiyotaka[1]

[1]Okayama University of Science

Cathodoluminescence (CL) has been widely applied in mineralogical and petrological investigations, especially for carbonates. Dolomite commonly red CL emission related to an impurity center of divalent Mn in Ca-site and Mg-site (Sommer, 1972; Walker et al, 1989). Furthermore, temperature effect on CL efficiency has not been discussed in spite of potentially important function to control CL emission mechanism. In this study we have clarified luminescent mechanism of dolomite in a wide range of temperature using a SEM-CL, and confirmed a temperature quenching of its emissions. The quenching process has been quantitatively evaluated by CL spectral deconvolution method assuming the Mott-Seitz model.

Five dolomite samples from Hase, Japan (D01), Nakase, Japan (D02), Raura, Peru (D03), Binntal, Switzerland (D04), Arizona, USA (D05) were selected for CL measurements after carbon-coating on their polished surfaces. SEM-CL analysis was conducted using an SEM (JEOL:JSM-5410) combined with a grating monochromator (Oxford: Mono CL2) to measure CL spectra ranging from 300 to 800 nm in 1 nm steps with a temperature controlled stage from -190 to 250 ^{o}C. The dispersed CL was collected by a photon counting method using a photomultiplier tube (R2228) and converted to digital data. All CL spectra were corrected for the total instrumental response.

CL spectra of all samples at room temperature exhibit almost similar pattern with a broad band at 525-800 nm in a red region. The spectral peaks are sharpened and enhanced at lower temperature due to reduction of thermal lattice vibration and an increase in luminescent efficiency, suggesting high spectral resolution of the emission bands at low temperature. Therefore, a Gaussian fitting was conducted to quantitatively deconvolute spectral data obtained at low temperature in an energy unit. The results confirmed that CL of all samples consist of two emission components at around 1.84 eV (Mg-site) and 2.15 eV (Ca-site) in red region, of which variation might be attributable to crystal field (Mn-ligands distance). In general, luminescence efficiency of the material decreases with a rise in temperature due to an increase in non-radiative transitions. This phenomenon has been recognized in several minerals such as quartz, cristobalite and tridymite as temperature quenching. Furthermore, an increasing temperature makes a shift of the emission peak to a higher wavelength side. The emission intensity varies depending on the samples with different concentrations of activator (Mn^{2+}) and quencher (Fe^{2+}), and site occupancy of the Mn^{2+} ion between two cation sites in dolomite structure. The facts suggest that the behavior of the emission intensity with changes in temperature is not explained on the basis of a temperature quenching theory based on an increase in the probability of non-radiative transition with the rise of temperature (Mott-Seitz model). Probably activator (Mn^{2+}) concentration affects temperature quenching effect on CL of dolomite considerably.

Cathodoluminescence of calcite decomposed from dolomite in high-temperature skarn

KUSANO, Nobuhiro[1*] ; NISHIDO, Hirotsugu[1] ; INOUE, Koichi[1]

[1]Okayama University of Science

Purple luminescent calcite associated with periclase has been found from the high-temperature skarn in Kanehira mine located in the eastern part of Hiroshima Prefecture. Calcite usually emits red to orange in cathodoluminescence (CL), but scarcely purple to blue. In this study we have conducted to clarify the emission center related to purple luminescence by using CL spectral analysis and the origin of the calcite during skarn mineralization.

The specimens collected from the skarn zone in the limestone contacted with intrusive granodiorite in the outcrop of the pit-tunnel. The polished thin sections of the selected samples were employed for optical observation and CL measurements. Color CL images were obtained using a cold-cathode type Luminoscope with a cooled-CCD camera. CL spectroscopy was made by a SEM-CL system, which is comprised of SEM (JEOL: JSM-5410LV) combined with a grating monochromator (OXFORD: Mono CL2). The CL emitted from the samples was dispersed by a grating monochromator (1200 grooves/mm), and recorded by a photon counting method using a photomultiplier tube. All CL spectra were corrected for total instrumental response, which was determined using a calibrated standard lamp.

Color CL imaging reveals two types of CL emission, red and purple, in calcite closely associated with spotted periclase. The CL spectra of both calcite show a broad emission band at 620 nm in a red region, which is assigned to an impurity center derived from an activator of divalent Mn ion substituted for Ca, where the intensity of red CL is higher than that of purple CL. Furthermore, the calcite with purple calcite exhibits a broad emission band at 400-500 nm in a blue region, which might be related to a defect center such as ”back-ground blue” found in low-Mn activated calcite.

The calcite with purple CL is accompanied by spotted periclase grains, which is usually found as a component of metamorphosed dolomitic limestone. If the hydrate condition would be presumed during its formation, periclase could easily hydrate and alter to brucite and other magnesium minerals by action of the humidity. According to the results of heating experiments of dolomite, dolomite decomposes to calcite and periclase at around 750 ^{o}C, whereas calcite causes its decarbonation above around 850 ^{o}C. It implies that the calcite with purple CL might be persisting after the decomposition of dolomite under a dry condition at relatively high-temperature near 800 ^{o}C, and leave the defects in the calcite structure during thermal decomposition of dolomite, which can be assigned to the component of an emission band in a blue region.

Cathodoluminescence characterization of terrestrial and extraterrestrial enstatite

OHGO, Syuhei[1*] ; MISHIMA, Maki[1] ; NISHIDO, Hirotsugu[1] ; NINAGAWA, Kiyotaka[1]

[1]Okayama University of Science

Enstatite occurred in meteorite shows various cathodoluminescence (CL) emissions, whereas CL emission in terrestrial enstatite has not been reported so far. We have confirmed several luminescent enstatite in terrestrial samples. In this study, we have conducted to clarify the luminescence centers of terrestrial enstatite and comparatively discuss the CL of terrestrial enstatite and extraterrestrial ones in enstatite chondrite (E-chondrite).

Three enstatite with CL emission from Morogoro, Tanzania and Chandrika, SriLanka were selected for CL measurements. The samples were fixed on a brass disk with low-luminescent epoxy resin, and polished with a diamond paste. The polished thin sections of E-chondrite (Dar al Gani 734 and Y-86004) and Aubrite (Al Haggounia 001) were employed for CL examination. Color CL images were obtained using a cold-cathode type Luminoscope with a cooled-CCD camera. CL spectroscopy was made by a SEM-CL system, which is comprised of SEM (JEOL: JSM-5410LV) combined with a grating monochromator (OXFORD: Mono CL2). The CL emitted from the samples was dispersed by a grating (1200 grooves/mm), and recorded by a photon counting method using a photomultiplier tube. All CL spectra were corrected for total instrumental response, which was determined using a calibrated standard lamp.

Color CL imaging reveals various types of CL emissions, red, blue and purple in the both of terrestrial and extraterrestrial samples. The CL spectra of these enstatite show a broad emission band at 670 nm in a red region, which is assigned to an impurity center derived from activated divalent Mn ion substituted for Mg, and a broad emission band at around 400 nm in a blue region, which might be related to a defect center such as ”intrinsic defect center” possibly raised during crystal growth.

CL spectra corrected for total instrumental response were converted into energy units for spectral deconvolution using a Gaussian curve fitting, because Gaussian curve in energy units can be assigned to one specific type of emission center (Stevens-Kalceff, 2009). The deconvoluted components can be assigned to the emission centers related to impurity centers of trivalent Cr ion (1.71 eV) and divalent Mn ion (1.87 eV) and to defect centers (3.18 eV). Furthermore, enstatite in Y-86004 E-chondrite gives additional emission component (3.87 eV) in a blue to UV region, which might be characteristic of the enstatite formed under the condition of low-oxygen partial pressure.

Cathodoluminescence study of metasomatic feldspar in aegirine syenite from Iwaki Island, Ehime Prefecture

MAKI, Seiya[1*] ; NISHIDO, Hirotsugu[1] ; KAYAMA, Masahiro[2]

[1]Okayama University of Science, [2]Hiroshima University

In Iwaki Island, aegirine syenite was emplaced in the Ryoke granite during late Cretaceous time by alkali-rich hydrothermal metasomatism. The syenite and related rocks show various types of petrographic textures in response to the process of hydrothermal alteration, e.g. feldspar minerals. Feldspar exhibits a variety of cathodoluminescence (CL) colors depending on kinds of impurity elements and their concentrations, and defect densities related to Si-Al ordering and other structural disorder. Recently, the deconvolution method of CL spectra enables to assign the luminescence centers characteristic of the feldspar with satisfactory reliability (Kayama et al., 2010). In this study, we have conducted to clarify the metasomatic process through granite to syenite by CL spectral analyses for various types of feldspar.

Polished thin sections of the rock samples collected from granite, altered granite and syenite were employed for petrographic observations under a polarizing light microscope, CL measurements, and electron microprobe analyses (EPMA). Color CL images were obtained using a cold-cathode type Luminoscope with a cooled-CCD camera. CL spectroscopy was made by a SEM-CL system, which is comprised of SEM (JEOL: JSM-5410LV) combined with a grating (OXFORD: Mono CL2). The CL emitted from the samples was dispersed by a grating monochromator (1200 grooves/mm), and recorded by a photon counting method using a photomultiplier tube. All CL spectra were corrected for total instrumental response, which was determined using a calibrated standard lamp.

The feldspar in the unaltered granite shows apple green and blue CL emissions. The former is identified to plagioclase (Ab80, An20) characterized by divalent Mn activator at 556 nm, and the latter to alkali feldspar (Or90, Ab10) by defect center at 417 nm related to Al-O-Al. Altered granite has albite with red CL emission at around 750 nm, and alkali feldspar with inhomogeneous color of red to violet-blue emissions at around 400 nm and 720 nm. These CL emissions in a red region can be assigned to trivalent Fe activator in tetrahedral sites. The feldspar in syenite are mostly altered to albite with enhanced red emission at 748 nm, but minor alkali feldspar as residual after hydrothermal alteration exhibits dull red emission at 722 nm. The results of the spectral deconvolution reveals oxygen defect centers associated with Al-O-Al and Al-O-Ti bridges and impurity centers of trivalent Fe ions substituted for tetrahedral Al sites according to Kayama et al. (2010). Kayama et al. (2010) investigated the peak changes of a blue emission peak at 420 nm in alkali feldspar and they found that the elimination of Al-O-Al defect center was affected by hydrothermal metasomatism possibly at 250 ^{o}C. Therefore, the disappearance of blue emission in alkali feldspar in syenite implies that alkali-rich (sodium-rich) hydrothermal metasomatism for the formation of syenite could act at relatively high temperature above 250 ^{o}C successively after granitic magmatism.

Provenance study of quartz grains in aeolian desert sediments using cathodoluminescence method

MASUDA, Risa[1*] ; SANEYOSHI, Mototaka[1] ; NISHIDO, Hirotsugu[1] ; TSOGTBAATAR, K.[2] ; CHINZORIG, T.[2] ; MAINBAYAR, B.[2]

[1]Okayama University of Science, [2]Mongolian Academy of Sciences, Mongolia

Cathodoluminescence (CL), the emission of light caused by electron irradiation, has been widely applied in earth science, most extensively used in sedimentology. In such studies CL has the advantage that it can reveal characteristics which are invisible using transmitted light, e.g. growth zones of the crystals such as silica and carbonate minerals. In the case of quartz, its CL spectral feature is so complicated to be simply used for the identification of the provenance due to many emission centers related to various types of structural defects. In this study, we have conducted to clarify the luminescence centers in quartz selected from desert sediments using SEM-CL and evaluate quantitative ratios of the emission components of the CL spectra by the deconvolution method.

The quartz grains (#60-80 mesh size) in the aeolian sediments collected from Djadokhta formation (upper Cretaceous) in the Gobi desert were fixed on the slide glass with low-luminescent epoxy resin, of which surfaces were polished with 1 micron diamond paste. Color CL images were obtained using a cold-cathode type Luminoscope with a cooled-CCD camera. CL spectroscopy was made by a SEM-CL system, which is comprised of SEM (JEOL: JSM-5410LV) combined with a grating monochromator (OXFORD: Mono CL2). The CL emitted from the samples was dispersed by a grating monochromator (1200 grooves/mm), and recorded by a photon counting method using a photomultiplier tube. All CL spectra were corrected for total instrumental response, which was determined using a calibrated standard lamp.

All samples show dark blue CL emission, and exhibit two broad bands at 400 nm in a blue region and at 600-650 nm in a red region. CL spectra corrected for total instrumental response were converted into energy units for spectral deconvolution using a Gaussian curve fitting, because Gaussian curve in energy units can be assigned to one specific type of emission center (Stevens-Kalceff, 2009). The deconvoluted components can be assigned to the emission centers related to trivalent Fe at 1.65 eV, NBOHC at 1.89 eV, tetravalent Ti at 2.75 eV and trivalent Al at 3.19 eV by referring to Stevens-Kalceff (2009). We employed 10 grains randomly selected from collected 80 grains for each sample, and determined quantitative ratios of the emission components for these quartz grains using their integral intensities. We discuss variations of characteristic components among the sediments based on the results by a statistical analysis.

This project should cover multidisciplinary scientific fields such as geology, geochemistry, geophysics, water-rock interactions, rock mechanics, seismology, drilling technology, well logging technologies, reservoir engineering, and environmental science.

(a) Characterization of rock mass in BDT

Preliminary work by the Japanese researchers has revealed some of the behavior of the rock mass in the BDT, such as hydrothermal brecciation and presence of hydrothermally derived fracturing (HDF) (Hirano et al., 2003). However, fundamental understandings of key parameters such as the stress state, lithological structure, mechanical and compositional homogeneity, and thermal characteristics require much additional work. Laboratory tests would be the most effective means to obtain fundamental knowledge on the ductile rock mass in the initial stages of the project combined with analysis of core samples and pore water collected from an experimental borehole. This combination of laboratory and borehole data will generate, new knowledge on the rock mass and provide constraints on, and validation of the laboratory tests.

(b) Creation and control of the reservoirs

The HDF would create a brittle fracture network consisting of very fine fractures at grain boundaries, is created by cooling and depressurization from the borehole in the BDT. If a similar process operates during drilling then cooling of the ductile rock by the drill fluid may be expected to induce a grain-scale fracture network in the near field of the borehole during the drilling phase.

(c) Numerical simulation

To achieve sustainable energy production from EGSs in the BDT, it is essential to design the area of heat exchange between water and rock, and the risk of shortcut flow paths must be carefully evaluated. Simulators with capability to handle T-H-M-C behavior of the rock mass are expected.

Deep seismic reflection profiling in geothermal area: case study of Shirasawa and Shichigashuku calderas

SATO, Hiroshi[1*] ; ABE, Susumu[2] ; UYESHIMA, Makoto[1]

[1]Earthquake Research Institute, The university of Tokyo, [2]Japex Geoscience Institute, Inc.

Along the Ou Backbone Range, northern Honshu, many piston-cylinder type calderas have been developed in Late Miocene to Pliocene. Recently, such calderas formed in late Miocene are focused as a possible resource of geothermal power plants. To obtain the physical data to estimate the sate of deep sited fluids and fractures is significance. Since late 90's, deep seismic reflection profiling was carried out to image the deeper extension of active faults. Some of the seismic lines are crossing such caldera (Sato et al., 2002a Tectonophys,: Sato et al., 2002b EPS). Here, we introduce the seismic sections and results of magnetotelluric investigation and discuss possible strategy for future's site survey.

Shirasawa caldera: The Shirasawa caldera is a piston-cylinder type caldera with 10-km-diameter and welded tuff and lake deposits are cropping out as caldera fill. By seismic reflection profiling using vibroseis trucks, low frequency strong reflectors are imaged 3 to 5 km beneath the caldera and estimated to be a possible evidence showing fluids. The estimation is well accord to the velocity structure obtained seismic tomography (Nakajima et al., 2006 EPS).

Shichigasuku caldera: This caldera is located southern part of Miyagi prefecture and shows piston-cylinder type. Across this caldera, deep seismic reflection profiling was performed in 2013 (Sato et al., 2013: JpGU). Also, magnetotelluric survey is carried out. P-wave velocity structure across the caldera shows low velocity part, which corresponds to the caldera fill, but does not suggest any characteristic feature showing existence of fluids. Magnetotelluric section suggest the distribution of vertical low resistivity zone connected slab to active volcanoes and low resistivity part which located in the md-to upper curst beneath caldera, showing the possibility of existence of fluids.

Significance of integrated geophysical exploration

To understand the physical state and material of deep sited portion beneath caldera, integrated research using several methods, active / passive seismic investigation, MT methods. Seismic reflection survey is not effective for rock unit, which does not have layering. However, it has a potential to evaluate the density of fractures and their pattern.

Occurrence of rock/mineral fracture under the rapid decompression boiling condition of water

HIRANO, Nobuo[1*] ; AOSHIMA, Satoshi[1] ; KASAHARA, Naoya[1] ; OKAMOTO, Atsushi[1] ; WATANABE, Noriaki[1] ; TSUCHIYA, Noriyoshi[1]

[1]Graduate school of Environmental Studies, Tohoku University

In our previous water-rock interaction experiments under the various hydrothermal conditions using granite or artificial quartz samples, clear cracks or fractures in the samples were observed under the specific hydrothermal condition. We have named this phenomenon as ”Hydrothermally Derived Fracture (HDF)”. Understanding of this fracturing phenomenon may be useful for technological development of geothermal reservoir usage or clarification of vein formation mechanism in the Earth crust. In our previous experimental results, HDF were progressed under the high temperature and low-pressure condition. The result of detailed observation, it was thought that the thermal stress occurred with rapid cooling of rock/mineral sample surface by condensed vapor dew. Similarly, rapid decompression from the high-temperature/pressure state causes, the temperature drop by latent/sensible heat effect. Therefore, when the such rapid decompression was occurred around the rock/mineral samples, HDF may occur under the hydrothermal condition. And so, we attempted rapid decompression experiment from the over 20 MPa / 400?C hydrothermal condition. As a result, the fracturing in the samples was progressed clearly. Therefore, decompression fracturing is possible and the same phenomenon may arise subsurface of near the volcano or hotter and deeper crust with water.

Fracturing of granite under pore pressure and evolution of permeability

HAMASAKI, Shohei[1*] ; KATAYAMA, Ikuo[1]

[1]Department of Earth and Planetary Systems Science, Hiroshima University

Hot Dry Rock (HDR) geothermal power generation, which is included in Enhanced Geothermal System (EGS) is characterized by making artificial geothermal reservoir and this is different from conventional geothermal power generation. This system does not require natural hot water and steam. In this system, artificial reservoir is made by hydraulic fracturing in the basement due to high-pressure water injection, and water circulates in the system. Evolution of permeability is important factor in reservoir assessment. To assess this type of geothermal system, we measured effect of pore pressure compared with permeability during triaxial deformation experiment.

Aji granite was used as experimental sample, which is dense and fine, consists of mainly plagioclase, quartz, and biotite. Permeability was measured by intra-vessel deformation and fluid-flow apparatus (IVA) at Hiroshima University. Aji granite was saturated water before triaxial deformation experiments. Confining pressure (Pc) was fixed 20 MPa and pore pressure (Pp) was ranged from 0 MPa (undrain condition during triaxial deformation) to 15 MPa by 5 MPa at room temperature in triaxial deformation. The recovered samples after deformation experiments were fixed by resin and observed by polarizing microscopes and scanning electron microscope (SEM).We discussed relation between permeability and pore pressure - fracture strength from triaxial deformation experiments.

In original sample, permeability is $2.0X10^{-19}$ m^2 at Pc = 20 MPa. Permeability of fractured samples increased against that of original samples. Permeability proportionally increased from $2.5X10^{-18}$ m^2 at Pp = 0 MPa to $7.0X10^{-17}$ m^2 at Pp = 15 MPa. Fracture strength decreased with Pp decreased, from 400 MPa at Pp = 0 MPa to 350 MPa at Pp = 15 MPa. In fractured sample, there are macro fracture surface and microcracks.

The increase of permeability depends on pore pressure suggests that increase of microcrack width and acceleration of crack-connection and propagation in large Pp. And fracture strength relates crack sharps. Therefore, crack sharp and distribution are important parameter in assessment of permeability. We plan to further experiments which try to reproduce hydraulic fracture and high temperature condition.

The numerical study for behavior of fracture aperture associated with cold fluid flow

KANETA, Kousuke[1*] ; MUKUHIRA, Yusuke[1] ; SWENSON, Daniel[2] ; ITO, Takatoshi[1]

[1]Institute of Fluid Science, Tohoku University, Japan, [2]Mechanical and Nuclear Engineering Department, Kansas State University, USA

Power generation of geothermal power plant sometimes decreases due to reduction of reservoir pressure. Reinjection of used geothermal fluid/cold fluid into the reservoir is conducted in several geothermal power plant to keep/recover the reservoir pressure. It is required for recharge of reservoir pressure that appropriate condition of reinjection in terms of injection pressure, amount of injected fluid, and heat balance. On the other hand, it is empirically observed at some of the geothermal field that amount of injected fluid increases when lower temperature fluid is injected. In this research, we investigated relationship between temperatures of cold fluid and fracture aperture, using numerical simulation.

We conducted numerical simulation for the change in fracture aperture when cold fluid flows into the fracture, using 2D FEM code ″ GEOCRACK2D ″ (Swenson et al., 1995). We set the condition that cold fluid was injected into a single fracture within high temperature rock mass. In this simulation, cold fluid flowed from center of fracture to edge of fracture. Fluid pressure was 1 MPa at center of fracture and 0 MPa at edge of fracture. This given pressure condition made fluid flow from center of fracture to edge of fracture. Initial temperature of rock mass was 300 ℃ and that of cold fluid was 100 ℃. Initial stress condition was 20 MPa in x direction and y direction.

As a result of simulation, the fracture aperture increased with time although 20 MPa of normal stress worked on the rock mass and fluid pressure was at most 1 MPa. It was also simulated that the rock mass around the fracture was cooled down by cold fluid and cooled area extended with time. Normal stress on the fracture decreased. The area where normal stress decreased extended over time.

These results can be interpreted that cooling of rock mass by cold fluid caused thermal shrinkage of rock mass, which decreased normal stress on the fracture surface. Finally, the fracture aperture became large, suggesting increasing in permeability.

We also conducted the simulation for the effect of difference in initial temperature between rock mass and cold fluid. We compared the change in fracture aperture about four temperature difference conditions. Fluid flow, fluid pressure, temperature of rock mass and initial stress condition were same with first simulation. Temperature of cold fluid was 100 ℃, 150 ℃, 200 ℃ and 250 ℃.

As a result of simulation, the fracture aperture increased drastically when the temperature difference between rock mass and cold fluid was bigger than 150 ℃. The fracture aperture slightly increased when the temperature difference is smaller than 100 ℃. The bigger temperature difference was, the earlier fracture aperture opened. The results of simulation suggested that there was the critical value in temperature difference between 100 ℃ and 150 ℃. It was summarized that the fracture aperture increased and that the fracture permeability became large when the temperature difference was bigger than the critical temperature difference.

Slip-able area: New index to evaluate the fault area under critical state based on microseismic data at stimulation

MUKUHIRA, Yusuke[1*] ; ASANUMA, Hiroshi[2] ; HARING, Markus[3] ; ITO, Takatoshi[1]

[1]Institute of Fluid Science, Tohoku University, [2]AIST, [3]Geo Explorer Ltd.

Unexpected occurrence of felt earthquake has been big issue as critical environmental burden associated with geothermal development and other energy extraction. The magnitude of seismic events induced by fluid stimulation is generally small enough to be perceived on the ground. However, at the Basel, Switzerland, some of the events had large magnitude, resulting in the shutdown of engineered geothermal system (EGS) project. Our previous study has revealed the fundamental characteristics and the trigger mechanisms of the large event at Basel. However, we have not reached full understanding of physics of the large events, which enable us to control or manage the magnitude of induced events.

Concept of Slip-able area

Our previous study suggested that the dynamic behavior of pore pressure especially propagation of pressure at the shut-in correlate the event magnitude because many of large events occurred at the shut-in phase in Basel. The pore pressure gradient should exist from the well head to the pressure front during the stimulation. At the shut-in when pumping is stopped, the pressure source despairs and subsequently the pressure gradient may become small with time. Finally, the pore pressure in the reservoir will go back hydrostatic state uniformly. In the relaxation process of the pore pressure gradient, it can be expected that the pore pressure at the far field from the well might slightly increase to average pore pressure increase in whole reservoir. Pore pressure increase at the front of the stimulated zone may put large part of the fault plane into near critical state. In contrast, only some part of the fault plane may become critical state, when the pore pressure increases with the pressure gradient. This is the expected scenario for occurrence of the large event at the shut-in.

So, in this study, we originally defined new concept of Slip-able area, which describes the summation of fault areas in study area, under critical state during/after the stimulation. The informations used in estimating Slip-able are given by the detailed analysis of microseismic events and stress information. Slip-able area can provide the information of the potential fault area which can have shear slip at semi real time. Slip-able area can be directly converted into the event magnitude, suggesting it is also available to the risk assessment of the large event.

Methodology of estimation for Slip-able area

We propose the methodology to estimate Slip-able area as follows.

1.Determine the number of the potential fracture within a given rock volume from microseismic data at the first stage of the stimulation.

2.Characterize the size of the fractures from source parameter of microseismic events and their critical pore pressure for shear slip.

3.Divide the reservoir area into a number of the block with the same size of step1.

4.Determine the stimulated volume in three dimensions by the divided block and information on occurrence of microseismic events.

5.Infer the number of the fracture in a stimulated volume determined in step 4.

6.Estimate maximum increase in pore pressure at given time in each block of stimulated volume.

7.Identify the fault area of the fracture under critical state using the information assummed in step 2.

8.Integrate all fault area of the fractures identified in step 7.

We have to note that the methodology shown above includes some steps with much difficulty or impossible because determination of critical pore pressure is based on the information on orientation of fracture plane and stress information in study area. These informations are not available in many of the geothermal field. Estimation of fault area also required high quality data set of microseismic events. In these cases, it can be valid for simplification to use appropriate constant values like b value as a substitute for characterizing of fault size.

Hydration of crust through brittle fractures: Example from Sor Rondane Mountains, East Antarctica

UNO, Masaoki[1*] ; OKAMOTO, Atsushi[1] ; TSUCHIYA, Noriyoshi[1]

[1]Graduate School of Environmental Studies, Tohoku University

Arc lower crust is expected to be amphibolite from its seismic velocity, and such lithology contains abundant hydrous minerals. However, the amount and mechanisms for supply of H_2O fluid to arc crust are not well constrained. Pervasive flow and channeling flow are the two mechanisms for the transfer of fluid in the crust. As grain boundaries are closed for crustal P-T condition, channeling flow accompanied by brittle fracture is expected. To investigate the role of brittle fracture to the supply of H_2O fluid for crust, crust-melt hydration reaction was investigated at Sor Rondane Mountains, East Antarctica.

In the survey area, biotite-hornblende-peridotite is intruded by numerous granitic brittle dykes, and reaction zones occurs at the boundaries (Fig. 1). The mineral assemblages indicate that the reaction has occurred under lower crustal P-T condition, thus the area is suitable for investigating both mechanical and physical aspects of fluid-rock interactions under the lower crustal condition. Four reaction zones are identified from the granitic dyke to the host rock as follows:

i) granitic dyke
[quartz + plagioclase + K-feldspar + biotite + rutile + zircon ± muscovite]
ii) hornblende-tremolite zone
[hornblende + tremolite ± quartz ± apatite ± biotite]
iii) tremolite-biotite zone
[tremolite + biotite + spinel ± hornblende ± pyroxene]
iv) biotite-hornblende-peridotite
[olivine + orthopyroxene + biotite + hornblende + Cr-spinel ± magnetite ± apatite]

Those reaction zones are product of hydration reactions of host peridotite with H_2O liberated from granitic melt. From plagioclase in granitic dyke and adjoining hornblende, the temperature of those reactions is estimated[1] to be 700 ^{o}C.

The amount of H_2O liberated from the granitic melt will be quantified by the modes of hydrous minerals formed at the reaction zones. Accordingly, the amount of H_2O supplied thorough hydrous melts, and the mechanisms for transport of H_2O and hydration of the crust will be discussed.

Keywords: geofluid, brittle fractures, melt, hydration reaciton, fluid-rock interaction, Antarctica

Fig. 1 Biotite-hornblende-peridotite (brown) intruded by granitic dykes (white), Sør Rondane Mountains, East Antarctica. Note that reaction zones occur at the boundary: green or black layers are hornblende-tremolite zone and grey to reddish brown layers are tremolite-biotite zone.

Composite basaltic andesite lava in Iwanuma (Miyagi, Japan): Differentiation along segregation veins and columnar joints

KIMOTO, Kazuki[2] ; ISHIWATARI, Akira[1*]

[1]Center for NE Asian Studies, Tohoku Univ., [2]Dept. Earth Sci., Grad. Sch. Sci., Tohoku Univ.

Occurrence of thin (3-5 m) composite lavas with central phenocryst-rich layers was reported by Kuno (1950; JGSJ, 56, 167-172) and others, but we found very thick (>110 m) composite lava comprising a single cooling unit (with penetrating columnar joints) but consisting of some distinct chemical layers with segregation veins at the layer boundaries.

The basaltic andesite lavas of the middle Miocene age (15˜13 Ma) occur in Iwanuma City, Miyagi Prefecture, Japan. Thickness of the main lava flow measures more than 110 m. Vertical columnar joints of 1 or 2 m intervals are well developed through the outcrop. This lava flow is a composite lava flow with the lower layer (0˜42 m from bottom) having rather felsic composition (SiO_2 55 wt. %) and the upper layer (45˜110 m from bottom) having more mafic compositions (SiO_2 52˜54 wt. %).There are no macroscopic differences between the two layers, but the size of plagioclase in the nearly holocrystalline groundmass of the upper layer is larger (<0.5 mm) than that of the lower layer (<0.3 mm) under the microscope. Red clinker is seen at the bottom of the outcrop, but the top of the flow has been eroded.

Many horizontal segregation veins are observed at the limited portions in the intervals of 6˜14 m (lower vein zone), 45˜64 m (central vein zone) and 80˜95 m (upper vein zone) from bottom. The lower veins are 1 mm in thickness at intervals of 1˜10 cm, have glassy structure and contain plagioclase and augite. The central veins are 5˜15 mm in thickness at intervals of 10˜15 cm at 45 m from bottom and 3˜5 mm at intervals of 5˜15 cm at 52˜64 m from bottom, have crystalline structure and contain plagioclase, pigeonite and subcalcic augite. The upper veins are 3˜5 mm in thickness at intervals of 5˜7 cm and have similar structure and mineral assemblage to the central veins. The segregated melt of the central veins forms after the approximately 70 % crystallization of the host magma. The segregation veins are apparently formed by the migration of the residual melt into the subhorizontal fractures (platy joints) which resulted from the shear deformation and cooling contraction in the crystallizing lava flow, especially near the bottom of the flow and at the bottom part of the flow and relatively mafic layers in the upper part of the composite lava flow. Rare en echelon segregation veins are the evidence for shear deformation.

The columnar joints always perpendicularly cut segregation veins, and the rocks adjacent to the columnar joint plane show low density and increase of vesicles in comparison with the rocks in the middle of the column. This suggests that columnar joints developed far later than the segregation-filled platy joints, but some melt was still present at that time so as to allow its vesiculation promoted by the columnar joint fracturing.

Keywords: composite lava flow, segregation vein, platy joint, colunmar joint, basaltic andesite, crystallization differentiation

The formation of the permeable-impermeable boundary within the Earth's crust revealed by silica precipitation

SAISHU, Hanae[1*] ; OKAMOTO, Atsushi[1] ; TSUCHIYA, Noriyoshi[1]

[1]AIST, [2]Tohoku University

Silica is one of the dominant constituents of the Earth's crust. The permeable-impermeable boundary corresponds to the brittle plastic transition at 300-450 C [1]. Ubiquitous occurrence of quartz vein is one of the evidences that the spatial and temporal variations in permeability within the Earth's crust are affected by silica precipitation in aqueous fluids. However, the role of silica-water interaction on fracture permeability is still unclear.

The Kakkonda geothermal field, Japan, has the well WD-1a that penetrated the boundary between the hydrothermal convection zone and the heat conduction zone [2]. Calculation of quartz solubility along the well WD-1a revealed that (1) the depth of a local maximum of quartz solubility correlates with that of the strong reflector in seismic data at 350 C isotherm [3], and that of a maximum of fracture numbers revealed by the logs of FMI [4], and (2) the depth of a local minimum of quartz solubility correlates with that of the permeable-impermeable boundary, in either case of hydrostatic or lithostatic conditions [5]. These results indicate that (1) the preservation of open fractures at the margin of the Kakkonda granite is controlled by dissolution of quartz, and (2) the quartz precipitation could occur from both downwards- and upwards-moving fluids, which could divide the hydrothermal convection zone and the heat conduction zone.

The hydrothermal experiments of temperature dependence of silica precipitation were conducted at 24 and 31 MPa and 170-430 C, by using the solution made by dissolution of granite. The large amount of silica precipitation occurred only in the supercritical conditions of water (>390 C). Strong temperature dependence can be explained by the homogeneous nucleation of quartz in the surface energy of quartz of 130 mJ/m^2 [5].

The results of the calculation of silica solubility at the Kakkonda geothermal field and the hydrothermal experiments of silica precipitation suggest that rapid quartz precipitation via nucleation could occur when fluids are brought to the depth in the supercritical conditions of water. The forming and sustaining the permeable-impermeable boundary within the Earth's crust could be controlled by precipitation of silica minerals.

Introduction of NANO-EPS

SUZUKI, Yohey[1*]

[1]Department of Earth & Planetary Science, The University of Tokyo

Nano, a prefix for 10^-9, represents vast frontiers for both Earth and Planetary Solid Sciences. Conventional tools such as Electron Probe MicroAnalysis (EPMA) for ppm-level quantification at the micrometer scale and Power X-Ray Diffraction analysis (XRD) for the identification of submicron minerals are being transformed into the next generation instruments. In addition, it is possible to reveal the heterogeneity and oscillation of chemical and isotopic compositions at nano-spatial resolutions. It is becoming more aware that nano-sized solids with extremely large surface areas and distorted structures are ubiquitous in planetary materials and intimately relevant to many issues such as soil and groundwater contamination with metals and radionuclides, mineral resources exploitation, carbon sequestration and so on. In my presentation, nano-frontiers from various fields of Earth and Planetary Sciences and key technological advancements will be overviewed as the introduction of this session.

Properties and depositional process of sub-micron scale manganese oxide minerals in the aqueous surface enviromnent

USUI, Akira[1*]

[1]Akira Usui

A large variety of minerals form submicron compounds or minerals in the surface aqueous environments (sea waters, rivers, soils, underground waters, organisms etc.) Especially iron and manganese oxide are most mobile elements among others in such environments. The iron and manganese oxides often scavenge numbers of metallic elements and play significant role in material cycling and geochemical cycles. In this paper, we attempt to introduce several types of occurrences of manganese oxide in the diverse environments. For example a phyllo-manganate minerals, nano-scale aggregate are shown in the paper.

Development of PF-STXM and its application to environmental geochemistry

TAKAHASHI, Yoshio[1*] ; TAKEICHI, Yasuo[2] ; SUGA, Hiroki[1] ; INAMI, Nobuhito[2] ; ONO, Kanta[2]

[1]Graduate School of Science, Hiroshima University, [2]Photon Factory, KEK

Scanning transmission X-ray microscopy (STXM) has been applied to various fields in earth and environmental sciences such as aerosol chemistry, geomicrobiology, soil science, and nanomineral sciences. In particular, the technique has been used in the world because of its great importance in imaging distribution of carbon, or in particular carbon functional group, with about 50 nm spatial resolution. However, STXM that can be used to measure NEXAFS at carbon K-edge has not been in use in Japan. We have constructed STXM in Photon Factory (PF-STXM) from 2012 and started to use it for various topics in earth and environmental sciences.

In the PF-STXM, soft X-rays from the undulator are monochromatized by the grating and focused at the four-way aperture slit. The FZP with the outermost zone width of 30 nm is placed at 1 m distant from the aperture slit. First order diffraction selected through an order sorting aperture (OSA) is focused onto the sample with the focal distance of 0.7-5 mm, and then the transmitted X-rays are detected. The PF-STXM at present is mainly operated at BL-13A in Photon Factor, where the energy range available is from 250 eV to 1600 eV, which covers K-edges of carbon, nitrogen, oxygen, potassium, and aluminum. The beamize of the STXM was around 50 nm focused with Fresnel zone plates (FZP). The intensity of focused X-rays at the sample was expected to be up to 10^7 photons/s. Instead of a photomul-tiplier tube (PMT) which is commonly used in STXM, a silicon avalanche photodiode (APD) is utilized to detect the transmitted X-rays in PF-STXM. Compared with other STXM system in the world, our STXM is made so compact and light that it is easily connected to and removed from the multi-purpose beamlines. The experiments reported below are performed at BL-13A and BL-16A of Photon Factory.

The PF-STXM has been used for various applications. Among them, we would like to present recent results on (i) speciation of calcium in mineral dust with 50 nm spatial resolution, (ii) characterization of carbon adsorbed on particulate matter in river water, and (iii) spatial distribution of rare earth elements in bacterial cell.

Nano-scale investigation of the microbe-mineral interaction by scanning transmission X-ray microscopy

MITSUNOBU, Satoshi[1*] ; SHU, Mei[1] ; TAKAHASHI, Yoshio[2] ; TAKEICHI, Yasuo[3] ; ONO, Kanta[3]

[1]University of Shizuoka, [2]Hiroshima University, [3]KEK-PF

Microorganisms in the environment critically impact global geochemical cycles and redox reactions of various elements. Many geochemically important redox reactions (e.g., sulfate reduction, Fe(II) oxidation) are largely associated with microbial activity. In addition, microbes can mediate both mineral formation (biomineralization) and mineral dissolution (bioleaching). Recent studies suggest a significant relationship between Fe(II)-oxidizing bacteria and ancient Banded Iron Formation, one of the large geochemical events in Earth's history. The general ecological importance of environmental microbial reaction has been well recognized; however, the specific mechanisms of the reactions in the environments such as the reaction rate and spatial dynamics are poorly understood. In the environment such as sediments, microbial reactions and habitability vary locally and form complicated geochemical networks, which makes it difficult to characterize the specific biogenic reactions in detail.

Scanning transmission X-ray microscopy (STXM), which uses near-edge X-ray absorption spectroscopy (NEXAFS) is a powerful new tool that can be applied to hydrated biological materials with high spatial resolution. The STXM provides spatial resolution of better than 50 nm, which is suitable for imaging bacteria and bacterial biofilms.

In the present study, we applied the STXM into the bioleaching of sulfide mineral (pyrite) to determine carbon, oxygen, and iron species in nano-scale. Both metal and biogenic organic materials in pyrite-microbe interface were investigated in the single cell level. Our study shows that the STXM could be a potential technique to provide direct information on specific biogenic reaction microorganism.

Formation rate of iron colloids at pH 2-3

NAGASAKI, Sagakuni[1*] ; YOKOYAMA, Tadashi[2] ; HISATOMI, Osamu[2] ; NAKASHIMA, Satoru[2]

[1]Department of physics , Osaka University, [2]Department of Earth and Space Science, Graduate School of Science, Osaka University

Various types of iron colloids are widely distributed in the earth's surface conditions, and their formation process, adsorption characteristic, and the material transport mediated by iron colloids are receiving attention. Iron colloids are often formed through several reactions including the dissolution of Fe^{2+} and Fe^{3+} from minerals, oxidation from Fe^{2+} to Fe^{3+}, hydrolysis, and crystallization. In the present study, the reaction rate was evaluated focusing on the process in which iron colloids are formed from dissolved Fe^{3+}.

A solution of Fe^{3+} 100 ppm was prepared by dissolving $FeCl_3$ into pure water. This solution was reacted at 15, 25, 35, 45, and 55 ℃. At 25 ℃, pH of the solution was ∼2.7 at the start of the reaction and decreased to ∼2.2 as reaction time passed. Such change in pH is known to occur as a result of the following reactions: hydration of Fe^{3+} (release of H^+) → formation of dissolved $Fe(OH)_3$ → formation of solid $Fe(OH)_3$ (Grundl and Delwiche, 1993). Therefore, information of the formation rate of iron colloids can be obtained by monitoring the pH of the solution. After the initial period of the reaction in which the rate of the decrease of dissolved $Fe(OH)_3$ concentration was slow presumably due to nucleation, the concentration of dissolved $Fe(OH)_3$ decreased in a manner like first-order reaction, and the reaction behavior deviated from the first-order reaction at the later stage. By assuming first-order reaction, rate constants of 3.3E-5 - 1.1E-2 s^{-1} were obtained at 15-55 ℃, and good linearity was confirmed in an Arrhenius plot of these rate constants.

In addition to the above experiments in which time variation of the total amount of solid is considered, the time variation of the grain size of iron colloids was evaluated. A solution of Fe^{3+} 100 ppm was prepared and the change of grain size at 25 ℃ was continuously measured using a dynamic light scattering apparatus (Zetasizer μV, Malvern). As a result, enough scattering intensity began to be detected after the mean diameter of iron colloids grew to 10 nm, then the grain size increased. The increase of the grain size almost stopped after 8 hours, and mean diameter at this stage was approximately 30 – 40 nm. By evaluating the number of grains from the total amount of solid and mean grain size, the grain number was estimated to decrease with time.

Surface complexation modeling for lead adsorption on nano-sized aluminum silicate

USHIYAMA, Tomoki[1*] ; FUKUSHI, Keisuke[2]

[1]Graduate School of Natural Science and Technology, Kanazawa University, [2]Institute of Nature and Environmental Technology, Kanazawa University

There are many abandoned lead-produced mines in Japan. The water pollutions by lead due to the weathering of the mine wastes are environmental concern. The concentrations of lead released from the mine wastes is usually low. Therefore, the adsorption process is expected to dominate the mobility of lead in the affected area. It is well recognized that the materials widely occurred in earth surface conditions are comprised with low-crystalline and/or nano-sized minerals. There are some reports for lead adsorption behavior on crystalline phases such as clay minerals and low-crystalline iron oxides. On the other hand, there are very little reports on nano-sized aluminum silicates which must be dominant phases in surface condition. The quantitative understandings of lead adsorption on nano-sized aluminum silicate is essential for the prediction of lead migration in earth surface conditions. The purpose of the study is to clarify the lead adsorption behavior on nano-sized aluminum silicate under wide range of solution conditions and model the adsorption behavior by means of surface complexation modeling.

Keywords: nano-sized aluminum silicate, lead, adsorption, surface complexation modeling

Mineralogical study of serpentinite from Akamatsu, Yatsushiro, Kumamoto prefecture.

IWAKI, Yasuyo[1] ; ENJU, Satomi[1*] ; UEHARA, Seiichiro[1]

[1]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

Serpentine group minerals are one of the 1:1 layer type sheet silicates and the main component of serpentinite. They are classified into three mineral species chrysotile, lizardite and antigorite. The ideal formula of chrysotile and lizardite is $Mg_3Si_2O_5(OH)_4$and that of antigorite is $Mg_{48}Si_{34}O_{85}(OH)_{62}$.

In our previous study, we researched serpentinite from a large area in Kyushu Kurosegawa belt (Tanaka et al., 2012), but there are only few reports for each area. So, the purpose of this study is to identify the composition minerals of serpentinite in Akamastutaro Pass and Tanoura, located in west of Kyushu Kurosegawa belt, and to conduct a detailed study of serpentine.

Mineral species was identified by XRD pattern and serpentinite was classified into three type: antigorite main serpentine (Type AA, 16 specimens), antigorite rich serpentine (Type A, 10 specimens) and antigorite poor serpentine (Type LC, 8 specimens). Antigorite was most abundant. Magnetite, chromite, clinochlore, brucite and hydrotalcite group minerals were identified in specimens from both areas. Only the specimen from Akamatsutaro Pass had andradite, calcite, heazlewoodite (Ni_3S_2) and millerite (NiS), while forsterite, hydromagnesite, pyroaurite and awaruite (Ni_3Fe) were seen only in Tanoura. The supply of H_2S in Akamatsutaro Pass can be estimated from the presence of heazlewoodite and millerite. Relict forsterite was observed in serpentinites from Tanoura, indicating the smaller degree of serpentization compared to Akamatsutaro Pass.

Sepentine contained in massive serpentinite had variable textures such as vein texture, reed shape texture and mesh texture with core and rim, which was formed after serpentization of olivine. In the specimens of Type LC, mesh texture was often observed, and there were cores with no rim in samples without mesh textures. Also some core texture was replaced by reed shape texture. Chemical compositions obtained by SEM-EDS show some trends for serpentines in each texture. Reed shape texture contains 0.041 (apfu) Al which replaces Mg, while core texture contain 0.07 Al and rim texture contains 0.006 Al, so reed shape texture is rich Al than mesh texture. Reed shape texture contain larger amount of SiO_2 weight percent compared with the ideal formula of chysotile and lizardite, and resemble that of antigorite.

The lithium existence form in a lithium ore deposit

SUZUKI, Masaya[1*] ; KON, Yoshiaki[1] ; EJIMA, Terumi[1] ; HIRABAYASHI, Eri[1] ; SATOU, Takumi[1] ; OOWADA, Akira[1] ; TAKAGI, Tetsuichi[1] ; TSUKIMURA, Katsuhiro[1] ; SAWAKI, Takayuki[1] ; MURAKAMI, Takayoshi[2] ; MOTOORI, Masayuki[2]

[1]AIST, [2]JOGMEC

In the ore deposit containing lithium, Spodumene, Petalite, Lepidolite, etc. are known as a lithium mineral, but these minerals are not contained in the lithium ore deposit examined this time. So, in this research, the result analyzed using XRD and SEM+EDS is released.

In the ore deposit containing lithium in this time, it roughly divides of a white portion and a portion of ashes green. From the result of XRD, it mainly becomes a white portion from Searlesite($NaBSiO_5(OH)_2$), Calcite($CaCO_3$), and Orthoclase($KAlSi_3O_8$), and the mineral containing lithium is not shown. On the other hand into the portion of ashes green, Calcite($CaCO_3$), Orthoclase($KAlSi_3O_8$), Illite($K(Al,Mg,Fe)_2(Si,Al)_4O_{10}$), Rozenite($FeSO_4 4H_2O$), and Cryolitionite($Li_3Na_3Al_2F_{12}$) are contained was obtained. Since the peak of various minerals had appeared, it could not declare that Cryolitionite existed clearly, but it was suggested that Cryolitionite may exist as a lithium content mineral.

Next, from the results of SEM+EDS analysis, in the white part, Calcite and Orthoclase were contained at about 10-100 micrometers, and Sealesite existed in it at those circumferences. And in the green gray part, Orthoclase, Calcite, Illite, Rozenite were contained at about 10-30 micrometers, and the particle with a size of 1 micrometer or less existed in those circumferences. Although measurement of Li was not completed in analysis of EDS, it was checked that F is contained in the analysis of these microscopic particles.

From the above result, it was surmised that the lithium content mineral examined this time was Cryolitionite.

The mathematical link between stratigraphic grain size variation of fall deposits and its time variation at the source

IRIYAMA, Yu[1*] ; TORAMARU, Atsushi[2] ; YAMAMOTO, Tetsuo[3]

[1]Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, [2]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, [3]Center for Planetary Science, Kobe University

Pyroclastic fall deposits which are produced by explosive volcanic eruption have various information on the eruption events. The areal distributions of pyroclastic fall deposits such as maximum grain size, median grain size, thickness, mass per unit area, etc. reflect the intensity in a single eruption and the wind conditions. Stratigraphic grain size variations of pyroclastic fall deposits also reflect the temporal behavior of the eruption intensity. For example, normal or reverse grading structures in the pyroclastic fall deposits have been attributed to temporal variation in the volcanic intensity (column height) and/or in the initial grain size distribution at the vent. However, no quantitative methodology has been developed to relate the temporal variation of source characteristics (column height and initial grain size distribution) to stratigraphic variation of grain size distribution at the deposits. In this study, we consider the mathematical description in 1D fall-sedimentation process, which relates the temporal variation of source grain size distribution to stratigraphic variation of grain size distribution.

The number of grains in a size bin must be conserved during sedimentation process and results in the same value at the arrival time on the deposits. The number of a specific-size grains between at the fallout time and at given times is linked by Lagrangian description. The key point is that the grain size and the departure time at the source are mutually related to the grain size and the arrival time at the deposits. As the arrival time corresponds to the stratigraphic location at the deposit, the stratigraphic variation of grain size in the deposit can be connected to the grain size characteristics and departure time at the source using the condition of grain number conservation. As a result, when the time variations of source grain size distribution and of fallout height are given, we obtain the temporal variation of grain size distribution at the sedimentation surface. It means that different sizes of grains which settle at the same arrival time are traced back to the different source time and height. The arrival time on the deposit can be related to the stratigraphic height in the deposit by the differential equation of increasing rate of the thickness, which equals to the volume flux through the sedimentation surface. By using these mathematical descriptions, we develop the mathematical method to link the temporal variation of eruption intensity to the stratigraphic variation of grain size distribution in the fall deposits.

Color and grainsize of ash samples collected continuously at Sakurajima volcano, Japan

SHIMANO, Taketo[1*] ; NISHIMURA, Takeshi[2] ; IGUCHI, Masato[3] ; MIKI, Daisuke[3]

[1]Graduate school of Enviroment and Disaster Research, Tokoha University, [2]Department of Geophysics, Graduate School of Science, Tohoku University, [3]Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University

Sakurajima volcano, Southwest Japan, is one of the most active volcano, and one of the leading volcano that are characterized by well-established geophysical observation network and enormous amount of data accumulation. Thus, the changes of magma plumbing system and the explosion processes at Sakurajima are now relatively well-understood for the time scale of years and of several hours, respectively (Iguchi et al., 2013). On the other hand, Sakurajima volcano has experienced several giant explosive eruptions every few hundred years, with some plinian eruptions and with erupted volume in the order of $>10^8$ m^3. However, we do not understand the mechanism of phase transition from the recent small eruptions to such bigger ones. Even though we now reached a certain level to recognize that our knowledge of " vulcanian eruption " was too simple relative to real one, the fundamental processes that lead to such eruption variety are not yet constrained well enough. As the variety of eruption styles occurs in a time scale of months to days, we have been focusing on the sample acquisition in this time range and collected daily ash samples for years.

We have been succeeded in collecting daily samples by automatic sampling system for more than five years at the site ca 2 km south of Showa crater, Sakurajima volcano (Shimano et al., 2013). We also analyzed matrix glass composition to track chemical evolution of the magma system, and found a shift of FeO^*/MgO in fall of 2009 before the waxing activity toward 2010. On the other hand, we have been searching for some real-time technique of petrological data for the comparison with geophysical data. The development of useful colorimeter and some results of heating experiments of ash resulted in understanding relationship between color of ash and condition of magma at depths (e.g., Yamanoi et al., 2008; Miyagi et al., 2013). So we have made time-series color measurements of ash samples for years. We found L^* value, degree of brightness, decreased broadly during waxing stage in 2009-2010 whereas a^* and b^* values increased broadly at first several months but decrease gradually. These changes can be explained by increase of black fresh lava block particles, increase at the first stage and gradual fluctuating changes of old red oxidized particles in ash sample. We also measured color change of some grain size group and compared with the color of bulk samples. The preliminary results show that the color differs with particle size as Miyagi et al. (2010) reported, but a correlation was found between the color values of bulk sample and those calculated from the weight fraction and each color values.

Numerical Simulation of Volcanic Ash Transport for the Eruptions at Mt. Shinmoe-dake during 26-27 January 2011

HASHIMOTO, Akihiro[1*] ; SUZUKI, Yujiro[2] ; SHIMBORI, Toshiki[1] ; TAKAGI, Akimichi[1]

[1]Meteorological Research Institute, Japan Meteorological Agency, [2]Earthquake Research Institute, The University of Tokyo

The volcanic ash transport associated with the eruptions at Mt. Shinmoe-dake during 26 to 27 January 2011 is simulated using Japan Meteorological Agency Non-Hydrostatic Model (JMA-NHM) to verify the model with satellite observation. In the model, the mixing ratio and number concentration of ash particles are prognosed with the advection, diffusion, sedimentation, and source terms to represent the behavior of ash cloud. Simulation has been performed in the calculation domain covering 2500 km x 2000 km wide area with the horizontal resolution of 5 km.

The model is coupled with one-dimensional eruption column model to define the source term of ash particles, which is simply given as a function of the column height, the level of the release point, and the size of released particle, following Suzuki (1983) and Shimbori et al. (2010). Although the simulated distribution of ash cloud roughly agrees with satellite observation, close examination of the simulation result shows that the model fails to reproduce some of the ash clouds observed by the satellite, which means that much room still remains for improvement in the eruption column model in terms of release point and size spectra of ash particles. Three-dimensional direct numerical simulation has been conducted on a major sub-Plinian eruption during the period at Mt. Shinmoe-dake (Suzuki and Koyaguchi, 2013), in order to make new eruption column model with more realistic function for the source term of ash particles. As a result, it is found that the maximum release rate of the ash particles smaller than 100 μm appears in the height lower than that predicted by the usual eruption column model for same column top height. The authors are developing new eruption column model with realistic profile of release rate, based on this result, so as to improve the reproducibility of the ash transport with JMA-NHM. The sensitivity of the ash transport to altering the new and usual eruption column models will be presented.

Sakurajima volcano has been active since February 2009. The total number of explosive eruptions was 966 in 2011, which was the highest number in recorded history. Corresponding to volcano activities, the ash accumulation in Kagoshima city increased and total ash amount of 3,500g/ m2 was recorded at Kagoshima local meteorological observatory. Because the volume of volcanic ash in rural area paralyze public ground transportations such as rail road and highway, fast recovery efforts are required to the railroad company and city government. However, no quantitative volcanic ash fall estimation has been established. The present study focuses on utilization of operational weather radar for quantitative ash estimation (QAE), quantitative ash forecasting (QAF), and utilization of crustal movement information for providing ash volume which is necessary for initial conditions of a numerical diffusion model. Although the target volcano of the present study is Sakurajima, the knowledge on volcanic ash and algorithm developed by the present study can be applied to any other volcano which is located in operational weather radar observation area.

Eruption types determined by the mass flux and volatile component content of ascending magma flow

IDA, Yoshiaki[1*] ; OIKAWA, Jun[2]

[1]Advance Soft Co., [2]Earthquake Res. Inst., Univ. of Tokyo

Volcanic eruptions include the effusive ones that erupt fluid lava and the explosive ones that emit magma fragments in gassy flows or other forms. Traditionally, explosive eruptions are further classified into Plinian eruptions accompanied by high eruption columns, Pelean eruptions involving abundant pyroclastic flows, Vulcanian eruptions with strong instantaneous explosions, Strombolian eruptions involving periodic lava fountains and so on. Effusive and explosive eruptions are clearly controlled by the efficiency of degassing, but what produces various types of explosive eruptions has not yet been explained quite clearly. In this paper I propose a simple idea about how various explosive eruptions arise depending on the natures of ascending deep magma flow based on a stationary conduit flow model.

The state of erupting magma may be represented by exit velocity and the volatile content that determines the vesicularity of volcanic products. The volatile content is specified by its mass ratio to the fluid magma (including solidified part). On the other hand, it is convenient to represent the deep state of magma flow by the mass flux of fluid magma and the volatile contents before degassing takes place. When the magma flow is in a stationary state the mass flux of fluid magma is constant so that it defines the deep state of magma flow with the initial volatile content independently of the specific depth at which magma ascent starts.

The relation between the surface and deep states of ascending magma is calculated using a stationary conduit flow model. In this calculation the volatile component is assumed to move at the same speed as the fluid magma neglecting relative motions. In bubbly magma horizontal permeable flow of volatile gas is assumed to control the rate of degassing. In this treatment, the pressure gradient that drives the permeable flow is considered to arise from the ascent velocity change from center to side and the resulting difference of relaxation of gas expansion due to decompression (Ida, JVGR, 162, 172-184, 2007). The wall friction is assumed to be proportional to ascent velocity in bubbly flow and to the square of ascent velocity in gassy flow with suitable friction coefficients. The relation for water steam in magma is used for solubility of volatiles in magma.

The integration of conduit flow is executed from the surface to a deep conduit. Namely, the deep state of magma flux and volatile content are calculated for various sets of the exit velocity and volatile content at the surface prescribed with the magma pressure equal to the atmospheric pressure. Compiling the calculation results shows that some groups characterize the relation between the surface and deep conditions. Each group can be interpreted in connection with eruption types in the following way.

Firstly, high-speed gassy flow erupts violently when the deep magma contains sufficiently abundant volatile component. This case may produce a Plinian eruption. In this case the exit velocity and gas content are determined by the deep magma flux alone independently of deep gas content because of adjustment by degassing during the ascent process. Secondly, a stationary conduit flow disappears below the critical value of fluid magma flux with high gas content in a deep conduit. In this case magma flow should be non-stationary and may produce Vulcanian or Strombolian eruptions. Thirdly, a relatively slow magma flow with low vesicularity flows out when volatile component is poor. This case likely results in Pelean eruptions because of difficult acceleration of gassy flow in the air.

Our analysis and interpretation suggest that various eruption types arise from different combinations of ascending magma flux and degassing efficiency. It is non-linearity involved in ascending magma flow with vesiculation and degassing that produces separate groups characterizing eruption types.

Magma eruption rates, eruption styles, and preeruptive magma viscosity

TOMIYA, Akihiko[1*] ; KOYAGUCHI, Takehiro[2] ; KOZONO, Tomofumi[3] ; TAKEUCHI, Shingo[4]

[1]Geological Survey of Japan, AIST, [2]Earthquake Research Institute, University of Tokyo, [3]Department of Geophysics, Graduate School of Science, Tohoku University, [4]Civil Engineering Research Laboratory, Central Research Institute of Electric Power Industry

Magma eruption rate is one of the most fundamental parameters for a volcanic eruption (e.g., Pyle, 2000). It is obtained mainly by geophysical or geological observations. We interpret this important parameter from a petrological point of view and also from a fluid dynamic point of view.

We have collected a hundred of data on magma eruption rates, bulk rock chemical compositions, and phenocryst contents for various styles of eruptions (Plinian, sub-Plinian, basaltic Plinian, lava flow, and lava dome). We are compiling these data on the basis of their 'preeruptive magma viscosities', which are important measures of magma eruptibility (Takeuchi, 2011). Preeruptive magma viscosity is the viscosity of magma (melt + crystals) in the magma chamber at the preeruptive conditions. This value can be obtained by the bulk rock chemical composition and phenocryst content, using an empirical formula (Takeuchi, 2010). We have found that eruption styles are closely correlated to preeruptive magma viscosities but poorly correlated to bulk rock compositions.

We have also examined the difference in magma eruption rates between the explosive phase(s) (e.g., Plinian) and the effusive phase (e.g., dome) in a series of eruptions, in order to understand the transition between these two eruption styles (e.g., Kozono and Koyaguchi, 2009a,b). We have found that the difference is positively correlated to preeruptive magma viscosity.

The above results indicate that preeruptive magma viscosities largely control eruption styles and eruption rates. Our results also show that the eruptive magmas are divided into two types, low-viscosity type (basalt to low-phenocryst-content andesite) and high-viscosity type (high-phenocryst-content andesite to rhyolite). The boundary is at about 10^4 Pa s. These two types may be closely linked to the magma generation processes (e.g., fractional crystallization and melt segregation from crystal mush).

Conditions for transition from lava dome to explosive eruption

KOZONO, Tomofumi[1*] ; KOYAGUCHI, Takehiro[2]

[1]Department of Geophysics, Graduate School of Science, Tohoku University, [2]Earthquake Research Institute, University of Tokyo

Conduit flow dynamics involving magma vesiculation, gas escape, and crystallization during a lava dome eruption lead to complex processes such as a transition to an explosive eruption. Because the transition from the lava dome to the explosive eruption is accompanied with a drastic increase in eruption intensity, it is important for volcanic hazard mitigation to determine conditions for this transition to occur. In this study, on the basis of a 1-dimensional conduit flow model, we investigated how the conditions for the transition from the lava dome to the explosive eruption depend on magmatic and geological parameters.

In order to systematically investigate the dependence of the transition conditions on the magmatic and geological parameters, we used the relationship between chamber pressure (p_{ch}) and mass flow rate (q) for steady conduit flow (the p_{ch}-q relationship). When the slope of the p_{ch}-q relationship (dp_{ch}/dq) has a positive value (positive differential resistance), the steady flow is stable. When dp_{ch}/dq has a negative value (negative differential resistance), on the other hand, the steady flow is unstable. The negative differential resistance is generated by two positive-feedback mechanisms. First, effective magma viscosity decreases with increasing q because of delay of crystallization, leading to reduced viscous wall friction (feedback 1). Second, magma porosity increases with increasing q because of less efficient gas escape, leading to reduced gravitational load (feedback 2). These two feedback mechanisms induce a sigmoidal p_{ch}-q relationship for some realistic conditions; the positive differential resistance in the low-q and high-q regimes, and the negative differential resistance in the intermediate regime. The analyses of time-dependent conduit flow model indicate that, because of the sigmoidal pch-q relationship, as magma supply at depth gradually increases from the low-q regime to the intermediate regime, magma discharge rate abruptly increases from the low-q to high-q regimes. This abrupt increase in magma discharge rate accounts for the transition from a stable lava-dome eruption to an explosive eruption. We, therefore, define the value of q at the boundary between the low-q and the intermediate regimes as the critical magma supply rate for the transition (q_{cr}).

Our results show that q_{cr} is mainly controlled by the feedback 2 for a wide range of magmatic and geological conditions, whereas it is controlled by the feedback 1 only when phenocryst content is very high. When q_{cr} is controlled by the feedback 2, the value of q_{cr} depends on parameters related to gas escape such as the permeability for vertical gas escape and that for lateral gas escape. We found that for a plausible range of vertical permeability which is constrained from permeability measurements of volcanic rocks, q_{cr} remarkably decreases with decreasing lateral permeability, and it becomes substantially lower than typical magma discharge rates for observed lava-dome eruptions in the limiting case of zero-lateral permeability (i.e. no lateral gas escape). This indicates that the presence of lateral gas escape is a necessary condition for a stable lava-dome eruption to occur. In addition, we found that q_{cr} strongly depends on conduit radius owing to the effects of the change in the conduit radius on the degree of gas escape. As the conduit radius decreases, the ascent of the liquid is suppressed because of the increase in wall friction force, which promotes vertical gas escape. The decrease in the conduit radius also induces an increase in the ratio of the perimeter to the cross-sectional area of the conduit and a decrease in the length scale of pressure gradient that drives lateral permeable gas flow, which promotes lateral gas escape. These promotions of gas escape lead to an increase in q_{cr}. The above results suggest that the variation of conduit radius is a key factor for the transition from a lava-dome to an explosive eruption.

A phreatic explosion model for Mayon volcano, Philippines, inferred from analyses of an explosion earthquake

MAEDA, Yuta[1*] ; KUMAGAI, Hiroyuki[1] ; LACSON, Rudy[2] ; FIGUEROA, Melquiades[2] ; YAMASHINA, Tadashi[3] ; OHKURA, Takahiro[4] ; BORNAS, Antonia[2]

[1]Nagoya University, [2]PHIVOLCS, [3]Kochi University, [4]Kyoto University

Mayon is one of the most active volcanoes in the Philippines with 49 known historical eruptions from 1616 to 2010. A phreatic explosion took place at Mayon on 7 May 2013 that killed five climbers. In this presentation, we show the results of the waveform inversion for the explosion earthquake and discuss a phreatic explosion model for Mayon.

During the explosion in 2013, a VLP event with a peak frequency of 0.4 Hz was recorded by three broadband seismometers which we had installed in 2011. We performed a frequency-domain waveform inversion in 0.1-0.6 Hz, which pointed to a combination of a subhorizontal tensile crack and a vertical single force at a shallow part beneath the summit crater. Contributions from the crack and force to the waveforms had amplitudes comparable to each other.

The source time functions obtained by the waveform inversion are bandpassed forms (filtered source time functions; FSTFs), which may be different from the source time functions without filters (deconvolved forms of the source time functions; DSTFs). Instead of performing numerically unstable deconvolution operations, we assumed simple step- and impulse-type functions with finite durations as candidates of the DSTFs. We applied the bandpass filter to these functions and compared with the FSTFs. The bandpassed waveforms of the impulse-type functions were similar to the FSTFs for both the crack and force, suggesting that the DSTFs can be approximated by the impulse-type functions. The estimated DSTF for the tensile crack showed an inflation followed by a deflation, whereas that for the single force showed a downward force around the time of the maximum opening of the crack.

The RMS seismic amplitudes, GPS baseline lengths over the volcano, ground surface temperatures around the summit, waveform correlations among the seismic stations, the sulfur dioxide emission, and rainfall did not show clear precursory signals.

Since the analyzed VLP event occurred during the phreatic explosion, the initial inflation in the DSTF for the crack may have been caused by boiling of underground water. This crack is subhorizontal and located at a shallow part, suggesting that the crack may be located on a boundary between permeable and impermeable layers where the water may have accumulated and finally boiled, generating the explosion. The downward force may represent the counter force of the explosion. The deflation of the crack in the latter half of the DSTF may have been caused by outgassing of water vapor during the explosion.

The estimated moment amplitude is explained by a volume change of 400 m $\times$ 400 m $\times$ 0.4 m. A topographic change comparable to this crack size was not observed during the explosion, suggesting that the explosion destroyed only a limited portion of the crack. This crack may repeat the explosion once the fragmented portion of the crack is sealed through the hydrothermal alteration. At Mayon, small ash explosions occurred in 2003, 2004, 2006, and 2009, with intervals of a few days to a few years (mostly longer than one month). These intervals are close to experimentally derived time scales of fracture sealing by the hydrothermal alteration; according to the experiments by Berger et al. (1994, Geochim. Cosmo. Acta), who used basalt samples with chemical compositions similar to magmatic eruption deposits at Mayon, a centimeter-order fracture is sealed in two months for 300 ℃ and 54 months for 150 ℃.

In this model, timings of the explosions are controlled by the sealing of the fracture. Therefore the explosions can occur even with a constant supply of heat and water. This may be the reason why no clear precursory signals were observed before the explosion in 2013. No VLP events other than that associated with the explosion in 2013 have been observed at Mayon since the beginning of the observation in 2011, which may be explained by the sealing of the fracture just prior to the explosion.

Magma accumulation process of Izu-Oshima volcano, as revealed from deep LF earthquakes, deformation and CO2 out-gassing

WATANABE, Hidefumi[1*]

[1]Disaster Prevention Division, Tokyo Metropolitan Government

In order to make successful mid-term eruption predictions, we need to detect particular precursory processes operating in magma-plumbing system. Since 1989, Izu-Oshima volcano has continued its re-inflation, after the last eruption in 1986, and further repeated deflation-inflation cycles, resulting a net inflation of the volcano. The rate of secular inflation decreased exponentially until 2006, while the amplitudes of the deflation-inflation cycles increased. Since 2007, the rate of secular inflation has kept a constant speed and has also increased the activity of deep low-frequency (LF) earthquakes occurring at the depth range of 30-40 km beneath the volcano. Each episodic LF earthquake activity was preceded by the volcano deflation and accompanied by the inflation. Based on these evidences, we may suppose that the volcano inflation is caused by the supply of magma from a source region at the depth range of 30-40 km beneath the volcano, and that an episodic out-gassing from the shallow magma reservoir triggers each deflation-inflation cycle. To demonstrate the proposed mechanism, we need to combine the data on magma accumulation and out-gassing processes. To monitor the out-gassing of basaltic magma accumulating beneath the volcano, CO_2 is most helpful. In September 2005, we started continuous monitoring of soil CO_2 concentration at the summit of Izu-Oshima volcano, and obtained an evidence for the out-gassing process; the correlated increase of soil CO_2 concentration during the periods of not only accelerated inflation but also deflation of the volcano. Integrating the observational data, we suppose that the rate of magma supply from the upper mantle has increased since 2007 and that the increase in amplitude of deflation-inflation cycles might indicate a volume increase of CO_2 over-saturated region at the upper part of the magma reservoir beneath the volcano.

Spatio-temporal characteristics of volcanic tremor during the 2011 Kirishima eruption by seismic wave analysis

NAKAMOTO, Manami[1*] ; MATSUMOTO, Satoshi[1] ; YAMANAKA, Yoshiko[2] ; SHIMIZU, Hiroshi[1] ; NAKAMICHI, Haruhisa[4] ; ICHIHARA, Mie[3] ; OIKAWA, Jun[3]

[1]SEVO, Kyushu Univ., [2]EVRC, Nagoya Univ., [3]ERI, University of Tokyo, [4]DPRI, Kyoto Univ.

Volcanic tremors are considered as oscillations occurred in magma supply system and provide us important information about condition of the system from magma chamber to crater through a conduit. Therefore, it is important to investigate locations of their source and their characteristics for understanding the condition and process of volcanic activity and modeling the magma supply system. In this study, we reveal features of volcanic tremor using seismic data at Kirishima volcano.

An array observation help us to get information of incident waves on the stations. The two array seismic observations were carried out around Shinmoe-dake during the 2011 Kirishima eruption. One consisted of 25 seismometers located 3 km southwest of the Shinmoe-dake crater (Matsumoto et al., 2013), and the other consisted of 16 seismometers located 5 km northeast of the crater (Nakamichi et al., 2013). The combining data from two arrays enable us to determine the tremor sources. Moreover, we estimated mechanism of the tremor source by using waveforms recorded at temporal seismic station in Kirishima volcanic area and tremor sources obtained by array analysis.

This study focus on the volcanic tremor which occurred on February 2, 2011, and its duration was about 40 minutes. Peak frequencies of the tremor were about 1, 2, 3, and 4 Hz. We investigated temporal variation in the source location of the tremor from the slowness and azimuth of incident wave by MUSIC method. we found that most part of the tremor were radiated around Shinmoe-dake crater. In this part, the tremor that had large slowness and relatively long duration was located in shallow region beneath the crater. In contrast, at some parts of the tremor, source location for waves with short duration were near Ohnami pond, 3.3 km northeast of the crater. Based on amplitude analysis for the seismogram recorded by the seismic network, we also found out difference in radiation patterns of the volcanic tremor among the tremor sources. Assuming single crack model, we found the strike and dip direction of the crack beneath the Shinmoe-dake crater is different from those near Ohnami pond.

Relationship BH-type earthquake swarms and ground deformations prior to eruptions at Showa crater at Sakurajima volcano

TAMEGURI, Takeshi[1*] ; IGUCHI, Masato[1]

[1]DPRI, Kyoto University

Vulcanian eruptions have occurred at the Minamidake crater at the summit since 1955 at Sakurajima volcano. Principal eruptive activity shifted to the Showa crater at the eastern flank of the summit in 2006. The eruptions at the crater become active and minor vulcanian eruptions occurred about 1,000 times per year in 2010-2013. Ash plume height of the eruptions sometimes reached to 3000m in 2013. The eruptive activities at the Showa crater gradually increase.

Inflationary strain changes are observed by extensometers a few tens of minutes to several hours prior to the eruptions and are caused by pressure sources located at depths of 0-1.5 km (Iguchi et al., 2013). The inflation rates decrease or sometimes suspend about 30 minutes before the eruptions. Small earthquakes dominated by high frequency components (5-6 Hz) swarm when duration of inflation is longer than 1 hour. The hypocenters of the earthquakes are located at a depth of 0.5 km beneath the crater and are close to depth of the pressure source. The earthquakes begin to occur a half hour to 1 hour after the start of the inflation. The amplitudes and number of the earthquakes further increase when the inflation rates decrease or suspend. And, the occurrences of the earthquakes suddenly stop at the start of the eruptions. The occurrences of the earthquake swarms are related to the decrease of inflation rate and the long inflation.

Seismic energy releases of the precursory earthquakes related to every eruption accelerate before eruptions. There are all kinds of large and small seismic energy releases in the eruptions. The accelerations of the seismic energy releases before eruptions with explosive events tend to be larger than those with non-explosive events. And, the accelerations of the seismic energy releases are rapid in the case of large deflations after eruptions. The precursory earthquakes may be generated by release of excess pressure accumulated by inflation of the pressure source. We might be able to predict eruption types and scales from occurrence patterns of the precursory earthquakes.

Volcanic tremor caused by flow-induced oscillation of a magma-filled dike

SAKURABA, Ataru[1*] ; YAMAUCHI, Hatsuki[2]

[1]Department of Earth and Planetary Science, University of Tokyo, [2]Earthquake Research Institute, University of Tokyo

Volcanic tremor (VT) is known to be long-period and long-duration ground motion generally observed during or before eruptions. Majority of VTs show an emergent onset and, when accompanied with eruptions, an exponentially growing phase in amplitude is typically observed (Konstantinou and Schlindwein 2002; McNutt and Nishimura 2008). This characteristic suggests that VT is manifestation of self-oscillation, in which a persistent steady forcing excites an eigen oscillation of a system and the amplitude exponentially grows until a nonlinear process leads to a limit cycle. In volcanic settings, a steady magma flow through an underground conduit may cause flow-induced self-oscillation of bedrocks, and this is the idea first presented by Julian (1994). In the case of the collapse of Tacoma Narrows bridge, which is known to be caused by flow-induced oscillation, the vibrating bridge can be modeled by an elastic plate placed parallel to an infinite flow. Here we consider a reversed setting: a fluid-flowing thin layer in an infinite elastic body. This system is also unstable if the flow speed is high enough, and may be a generation mechanism of some VTs.

We consider a fluid-flowing plane layer sandwiched between two semi-infinite elastic bodies, expanding Julian's idea to a more general elastodynamic model (for details, see Sakuraba and Yamauchi 2014 to appear in *Earth, Planets and Space*). The eigen oscillation that should be excited in this self-oscillation model is an elastic surface wave. Therefore, we solve the Navier-Stokes equation linearized about a laminar flow with the boundary condition that can maintain a surface wave traveling along the layer. We succeeded in obtaining a complex phase speed of the surface wave as a function of wavenumber (and some parameters) using a shooting method, and found that a relatively slow magma flow could lead to instability in which the imaginary part of the phase speed is positive. Remarkably, the most unstable mode exhibits an antisymmetric (flexural) deformation, which has not been discussed in previous similar studies (Balmforth, Craster and Rust 2005; Dunham and Ogden 2012). The unstable mode is identical to two parallel Rayleigh waves traveling against the basic magma flow. The instability can be understood as acceleration of nearly circular particle motion of the Rayleigh wave due to viscous drag of the main laminar flow. As the critical flow speed giving a neutrally stable state decreases in inversely proportional to wavelength, instability will occur with the largest possible wavelength, which could be several kilometers and produce an oscillation period of around 1 second. In that case, the critical flow speed can be reduced to less than 1 m/s when the magma is basaltic. As the magma flow speed in a dike will not exceed several meters per second, there would be a lower bound in the critical wavelength, producing a period of 0.1 second. Thus our model naturally explains typical periods of 0.1-1 seconds observed on volcanoes. Our model also explains typical timescales of the linearly growing phase in some VTs.

Magnitude-frequency distribution of volcanic eruptions from an open conduit

NISHIMURA, Takeshi[1*] ; IGUCHI, Masato[2] ; MUHAMAD, Hendrasto[3] ; AOYAMA, Hiroshi[4]

[1]Science, Tohoku Univ., [2]DPRI, Kyoto Univ., [3]CVGHM, Indonesia, [4]Science, Hokkaido Univ.

Explosive eruptions such as vulcanian, strombolian, or significant gas burst excite seismic waves. Such seismic signals, which are often called as explosion earthquakes or explosion quake, are used to quantitatively evaluate the magnitude of such volcanic explosions. In the present study, we systematically examine magnitude-frequency distributions of explosion earthquakes observed at Sakurajima and Suwanosejima volcanoes in Japan, and Semeru and Lokon volcanoes in Indonesia. We use the long-term catalog data of Sakurajima explosions for the period from 1963 to 2011, which are routinely summarized by Sakurajima Volcano Research Center (SVRC). Also, we measure the amplitudes of explosion earthquakes from continuous seismic records observed at Suwanosejima and Semeru and Lokon volcanoes in Indonesia. We measure the number of earthquakes that exceed a given amplitude, and then plot the cumulative number of earthquakes versus amplitude, as is often done for examining Ishimoto-Iida's relation, which expresses a power law distribution. However, the observed frequencies of earthquakes at the four volcanoes do not seem to fit the Ishimoto-Iida's relation. The cumulative numbers are well explained by exponential functions. This means that the magnitude of explosion earthquake at each volcano is randomly determined with an average scale.

Rheological transition of plagioclase-bearing magma: high-temperature uniaxial deformation experiments of sanukite lava

ISHIBASHI, Hidemi[1*]

[1]Graduate School of Science, Shizuoka University

High-temperature uniaxial compression experiments were done for bubble- and phenocryst-free, plagioclase-bearing lava to investigate the effect of tabular crystals on rheological properties of highly crystalline magma. High-Mg andesite lava from Goshikidai lava plateau, southwest Japan, was used for starting material. The lava is bubble- and phenocryst-free, composed of 60 vol.% rhyolitic glass, 36 vol.% of tabular plagioclase and 4 vol.% of pyroxenes and magnetite and plagioclase crystals are well aligned parallel. High-temperature uniaxial defomation apparatus at Earthquake Research Institute, the University of Tokyo, was used for experiments. The lava was cut to 10 x 10 x 20 mm rectangular solids and deformed under conditions of temperatures of 1238, 1188, and 1138 K and deformation rates from 3.16 to 0.003 mm/min. Run samples were quenched and processed to thin section for textural and compositional analyses by using EPMA.

Phase proportions in all run samples were the same as that of starting material, indicating crystallization did not occur during experiments. The lava behaves as shear thinning fluid under all temperature conditions. Viscosity at strain rate of 10^{-4} s^{-1} increases from $10^{8.7}$ to $10^{9.4}$ Pas with decreasing temperature. Power law exponent [= d(log viscosity)/d(log strain rate)] is ca. 0.64, which is consistent with extrapolation of previous studies for natural plagioclase-bearing magmas. Relative viscosity [= (bulk viscosity)/(melt viscosity)] is ca. $10^{2.4}$ at strain rate of 10^{-4} s^{-1} under all temperatures, indicating that the concept of relative viscosity works well under present experimental condition. The relative viscosity-crystal fraction relation is also consistent with extrapolation of previous studies for natural plagioclase-bearing magmas. Marron-Piece equation well explains the relation with the maximum packing fraction of 0.43. Present results suggest that rheological transition occurs at crystal fraction near 0.43 for plagioclase-bearing natural lava in which plagioclase crystals are well aligned parallel. The value is higher than ca. 0.3 proposed by Picard et al. (2013)'s experiments in which plagioclase orientation is random in starting materials, indicating the first order importance of plagioclase orientation distribution on rheological transition.

Conduit flow of silicic magma: Viscous flow or Frictional sliding?

OKUMURA, Satoshi[1*] ; UESUGI, Kentaro[2]

[1]Department of Earth Science, Graduate School of Science, Tohoku University, [2]Japan Synchrotron Radiation Research Institute

Outgassing rate and bulk magma viscosity that control the style of volcanic eruptions depend on flow type of magma ascending in a volcanic conduit. When magma behaves as a Newtonian fluid, magma in the conduit experiences shear strain large enough to cause effective outgassing. On the other hand, once shear starts to localize, bulk magma viscosity may decrease due to slip deformation and outgassing rate also decreases in parts other than shear-localized region (Okumura et al., 2013 EPSL). Silicic magma experiences shear-induced brittle fracturing and subsequent frictional sliding along the fracturing zone during its ascent (e.g, Gonnermann and Manga, 2003 Nature; Tuffen et al., 2003 Geology). Therefore, outgassing rate and bulk magma viscosity during the ascent are expected to change dramatically. Previous studies (Tuffen et al., 2003 Geology; Gonnermann and Manga, 2005 EPSL) also proposed that fractured magma can heal during magma ascent and that fracturing and healing processes may control the dynamics of magma ascent. In contrast to this model, some experimental studies (e.g. Okumura et al., 2010) indicated that fractured magma cannot heal as long as the deformation continues. In this study, we perform deformation experiments for fractured magma to investigate flow type of magma in the conduit, i.e. viscous flow or frictional sliding, and controlling factors of the transition from viscous flow to frictional sliding.

The deformation experiments were carried out using a custom-made torsional deformation apparatus which was installed in synchrotron radiation X-ray imaging system (BL20B2) of SPring-8. To simulate fractured silicic magma, we crushed rhyolite obsidian and sorted them into fragments of 75-250 μm in size. The powdered sample was sandwiched by two obsidian discs and they were twisted by rotating a piston attached with a rotational motor. The torsional deformation experiments were performed at temperatures of 800 and 900 ℃ under 1-10 MPa pressures. The rotational rate was set to be 0.1 to 10 rpm, corresponding to strain rates of 10^{-2} to 1 s^{-1} if the sample deforms homogeneously. The deformed samples were observed in situ using an X-ray radiography.

At a temperature of 900 ℃ and rotational rates of 0.1-1 rpm, homogeneous deformation through a sample was observed under a pressure of 10 MPa, which indicates viscous deformation. In contrast, the sliding at the interface between powdered obsidian and the disc was observed under 1 and 5 MPa pressures. At a temperature of 800 ℃, the sliding was found under 1-10 MPa pressures. These results indicate that frictional sliding along fractured zone is flow type of magma in shallow parts of the conduit ($<$10 MPa).

We assume that flow type is determined by competition of shear stress necessary for viscous flow and frictional sliding. If magma has high viscosity and shear stress to deform a sample viscously is large, the flow type becomes frictional sliding. At a temperature of 900 ℃, viscous flow and frictional sliding were found at 10 and 1-5 MPa pressures, respectively. At this condition, magma viscosity is approximately 10^7 Pa s (Hess and Dingwell., 1996) and shear stress necessary for viscous deformation is 1 MPa at a strain rate of 0.1 s^{-1}. Because the frictional sliding was observed at pressures of 1-5 MPa, the frictional coefficient is estimated to be ca. 0.1. When we use this value and the criterion for shear-induced brittle fracturing proposed by Okumura et al. (2010), the dynamics of magma ascent is controlled by frictional sliding at shallow parts of the conduit. In addition, silicic magma can ascend quickly due to low frictional coefficient of fractured magma.

Mechanism of delayed brittle-like fragmentation of vesicular magma analogue

KAMEDA, Masaharu[1*] ; SHIDA, Tsukasa[1] ; ICHIHARA, Mie[2] ; TSUGO, Mitsuaki[1] ; OKUMURA, Satoshi[3] ; UESUGI, Kentaro[4]

[1]Mech. Sys. Eng., TUAT, [2]ERI, Univ. of Tokyo, [3]Earth Sci., Tohoku Univ., [4]JASRI

Magma fragmentation is a key phenomenon controlling volcanic eruptions. The fragmentation is classified into two styles: solid-like brittle fragmentation and liquid-like ductile fragmentation. Brittle fragmentation is more hazardous than ductile fragmentation because violent release of pressurized gas in the bubbles contained in the magma may lead to explosive eruptions

The fragmentation of magma, which is a viscoelastic fluid, occurs through a combination of viscoelasticity and rapid deformation. We conducted a rapid decompression experiment over ten years in order to clarify the viscoelastic effect on the fragmentation using a magma analogue, syrup containing gas bubbles (Kameda et al GRL 2008; Kameda et al. JVGR 2013).

Through the experiment we demonstrated the existence of a transitional fragmentation behavior. This transition behavior, which we refer to herein as brittle-like fragmentation, occurred even if the response of material should be in a ductile manner. Comparing the realistic decompression time with the viscoelastic relaxation time for magma, it is more probable that the fragmentation in the real volcanic system occurs in a brittle-like manner.

Observation by high-speed photography using a visible light-source indicated that the onset of brittle-like fragmentation was triggered by the sudden release of a considerable amount of gas from a crack in the specimen. Further observation (Shida et al. IAVCEI 2013) showed that reducing the volume of the specimen suppressed the onset of fragmentation even if their brittleness (Ichihara and Rubin 2010) was close to unity. In our case, the pore distribution of the small samples was more uniform than that of large samples. This observation implies that the crack is initiated from the interior of the specimen due to non-uniform spatial distribution of bubbles.

Then, we observed the interior of the specimen by synchrotron X-ray tomographic microscopy. The X-ray tomographic microscopy was performed at the BL20B2 beamline of the Japan Synchrotron Radiation Research Institute (JASRI, Hyogo, Japan). Initial structure of the specimen was observed by three-dimensional tomographic imaging. High-speed radiography was performed during the decompression. A digital charge-coupled device (CCD) camera was used as the detector whose imaging area is about 16 mm (horizontal) by 5 mm (height) with spatial resolution of 8 μm/pixel. We took 1800 projections over 180 degrees of rotation for tomographic imaging. The framing rate of radiography is 200 frames per second. We successfully captured a series of images during the brittle-like fragmentation. The reconstructed 3D image of the specimen indicated that the brittle-like fracture was initiated at a notch and a chain of small bubbles in the vicinity of a large bubble.

We propose the following scenario for brittle-like fragmentation: It is initiated from ductile growth of internal cracks by connection of bubbles. The stress concentration and the brittleness at crack tip may exceed the critical level at some moment, which leads to brittle failure of the crack. Rapid decompression due to sudden release of a considerable amount of gas from the crack may increase local brittleness to cause partial fragmentation. Such a sequence from ductile crack growth to partial fragmentation may successively occur in brittle-like fragmentation.

Approach by volcanic observation for dynamics of volcanic phenomena

IGUCHI, Masato[1*]

[1]DPRI, Kyoto University

Dynamics of volcanic activity has been revealed by various kinds of observation. Inflation of volcanic body prior to eruptions corresponds to intrusion of magma to the underground of volcanoes and deflation is accompanied by eruptive activity.

Prior to vulcanian eruptions, minor deflation is detected. This corresponds to leakage of volcanic gas from a gas pocket formed at the uppermost conduit. The minor deflation reflecting minor pressure decrease induces a sudden degassing in oversatulated magma. The sudden degassing corresponds to a volume increase at a deep part in the conduit, as revealed by outward first motions of explosion earthquakes. The volume increase attained at the top of the conduit and the gas pocket overbursts. As the results of collapse of the gas pocket, infrasound of air-shock type is generated with ejection of incandescent bombs followed by ejection of volcanic ash.

Tephra-Fall Predictions with the JMA Regional Atmospheric Transport Model for the 1914 Eruption at Sakurajima Volcano

SHIMBORI, Toshiki[1*] ; SHIRATO, Shomei[2] ; HASEGAWA, Yoshihiko[3] ; HASHIMOTO, Akihiro[1] ; TAKAGI, Akimichi[1] ; YAMAMOTO, Tetsuya[1] ; YAMAMOTO, Akira[1]

[1]Meteorological Research Institute, [2]Kagoshima Local Meteorological Office, [3]Japan Meteorological Agency

A hundred years ago, the largest eruption in 20th century Japan, *i.e*. the Sakurajima Taisho Eruption occurred on 12 January 1914. With this eruption, tephra-falls were observed large-area in Japan from Kyushu to Tohoku region (Hasegawa, 1914; Omori, 1916). For such large-scale eruptions, the Meteorological Research Institute (MRI) is going to do new research project of the tephra-fall predictions with the JMA Regional Atmospheric Transport Model (JMA-RATM) from this year. The research will lead to the improvement of the Volcanic Ash Fall Forecasts (VAFFs) of the Japan Meteorological Agency (JMA). For the purpose of investigating the predictability of the current JMA-RATM against large-scale eruptions, predictions of volcanic-ash dispersion and tephra-fall for the Sakurajima Taisho Eruption were carried out. The initial values which are the total volume (ash and pumice) of 6×10^8 m^3, the plume height of 3000-18000 m and the eruption duration of 38 hours are assumed based on Yamashina (1999), Yasui *et al*. (2006), Iguchi (2014) and so on. The input GPVs are the JMA Mesoscale Analysis after 28 March 2013. The forecast time by the JMA-RATM is 72 hours from starting time. Results of the calculations indicate that, under the assumption of the ash-density of 1 g/cm^3, the predictions of tephra-fall depths are over 1 m in Sakurajima Island for weak-wind weather condition, several 10 cm at Kagoshima City for easterly wind in summertime, and of the order of 0.1-1 mm at Osaka, Nagoya and Tokyo Metropolitan area for southwesterly wind field. In the atmosphere, dispersions of volcanic-ash up to Tohoku and Hokkaido region are also predicted at the same forecast time.

In the presentation, from the results of volcanic-ash dispersion and tephra-fall prediction, the predictability and problems of the current JMA-RATM for large-scale eruptions will be reported.

Evaluation of wind data for tephra dispersion simulations

KIYOSUGI, Koji[1*] ; KOYAGUCHI, Takehiro[1] ; SUZUKI, Yujiro[1]

[1]Earthquake Research Institute, University of Tokyo, Tokyo, Japan

Understanding how pyroclasts disperse from volcanic plumes is a fundamental problem of volcanology to reconstruct eruption conditions from tephra fallout deposits. Tephra dispersion is not only a scientifically interesting but also socially and economically important problem. For this reason, advection-diffusion models for tephra transportation have been developed with simplified assumptions (e.g. TEPHA2, PUFF, FALL3D). Simulation results of these advection-diffusion models are affected by the input wind data. For example, in a case study of the Kirishima 2011 eruption with PUFF, simulation results with finer temporal-spatial resolution wind data (Japan Meteorological Agency Mesoscale Model and ERA Interim) reproduced a more wavy shape of observed eastward extending plume (about 900 km from the vent) than that with coarser temporal-spatial resolution wind data (NCEP/NCAR Reanalysis).

Some wind data are available from Japan Meteorological Agency Mesoscale Model, ERA Interim of the European Center for Medium-Range Weather Forecasts and NCEP/NCAR Reanalysis of the National Oceanic and Atmospheric Administration of the United States. Between these wind data, there are differences in data assimilation methods, forecast models and temporal-spatial resolution. In addition, a finer temporal-spatial resolution wind data can be generated with using weather forecast models, such as the Weather Research and Forecasting (WRF) model. The WRF model is a fully compressible, Euler non-hydrostatic mesoscale forecast model developed by a multiagency collaboration. The WRF model is suitable for use in a broad spectrum of applications across scales ranging from meters to thousands of kilometers.

We are developing a system to generate wind data suitable for simulations of the advection-diffusion models. Such wind data should have a spatial resolution of several hundred meters near the vent, that of several kilometers far from the vent and vertically several tens of layers. In addition, it must be required to reproduce the interaction between ambient atmosphere and volcanic plumes. For this purpose, we are carrying out numerical calculations with the WRF model and the available wind data sets; we attempt to generate wind data with higher temporal-spatial resolution using data assimilation based on the observations from the regions of interest (e.g. volcano locations and downwind area) and other observations (e.g. the radar observations).

Classification of infrasound waveforms and analysis of video images at volcano eruption

SATO, Yusuke[1*] ; YOKOO, Akihiko[1]

[1]Graduate School of Science, Kyoto University

Volcano infrasound is an increasingly useful technique for measuring and analyzing eruptive activity. In order to reveal causes of characteristics of infrasound waveform, we analyzed infrasound records and video images at eruptions that occurred at Yasur Volcano, Vanuatu during an hour at 15:00, 21th September, 2011. Yasur Volcano has three active vents in the summit crater. Infrasound waves are generated every 1-3 minutes at various eruptions with reddish magma, vapor rich gas and ash. Infrasonic waveforms are mostly symmetric with a sharp compressive onset, followed by a small rarefaction phase. In this study, we analyzed infrasound events whose maximum amplitude is more than 50 Pa at one station on the summit crater rim. We conducted cross correlation analysis to 29 wave records and classified them into 3 types; A (13 events), B (12 events) and C (4 events). Time window of the analysis was 5s from a second before the maximum peak time. In contrast to type C, cross correlation coefficient among wave forms of types A and B was very high (>~ 0.75). The compressive ratio and the ratio of positive and negative peak are different between type A and B. On the other hand, we analyzed selected video sequences of these eruptions. We read the RGB and brightness values on horizontal line above each vent until the end of the eruptions from 2s before the ejecta reaches the line. The maximum R and brightness value of type B events was twice as other type eruptions. This result may suggest that type B eruptions release relative much reddish magma and whitish gas compared to those of type A and C.

Numerical treatment of dry bed problem in the model of pyroclastic flows based on the 1-D shallow-water equations

SHIMIZU, Hiroyuki[1*] ; KOYAGUCHI, Takehiro[1] ; SUZUKI, Yujiro[1]

[1]Earthquake Research Institute, The University of Tokyo

During explosive volcanic eruptions, a mixture of pyroclasts and volcanic gases is released from the vent. When the mixture loses its upward momentum before the density of the mixture becomes lower than the atmospheric density, the mixture forms a pyroclastic flow. Dynamics of pyroclastic flows can be approximated by that of an inviscid gravity current. The dynamics of inviscid gravity currents are controlled by an inertial-buoyancy balance on the front (e.g., Benjamin, 1968); we refer to this condition as "the front condition". The front condition, and hence, the dynamics of the inviscid gravity currents strongly depends on the density ratio of the current (ρ_c) to the ambient (ρ_a) (e.g., Ungarish, 2009). When $\rho_c/\rho_a \sim 1$, the current is characterized by a high front, whereas a front height does not develop when $\rho_c/\rho_a \gg 1$. In pyroclastic flows, because density ratio ρ_c/ρ_a varies spatially and temporally, the dynamics of pyroclastic flows becomes complicated; the basic features of pyroclastic flows, such as the run-out distance, have not been fully understood. The aim of our study is to develop a unified model of the inviscid gravity currents for various density ratio ρ_c/ρ_a.

In general, the dynamics of shallow inviscid gravity currents can be described by the shallow-water equations. There are two numerical models to solve the shallow-water equations: "shock front condition model" (SFC model) and "artificial bed-wetting model" (ABW model). SFC model is a model, in which the front condition is applied to the boundary condition (e.g., Ungarish, 2009). The boundary condition is given as a function of ρ_c/ρ_a. On the other hand, in ABW model, an artificial wet bed with the height of ϵh_0 is set on the dry bed in order to express the front condition, where h_0 is a characteristic height scale (e.g., Toro, 2001; Larrieu et al., 2006; Doyle et al., 2007). This model has the only parameter ϵ for the front condition. Although the front condition, and hence the appropriate value of ϵ must be a function of ρ_c/ρ_a, the relationship between ϵ and ρ_c/ρ_a has not been studied. In order to resolve these problems, we carried out parameter studies using the two models for solving a simple "one-dimensional (1-D) dam-break problem".

On the basis of systematic comparisons between the results of SFC model and ABW model, we found the relationship between the parameter ϵ and ρ_c/ρ_a : $\epsilon \sim 8.62 \cdot 10^{-2} \cdot (\rho_c/\rho_a)^{-1.87}$. We also found that the application of ABW model should be limited to $15 < \rho_c/\rho_a$. In the case of $1 < \rho_c/\rho_a < 15$, an unphysical shock wave propagates into the artificial bed so that the velocity and height of the current substantially deviate from the solution satisfying the correct front condition.

Moment tensor representation of elliptical volume sources

MIZUNO, Naoto[1*] ; KUSAKABE, Tetsuya[2] ; ICHIHARA, Mie[2] ; KAME, Nobuki[2]

[1]School of Science, The University of Tokyo, [2]Earthquake Research Institute, The University of Tokyo

A moment tensor inversion is a powerful tool to extract source information from seismic and geodetic observations. However, widely-used moment tensor representation for volumetric sources has been limited to a few basic geometries such as a sphere, a flat crack, and a cylinder. These sources give particular diagonal component ratios: (M_1:M_2:M_3)=(1:1:1) for a sphere, (1:1:3) for a crack, and (2:2:1) for a cylinder. When different component ratios are obtained from the inversion analysis, they are interpreted as combination of these simple geometries without considering internal pressure balance.

Although the moment tensor representation for elliptical sources was obtained 30 years ago (Davis, 1986), the solution has been rarely applied in volcanology. We consider two disadvantages of Davis (1986). The one is that the theories to relate the actual volume change to moment tensor have been proposed but not unified , which has caused some confusion. The accompanying paper (Ichihara et al., 2014, this meeting) presents a unified explanation based on the representation theorem and makes a clear link among volume change, geometry, and moment tensor. In this context, we have confirmed the applicability of Davis (1986) to the observed moment tensor.

The other disadvantage is that researchers have to search in the numerical table to find a geometry fitting to the observed moment tensor. Here we develop a facilitative tool that diagnoses the diagonal part of observed moment tensors to given the aspect ratios and the apparent compressibility. In addition, if the density and the compressibility of the internal material are given, the tool estimates mass change inside the source, which is an important parameter in volcanology.

This tool will provide a reference model satisfying pressure balance and help improving the volumetric source modeling beyond the conventional kinematic summation of simple sources.

Volume source representations: a possible unified explanation based on the representation theorem

ICHIHARA, Mie[1*] ; KUSAKABE, Tetsuya[1] ; KAME, Nobuki[1] ; MIZUNO, Naoto[2] ; KUMAGAI, Hiroyuki[3]

[1]Earthquake Research Institute, The University of Tokyo, [2]School of Science, The University of Tokyo, [3]Graduate School of Environmental Studies, Nagoya University

The moment tensor inversion is a powerful tool to extract source information from seismic and geodetic observations. A moment tensor for earthquake faulting has been determined and its non-diagonal components give the seismic moment (rigidity x slip x fault area), which is one of essential source parameters of an earthquake. The sum of the diagonal components (the trace) of a moment tensor represents volumetric change at the source. A moment tensor determined for a volcanic source frequently has non-zero trace. However, it has been failed to uniquely relate the diagonal components to the actual volume change, which remains a critical issue in volcanic seismology (Kazahaya et al., 2011). For example, two different volume changes DV and dV have been proposed for the seismic moment of a spherical source geometry; DV comes from the moment tensor definition of a seismic fault having opening displacements whereas dV is obtained from the equivalence of resultant displacement fields due to the former moment tensor and an isotropically expanding sphere in an elastostatic equilibrium.

The difference between DV and dV has been discussed in the last decade. Muller (2001) considered an open crack of a spherical shell shape and showed that DV is the volume of the opening and dV is only the part opening outward. Aki and Richards (2002) and Richards and Kim (2005) adopted Eshelby's approach which considers virtual operations consisting of cutting, stress-free transformation, elastic straining, and welding, and concluded that the difference is due to whether the volumetric change occurs in an unconfined condition (DV) or in a confined condition (dV). Kumagai et al. (2013)reconsidered this problem and concluded that the displacement field due to a spherical source does not coincide with that due to a three-perpendicular-crack source though they both are represented by isotropic moment tensors. They also extended the insights into sources in a bimaterial medium. It is worth mentioning that the approaches of AR2002 and RK2005 give a conceptual explanation on how to adjust DV to the actual volume change dV for a sphere, but not for arbitrarily shapes. Here we address how to make such adjustments for general geometries on the basis of the representation theorem. Our imaginary operation below gives a unified explanation for the two different volumetric changes and newly proposes a method of estimating dV of the inversion results for arbitrary source geometries.

We start with the representation theorem that gives the displacement field by two terms (without a body force): a surface integration on the source region with convolution of the surface displacement and the gradient of the Green's function normal to the surface (1), and that with convolution of the surface traction and the Green's function (2). Only (1) has been considered for the seismic fault because (2) vanishes due to the balance of the traction at the contacting surfaces of a fault. On the other hand, (2) does not vanish in the case of a volumetric source, and therefore a quantitative adjustment is required to include the effect of (2) into (1). We here demonstrate that such an adjustment,is always realized by introducing an additional imaginary volumetric change, which works as 'displacement glut' in our representation of moment tensor. Our representation is found to be mathematically equivalent to the rather conceptual 'stress glut' representation proposed by Backus and Mulcahy (1976). We present a unified explanation for the existing various representations and propose a method to practically evaluate the moment tensor components from the boundary conditions of the volumetric source. The proposed representation will be useful in connecting dynamical models of volcanic processes and moment tensors.

X-ray CT observation of delayed fragmentation of vesicular magma analog

SHIDA, Tsukasa[1] ; AOKI, Yamato[1*] ; KAMEDA, Masaharu[1] ; ICHIHARA, Mie[2] ; OKUMURA, Satoshi[3] ; UESUGI, Kentaro[4]

[1]Mech. Systems Eng., TUAT, [2]ERI, Unv. of Tokyo, [3]Earth Sci., Tohoku Unv., [4]JASRI

A laboratory experiment was performed to understand the mechanism of fragmentation of vesicular magma, which is a trigger of explosive volcanic eruption. From the observation of Shinmoe-dake 2011 eruption, the viscosity of magma is not so high as its response is in solid manner. Thus, we aim to reveal the mechanism of brittle-like fragmentation of the magma which behaves in fluid manner.

Rapid decompression test was conducted using syrup containing oxygen bubbles as a magma analogue. The decompression facility consists of a high-pressure chamber in which the specimen can be placed, and an electromagnetic valve. The pore structure of interior of the specimen was observed by X-ray microscopic tomography. The X-ray tomographic microscopy was performed at the BL20B2 beamline of the Japan Synchrotron Radiation Research Institute (JASRI, Hyogo, Japan). Initial structure of the specimen was observed by three-dimensional tomographic imaging. A digital charge-coupled device (CCD) camera was used as the detector whose imaging area is about 2048 pixels (horizontal) by 644 pixels (height) with spatial resolution of 8 μm/pixel. We took 1800 projections over 180 degrees of rotation for tomographic imaging. High-speed radiography was performed during the decompression. The framing rate of radiography is 200 frames per second.

The specimen has a semi-spherical shape whose diameter was 20 mm. The initial pressure (p_0) was 1.5 MPa, the characteristic time of decompression (t_{dec}) was 50 ms, the viscosity of syrup was about 1×10^8 Pa s, the initial averaged void fraction ϕ_0 was about 10%. We tested nine samples whose pore structure was different to each other.

The fragmentation occurred with two samples in which a 10-mm-diameter bubble was contained, while the fragmentation did not occur using the seven samples whose pore structure was relatively uniform. The onset of fragmentation is 960 ms after the decompression was started. The onset was substantially delayed not only from the characteristic decompression time but also from the relaxation time of Maxwellian viscoelastic material (viscosity/rigidity = 150 ms). Referring to the radiographic images, we found that the fracture was initiated from a chain of small gas bubbles and a notch in the vicinity of the 10-mm (large) bubble. The internal crack may grow in ductile manner when the hoop stress around the large bubble increased due to decompression. At a certain instance the stress concentration and the brittleness at crack tip may exceed the critical level, which leads to brittle failure of the crack.

The experimental result indicates that brittle-like fragmentation can occur in the non-uniform vesicular magma even if the response of magma is in fluid manner.

Model experiments on magma migration in a viscoelastic host rock : effect of viscosity

TAKEGUCHI, Izumi[1*] ; SUMITA, Ikuro[1]

[1]Graduate School of Natural Science and Technology, Kanazawa University

Magma generated from partial melting ascends upwards by its buoyancy to the magma chamber, some of which erupt at the Earth's surface. Magma is considered to ascend in the form of diapir in the asthenosphere and transforms to dykes in the lithosphere (Rubin, 1995) . These two end member cases have been studied in detail, but the mechanism of magma ascent in the transitional regime is still poorly known. We have been studying the ascent mechanism in the transitional regime by model experiments using a viscoelastic agar (Sumita and Ota, 2011). Here we report the results of experiments which focus on the effect of fluid viscosity on the magma migration in a viscoelastic medium.

We conducted (1) rheology measurement of agar and (2) fluid injection experiments. We inject magma (CsCl solution to which a thickener is added) using a syringe from the top of a cylindrical acrylic tank (height of 250 and 500 mm). The fluid has a volume of 1ml, density difference with the agar of 0.108 g/ml, and is injected at a constant rate of 0.1 ml/s. We vary the agar concentration in the range of 0.04-0.5 wt% and the fluid viscosity in the range of 10^-3 - 650 Pas. As we increase the agar concentration in this range, we find that the yield stress and the rigidity of the agar increases by 3 orders of magnitude. By shearing the sample under a constant stress (creep test) we find that the agar can be approximated by a Voigt model to which a spring is connected in series. The experiments are recorded using video cameras from two sides and from the bottom of the tank.

From the injection experiments, we find that as the agar rigidity (G) decreases, the crack shape transforms from 2D (blade-like) to 3D (having a bulged head). The critical rigidity (Gc) of the 2D-3D transformation is around Gc=10 Pa, and this value becomes smaller when a high viscosity fluid is injected. The value of Gc is consistent with the rigidity estimated from the balance between the elasticity and buoyancy at which the strain becomes 1. The crack consists of a bulged head and a thin sheet-like tail, and the head becomes thinner and smaller as the crack elongates. When a stiff agar is used as the host, or when a high viscosity fluid is injected, the crack propagation stops within a certain distance from the injection point. We find that this propagation distance becomes shorter as we increase the agar yield stress or the viscosity of the injected fluid, and this result can be associated with the transformation of the crack shape to 2D. We fit the time-distance data to a power-law relation, and find that the exponent varies from 1/3 to 1. An exponent of 1/3 corresponds to the scaling obtained for a 2D crack which thins uniformly as it elongates (Taisne et al, 2011). An exponent larger than 1/3 corresponds to the crack shape becoming more 3D. To conclude, we find that the magma viscosity not only slowers its migration velocity, but also controls the crack shape, its deceleration, and the propagation distance until it stops.

Bubble growth and resorption in magma: insights from dissolved water distributions in volcanic glass

MCINTOSH, Iona[1*] ; LLEWELLIN, Ed[2] ; HUMPHREYS, Madeleine[2] ; NICHOLS, Alex[1] ; BURGISSER, Alain[3] ; SCHIPPER, C ian[4]

[1]IFREE, JAMSTEC, Japan, [2]Department of Earth Sciences, Durham University, United Kingdom, [3]ISTerre, Universite de Savoie - CNRS, France, [4]SGEES, Victoria University, New Zealand

Volcanic eruptions are driven by the growth of gas bubbles in magma, which grow and shrink as volatile species exsolve from and dissolve back into the melt in response to changes in the local environment, particularly in pressure and temperature. This movement of volatiles, particularly water, is recorded in the glass around vesicles and recent studies have used this record to interpret natural samples. Here we investigate the processes that control bubble growth and resorption in magma, by measuring the distribution of dissolved water in experimentally-vesiculated volcanic glasses. Water concentration profiles obtained using SIMS-calibrated BSEM imaging and water speciation data obtained using FTIR spectroscopy, are interpreted in the context of the known pressure and temperature history of the samples.

Samples are found to have undergone partial bubble resorption during the quench to glass at the end of experiments, as a result of increasing water solubility with decreasing temperature. Analysis of the lengthscale and timing of the resulting water concentration profiles demonstrates that the majority of resorption occurs above the glass transition. This quench resorption is associated with a reduction in bubble volumes that creates characteristic textures, such as buckled melt films between adjacent vesicles and reoriented cracks around resorption halos. Highly disequilibrium water speciation ratios within resorption halos are found to be diagnostic of quench resorption and can preserve evidence of pre-quench bubble growth

Quench resorption can increase sample water concentrations and ratios of molecular to hydroxyl water species, and reduce bubble volumes and sample porosities. Studies based on these parameters must therefore consider the potential impact of quench resorption, which is expected to be greatest for samples with high water concentrations, slow quench and low initial sample porosities. Water speciation data offer a way to investigate these impacts in unconstrained natural samples and could provide a tool for forensic interrogation of their eruptive history.

Formulation of the 1-D magmatic flow including vesiculation kinetics

TORAMARU, Atsushi[1*]

[1]Department of Earth and Planetary Sciences, Kyushu University

In most of existing fluid mechanical modeling and numerical calculations, the equilibrium vesiculation has been assumed according to the solubility relation. However, in order to understand the transient behaviors such as triggering of eruptions and shifts of eruption intensity, we need to examine the effect of vesiculation kinetics on the fluid mechanical behaviors in the conduit. In this study, we formulate the governing equations describing the one dimensional fluid mechanics taken into account the vesiculation kinetics, that is, the nucleation and growth of bubbles, assuming the homogeneous flow.

As we adapt the single fluid approximation, we build upon the advantage of the formulation in which the mass conservation equation about density is converted to the pressure equation through the equation of state. We make the similar procedure to obtain pressure equation while in our case the density is a function of not only pressure but also gas phase fraction. The gas phase fraction is calculated by the vesiculation kinetics. As a result we have four equations; 1) pressure equation (mass conservation), 2) equation of motion (momentum conservation), 3) constitutive equations describing vesiculation kinetics. These partial differential equations consisting of pressure, velocity and gas phase fraction, can be solved numerically.

In order to confirm the validity and fundamental characters of the formulation, we numerically solve the shock tube problem, using modified CIP method for advective terms. In the case that the kinetic effect is negligible due to relatively large initial gas fraction in the high pressure region, we obtain the similar solution to that of single fluid, consisting of shock wave in downstream and rarefaction fan in upstream. On the other hand, in the case that kinetics of vesiculation works effectively, we have different behaviors in the high pressure region in which rarefaction front, nucleation pressure front and nucleation event propagate with different velocities, while the behavior in the low pressure region is basically same as the case without the kinetic effect. Each propagation velocity depends on nucleation pressure (liquid/gas interfacial energy), bubble growth rate, initial gas faction in the high pressure region. The essential difference between two cases, the pressure of bubble formation becomes lower in the case with the kinetic effect than in the case without kinetic effect. If the kinetic effect is dominated, it is expected that the time to the vent from the bubble nucleation is relatively short. On the other hand, in the case that the vesiculation proceeds at equilibrium without the kinetic effect, it needs longer time to the vent, suggesting that the relative motion between gas and liquid, the bubble coalescence and degassing become dominate. Thus, this suggests that the kinetics of vesiculation may control the transition of eruption styles such as explosive and non-explosive eruptions.

Pre-eruptive conditions of rhyolitic magma from Kawagodaira Volcano, Izu Peninsula

TAKASHIMA, Jun[1*] ; ISHIBASHI, Hidemi[1]

[1]Graduate school of science, Shizuoka University

Kawagodaira volcano is a rhyolotic monogenic volcano located in the Higashi-Izu monogenic volcano field at Izu Peninsular. The volcano erupted at ca. 3060˜3190. During the eruption, transition of eruption style was occurred from Plinian explosion to obsidian extrusion. Such transition offen occurred in silicic magma, and depend on pre-eruptive condition and outgassing during magma ascent in the vent. However, detailed mechanism is still under study. In this study, we collect volcanic products of 3 eruption style which are plinian eruption, pyroclastic flow, and lava flow. We conducted petrography and analysis of chemical compositions of glass and phenocryst minerals for these volvanic products, and we estimated the pre-eruptive condition of temperature and pressure and water content to examine mechanism in transition of eruption style.

All samples in this study include ca. 15 vol. % of phenocrysts chiefly composed of hornblende and plagioclase with minor amount of orthopyroxene and magnetite, and include ca. 85 vol. % of grandmas composed of glass. Hornblende phenocrysts show chemical zoning with obvious gap of Al content near rim. Al content is higher in core part (ca. 1.7 atoms per formula unit (apfu)) than rim part (ca. 1.2 apfu).

The estimated pressure using hornblende Al content geobarometer shows bimodal distribution with ca. 100 MPa and 200-300 MPa in each sample. The former and the latter correspond to the crystallization pressure of rim and core part of hornblende, respectively. The estimated temperature using plagioclase-hornblende geothermometer indicate constant in all samples, and average to be 1132K. The water content is estimated to be 5wt. % by using plagioclase-melt geohydrometer, and this value coincident with H2O solubility in rhyolitic melt at 100MPa.

The estimated P-T conditions show that magma decompressed from 200˜300MPa to 100MPa without change of magma temperature. This indicates that transition of eruption style occurred less than 100MPa. The coincidence between water content and the H2O solubility at 100MPa suggest that bubbles were already formed at this pressure. And, we think that magma stopped at 2.5˜3km depth until growth of hornblende and plagioclase phenocrysts finished. During cessation of magma ascent, bubbles rised to upper part of magma chamber, forming bubble zoning in magma chamber. This zoning might relate to transition of eruption style.

Hydrothermal system around the Bandaiko hot spring inferred from a 3-D resistivity structure

KANDA, Wataru[1*] ; TAKAKURA, Shinichi[2] ; KOYAMA, Takao[3] ; OGAWA, Yasuo[1] ; SEKI, Kaori[1] ; HINO, Yuta[1] ; HASE, Hideaki[1]

[1]Tokyo Institute of Technology, [2]The National Institute of Advanced Industrial Science and Technology (AIST), [3]Earthquake Research Institute, University of Tokyo

Bandaiko is a hot spring located in the eastern flank of the Kusatsu-Shirane volcano, 3km west from Kusatsu-Onsen. It was discovered in 1967 during excavation of a sulfur mine, and has been utilized as one of the sources of Kusatsu-onsen since 1976. It is presumed that a gush point is located in 505 m west from a tunnel entrance. The ground temperature above the presumed gash point exceeds 80 degrees. About 10 to 20 percent of the hot spring water is always discharged as vapor, so that existence of a two-phase hydrothermal system in a shallow part of tunnel end is considered to be certain. Moreover, since the chemical nature of hot spring is well investigated, Bandaiko is a suitable field which clarifies the resistivity image of a hydrothermal system.

We investigated the shallow resistivity structure around the Bandaiko hot spring using the AMT (audio-frequency magnetotelluric) method. The measurement was done on Oct.19th through Oct.26th, 2013. Five components of EM fields were measured at 19 sites around the presumed gush point: measurements were carried out during the nighttime at 15 of them with sufficient S/N. Because the measuring frequency was 1-10400Hz, information on the resistivity structure from the vicinity of surface to the depths of 1-2km can be obtained. A site for the remote-reference was not installed. Instead, a local-site-reference was applied each other. The 60 Hz noise as well as the 50 Hz noise caused by the local commercial power was extensively seen, because the survey area is located in close proximity to a prefectural border of Nagano where 60 Hz power is used.

Three-dimensional (3-D) analysis was performed in this study. A 3-D resistivity structure model was estimated from the inversion code of Siripunvaraporn and Egbert (2009) using 15 frequencies of all components of impedance data. The inferred model shows low resistivity near the end and the entrance of tunnel. In this presentation, we will report the up-to-date model of the 3-D resistivity structure and discuss the hydrothermal system around Bandaiko in consideration of the measured values of the electrical conductivity of hot spring water, etc.

This study was supported by the Earthquake Research Institute cooperative research program.

Resistivity structure around the Jigokudani valley, Tateyama volcano, Japan, inferred from AMT

SEKI, Kaori[1*] ; KANDA, Wataru[2] ; OGAWA, Yasuo[2] ; HASE, Hideaki[2] ; HINO, Yuta[1] ; KOBAYASHI, Tomokazu[3] ; TANBO, Toshiya[4]

Midagahara (Tateyama volcano) is situated in the northern part of the Japan Alps, and fumarolic activity occurs in the Jigokudani valley located in the northeast end of the Midagahara Plateau. Jigokudani valley was formed by the periodically repeated vapor explosions. Increase in volcanic activity is a great concern because of recent events such as a sulfur outflow, a composition change of the fumarolic gases and the emergence of high temperature fumaroles. We investigated the distribution of hydrothermal fluid and gas reservoir beneath Jigokudani using the AMT method to image the 2D resistivity structure and checked the position of fumaroles. In this observation, the AMT sites were installed along the ENE-SWS survey line around the Jigokudani Valley. The final model revealed that there is a conductive body beneath the Jigokudani valley, and that a relatively low resistive body extends through between the high resistivities beneath the conductor. Near-surface conductor is divided into slightly conductive upper part and lower part. The upper part is explained by clay sediments and hydrothermal fluids. The lower part indicates the presence of gases and fluids. Because of clay's impermeability, the upper clay sediments play the role as a cap for gases. The deep resistive layer is estimated to be the basement of granites that are widely exposed around the Jigokudani valley. We inferred that the relativity conductive body separating these granites is a path of the magmatic gases. The most active fumarole in the Jigokudani valley is on extension of this path.

Hydrothermal system at Tatun Volcano Group, northern Taiwan, inferred from resistivity structure

KOMORI, Shogo[1*] ; UTSUGI, Mitsuru[2] ; KAGIYAMA, Tsuneomi[2] ; INOUE, Hiroyuki[2] ; CHEN, Chang-hwa[1] ; CHIANG, Hsieh-tang[3] ; YOSHIMURA, Ryokei[4] ; KANDA, Wataru[5]

[1]Institute for Earth Sciences, Academia Sinica (Taiwan), [2]Aso Volcanological Laboratory, Kyoto University, [3]National Taiwan University, [4]Disaster Prevention Research Institute, Kyoto University, [5]Tokyo Institute of Technology

Tatun Volcano Group is composed of over twenty volcanoes, which were formed within faults at the northern tip of Taiwan. So far, these volcanoes were regarded as extinct because of no historical record of eruption. However, recent studies have found the relatively young ejecta (Chen and Lin, 2002; Belousov et al., 2010), high 3He/4He ratio (Yang et al., 1999; Ohba et al., 2010), and hypocenter distribution suggesting the fluid flow and the high temperature condition (Konstantinou et al., 2007); that suggest the presence of potentially eruptive magma beneath TVG. Further, active heat discharge from fumaroles and springs also suggests a large amount of the volcanic fluids released from magma beneath Chishinshan volcano. Focusing on this phenomenon, Utsugi et al. (2012, JPGU) conducted AMT surveys at the volcano for a better understanding of this magma degassing, and showed the preliminary resistivity structure suggesting the low resistivity region at the depths of 1-2km.

On the basis of their work, the authors conducted further AMT surveys around Matsao hot spring and Da-you-keng fumarole areas, about 2 km northeast of the volcano. Time series of the electric and magnetic fields were acquired for about 4 hours at each site. Totally 10 observation sites were configured to cover the areas. After data acquisition, the frequency domains were obtained from the time series, using FFT processing. The impedances were estimated for each frequency. The obtained frequency range was between 1 and 10400 Hz. The authors used not only the data of the present study but also those of Utsugi et al. (2012, JPGU).

This study categorized the study area into two areas, mainly from the characteristics of the main axes of the impedance phase tensor ellipse by the method of Caldwell et al. (2004): 1) Mt. Chishinshan area and 2) Matsao and Da-you-keng areas. In this study, two-dimensional resistivity structure was estimated for each area, using the inversion code of Ogawa and Uchida (1996). By incorporating them with the evidences from geochemistry and geophysics (MRSO, 1969, 1970, 1971, 1973; Ohba et al., 2010; Ohsawa et al., 2013; Murase et al., 2013, IAVCEI), the following features of the hydrothermal system was inferred.

Beneath Mt. Chishinshan two-phase fluids are supplied; which is represented by the extremely-low resistivity column (less than 3 Ohm-m) and the deflation pressure source below 1 km depth. As the fluids ascend, their phase is changed into vapor-phase, leading to low to relatively-low resistivities (6-30 Ohm-m) at the depths of 0.3-1 km. The vapor-rich region is covered by the low-permeability cap represented by the extremely-low resistivity layer near the surface (less than 3 Ohm-m). A portion of the vapors is mixed with shallow groundwater, and flows along a topographical relief to form Matsao hot spring; whose area is represented by resistivities less than 10 Ohm-m.

On the other hand, Da-you-keng area has intense fumaroles; whose vapor-dominated fluids are supplied from the region beneath Cing-tian-gang, represented by the low to low-resistivity region (3-30 Ohm-m) and the inflation pressure source below 1 km depth. This vapor-bearing region is covered by the overlying low-permeability cap represented by the extremely-low resistivity region (less than 3 Ohm-m).

This study estimated the horizontally-extending vapor-rich region beneath Mt. Chishinshan, Da-you-keng, and Cing-tian-gang. Actually, this area has experienced a phreatic eruption ca. 6 Ka (Belousov et al., 2010). These suggest that the vapors have been maintained for at least several thousands years, and that there is still a possibility of phreatic explosions.

Conductivity distribution of the surface layer in Aso Caldera

KAGIYAMA, Tsuneomi[1*] ; YOSHIKAWA, Shin[1] ; UTSUGI, Mitsuru[1]

[1]Graduate School of Science, Kyoto University

Kagiyama and Morita(2008) proposed that volcanism has a wide range of diversity represented by two typical end members controlled by the easiness of magma storage beneath volcano; Eruption dominant (ED) volcanism in difficult condition and Geothermal activity dominant (GD) volcanism in easier condition. In GD volcanoes, magma stagnates beneath volcanoes and maintains geothermal activity. This seems GD volcanoes continue to give much benefit to human society. However, GD volcanoes sometimes have large eruptions after repeated stagnations of magma. This fact suggests it is very important to understand where and why magma stops ascending. Kagiyama and Morita (2008) indicated magma degassing is one of the important factors to control magma ascending. On this aspect, the authors have carried out VLF-MT survey around some active volcanoes in Japan, because electrical conductivity of ground strongly depends on the conductivity of pore water.

Aso Caldera has an acid crater lake in Nakadake, which is one of the post caldera cones, and has many hot springs such as Uchinomaki, Akamizu. Conductivity distribution shows two typical features; caldera floor has almost homogeneous and high conductivity (>10mS/m), while the post caldera cones show wide range.

Most cones such as Kishima-dake and Ohjo-dake have lower conductivity (<3mS/m), except around Naka-dake Craters and western flank of post caldera cones such as Yoshioka, Yunotani and Jogoku-Tarutama (>30mS/m). Kusasenri Volcano, located between Naka-dake and Yoshioka has also rather high conductivity (3-10mS/m). These areas locate along the E-W trend of the major post caldera cones. Most part of the northern flank of the post caldera cones shows low conductivity (<3mS/m). However, higher conductivity was found around Sensuikyo, just north of Nakadake Craters. This suggests down flow of hydrothermal water from Naka-dake Craters to the caldera floor. Similar features are detected in the southern flank; from Nakadake to Shirakawa Hot Spring, from Jigoku-Tarutama Hot Springs to Tochinoki Hot Springs.

Caldera floor has almost homogeneous conductivity. This feature is explained by the fact that the caldera floor was under the lake until 9 ka and is covered by lake deposit. However, extremely high conductivity was found at three areas (>50mS/m). Two of them correspond hot spring areas; Uchinomaki in the north and Akamizu in the west. The third area is distributed around old post caldera cones, Mietsuka. The age of these cones was estimated around 46 ka, and no hot spring is distributed. High conductive zones, Uchinomaki, Mietsuka and Naka-dake are located along the NNW-SSE line. Hydrothermal water may be supplied along this line.

These results suggest that hydrothermal water is supplied along the E-W trend crack from Naka-dake to Yoshioka, mainly supplied beneath Naka-dake, and expanded to the northern caldera floor. The NNW-SSE trend from Naka-dake to Uchinomaki may suggest a tectonic fault. Aso has wide high conductivity area and degassing in Aso might be large to be GD volcano.

The thermal expansion model and the Mogi model for volcanic ground deformation

KITSUNEZAKI, Choro[1*]

[1]none

(1) Basic aspects of the thermal expansion model, which was proposed by the author in this meeting of the last year (Kitsunezaki and Muraoka, 2013), is reorganized in relation to the Mogi model (Mogi,1958). In the Mogi model, the earth's crust is assumed to be a semi-infinite isotropic homogeneous elastic solid with the horizontal free plane (the ground surface). Displacement of the ground surface caused by a spherical pressure source set up in the earth's crust is evaluated. Gravity change associated with the deformation was estimated by Hagiwara(1977). Basically, the inside of the spherical source of this model is void (or material different from the surroundings). As a special case, we assume that the inside is filled with the same material as the surroundings and that temperature in the inside is raised (keeping the outside temperature constant). Thermal expansion of the sphere behaves as a pressure source, and the Mogi model is transformed to the spherical thermal expansion model (ST model). In this case, as the mass of the sphere does not change, the change in gravity on the ground surface is caused by the free-air effect (FE) due to uplift of the ground surface alone.

(2) The above ST model can be extended to the case in which the temperature-rise region (T region) has arbitrary shape. Let the T region be subdivided into a large number of small cubic cells. Every cell effectively behaves as a spherical thermal element. Its outputs (displacement and gravity change on the ground surface) are given by the ST model. The output of the entire T region is given as a sum of the output of each element. Hence in the T region with any shape, the change in gravity is caused by the FE due to the vertical displacement of ground surface alone.∗

∗[Note] The related description in Kitsunezaki and Muraoka(2013) has been corrected here.

(3) Shallow regions of actual volcanoes may be regarded as porous media. Let's assume that the pores are saturated by water and are in open condition. In the thermal expansion model described in (1) and (2), the earth medium is replaced by such a water-saturated porous medium. In this case, pressure of pore water is kept constant. Hence the solid part (skeleton of the medium) behaves in deformation independently from pore water. Thermal expansion of the solid part causes the displacement of the ground surface and the gravity change due to the FE as described in (2). On the other hand in the T region, the pore water expands freely responding to the temperature-rise (below the boiling point), hence its density decreases. (Thermal expansion coefficient of water is more than ten times larger than that of solid part (rock)).This effect causes negative gravity change, which is added to the FE so as to amplify the total gravity reduction to some degree. This example is numerically demonstrated in gravity variation observed in Akita-Komagatake volcano after the 1970-eruption.

El Cobreloa: A geyser with two distinct eruption styles

NAMIKI, Atsuko[1*] ; MUNOZ, Carolina[2] ; MANGA, Michael[2]

[1]DEPS, Univ. of Tokyo, [2]UC Berkeley

We performed field measurements at a geyser nicknamed “El Cobreloa”, located in the El Tatio Geyser Field, Northern Andes, Chile. The El Cobreloa geyser has two distinct eruption styles: minor eruptions, and more energetic and long-lived major eruptions. Minor eruptions splash hot water intermittently over an approximately 4 minute time period. A major eruption begins with an eruption style similar to minor eruptions, but then transitions to a voluminous water-dominated eruption, and finally ends with energetic steam discharge that continues for approximately 1 hour. We calculated eruption intervals by visual observations, acoustic measurements, and ground temperature measurements. All measurements consistently show that each eruption style has a regular interval: 4 hours and 40 minutes for major eruptions, and approximately 14 minutes for minor eruptions. We develop a model, in which the geyser reservoir, connected to the surface by a conduit, is recharged by the deep, hot aquifer. More deeply derived magmatic fluids provide the enthalpy to heat the reservoir. Boiling in the reservoir releases steam and hot water to the overlying conduit causing minor eruptions, and heating the water in the conduit. When the conduit becomes warm enough, the water in the conduit is able to boil, leading to a steam-dominated eruption that empties the conduit. The conduit is then recharged by the shallow, colder aquifer, and the eruption cycle begins anew. El Cobreloa provides insight into how small eruptions prepare the geyser system for large eruptions.

Time variation in the chemical composition of fumarolic gases at Hakone volcano, Japan

OHBA, Takeshi[1*] ; KUNO, Yuki[1] ; SAGOU, Masakazu[1]

[1]Dep. Chem. School Sci. Tokai Univ.

Introduction

Mt Hakone having the caldera structure is an active volcano located on the western end of Kanagawa prefecture. At the central region of caldera, several volcanic cones are located. On the flank of cones, geothermal areas have been developed. The magmatic activity, which formed the cones, started 50 Ka (Kuno, 1972). The activity is estimated to have continued until 3 Ka (Kobayashi et al., 1997). At the last eruption, the western flank collapsed at one of the central cones, resulting in the formation of dammed Lake Ashi (Ooki and Hakamada, 1975).

At Mt Hakone, volcanic earthquakes have been observed frequently, although no historical eruption is known. Especially in 2001, the occurrence of volcanic earthquake was intense. The seismic activity was accompanied with an inflation of body at the central cones. The inflation was interpreted to be brought by a pressure source at 7 km of depth (Daita et al., 2009).

Sampling of fumarolic gas

We sampled fumarolic gas at two sites since May 2013 at Owakudani geothermal area developed on the central cones. One of the sites is located 200m far from the Owakudani car parking in the direction of southeast. At the site we had sampled fumarolic gas in previous study. We call the fumarole as the regular fumarole. Another fumarole is located 500m far from Owakudani car parking in the direction of north. The fumarole has been generated recently. Before the generation, the area was forest. Now many large stout trees were killed by the geothermal effect. We call the fumarole as the new fumarole. Both of the fumarolic gases were sampled in the evacuated Giggenbach bottle containing 20 ml of 5M KOH solution.

Result

The main component of the regular and new fumarole was water vapor (H2O). The molar percentage of H2O was about 98% for the both fumaroles. Both of the gas contain CO2 gas as the major component next to H2O, the percentage was about 1 to 2%. The regular fumarolic gas contained H2S as much as 0.2 to 0.4%. The H2S concentration in the new fumarolic gas was only 0.036 to 0.050%, about 1/10 to the regular fumarolic gas.

The CO2/H2S molar ratio indicated a time variation, a monotonic decrease since May 2013 to Oct 2013. Daita (2013) reported a similar trend based on the observation with detecting tubes. Daita (2013) found an abrupt increase in the CO2/H2S molar ratio on Jan 2013. The increased ratio had been kept until April then decreased gradually toward Oct 2013. According to the seismic observation by Hot Springs Research Institute of Kanagawa Prefecture, volcanic earthquakes occurred frequently in Jan and Feb 2013. We suppose the change in the CO2/H2S ratio has been synchronized with the occurrence of volcanic earthquakes.

Geochemical characteristics and changes of thermal waters around Tokachidake volcano, Japan

TAKAHASHI, Ryo[1*] ; SHIBATA, Tomo[1] ; MURAYAMA, Yasuji[1] ; OGINO, Tagiru[1] ; OKAZAKI, Noritoshi[1]

[1]Geological Survey of Hokkaido, HRO

Tokachidake volcano, located in central Hokkaido, caused three magmatic eruptions (AD 1926, 1962 and 1988-89) in the 20^{th} century. The seismic and thermal activities at the summit crater area have increased since AD 2010. We have continuously investigated thermal waters around the volcano since AD 1986 in order to understand the volcanic activity. Around the AD 1988-89 eruption, the chemical compositions and temperature of the thermal waters had obviously changed (Murayama et al., 1991). Therefore, we need to reveal the origin and changes of the thermal waters in order to forecast the future volcanic activity.

The thermal waters are discharged in the Nukkakushi crater (Ansei crater) and at its lower reaches, which is located at about 2 km southwest from the summit craters. Each thermal water is acidic with pH $<$3.2. At the time of AD 1986, all thermal waters were rich in sulfate ion but were scarce in chloride ion. In addition, anion content of the thermal waters decreases in proportion to the distance from the Nukkakushi crater. Therefore, the thermal waters derived from the Nukkakushi crater area flow, while mixing with groundwater, and are discharged at the lower reaches.

At the Fukiage hot spring area (1,000 m a.s.l.), the concentration of chloride and sodium ions in the thermal waters had abruptly increased since AD 1986. The increase of these chemical concentrations had continued until AD 1992, and the concentration of them had decreased since then. Accompanied with the chemical change, the temperature of the thermal waters had also increased more than 20 ^{o}C around the AD 1988-89 eruption. Such increase of the chemical compositions and temperature of the thermal waters had occurred related to the increase of the volcanic activity. Thus, these increases can be explained by mixing of highly dense NaCl type thermal water into shallow aquifer, and its mixing ratio changed with the volcanic activity. The chemical and thermal changes of the thermal waters have not occurred at the Okina hot spring (1,060 m a.s.l.). This indicates that the input of highly dense NaCl type thermal water has occurred at the lower reaches of the Okina hot spring.

Based on our investigations, the thermal waters in this area are formed by mixing of three end-members, sulfate ion rich thermal water, dense NaCl type thermal water and groundwater. The effect of the dense NaCl type thermal water is recognized only at the Fukiage hot spring area, and the mixing ratio changes according to the volcanic activity. The concentration of chloride and sodium ions in the thermal waters has begun to increase again since AD 2012. However, the increase is obviously small compared with that before the AD 1988-89 eruption, and the oxygen and hydrogen isotopic compositions of these thermal waters have not shown obvious change yet. Observations of the thermal waters will provide useful information to forecast the future volcanic activity in Tokachidake volcano, and hence we will continue the observations.

Case study of the behavior of isotope in several hot-spring field

YANAGISAWA, Norio[1*]

[1]AIST

1. Introduction

The behavior of oxygen and hydrogen isotope in geothermal field suggests the origin of fluids and the water rock interaction in fluid path. And there are various origins of high temperature hot springs in Japan, for example, separation from magma, heating meteoric water in the underground.

In this paper, we show the several samples of the isotopic analysis in high temperature hot spring fields including hot spring binary test field and we discuss the diversity of origin of the hot springs.

2. Examples of several hot spring fields

(1) Hachijo Island

There is a geothermal power plant (3.3MW) in Hachijo Island. To clarify hydraulic system, we measured oxygen and the hydrogen isotope ratio of the hot spring fluid, underground water as spring and the fluid at geothermal power plant. The isotope ratio of spring is similar as rain in Hachijo Island and the value of d is about 20 and hydrogen isotope ratio of spring is about -35 ‰. The hot spring fluid in Hachijo Island has two patterns. One is the origin of meteoric water due to similar isotope ratio as spring water. And another is the origin of seawater due to similar isotope ratio as seawater. The isotope ratio of fluid of geothermal plant is higher oxygen ratio than spring and hot spring water and this suggest that the origin of the fluid of geothermal plant is mixture meteoric and magmatic water.

(2) Matsunoyama hot spring field

In Matsunoyama hot spring field, the test of binary power plant is carried out using Takanoyu #3 hot spring fluid with about 100 ℃ and 10,000 mg/l Cl. The hydrogen isotope ratio is about -25 ‰ and oxygen isotope ratio is about 0 ‰ higher than meteoric water. And the isotope ratio of Matsunoyama #4 well with 2,000mg/l shows the mixture of meteoric water and Takanoyu #3. The origin of Takanoyu#3 is fossil salt water with methane gas and geo-pressure structure.

(3) Minami-Izu hotspring field

There is high temperature hot spring with about 100 ℃ and 10,000 mg/l Cl in Minami-Izu hot spring field, too. In this field the temperature and Cl concentration decrease eastern area. The isotope ratios of the several hot springs and underground water exist on the meteoric line. This suggest the origin of hot spring is meteoric water and the reason of temperature and cl concentration decreasing is mixture with low temperature meteoric water.

Fluid geochemistry of hot springs at Kotakara-jima,Tokara Islands

TSUTSUMI, Saki[1*] ; ISHIBASHI, Jun-ichiro[1] ; KONNO, Uta[2] ; YOKOSE, Hisayoshi[3]

[1]Department of Earth and Planetary Sciences, Graduate School of Sciences, 33 Kyushu University, [2]JAMSTEC, [3]Graduate School of Science and Technology, Kumamoto University

Yokose et al.(2010) proposed giant calderas related to Quaternary volcanic activity, on the seafloor along the Tokara Islands. Kotakarajima is located on the rim of the Takarajima Caldera, which belongs to this caldera chain. A hot spring called as Yutomari-onsen is located at the coastline of the Kotakarajima island, which water temperature reaches higher than 90 degC. Fluid chemistry of this hot spring was studied with the aim of understanding a hydrothermal sytem associated with the seafloor caldera.

Hot spring water was collected in May, 2013. Temperature, pH, electorical conductivity, and oxidation-reduction potential were measured on site. Fluid samples were filtered with a 0.45 um diskfilter and stored. Major cations and anions were analyzed by ICP-AES and ion chromatography. Alkalinity was determined by HCl titration and Si concentration was determined by colorimetry.

Fluid chemistry of the hot spring water is characterized by high Cl^- concentration, Na/Cl ratio (=0.75) closed to that of seawater, and isotopic composition similar to seawater, which strongly suggests that it is originated from seawater. Depletion in Mg^{2+} and $SO_4{}^{2-}$ and enrichment in K^+ and Ca^{2+} compared with seawter, are in accordance with the idea that the fluid experiences seawater-rock interactions. Fluid temperature in the aquifer where interactions attain to equilibrium is estimated as 250-300 degC based on chemical geothermometers.

From these results, the Yudomari-hotspring at the Kotakarajima Island is considered as fluid discharge of a submarine hydrothermal system that is associated with Takarajima Caldera.

Hydrothermal system beneath Shirahone hot spring, Nagano, Central Japan, revealed by resistivity survey

YAMAYA, Yusuke[1*] ; MOGI, Toru[2]

[1]GSJ, AIST, [2]ISV, Hokkaido Univ.

Shirahone hot spring is one of the most active geothermal area, located in the western part of Nagano prefecture, Japan. A source of hot water has not been clarified, because there are few geophysical exploration and borehole logging. We performed an electrical resistivity exploration employing the magnetotelluric (MT) method in order to identify a hot-water reservoir and whole hydrothermal system providing the Shirahone hot spring. The MT data were measured at six stations along the NNE-SSW line crossing the Shirahone area. The apparent resistivity and impedance phase were inverted to a two-dimensional resistivity section down to 3 km deep with the aid of the code developed by Ogawa and Uchida (1996). The estimated resistivity section generally indicates a range of resistivity 1-3000 Ωm, including two considerable conductors below 3 Ωm. These conductors are found at a depth 400-1000 m and deeper than 2000 m beneath the Shirahone hot spring. The upper conductor is interpreted as a hot-water reservoir which acts as a source of the Shirahone hot spring. The hot water would ascend from this reservoir to the discharge area through a fracture zone. The deeper conductor can be a heat source consisting of high temperature intrusive complex. This source might sustainably supply heat to the upper reservoir, which can keep itself a long time. A high resistivity zone is found beneath the Sakaigawa active fault zone. In general, an active fault is identified as a conductive zone due to saturated water into a fractured zone. Conversely, our resistivity section indicates a relatively resistive zone beneath the fault. This implies a locked part of the fracture zone where groundwater had declined after the last active phase of the fault.

Ground deformation around Ohaaki geothermal field, New Zealand inferred from persistent scatterer SAR interferometry

ISHITSUKA, Kazuya[1*] ; TSUJI, Takeshi[2] ; MATSUOKA, Toshifumi[1] ; FUJIMITSU, Yasuhiro[3] ; NISHIJIMA, Jun[3]

[1]Graduate School of Engineering, Kyoto University, [2]International Institute for Carbon-Neutral Energy Research (I2CNER), Kyushu University, [3]Faculty of Engineering, Kyushu University

There are several producing geothermal fields in Taupo Volcanic Zone (TVZ), northeast-trending zone of mainly andesitic to rhyolitic arc/back arc volcanism, within the central North Island, New Zealand. It has been reported that ground subsidence with the rate of 30-50 mm/year has occurred at the Wairakei geothermal field, one of the biggest geothermal fields in TVZ [Allis et al., 2009]. Such a research on ground deformation around geothermal field is, however, rarely documented. Thus, it would be important to study deformation pattern at the geothermal field.

In this study, we mapped ground deformation around Ohaaki geothermal field located northeast of TVZ using persistent scatterer SAR interferometry (PS-InSAR). Since the analysis makes use of high quality phase information of the coherent target of SAR image, the estimated deformation is more accurate compared with the standard differential SAR interferometry (DInSAR). We processed 21 ALOS/PALSAR images acquired from January 2007 to January 2011 from an ascending orbit. As a result, we estimated ground deformation opposite to line of sight direction, which may correspond to ground subsidence. Moreover, the deformed area showed sharp boundary which we can be attributed to fault location in the area.

Gravity Monitoring at Takigami Geothermal Area, Oita Prefecture, Japan

PRATIWI, Maryati[1*] ; FUJIMITSU, Yasuhiro[1] ; NISHIJIMA, Jun[1]

[1]Kyushu University, Fukuoka, Japan

The gravity monitoring at Takigami geothermal area has been applied since November 1996 (Oka et al., 2011). In this area, the nearest geothermal manifestations are about 1-2 km to north and east of Takigami (Furuya et al., 2000). So, there are no geothermal manifestations at the surface. The geothermal power plant was built at Takigami in August 1991. It was reported that its power plant output was changed from 25,000 kW to 27,500 kW in June 2010 (Kyushu Electric Power Co., Inc., 2010)

We analyzed the gravity data from August 2008 until August 2013. We found that the gravity changes at the northern zone, the western zone, and the southwestern zone of this area are quite stable historically. This result indicates that the recovery state for these zones is almost done. However, the data at the eastern zone shows gravity increasing. It was assumed that the subsurface fluid at Takigami area flows from south, which is the direction Kuju Mountain area. Then, we noted that the fluid from south is filling the faults in eastern area in the beginning before going through to northern area (due to its high permeability (Jalilinasrabady et al., 2011)), thus the recovery state in the eastern zone has not been done.

By using theorem of Gauss, we calculated the mass changes based on the gravity changes from August 2009 to August 2012. This calculation is excluding the northern area as it has different water system, and removed the effects of precipitation and evapotranspiration by Gwater-e program (Kazama, 2011). And, we found that the mass increases as much as 10.12 Mt in the Takigami geothermal area. This mass change is associated with the production and reinjection process of geothermal fluids.

Heat balance technique under the condition that the influence of solar radiation can be negligible

FUJIMITSU, Yasuhiro[1*] ; NISHIJIMA, Jun[1]

[1]Faculty of Engineering, Kyushu University

The coefficient of geothermal flux is essential for the heat balance technique (Sekioka and Yuhara, 1974), which is one of the methods for measurement of heat discharge rate from geothermal fields, and is determined by micrometeorological data of a target area. In order to comprehend the temporal change of the micrometeorological conditions and the coefficient of geothermal flux, we have manufactured an automated continuous micrometeorological measurement system and measured micrometeorological data at some geothermal fields. And we have discussed about the coefficient of geothermal flux (Fujimitsu et al., 2009; Fujimitsu et al., 2010; Fujimitsu et al., 2011).

In the heat balance technique, a reference temperature is set on a ground surface where there is no geothermal anomaly, and the area that indicates higher ground surface temperature than the reference temperature is regarded as the geothermally anomalous area. However, the influence of solar radiation on the determination of the reference temperature is one of the main factors in accuracy of the estimated heat discharge rate by the heat balance technique. Therefore, we assumed the condition that the influence of solar radiation can be negligible, and conducted the observation experiments during the nights by using an artificial heating element as a heat source in order to improve the accuracy of the heat balance technique by a new analytical method.

For the new analytical method, we considered the heat balance at the ground surface under the condition of no solar radiation, adopted Richardson number for determination of the transfer velocity, and changed the determination procedure of the reciprocal of the Bowen ratio. As a result, the new analytical method estimated the heat discharge rates that are almost the same as the actual heat generation rates from the artificial heating element.

We are grateful to Mr. Shohei Oshikata who had progressed this study.

Simulation of the Daisen-Kurayoshi tephra, in the San-in district, SW Japan, using Tephra2

YAMAMOTO, Takahiro[1*] ; SUGIYAMA, Minoru[2] ; TAJIMA, Yasuhisa[2]

[1]Geological Survey of Japan, AIST, [2]Nippon Koei Co Ltd

The Daisen-Kurayoshi tephra, which erupted from Daisen volcano at about 53 ka, is one of the most voluminous Plinian fall deposits in Japan. Its apparent volume was estimated as more than 20 km^3, but quantitative study of this tephra have not be done. So, we try to analyze this tephra using Tephra2 and decide its eruption parameters. In the simulation, we set 5 cases in height of the eruption column from 10 to 18 km, 4 cases in weight of the erupted magma from 1 to 8x10E+18 kg, 4 cases in medium grain size of the ejected materials from 0 to 3 phi, and 5 cases in sorting of the ejected material under the average wind data above Yonago. A total of 400 cases have been calculated. To explain the observed distribution of the tephra, the column height and ejecta weight have to be 18 km and 4 to 8x10E+18 kg (40 to 80 km^3), respectively.

Insight into setup of typical meteorological conditions for evaluating volcanic ash hazard

HATTORI, Yasuo[1*] ; SUTO, Hitoshi[1] ; GO, Yumiko[2] ; TOSHIDA, Kiyoshi[1] ; HIRAKUCHI, Hiromaru[1] ; ISHIHARA, Shuji[2]

[1]Central Research Institute of Electric Power Industry, [2]Denryoku Computing Center

Estimation of ash concentration and deposition is of practical interest in evaluation of volcanic ash risk on critical infrastructure (e.g. Wardman et al. 2012). For estimating ash concentration and deposition, numerical simulations with an ash transport- and deposition-model have become a powerful tool (e.g. Folch 2012). However, the setup of meteorological conditions, which mainly control the ash transport- and deposition- processes in the atmosphere and on the ground, has not been discussed in details.

In the present study, we examine the estimation of ground deposition for a real test case, a volcanic ash hazard in Kanto-area for an eruption at Mt. Fuji, with various meteorological conditions by using an ash transport- and deposition-model, fall3d. The meteorological conditions are generated with the 53 years reanalysis meteorological dataset, CRIEPI-RCM-Era2, which has a temporal- and spatial resolutions of 1 hr and 5 km; the typical and extreme conditions were sampled by using Gumbel plot and an artificial neural network technique.

The ash deposition is invariably limited to the west area of Mt. Fuji, even with the typical wind conditions on summer, while the isopach of ground deposition depicted various distributions, which strongly depends on meteorological conditions. This implies that the concentric circular distribution must not be realistic. Also, a long-term eruption, such as the Hoei eruption during stage3, yields large deposition area due to the diurnal variations of wind direction, suggesting that the attention to the differences between diurnal variation and fluctuations of wind direction on evaluating of volcanic ash risk is vital.

More details will be presented in the presentation, and we believe that our study must be helpful to develop the numerical simulations for evaluation of volcanic ash risk.

Numerical model of 3D ballistic trajectory for hazard assessments at Upper Te Maari eruption of Tongariro volcano in New

TSUNEMATSU, Kae[1*] ; FITZGERALD, Rebecca[2] ; KENNEDY, Ben[2]

[1]Graduate School of Environmental Studies, Nagoya University, [2]Department of Geological Sciences, University of Canterbury

Ballistic bombs and blocks are energetic pyroclasts deposited around volcanic craters. Hazard assessments of ballistic projectiles are important for people, buildings, and roads around vent especially in tourist and residential areas. Tongariro volcano, an active volcano in a popular national park in New Zealand, erupted August 6th, 2012 after one hundred years. By combining acoustic signals with eyewitness descriptions, five eruption pulses from fissures around Upper Te Maari crater were characterized and conditions of particle ejection were defined. A distribution of ballistic blocks was mapped from orthophotos and field campaigns. In order to clarify characteristics of ballistics at Tongariro volcano and assess future hazards, a numerical model of ballistics is modified and applied to the 2012 eruption. At first, 3D multiparticle model based on Discrete Event Simulation (DES) method is converted to the model based on semi-Lagrangian method to include an effect of air drag and gas flow around airborne particles. Initial conditions, such as ejection direction and speed, were calibrated to explain both spatial and size distribution of deposit bombs. Finally, an initial particle velocity of 200 m/s and gas flow velocity (constant) of 150 m/s are obtained as conditions of best fit. Furthermore, we applied this model to the assessment of future eruption regarding Tongariro Alpine Crossing, a walking trail in the national park frequented by ˜80,000 people each year. Impacts of two extreme eruption cases are simulated by the numerical model. Negligible probabilities of fatality along the TAC are found from a magnitude smaller eruption, similar in size to the November 2012 eruption. However, a magnitude larger eruption could result in higher probabilities in certain areas of the track which it would be unlikely to survive the eruption. Varying the input parameters from the calibrated model allows for the assessment of future ballistic hazard from larger and smaller eruptions of Upper Te Maari Crater. A possibility of applying this model to the assessment of Japanese volcanoes such as Mt. Fuji will be discussed.

Estimation of locations and migration of debris flows on Izu-Ohshima Island on 16 Oct., 2013 by seismic amplitudes

OGISO, Masashi[1*] ; YOMOGIDA, Kiyoshi[2]

[1]Matsushiro Seismological Observatory, JMA, [2]Grad. Sch. Sci., Hokkaido Univ.

Typhoon 1326 (Wipha) with heavy rainfall caused severe damage at Izu-Ohshima Island on 16 October 2013 with large-scale debris flow, probably not only a single event but sequence of flows.

Seismic networks on Izu-Ohshima recorded the signals originated from those debris flows. At least five events of large amplitudes are recognized in continuous records of seismographs.

It is hard to estimate the location of such events with conventional methods of epicenter determination because of the difficulty to identify any seismic phase arrivals. We estimate the locations of the five events with spatial distribution of seismic amplitudes (Battaglia and Aki, 2003; Kumagai et al., 2010). In this method, after correcting the site effect of each station, the RMS amplitude of high-frequency seismic waveform is assumed to decay only with geometrical spreading and intrinsic absorption. Although amplitudes depend on radiation pattern of seismic waves, the isotropic distribution of amplitudes could be assumed at high frequencies because of the scattering effect by small scale heterogeneity in the crust (Takemura et al., 2009). The location of each event is derived as the point of the minimum residual between observed and calculated amplitudes of all the seismic stations. Before estimating the locations of the five events, we apply the band pass filter of 5-10Hz to each seismic record. We assume that the filtered waveform is composed of S body waves only, S-wave velocity is 1.44km/s, and Q=100 for intrinsic absorption. We limit the search range of each event only on the surface of the island. Site factors of stations are estimated by amplitudes of coda waves for regional earthquakes.

The estimated locations of all the five events are located in an eastern side of Motomachi district, where huge causalities were suffered, agreeing with the debris flow traces mapped carefully after the disaster occurred. In addition, the location is migrated to the west (i.e., from the volcano flank to the sea coast) within its duration time of 60-80 sec except for one event with small duration time. Such migrations may correspond to the flow of debris, with its speed about few tens km/h. Time series of source amplitudes, that is, the maximum value and duration time of each event show the variability of the debris flows occurred on Izu-Ohshima Island within several hours on that day.

Generally, seismic networks focused on volcanic activities are generally composed of stations of higher density than other seismic networks. The records of such dense seismic networks are useful to analyze not only earthquakes and tremor on volcanoes, but also debris flows or other disastrous events, as shown in this study. The present location method using the spatial distribution of seismic amplitudes is conceptually able to apply in quasi-real time, so it should be useful to early estimation of location and magnitude of various disasters in and around volcanoes.

Acknowledgements

We analyzed the seismic waveforms recorded in the networks on Izu-Ohshima Island which are operated by Earthquake Research Institute of the University of Tokyo, the National Research Institute for Earth Science and Disaster Prevention, and the Japan Meteorological Agency. We used the digital elevation model and topographical map images of Digital Japan Web System provided by the Geospatial Information Authority of Japan.

G-EVER Next-generation Volcanic Hazard Assessment System

TAKARADA, Shinji[1*] ; BANDIBAS, Joel[1]

[1]Geological Survey of Japan, AIST

The Asia-Pacific Region Global Earthquake and Volcanic Eruption Risk Management (G-EVER) is a consortium of geohazard research institutes that was established in Asia-Pacific region in 2012. G-EVER aims to formulate strategies to reduce the risks caused by earthquakes, tsunamis and volcanic eruptions worldwide. The G-EVER next-generation volcano hazard assessment working group is developing a useful system for volcanic eruption prediction, risk assessment, and evacuation strategy at various eruption stages. The assessment system is based on volcanic eruption history datasets, eruption database and numerical simulations. Eruption history datasets including precursor phenomena leading to major eruptions are important for the prediction of future volcanic eruptions. A high quality eruption database which contains compilations of eruption dates, volumes, and styles, is important for the next-generation volcano hazard assessment system. Formulating international standards on how to estimate the volume of volcanic materials is important to establish a high quality volcanic eruption database. GIS-based spatial distribution database of volcanic materials (e.g. Tephra and pyroclastic flow distributions) is important for accurate area and volume estimation and risk assessments. The volcanic eruption database is developed based on past eruption results, which only represent a subset of possible future scenarios. Therefore, numerical simulations with controlled parameters are needed for more precise volcanic eruption predictions. The ”best-fit” parameters of the past major eruptions in the world have to be estimated and the simulation results database should be made.

The use of the next-generation system should enable the visualization of past volcanic eruptions datasets such as distributions, eruption volumes and eruption rates, on maps and diagrams using timeline and GIS software. Similar volcanic eruption types should be easily searchable from the eruption database. Using the volcano hazard assessment system, prediction of the time and area that would be affected by volcanic eruptions at any location near a volcano should be possible using numerical simulations. The system should be able to estimate volcanic hazard risks by overlaying the distributions of volcanic deposits on major roads, houses and evacuation areas using a GIS enabled systems. The next-generation real-time hazard assessment system will be implemented with user-friendly interface, making the risk assessment system easily usable and accessible online.

Preliminary version of the next-generation volcanic hazard assessment system is available since June 2013. This can run energy cone simulations at any volcano in the world using ASTER Global DEM, and the links to major volcanic databases, such as Smithsonian, VOGRIPA and Quaternary volcanoes. Almost all volcanoes in the world can be evaluated using this volcanic hazard assessment system. Currently, the system covers more than 3200 Quaternary volcanoes worldwide. Links to major volcanic databases in the world are useful to examine eruption history in detail. Using Google and Bing maps as base maps provide more information for hazard evaluations. A hazard evaluation system using Titan2D will be available soon. Hazard assessment system using probabilistic analysis is also being planned in collaboration with INGV in Italy. This hazard assessment system is expected to be used for hazard mapping and risk management planning by government authorities and policy makers.

An attempt to obtain empirical evidences for petrological assessment of volcanic activity based on magma database

TAKEUCHI, Shingo[1*] ; TOSHIDA, Kiyoshi[1] ; MIURA, Daisuke[1]

[1]Central Research Institute of Electric Power Industry

For Japanese volcanoes, high-quality databases of volcanic eruptions have been developed, for example Japanese active volcanoes (Kudo and Hoshizumi, 2006-) and one-million years chronology of volcanic eruptions (Hayakawa, 1996-). These databases involve eruptive age, eruption style and eruption magnitude, M. In contrast, it is often the case that properties of magma that caused these eruptions remain unrevealed. We have sampled and analyzed eruptive products of ca. 90 eruptions in Japan during the last one hundred thousand years and are constructing a database of magmatic properties (petrological properties), as a magma database. This database involves mainly large scale eruptions with M=4-8 and additionally recent small eruption of M=1-3. In the magma database, we estimate melt compositions, and phenocryst contents, which are important factors controlling physical properties of magmas, and thus eruption dynamics. Based on the magma database, we have attempted to obtain empirical evidences between these magmatic properties and eruption characteristics (eruption magnitude, eruption style and so on).

Examining relationship between eruption magnitude, M, and magmatic properties for ca. 100 eruptions, including 11 eruptions compiled in Takeuchi (2011), some relationships are found.

(1) Rhyolitic melt (>70 wt% SiO2)-bearing magmas (andesitic to rhyolitic magmas) caused M=4-8 eruptions. In contrast, basaltic to dacitic melt (<70 wt% SiO2)-bearing magmas (basaltic to dacitic magmas) caused M=1-5 eruptions.

(2) For rhyolitic melt-bearing magma, the maximum eruption magnitudes are correlated with phenocryst content. Phenocryst-poor magmas with 0-20 vol% caused caldera-forming eruption with M=8 at the maximum, where phenocryst-rich magmas with 20-50 vol% phenocryst have the maximum eruption magnitude with ca.6.

These empirical evidences suggest that petrological properties, such as melt composition and phenocryst content, are some level of constraint on eruption magnitude. Thus, petrological analysis of eruptive materials in early eruptive stage may contribute to constructing eruption scenario.

Temporal variation (2011-2013) of the amount of CO2 dissolved in Lake Monoun, Cameroon

OHBA, Takeshi[1*] ; ISSA, I[1] ; SASAKI, Yuka[1] ; KUSAKABE, Minoru[2] ; YOSHIDA, Yutaka[3] ; UEDA, Akira[2] ; ANAZAWA, Katsuro[4] ; SAIKI, Kazuto[5] ; KANEKO, Katsuya[6] ; MIYABUCHI, Yasuo[7] ; AKA, F t[8] ; TANYILEKE, G[8] ; HELL, J v[8]

[1]Tokai Univ, [2]Univ Toyama, [3]Yoshida Eng Office, [4]Univ Tokyo, [5]Osaka Univ, [6]Kyoto Univ, [7]Kumamoto Univ, [8]IRGM Cameroon

Introduction

On 15th Aug 1984, the people living Lake Monoun, western Cameroon, heard a loud sound and experienced earth tremors. After the event, a deadly phenomenon occurred as 37 people were asphyxiated by gas that was discharged from the lake. Sigurdsson et al (1987) attributed the cause of the outburst of CO2 to landslide that plunged into the Lake's depth, which was CO2-charged. After a scientific consensus that proceeded from a similar phenomenon at Lake Nyos (100 km NW of Lake Monoun) in 1986, the explosive discharge of CO2 gas from lakes was named "limnic eruption". In 2001, the concentration of CO2 dissolved in Lake Monoun approached saturation at the depth of 50 m (Kusakabe et al., 2008), suggesting a possibility of recurrence of the limnic eruption if no preventive measures were taken. To prevent another limnic eruption, a degassing pipe was installed at Lake Monoun in 2003 (Halbwachs et al., 2004), and by 2009, the lake was almost free of dissolved CO2 and lost its natural gas self-lifting capability through the pipes. Recently we observed that concentration of CO2 has increased slightly in the bottom water. To avoid gas re-buildup in the lake, in 2013, we installed a solar energy driven system to artificially pump the CO2-rich water to the surface.

So far we have employed two methods (MK and CTD) to determine a reliable CO2 concentration profile in lakes.

The MK method (Kusakabe et al, 2000)

With this method, we determine CO2 concentration in lake water as follows. A disposable plastic syringe that contains 10 ml of 5M KOH solution is immersed in the lake at a given depth using an MK sampler. After that, we suck 30ml of lake water into the syringe to fix the total dissolved CO2 (CO2 dissolved gas, HCO3- and CO3–) as CO3–. Then a volumetric titration with standard HCl solution allows the determination of the total carbonate in the syringe. The results obtained so far indicate that the MK method is accurate and reliable. However, the method gives discrete data in terms of depth.

The CTD method

The CTD (Conductivity, Temperature, Depth) enables us to estimate the CO2 concentration as a smooth depth profile. The absolute value of CO2 concentration by the CTD method depends strongly on pH and conductivity values, thus the data from the CTD method need to be carefully examined compared to those from the MK method. We introduced an adjustable parameter k as defined by C-corr=k∗C, where C is the measured raw conductivity and C-corr is the corrected conductivity. Assuming an appropriate molar conductivity for HCO3-, the C-corr gives the total CO2 concentration under the assumption of chemical equilibrium among the dissolved carbon species (CO2aq, HCO3- and CO3–). We compared the total CO2 concentration by MK method and CTD method at the every depth where we have the values by MK method. The difference between the two methods was squared and the summation of squared values was calculated. The summation was minimized with changing the parameter k.

Results

As shown in Fig. 1, the thickness of bottom water with CO2 concentration higher than 20 mmol/L increased significantly in 2012 relative to 2011. This tendency continued in 2013, although CO2 concentration of the bottom water decreased slightly. The lake water shallower than 30m is affected by inflowing river water contains low concentration of total CO2. The total CO2 profile was integrated between -98m (near bottom) to -30m and estimate of the total amount of CO2 in the lake were 101, 118 and 119 Mmol in 2011, 2012 and 2013, respectively. Those values are much smaller than 600 Mmol, which was the amount of CO2 gas in lake just before the degassing pipe started functioning (Kusakabe et al., 2008). However, it should be noted the amount of dissolved CO2 is gradually increasing, so a regular monitoring of the lake is imperative.

Topographical features of Fuji volcano as seen in the polar coordinate system

CHIBA, Tatsuro[1*]

[1]Asia Air Survey Co., Ltd.

Introduction

Fuji volcano is the highest mountain in Japan and the most active volcano in past 12 thousand years, in Japan except for the caldera eruption (Miyaji 1988) . The inclination is loosely about 300,000 people each year climb to the summit.

As a result of repeated eruption of central vent , volcanic body of a huge cone-shaped with a diameter of 10km high specific 2000m is formed around the crater . Fuji volcano had piled up in stages on Komitake , Old-fuji , and New-fuji. The remaining part of the old edifice also so as to project on the slope .Fuji is seen variety profile from the direction by such features .

Study range

In this paper , the technique of polar coordinate conversion. Study subjects ranged circular radius 13.5km centered summit. This point is not the highest point , the approximate center of Dainai-in Institute(The latitude is 35.36295 and longitude is 138.73035) . The terrain data is base map information 0.4 seconds mesh of the Geographical Survey Institute (about 10m) source , was used in resampled to 50m mesh japanese orthogonal coordinate system (VIII, system) .

Angle of repose

Slope gradient of the volcano , is determined by the movement mechanism and state of matter that has been brought to the ground from the crater in general , the angle of repose and stable gradient . Looking at the topography of the polar coordinate transformed , it can be seen that the portions to concentrated lateral cone is higher than ambient , and is raised as acne . In particular , it is found that it is concentrated in a direction 315 degrees and 135 degrees direction . It should be noted that the gap of advanced 250 degrees around , under the influence of Tanzawa is protruding from the east , to the south of Gotemba is lower .

Projected section

Take the elevation direction from the summit , the Y -axis in X -axis , to prepare a projected section shows the projection section color grid point frequency distribution of 50mDEM. If likened to Mount Fuji skirt , bright line of lower limit corresponds to the height of the perimeter of the flared skirt . According to this chart , it can be seen that the low altitude most Fujinomiya direction of southwest . Then , a Fuji-Yoshida direction Gotemba direction , finally . Design such as bubbling southeast and northwest direction direction can be seen , but it is the effect of mountain body side of the volcano . In addition, over the surface of Lake Yamanaka from Oshino of 250 degrees from 200 degrees azimuth , elevation is significantly higher than at the periphery . In this direction there is a mountain slope body of old Fuji.

Tool handing down disaster experiences using Geoparks: examples of Unzen Volcanic Area Global Geopark

OHNO, Marekazu[1*]

[1]Unzen Volcanic Area Geopark Promotion Office

Local inhabitants living in Shimabara peninsula has suffered volcanic disasters of Mt. Unzen repeatedly, which include the worst volcanic disasters occurred in 1792 (Kansei eruption and Shimabara Catastrophe). Nevertheless these conditions, they stay near Mt. Unzen to take good living environments.

Since they continue living in the near active volcano, they are always at risk of the volcanic disasters. If these experiences of disasters pass down to next generations, disaster prevention awareness in local inhabitants and, as the result, risk from disasters should be reduced. However, because of a long eruption interval (a few hundred years) of Mt. Unzen, it is difficult to pass down these experiences to next generations. Furthermore, the information that emphasized a disaster more than required may lead the uneasiness of local inhabitants. The system to overcome these problems is a Geopark.

Education is one of main component of businesses of geoparks. Thus, we have carried out an education program of disaster prevention for local school students as a business of Geopark and promote their awareness of disaster prevention.

Actually, all of 6th grade of elementary school students in Shimabara city visit geosites for a day as a geotour and learn the highlights of the Geopark. Main theme of the geotour is *a Kansei and Heisei eruptions and their disasters*. School students learn what happened at their home town in about 20 years ago through observation of a building of elementary school burned by a fire derived from pyroclastic surge and a memorial park preserved houses buried by lahar. In the tour, I also try to inquire why you stay near the active volcano introducing great landscapes created by big landslides occurred in 1792, spring water sprung out from a head of a lava flow emitted in 1792 and local special foods using local natural environments.

This is not a program to learn disaster prevention directly. However, when local inhabitants (especially children) understand academic value of local resources (e.g. strata, landscapes, human history, culture, and so on) and realize reasons to stay near active volcanoes, their consciousness of disaster prevention must be promoted. I believe the system of Geopark must contribute promotion of volcanic disaster prevention in Japan.

Reproduction of the Eruptive sequence of the 2011 Shinmoedake eruption using the kitchen volcano experiments

IMURA, Ryusuke[1*] ; TANIYAMA, Hirokazu[2]

[1]Graduate School of Science and Engineering, Kagoshima University, [2]Takaharu Town Office, Miyazaki Prefecture

For elementary and junior high school students, we conducted a program for the reproduction of the eruptive sequence of the 2011 Shinmoedake eruption using the kitchen volcano experiments. Learning about the Shinmoedake eruption in 2011 will lead to disaster prevention. This program plays an important part of education and disaster prevention activities in the Kirishima Geopark.

HOMURA: Development of mobile sensor for volcanic exploration

KANEKO, Katsuya[1*] ; ITO, Koichi[2] ; ANBE, Yuichi[3] ; IWAHORI, Kodai[4]

[1]Human and Environmetal Studies, Kyoto University, [2]Graduate school of Science, Kyoto University, [3]Graduate school of Technology, Kyoto University, [4]Facultiy of Science, Kyoto University

Monitoring of phenomena near craters of active volcanoes is important to learn symptoms of volcanic eruptions and to understand eruption dynamics. At present, some devices such as crater camera, volcanic gas sensors, and seismographs that have been installed in a calm period of volcanic activity are monitoring volcanic phenomena near the craters. On the other hand, we cannot approach the crater and cannot install new devices after beginning of a volcanic eruption, even if we want to observe unexpected volcanic phenomena. Therefore, unmanned robots that observe them on an ad hoc basis are needed. Previously some projects have tried to develop robots for volcanic exploration. However, those projects which required large budgets ended before a practical application.

We hope to destroy the status quo and are trying to develop a practical unmanned-ground-vehicle-type robot for volcanic exploration that carries out monitoring near active craters. We named this system ”Homura”. Homura is controlled by wireless remote control, move in volcanic field, approach an active crater, monitor volcanic phenomena with sensors equipped in the vehicle, and send their data to the base stationin real time. In this presentation, we introduce a prototype of Homura and report a test campaign in Mihara-yama volcano, Izu-Ohshima.

Guidelines of development of Homura are two: (1) the vehicle does not readily become undrivable in volcanic fields, and (2) assemblage and use of Homura require low conts. We produced the prototype of Homura these guidelines. Homura is a six-wheeled vehicle with a vertically symmetric shape. Its size is 750 length x 430 width x height 310 height mm, its weight is about 12 kg. The power source is two-cell lithium polymer battery (7.4 V, about 250 Wh capacity). Some sensors such as camera, GPS, CO2 gas sensors are installed in the vehicle. Homura communicates with the base station by digital radio communication, and receives and send commands from base stations and data in real time. An installed small computer control all telecommunication, movement, and sensors. Production cost of vehicle is about 200,000 JPY, which is much lower than the robots developed in the previous projects.

Means of stable radio communication are needed for practical missions in volcanic field. Homura can use wireless transceiver modules that directly communicate with another module and Docomo FOMA modem using mobile phone network. The former wireless transceiver modules can be used in any volcanic field but distance between Homura and the base must be less than 1 km. The latter FOMA communication needs cell phone network. If the network is available, we can control Homura in any place.

We carried out a test campaign of Homura around Mihara-yama volcano, Izu-Ohshima in November, 2013 to examine remote control with FOMA communication. The base station was placed at Ohshima Spa Hotel which is about 2 km distant from the summit crater. Homura started Ohshima Spa Hotel. We controlled Homura only with information from sensors such as camera, GPS, and gyro. Homura moved on the mountain trail and reached the summit. Then, it climbed down on scoria slope without trail. This campaign result indicate that we can control Homura with remote control in volcanic fields. On the other hand, the radio communication with FOMA was not stable enough in Izu-Ohshima. At four areas where lava walls were barriers between Homura and a relay antenna of FOMA, the communication became unstable or disconnected. This indicates that we cannot move Homura to the summit only by remote control in Mihara-yama. When a UGV robot carries out missions in the volcanic field, we must obtain means of stable telecommunication before the missions. There are some cases where temporal stations of relay antenna are needed to use cell phone network.

Particle fallout from an eruption column (2) - evaluation of reproducibility

MANNEN, Kazutaka[1*]

[1]Hot Springs Research Institute of Kanagawa Prefecture

One of the major sources of error in tephra fall simulation is considered to be the source term, which depicts amount of particle release as a function of height in eruption column. The source term has been assumed to be linear or modeled using relationship between particle size and plume velocity (Suzuki function); however, no direct observation of the source term has been reported. The author has tried to obtain source term of the 1986 Izu-Oshima B eruption based on inversion technique using a tephra simulation code named Tephra2. Here the reproducibility of the inversion is evaluated.

In this study, two methods are applied to evaluate reproducibility. One is validation using a dummy source term. In this method, a dummy source term is given and tephra loads on each observation point is calculated using Tephra2. Based on the calculated loads, the source term is inversely calculated and compared with the originally given source term.

The other method is jackknifing. In this method, source terms are calculated using dataset in which a single observation is deleted one by one. The calculated source term is called as pseudo-value and the estimated source term is defined as an average of the pseudo-values. The error of the source term is also defined as a standard deviation of the pseudo-values.

In the 1986 Izu-Oshima B eruption, range of reproducible height changes as a function of grain size; 0-7 km for -3 phi particles and 0-4 km for 0 phi particles. The errors of obtained source parameter was limited; less than 10 % in the most cases.

Detection of thermal anomaly associated with volcanic activity from MODIS data

TSUTSUMI, Rika[1*]

[1]Chiba University

There are a lot of volcanoes in the world.And then, it is difficult to monitor all volcanoes because of costs.But we can monitor efficiently a lot of volcanoes using satellite remote sensing, because a volcanic activity will cause the increase in surface temperature and satellite (whose sensor can observe the surface temperature) remote sensing can cover a large area on surface.Therefore, various approaches have been suggested to monitor volcanic activities using remote-sensing satellite data.

Removing cloud pixel is essential to monitor volcanic activities using remote-sensing satellite data. Therefore, the purpose of this study is to remove cloud accurately and to develop an adequate algorithm continuously to detect thermal anomalies related to volcanic activities (especially lava activity which causes serious damages involve human lives) using MODIS (Moderate Resolution Imaging Spectroradiometer) infrared sensor onboard Aqua satellite.

We investigate spatial-time changes in thermal infrared in the statistical way. In order to detect only hotospots related to lava activities without faints, the developed algorithm investigates the difference temperature behavior between a target point and reference points, and we get spatial difference of brightness temperature (S). The presence of cloud causes large value of S that doesn't related to volcanic activities (Noguchi 2011). Therefore, removing cloud is essential in the proposed algorithm. To remove cloud, we use some BTD(Brightness Temperature Difference) which is sensitive to cloud. And we verified the technique of cloud removal as compared with Lidar data.

Variations of basaltic magmas and their timing of injection into the magma system of Sakurajima volcano since AD 1779

EBIHARA, Kaho[1] ; NAKAGAWA, Mitsuhiro[1*] ; YOSHIMOTO, Mitsuhiro[1] ; KOBAYASHI, Tetsuo[4]

[1]Earth & Planetary System Sci., Hokkaido Univ., [2]Earth & Planetary System Sci., Hokkaido Univ., [3]Earth & Planetary System Sci., Hokkaido Univ., [4]Earth & Enviromental Sci., Kagoshima Univ.

Sakurajima volcano has repeated plinian eruptions three times during the last 600 years and changed the mode of eruptive activity since the AD 1914 plinian eruption. Frequent vulcanian eruptions has continued since AD 1955. Nakagawa et. al(2011) concluded that two-end-member magma mixing of silisic magma(S-magma) and andesite magma(A-magma) occurred in 1471 and 1779, and three-end-member magma mixing of mixed magma(S+A) and basaltic magma(B-magma) since the 20th century. They concluded that the injection of the B magma has frequently occurred since then to change the mode of eruptive activity. Their evidences of the injecting were presence of Olivine and An=90 plagioclase phenocrysts and different mixing trend in SiO2 variation diagrams between the 20th century and previous products. However, petrological features of AD 1779 submarine eruptive products just after the terrestrial plinian eruption have not been revealed in detail. In this study, newly collected 1779 submarine products are investigated to discuss the magma plumbing system.

The AD 1779 submarine products are banded pumice and slightly vesiclated lavas. These contain plagioclase, orthopyroxene, clinopyroxene and magnetite as phenocryst associated with small amounts of olivine microphenocrysts, which were not recognized in the AD 1779 terrestrial products. These olivine phenocrysts do not have reaction rims of orthopyroxene. Average core compositions of these are about Fo=77. Compositional variations of other phenocrysts, except for magnetite, are nearly the same as those in the AD 1779 terrestrial and 20th eruption products. These olivine phenocrysts are diequilibrium with pyroxenes on the basis of Fe-Mg partitioning, suggesting that the basaltic magma injected into the mixed magma between the S and A magmas, which erupted as the AD 1779 terrestrial products. It should be noted that the injection of the basaltic magma had started just before the submarine eruption. On the other hand, olivine phenocrysts in the 20th century products are composed of two types, with or without reaction rims of orthopyroxene. Average core compositions of those without reaction rims are Fo=81, whereas those with reaction rims are less than Fo=74. These suggest that the 20th century products had been repeatedly injected by the basaltic magmas and that the basaltic magma injecting just before each eruption had olivine phenocrsyts with Fo=81. Although the injections of the basaltic magma has occurred just before the AD 1779 submarine eruption, two types of basaltic magma have injected . The basaltic magma in AD 1779 was less magnesian and contained olivine pehnoctysts with Fo=77, whereas those in 20th century were magnesian, having olivine phencorysts with Fo=81. This is consistent with distinct two chemical trends of AD 1779 submarine and 20th century products in SiO2 variation diagrams, such as P2O5 and MgO. Considering the presence and absence of the relict olivine phenocrysts, with reaction rims, the erupted magma during the 20th century were effected by previous injections of basaltic magmas. After the injection of olivine (Fo=77) in AD 1779, these olivine phenocrysts were reacted with more silicic melt not only to form the reaction rim but also to change their chemical compostions with less magnesian. Just before AD 1914 eruption, voluminous another basaltic magma with more magnesian olivine (Fo=81) had injected just before the AD 1914. The injected magma since AD 1955 has been similar to that of AD 1914, whereas volume of the magma has become smaller. However frequent, small scale of injection has continued to cause number of small, but explosive vulcanian eruptions.

Bulk density change of juvenile clasts during the climactic phase of the 2011 Shinmoe-dake eruption

SUZUKI, Yuki[1*] ; ICHIHARA, Mie[1] ; MAENO, Fukashi[1] ; NAGAI, Masashi[2] ; NAKADA, Setsuya[1]

[1]ERI, Univ. of Tokyo, [2]NIED

In the 2011 eruption of Shinmoe-dake, three sub-Plinian events occurred intermittently between Jan 26 PM and Jan 27 PM (1/26PM, 1/27AM and 1/27PM). This was followed by lava accumulation in the crater (Nakada et al. 2013, EPS). Based on Suzuki et al. (2013a, JVGR) that clarified characteristics and plumbing system of the erupted magmas, we reveal evolution of conduit magma flow during the climactic phase as above, by using groundmass textures. The questions we would like to address are, 1) mechanisms that led to the intermittent sub-Plinian events, including triggering process of each event, 2) timing and condition of syneruptive magma ascent that were responsible for the shifting eruption intensity and style.

As a preliminary result, we here present bulk density data for samples (gray and brown pumices and lava) of the same chemical and storage conditions just prior to ascent from the reservoir. If lithic fragments in sub-Plinian deposit can be judged juvenile (i.e. from the 2011 magma) based on whole rock composition and appearance under the microscopy, they were included in the sample set for the bulk density analysis. Generally, the bulk density data reflect syneruptive ascent condition and resultant degree of syneruptive outgassing. This time, the data allowed us to select representative samples for further textural analyses. The bulk density data also helped us newly define the horizon corresponding to the start of the second sub-Plinian event.

Following the results in Maeno et al. (revised) and Nakada et al. (2013, EPS), the sub-Plinian deposit was collected at locations on dispersal axes and 2-3km from the crater. The following unit numbers are after Nakada et al. (2013). We had no difficulty in identifying the deposit of the third sub-Plinian event (Layer5), because the field survey was in progress at the time of occurrence. The lower units (Layer2, 3 and 4) exhibit reverse grading from layer2 to layer3 and normal grading from layer3 to layer4, as if it was generated in a single event. This occurrence had prevented us from identifying the boundary between the first and second sub-Plinian events. As far as area of the sampling is considered, we believe no deposition during the resting phase between the first and second sub-Plinian events (Jan 26, 19:00 - Jan 27, 2:00) . The most likely deposit for the resting phase is ash, if plume height of 3.5km and lower (Shimbori and Fukui, 2012; lower than 6-7km during the sub-Plinian events) is considered. We did not find ash layers between the two of the three layers (layer2, 3 and 4).

The bulk densities of the samples change systematically with the subunits; 1.0-1.7 g/cm^3 from Layer2-low to Layer3-low, 1.0-2.0 g/cm^3 in Layer3-up, and 0.8-1.4 g/cm^3 from Layer4-low to Layer4-up. The average densities for the subunits are 1.25 g/cm^3, 1.28 g/cm^3, 1.27 g/cm^3, 1.44 g/cm^3, 1.14 g/cm^3, 1.17 g/cm^3 in order from Layer2-low.

We propose that Layer3-up corresponds to the start of the second sub-Plinian event, based on a judgment that high-density pumices in Layer3-up are from upper-conduit degassed magma that was generated during the resting phase (Jan 26, 19:00 - Jan 27, 2:00). The infrasound and seismic data (Ichihara et al., submitted) recorded no explosion for the resting phase. Therefore, we infer the degassed magma did not block the conduit completely.

We could not know exact time of the Layer4 deposition. However, the lower bulk densities in Layer4, in comparison with those of layer3-up, is consistent with the temporal increase of plume height (e.g. ca. 5km at AM2 of Jan 27 $<$ca. 7km at AM4 of Jan 27) and mass eruption rate (Ueda et al., 2013) during the second sub-Plinian event. In this model, we however must explain smaller pumice sizes in Layer4 in comparison with those of Layer3-up.

Hypocentral migration associated with magma intrusion in the 2000 Miyakejima eruption

MATSUYAMA, Ryotaro[1*] ; MORITA, Yuichi[1] ; SAKAI, Shin'ichi[1] ; UEDA, Hideki[2]

[1]ERI, Univ. of Tokyo, [2]NIED

A dike intrusion is a phenomena that large amount of magma emplaces in the shape of vertical plane. It is much controlled by tectonic stress. A dike intrusion process is one of the important key informations to understand the relation between tectonic stress and volcanoes. In the case of the Miyakejima eruption in 2000, it is confirmed that a large scale dike intruded beneath sea floor from the following observations; Hypocenters migrate from inland area of Miyakejima to the area near by Kozushima and Niijima. Large ground inflation is measured by nation-wide GNSS network. However, the detail process in this event has been unsolved because hypocenter locations cannot be estimated precisely. Therefore, we try to relocate hypocenters and to reveal the dike intrusion process of the 2000 Miyakejima eruption in this study.

Because hypocenters migrated to the offshore of Miyakejima, hypocenters could not be located precisely from the data recorded at inland of islands surrounding hypocenter area. Eight days after the initiation of the activity, ocean bottom seismometers(OBSs) were installed just above hypocenters. The hypocenter locations was improved very much using the OBSs data. However, analysis of OBS's data did not cover a whole period of the activity. We try to relocate hypocenters that has no OBS's data (approximately 30,000 events) relative to the reference hypocenters (approximately 3000 events) that are located precisely using OBSs data. In our analysis, we modify Double Difference method to give constraints not to move the reference hypocenters and apply it to all earthquakes occurring during 26 June and 31 August, 2000. We also use the velocity structure that is smoothly varying in the depth because of prevention of artificial hypocenter concentration.

From the relocated hypocenters, we find out the following features in the seismic activity associated with the 2000 Miyakejima eruption. 1) There are two groups in the seismic activity. One is the hypocenters aligned from the summit of Miyakejima to the point around 8km off the coast line (near coast activity), the other is the seismic activity distributed on a sub-vertical plain located beneath sea floor at the area surrounded by Miyakejima, Kozushima and Niijima (main activity). The alignment of the hypocenters match with the direction of the maximum tectonic stress. 2) The near coast activity began with an initiation of the volcanic activity and concluded on July 1st. The seismicity in this area was active only in the first week of the whole volcanic activity, and earthquakes did not occur after the period at all. 3) The main activity lasted during two months, and it was accompanied with gradual ground deformation measured by nation-wide GNSS network that represents a large scale of dyke intruded at hypocentral area. The vertical section of the hypocenters shows that the vertical alignment changes at the depth of 12 km where the structure discontinues is implied from a seismic survey. 4) In the later periods of the activity, there are many earthquakes at the area next to the main activity. Their focal mechanisms were strike slip types that agree with the direction of tectonic stress.

Considering the features of the hypocentral distribution mentioned above and other observational facts, we can conclude that there are two types of the magma flow during the 2000 Miyakejima eruption. One is horizontal emplacement just after an initiation of the volcanic activity and the other is gradual upward migration from deep zone to the main activity. Because the cost activity was inactive after July 1st, we suppose that the two magma flow is independent during almost whole period except at the beginning of the activity. In other words, the magma that generate the main activity is not supplied horizontally from Miyakejima but from just beneath hypocenter area.

Acknowledgments: We are much grateful to JMA, NIED, Tokyo Pref. for permitting to use their seismic data.

Temporal variation of mineral composition of Hanafusa Formation distributed in the western area of Aso caldera

SUGIYAMA, Fumiko[1*] ; HASENAKA, Toshiaki[1]

[1]Guraduate school of Science and Technology,Kumamoto university

Aso volcano made four large-scale pyroclastic eruptions, with magma composition changing with time, so that hornblende phenocryst appeared in the latest Aso-4 pyroclastic flow deposits (Watanabe, 1979). Hornblende becomes a key mineral to detect the physicochemical change, as it also appeared as microphenocryst in volcanic products of Omine volcano and associated Takayubaru lava flow, which erupted just before Aso-4 event (Kurokawa et al., 2012). Hanafusa Formation is a lake deposit forming 20 km west of Aso caldera just before Aso-4 pyroclastic eruption, thus it is suitable for finding the appearance time of hornblende from the minerals included in the deposits.

Hanafusa Formation consists of silt and sand with thickness of up to 10 m, and formed between Aso-3 and Aso-4 pyroclastic flow events. We collected samples from pumice deposit and overlying sand in Kajisako, Kikuchi city. We also collected samples from silt layer just below the contact with Aso-4 pyroclastic deposit, and from the type locality of Hanafusa Formation in Kikoji, Kikuchi city. We divided silt layer into upper unit and lower unit with boundary at the tephra layer, which we identified as Ata regional tephra by its mineral assemblage and existence of abundant bubble-shape glass and estimated age of 100 ka.

(1) The lower unit contain plagioclase, clinopyroxene and orthopyroxene. Plagioclase crystals indicate auhedral and have the surface which give a dirty impression.

(2) The upper unit contains euhedral hornblende and euhedral plagioclase crystals which are not observed in the lower unit. The upper unit contains clinopyroxene and orthopyroxene crystals. The mineral assemblage and their ratios are the same as observed among Aso-4 pyroclastic flow deposit.

(3) Chemical compositions of pumice fragments in Pumice layer resembled those of all Aso-4 pyroclastic flow deposits. However, in detail, Oyatsu pumice flow deposit, Benri scoria flow deposit and Omine volcanic products show distinct compositional trends from this pumice layer(Kurokawa et al., 2012; Yamasaki et al., 2013).

(4) Observed crystals in sand just above the pumice layer include plagioclase, clinopyroxene, orthopyroxene, opaque minerals and olivine, which isnot included in the lower pumice layer.

Our findings suggest that the appearance of hornblende was 10,000 years before Aso-4 pyroclastic eruptions, however their source is unknown, because we did not find obvious tephra layers other than Ata regional tephra.

Estimating composition of primitive magma by using opx, and temporal and spatial change of HMA magmatism in NE Shikoku

MORISATO, Fumitoshi[1*] ; OZAWA, Kazuhito[1]

[1]School of science, The University of Tokyo, [2]School of science, The University of Tokyo

In the subduction zone, oceanic plates start sinking into the mantle, and continental crusts are generated and eroded. So it is important for understanding the evolution of plate-tectonics. As for the subduction initiation, temporal change of thermal structure and water content of the mantle wedge is mainly estimated by numerical simulations (Iwamori, 2000 *etc*.), but there are few constraints from material informations. Using magma information is a possible method to estimate thermal structure of the Earth (Green, 1981). Although it is necessary to estimate chemical composition of the primitive magma, the effects of crystal differentiation and, especially in subduction zone, crustal process (magma mixing, crustal assimilation, and degassing) should be evaluated. Moreover, the magmatism in subduction zone is assumed to be affected by mantle flow in mantle wedge (Tatsumi *et al*., 1983; Tamura, 2003). To estimate such upwelling, Sakuyama *et al*. (2009) investigated temporal and spatial change of the magma generation field.

SW Japan is an example of juvenile subduction zone. Shikoku basin initiated to sink 17 Ma ago, and magamatisms migrated from forearc to reararc (Kimura *et al*., 2005). In the Setouchi volcanic zone, the generation of high-Mg andesite (HMA) has been discussed from the view of thermal structure of the mantle wedge and subducting plate (Tatsumi & Hanyu, 2003 *etc*.), but there remains some questions about magma mixing and degassing, and about temporal and spatial change of magma generation field.

In this study, we suggest a method to estimate the primitive magma composition by using oscillationally-zoned opx, and apply to the HMA in the Setouchi volcanic zone. And we try to estimate the magma generation mechanism by evaluating temporal and spatial change of magmatism in the area.

Firstly, we investigated a HMA in Mt. Kiyama, central part of NE Shikoku, Japan (Sato, 1982 *etc*.). It has the most primitive composition (SiO_2: 57.3wt%, MgO: 8.56wt%, Mg#: 69.3), and it contains olivine, opx, and cpx as phenocrysts. The olivine phenocrysts are normally-zoned, and their highest Mg# (87.6) is lower than the equilibrium value calculated from whole rock composition of the HMA (88.7). Therefor the olivine phenocrysts are considered to be crystallized in closed system. On the other hand, opx phenocrysts are reversely-zoned, and their composition boundaries are sharp. Moreover they have higher Mg# (up to 91.5) than calculated equilibrium value (88.8). Accordingly, these opx could record the composition of more primitive melts. And zoning pattern among opx is consistent, so they could reflect compositional change of the same melt.

According to Putirka (2005), the composition of primitive magma can be estimated by adding fractionated olivine or opx until the melt's composition become in equilibrium with the opx which has the highest Mg#. But we must remove the effects of magma mixing before it. Kuritani (1998) used the fact that the An content of plagioclase phenocryst can be changed in a magma chamber reflecting the difference of temperature or water content. He investigated the pattern of zoning and quantity ratio of them, and estimated mixing ratio.

We estimated the change of melt composition. (1) Calculating the melt compositions from opx composition by using distribution coefficients. (2) Comparing the change of the melt composition and modeled composition in Rayleigh fractionation or magma mixing. (3) Estimating mixing ratio by evaluating the pattern of zoning in opx and their quantity ratio, and estimating end member of mixing. (4)According to the true fractionation trend, determining primitive magma composition which is in equilibrium with opx having the highest Mg#.

By applying this method to the HMA in Mt. Shichihousan, western part of NE Shikoku (Kawabata & Suto, 2000), we estimated the spatial change of primitive magma composition and magma generation field.

The relation of volcanic stages for the recent 10000 years of Kirisima and Southern Kyushu volcanoes

TAJIMA, Yasuhisa[1*]

[1]Nippon Koei Co., Ltd.

In this study the eruption ages of tephra and lava generated from Shinmoedake volcano and Ebinokogen volcanic area by 14C dating were determined. Those ages indicate that the Kirishima volcanoes have three eruptive stages among the recent 10,000 years. The eruptive stage C started from 9.0 to 8.0 cal ka BP with RyD-L from Shinmoedake volcano and Fd-TmA tephra and Fudoike lava from Ebinokogen volcanic area. Old-Takachihono volcano and Takachihonomine volcano grew rapidly in this stage. The eruptive stage B continued from 5.6 to 2.3 cal ka BP growing the Shinmodedake and Nakadake volcanic edifices. Three eruptions at the same time, which were the Miike plinian eruption at 4.6 cal ka BP from Miike maar, Sm-Sy eruption at 4.5 cal ka BP from Shinmoedake volcano and Kn-EbD eruption at 4.3 cal ka BP from Ebinokogen volcanic area in this stage. The time interval between eruptive stage B and eruptive stage A was 2.3 to 1.6 cal ka BP. The yougest eruptive stage A started with Fd-EbC tephra from Ebinokogen volcanic area at 1.6 ka. In this stage, the Ohachi volcano grew from 6th century and Shinmoedake volcano erupted from 18th century. This result indicates that the Kirisima volcanoes repeated a few thousand years of eruptive stages and 500 to 1000 years intervals. The current eruptive stage A pasts about 1600 years. The relation of eruption ages of Kirishima volcanoes and Sakurajima volcano is well.

Investigation report of rootless cone in Iceland -as an analogue of that of on Mars-

NOGUCHI, Rina[1*] ; SARUYA, Tomotaka[1] ; SUZUKI, Yuki[1] ; KURITA, Kei[1]

[1]Earthquake Research Institute, the University of Tokyo

Rootless cone is a pyroclastic cone which has a variety of shape. It's formed by lava-water interaction [e.g. Fagents et al., 2002, Hamilton et al., 2010], but details such as formation conditions are still unknown. Since pervasive existence of various types of rootless cones has been clarified on the martian surface, terrestrial rootless cones are key to understand Martian volcanism and strong interests have been paid in the field of planetary science. We surveyed rootless cones in Iceland by RTKGPS (Real-Time Kinematic GPS) with material-scientific investigations on the constituent materials.

We investigated 3 rootless cone fields; Myvatn (northern Iceland), Landbrot (eastern Iceland), and Thjorsardalur (western of Hekla volcano). In this presentation, we will focus on Myvatn area. In Myvatn, rootless cones were formed by lava-lake water interaction. The lava is basaltic, and emanated from the fissure which locates in east of the lake [Thorarinsson, 1951], and flowed into the lake. We mapped more than 500 rootless cones by aerial photo survey. Most of cones locate around the lake, but some cone locates in in the down-flow region (40 km far from the lava source) area. In Myvatn, here exists unique rootless cone which has an inner cone in the summit crater. We named this as double cone. We focus on this type and conducted detailed morphological survey.

We found that slope angle of rootless cone depends on its size. For double cone, inner cone has gentler slope than that of outer cone. In case of single cone (no inner cone), large cones have steeper slope than that of small cones. Also, large cones have constant slope (repose angle: 32-33 degree), despite the slope angle of small cone varies. In case of the double cone, we found that the constituting material of the inner cone differs from that of the outer cone. The component material of the outer cone is lapilli - coarse ash size pyroclast. On the other hand, that of the inner cone is welded pyroclasts or agglutinate. For small cones, the summit part is covered with agglutinate. These differences should indicate different condition of the formation such as the amount of available water/heat supply by magma.

A We measured bulk chemical composition of the lava and the pyroclasts by XRF confirming no significant change along lava flow traveling. We also measured bulk density and size distribution of the pyroclasts of the rootless cones. We found density of the lava concordantly increases with traveling distance, which means bubbles progressively escaped from the lava during traveling while the formation of rootless cone seems not to be influenced by the vesicularity of lava. The size distribution seems to be correlated with the slope value of the cone, which strongly suggests the control of fragmentation on the formation of rootless cone.

Volume of magma chamber and eruption ratio for caldera collapse

GESHI, Nobuo[1*]

[1]Geological Survey of Japan, AIST

Mechanism of caldera collapse is modeled with a comparison of a piston-cylinder caldera model and the compiled data of caldera size and eruptive volume in nature.

Collapse caldera is formed by the fracturing and subsidence of the roof of magma chamber with rapid withdrawal of massive magma from a magma chamber. As the fracturing and subsidence of the roof of magma chamber may enhance the additional eruption of magma inside the magma chamber, understanding of the mechanisms of the precursory eruption is crucial to evaluation of the potential eruption from caldera volcanoes.

Collapse calderas are formed only by the largest eruptions of its life, though, in many cases, caldera volcanoes repeat many eruptions with various scales before and after caldera formation. Smaller eruptions have no significant contribution for collapse. Aira caldera in Japan was formed at 29ka eruption during which ~400 km^3 of magma was erupted. Though many smaller eruptions including Fukuyama pumice eruption (10km^3DRE) and Sz-S eruption (4km^3DRE) occurred from the Aira caldera, no significant collapse was occurred. During the 29 ka eruption, Osumi pumice fall was erupted prior to the onset of collapse, and the emission of Ito pyroclastic flow followed the collapse. The erupted volume of Osumi pumice fall (~40 km^3DRE) is larger than those of the eruptions without collapse. This relationship is commonly observed in other caldera volcanoes. The erupted volume during the precursory eruption is in correlation with the size of caldera.

The volume of magma withdrawal to induce collapse is modeled with piston-cylinder model. The driving force of collapse is the decompression in magma chamber by the magma extraction. The friction in the ring fault sustains the roof. Competition between the decompression of magma chamber and the friction controls the onset of collapse. The decompression of magma chamber is in the function of the eruption ratio (volume of magma withdrawal / total volume of magma chamber). This model shows that a larger volume of magma withdrawal is required for the onset of collapse with larger diameter. The critical eruption ratio for collapse is smaller for the larger caldera.

Though this model has potentially large ambiguity from the simplified shape of caldera fault and the assumption of the bulk modulus of magma, this model can give the total volume of magma chamber associating collapse caldera. In the case of Aira caldera, with 15 km in diameter and 6 km to the roof of magma chamber, the total volume of magma chamber before the eruption is estimated as 600 km^3. The caldera collapse occurred when the erupted volume reached to 8% of the total magma chamber, and 60 % of magma was erupted as Ito pyroclastic flow after the onset of collapse.

Identification and Geology of Taftan volcano Calderas, Sistan and Baluchestan, Southeast of Iran

BIABANGARD, Habib[1*]

[1]Department of Geology, Sistan and Baluchestan University of Zahedan, Iran

The Taftan volcano, Sistan and Baluchestan province, SE Iran, is above 4050 m sea level and currently dormant, showing fumarolic activity near the summit. This volcano is located in a structural zone along the subduction of Oman oceanic crust below the Eurasia plate. Large volcanic centers including Chah-Shahe, Bazman and Taftan in Iran and Soltan in Pakistan have been developed during the Quaternary. Anjerk and Tamandan are two calderas from of Taftan volcano that identified for the first time. Theses calderas are mostly composed of pyroclastics, lava flows, ignimbrites and tuffs. Various volcanic eruptions had occurred during these calderas formation. The exposed lava flows and pyroclastics of these calderas mainly consist of andesitic and dacitic in compositions. The geochemical evaluation of the major and trace element compositions indicate the magma erupted from this volcano show a calk-alkaline trend.

K-Ar ages of Kelut-Welirang volcano cluster, East Java, Sunda arc: comparison with clusters that hosts large calderas

TOSHIDA, Kiyoshi[1*] ; TAKADA, Akira[2] ; KITSUKAWA, Takashi[3] ; TAKEUCHI, Shingo[1]

[1]CRIEPI, [2]AIST, GSJ, [3]Ceres, Inc.

Sunda arc, Indonesia, has many active caldera volcanoes and is well suited for studying the evolution of large caldera systems. Volcano groups are distributed in clusters at Sunda arc. Two adjacent volcano clusters in East Java, Semeru-Tengger and Kelut-Welirang, are compared. Semeru-Tengger volcano cluster consist of Semeru and Tengger-Bromo volcano systems. Tengger-Bromo system has formed Ngadisari and Sand Sea calderas. Kelut-Welirang volcano cluster consists of multiple active volcano groups and has comparable footprint and cumulative volume as Tengger-Bromo. However, large-scale eruptions in the order of 10km3 or greater have not taken place at Kelut-Welirang volcano cluster.

Kelut-Welirang volcano cluster consists of five volcano groups. They are Penanggungan, Arjuno-Welirang, Argowayan, Butak-Kawi-Panderman, and Kelut from northeast to southwest. They are classified as active volcanoes except for Argowayan, and Kelut is currently active. However, their formation ages are not understood.

K-Ar dating is performed in order to determine and compare the long-term activity of the two clusters. Mass fractionation correction method is used for argon measurement, for many of the samples are very young. Samples with crystalline groundmass are selected for dating to obtain precise and reliable age. Groundmass is separated from phenocryst and used for dating.

The active periods and the ages of the volcano groups are identified by K-Ar dating as follows. (a) Argowayan, which consists about half of the volume of Kelut-Welirang cluster, has formed between 1.0-0.8Ma. (b) There was long dormancy in the area of this cluster, and the four volcano groups have formed within the past 0.2 m.y. (c) Kelut has started to form by 0.2Ma, and has repeatedly produced lava domes to present. (d) Much of Butak-Kawi-Panderman has formed around 0.2Ma. The group is considered active, but the long-term eruption rate of the group has decreased substantially since the early stage of edifice building activity at 0.2Ma. (e) Arjuno-Welirang is younger and likely started to form by 0.1Ma. (f) Penanggungan is the youngest volcano group and likely to have formed within the past 0.05 m.y.

The obtained ages allow us to compare Kelut-Welirang and Tengger-Semeru volcano clusters. Although Kelut-Welirang cluster has comparable volume to Tengger-Semeru, it consists of separate volcano groups formed at different ages. The long-term eruption rate for the past 0.2Ma is relatively large, but much of the erupted volume is contributed from new volcano group. In contrast, the volcano edifices of Semeru-Tengger have almost entirely formed from 0.5Ma to present. The eruptive centers are concentrated at Tengger and Semeru, and have repeated active periods.

Correlation between petrology and magneto-stratigrapphy of Holocene volcanic products from Aso central cones

HIRAKAWA, Yuichiro[1*] ; HASENAKA, Toshiaki[1] ; MOCHIZUKI, Nobutatsu[2] ; MORI, Yasushi[3]

[1]Grad School Sci & Tech, Kumamoto Univ., [2]Priority Organization for Innovation and Excellence, Kumamoto University, [3]Kitakyushu Museum of Natural History and Human History

We collected samples from 25 sites where Yato et al. (2013) and Miyabuchi et al. (2012) reported magneto-stratigraphy of six different lava flows distributed in the northwestern region of Aso central cones. We conducted petrographic descriptions and chemical analyses of these samples and correlated them with paleomagnetic directions and stratigraphy of Miyabuchi (2009) based on radiocarbon dating.

Kijimadake lava is divided into two lava flow units with different paleomagnetic directions suggesting interval of at least several hundreds of years. They show the same mineral assemblage, but different groundmass texture, modal composition and whole-rock chemical composition. The upper lava flow unit has the same petrological characteristics as Kishimadake scoria, whose estimation age was 4000 y.b.p. from the radiocarbon dating.

Possibility of multiple eruptions has been suggested for Ojodake lava flows, because they are intercalated by soil, and show different paleomagnetic directions. However, no distinction was made in petrographic descriptions and chemical compositions between these lava flows.

Six different lava flows younger than Akahoya tephra have similar appearance and similar petrographic characteristics, however they are distinguishable by chemical compositions. Lava flow units with possible simultaneous eruptions (e.g. old Kijimadake lava and Nakadake younger stage lava, Kamikomezuka scoria and old Ojodake lava) show about 1% difference in SiO_2 content. A series of Holocene lava flows in Aso central cones are possibly derived from a common magma supply system with different conduits.

Magma genesis of Miocene basalts from Ootsu district, Yamaguchi Prefecture, SW Japan arc

HIGASHIYAMA, Yoji[1] ; HASENAKA, Toshiaki[1*] ; SHIBATA, Tomoyuki[2] ; YOSHIKAWA, Masako[2] ; NAGAO, Takashi[3]

[1]Grad School Sci. & Tech., Kumamoto Univ., [2]Beppu Geothermal Res. Lab., Kyoto Univ., [3]Grad School Sci. & Eng., Yamaguchi Univ.

The geological, petrological and geochemical studies of Miocene Ootsu basalts, distributed in Tsunoshima and Yuyashima islands along the coast of the Japan Sea, revealed the temporal and vertical changes in mantle melting processes. Based on their volcanic stratigraphy and petrological data, Ootsu basalts were grouped into; (1) clinopyroxene-olivine basalt (COB), (2) olivine basalt, magnetite-rich type 1 (MRB1), (3) olivine basalt, magnetite-rich type 2 (MRB2), and (4) olivine basalt, magnetite-poor type (MPB). MRB1 and MRB2 are rich in FeO$*$ and TiO_2 contents, and MPB is rich in SiO_2 and Al_2O_3 contents. MRB1, MRB2 and COB are alkalic and MPB is tholeiitic.

Phase diagram and mass balance calculations indicate that these four groups were derived from different primary magmas, and had experienced polybaric crystallization. The compositions of primary magmas for these four groups suggest that MRB1 and MPB were generated at the deepest and shallowest depths, by the lowest and the highest degrees of melting, respectively. Multi trace element plots (normalized by the primitive mantle values) of Ootsu basalts show the strong enrichment of LILE (Rb, Ba, and K), and distinct negative anomaly of Nb and Sm. The compositions of coexisting olivine and spinel (OSMA) suggest that MPB's mantle source is the most fertile among four groups. The different ratios of LREE/HREE among four groups suggest different mantle source and different degree of partial melting. B/Nb ratio of four groups is getting higher with decreasing segregation depth. These systematic differences in B/Nb ratio indicate that the upper mantle beneath Ootsu district is characterized by an increased degree of metasomatism at shallow level.

We concluded that the diversities of chemical composition in Ootsu basalts attribute largely to different segregation depth and heterogeneous mantle source.

The Middle Miocene tectonics and volcanism in the intra-arc and the back-arc region, Northeast Japan

HOSOI, Jun[1*] ; AMANO, Kazuo[2]

[1]Graduate School of Science and Engineering, Ibaraki University, [2]Faculty of Science, Ibaraki University

In northeast Japan, many submarine volcanic rocks related to opening of the Japan Sea in the Early Miocene are widely distributed. They are very important to consider the evolutional process of Japan Arc and to elucidate the submarine volcanism. Despite the importance, there were no detailed sedimentological studies of these volcanic rocks, and the detailed sedimentary processes, sedimentary basin formation, paleo-volcanism and tectonics were poorly understood. In this study, we tried to reconstruct the detail volcanic edifices and volcanism based on the facies analysis of volcanics in typical two area; one is Ou Backbone Ranges in Nishiwaga town, Iwate prefecture and the other is Dewa Mountains in Sakata, Yamagata prefecture, that were located in the intra arc and the back arc in the Miocene respectively.

As results, we could elucidate paleo volcanism in each area. Remarkable tectonic change occurred in 15Ma with active volcanism, counterclockwise rotation and rapid subsidence (Hosoi et al., 2013). Regional paleostress around 15 to 12Ma is NW-SE tensional stress (Otsuki, 1989; Hosoi, 2013). This tectonic change happened in 15Ma with opening of Japan Sea, and active bimodal volcanism, rotation movement and tectonic subsidence occurred.

Paleostress analysis of dilational fractures using genetic algorithm

YAMAJI, Atsushi[1*]

[1]Kyoto University

The attitudes of dilational fractures, including dikes and veins, are clues to the paleostresses under which the structures were formed. A software tool for clustering their 3D orienatations has been developed in this study. The software fits mixed Bingham distributions to them, and detects girdle, elliptical and circular clusters. In addition, it determines the three principal stress axes, stress ratios and maximum fluid pressure for each of the clusters. Fitting a mixed Bingham distribution is not a well posed problem, because the mathematical inversion is highly non-linear and its object function is multimodal. It is demonstrated that genetic algorithm is more effective than the expectation-maximization algorithm which was used by previous researchers (Yamaji and Sato, 2011).

Eruption History and Future Scenario of Sinabung volcano, North Sumatra, Indonesia

YOSHIMOTO, Mitsuhiro[1*] ; NAKADA, Setsuya[2] ; ZAENNUDIN, Akhmad[3] ; PRAMBADA, Oktory[3] ; HOKANISHI, Natsumi[2] ; TAKAGI, Natsuko[2] ; HENDRASTO, Muhamad[3] ; IGUCHI, Masato[4]

[1]Faculty of Science, Hokkaido University, [2]Earthquake Research Institute, University of Tokyo, [3]Center for Volcanology and Geological Hazard Mitigation, Indonesia, [4]Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University

Sinabung Volcano is an andesitic stratovolcano located 40 km northwest of Lake Toba, North Sumatra. The activity began after the latest caldera-forming eruption of Toba Lake (ca. 74ka). The eruption history can be divided into two stages (old and young stages) based on topographical and geochemical features. The edifice is characterized by multiple thick lava flows/domes, and their collapsed materials of block-and-ash flow and associated surge deposits. The lava spine is located at the southern end of one of the summit craters which trend in N-S. Pumice-fall deposits by relatively large explosive eruptions, such as plinian- to subplinian types, were not recognized. The last magmatic eruption before 2010 occurred during 9 to 10th century, whose products are mainly pyroclastic-flow deposits, distributed in the SE slope.

The present activities began with phreatic events in August and September 2010. It resumed its activity in September 2013 with phreatic events. After the repeated phreatic to phreatomagmatic events, lava appeared in the summit crater in late December and started its partial collapse on 30 December. Several tens collapses occurred everyday in January 2014. Those pyroclastic flows descended on the SE slope of the volcano and traveled 4.5 km in maximum.

Lavas of the volcano are basaltic andesite to andesite in composition, and andesitic lavas contain hornblende phenocrysts. Although old lava have a SiO2 range similar to young lavas, the old lava are more enriched in K2O than the young lava. The lava spine is highly enriched in SiO2 and extremely depleted in Na2O, a result of high alteration by volcanic gases, suggested by the mineralogical features. Bulk composition of 2010 ash seems to be intermediate between the young lava and the altered lava spine. In contrast, pumice of 2013 eruption has a similar composition of juvenile materials of 9-10th eruption.

Before the 2013-2014 events, highly possible scenario for future eruption have been proposed the similar case of lava-dome eruptions at Unzen, Japan, in 1991-95 and at Soufriere Hills, Montserrat, West Indies, in 1995-present, based on the eruption history. The present eruption at Sinabung follows the proposed scenario of the highest probability.

This work was supported by SATREPS research project (Multi-disciplinary Hazard Reduction from Earthquakes and Volcanoes in Indonesia) and the Indonesian Center for Volcanology and Geological Hazard Mitigation (CVGHM).

Petrological study of monogenetic volcanoes in the fore-arc region of the northern Kamchatka Peninsula

NISHIZAWA, Tatsuji[1*] ; CHURIKOVA, Tatiana[2] ; GORDEYCHIK, Boris[3] ; ISHIZUKA, Osamu[4] ; NAKAMURA, Hitomi[1] ; IWAMORI, Hikaru[5]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [2]Institute of Volcanology and Seismology Far East Division, Russian Academy, [3]Institute of Experimental Mineralogy, Russian Academy, [4]Research Core for Deep Geological Environments, AIST, [5]Japan Agency for Marine-Earth Science and Technology

The western part of the Pacific Plate is subducting under the Okhotsk Plate along Kuril-Kamchatka Trench, and the northern part of it is subducting under the Bering Sea Plate with high obliquity along the western Aleutians arc. The three plates form the Aleutian-Kamchatka triple junction (Eichelberger *et al*., 2013). The northern edge of the Pacific Plate is separated from Bering Sea Plate by transform fault, and the mantle edge beneath the Kamchatka Peninsula is thought to be open towards the Bering Sea.

There are at least 29 active volcanoes in the Kamchatka Peninsula. From the east to the west, arc volcanism on the Kamchatka Peninsula forms three zones parallel to the Kamchatka trench: the Eastern Volcanic Front (EVF), the Central Kamchatka Depression (CKD) including Klychevskaya Volcano Group (KVG) where the large volcanoes concentrate, and the Sredinny Ridge (SR) in the back arc side.

Along EVF, the straight volcanic chain is terminated around 55^{o}N (near the Kizimen volcano), and in further north the volcanic chain seems to deflect toward KVG corresponding to deeper depth of subducting slab. However, monogenetic volcanoes on the northward extension of the EVF exist and were studied in 1960s, called ‘ Kumuroch range ’ (Fedororenko., 1969). The present-day slab depth beneath the monogenetic volcanoes is about 60km (Gorbatov *et al*., 1997), and the crustal thickness is about 20-30km (Levin *et al*., 2002). These volcanic rocks were reported as basalt to andesite, having relatively high MgO content ($\sim$11.8 wt. %) and low FeO/MgO ratio ($<$1.0) (Uspensky and Shapiro., 1984). In summer 2013, we have identified 15 monogenetic volcanoes in this area (hereafter ‘ East Cone volcanic group ’ , EC) by using stereogram, and had investigated 8 volcanoes by using a helicopter.

In this study, we aim to reveal the origin of the EC lavas. For this purpose, we have first examined mineral assemblages under optical microscope and analyzed the whole rock major element compositions by XRF. All 16 samples are classified as basalt or basaltic andesite, of which the two lavas contain xenoliths, and one sample oxidized to red. The rocks exhibit porphyritic to seriate texture, containing plagioclase, clinopyroxene, olivine, opaque minerals, although, the proportion of minerals varies from sample to sample. The silica contents of all samples are over 50 wt. %, with the FeO/MgO ratio less than 2, indicating relatively undifferentiated characteristics.

In comparison to the typical island arc basalts having a similar silica content, the MgO contents of the EC lavas are higher by $\sim$4 wt. %. Accordingly, the EC lavas are similar to or classified into high-Mg andesite, which is considered to be generated by melting of relatively hydrous mantle (as an example, unsaturated with H_2O, 1.0GPa, 1100-1250 ℃, saturated with H_2O, 1.5GPa, 1030-1150 ℃) (Tatsumi., 1995; 2003).

The EC lavas scarcely include orthopyroxene, on the other hand, volcanic rocks of KG include orthopyroxene (Churikova *et al*., 2013). Mantle xenoliths from the Bezymianny volcano of KG is reported to be spinel harzburgites (Ionov *et al*., 2013). Combining these constraints, we discuss a regional variation in mineral assemblage and H_2O content in source mantle, H_2O content in the primary magma, and the crystallization temperature and pressure of the magmas.

By comparing the petrological characteristics of the EC lavas with those from other regions (e.g., KG), cleare constraints on the relationship between magma genesis and the tectonic setting are expected to be imposed.

Geology and petrology of Taisetsu volcano group, Japan; Evolution of magma and long-term time variation of eruption rate

ISHIGE, Kosuke[1*] ; NAKAGAWA, Mitsuhiro[1] ; MATSUMOTO, Akikazu[2]

[1]Department of Natural History Sciences, Graduate School of Science, Hokkaido University, [2]Geological Survey of Japan, National Institute of advanced Industorial Science and Technology

Taisetsu volcano group locates at the northern part of the Taisetsu-Tokachi volcanic chain, which is situated at the southern end of Kuril arc. The volcano group started its activity ca. 1 Ma and is composed of andesitic lava domes and stratovolcanoes. Although previous studies (eg., NEDO, 1990; Katsui, 1979) revealed the outline of structure and eruptive history of the group, detail chronological and petrological studies have not been carried out. We have revealed the volcano stratigraphy and petrological features of the whole area of the volcano group. In addition, K-Ar ages of representative samples are also determined. Based on these data, we focus on the temporal change of eruption rate and magma types during 1 My in the volcano group.

According to the stratigraphy, location of eruption centers, mode of eruptive activity and petrological features, the activity of the volcano group can be divided into four major stages, as follows. Stgae 1(1.0 ˜0.75Ma): Fluidal andesite lava were effused from several eruption centers to form flat-shaped volcanic edifices which are distributed in N-S direction. Their total estimated eruptive volume is 26km^3(DRE). Stage 2: It can be subdivided into sub-stage 2-1 (0.6Ma) and 2-2 (0.35 ˜0.05Ma). Eruptive lavas of the former sub-stage are mostly coverd by younger deposits. Detail structure of the edifice and the distribution of deposits have not been clear. The sub-stage 2-2, is further subdivided into central and western group according to the differences in mode of activity and location of eruption centers. The total estimated eruptive volume of stage 2 is 23km^3. Stage 3(ca. 30 ka): The stage is characterized by most explosive eruptions in the volcano group, resulting to the formation of a plinian column and related pyroclastic flows. These activities formed the Ohachidaira caldera with 2 km in a diameter. The total eruptive volume is estimated to be 13km^3. Stage 4 (ca. 30 ka - present): Main eruption centers moves to the southwestern part of the caldera to form several stratovolcanoes and lava domes. The total eruptive volume of stage 4 is 10km^3.Based on the ages and estimated eruptive volume, the magma discharge stepdiagram of the volcano group is created to discuss a temporal change of magma discharge rate. The eruption rate of each stage is as follows; $>$0.07km^3/ky for stage 1, $>$0.01km^3/ky for stage 2-1, $>$0.06km^3/ky for stage 2-2, $>$0.33km^3/ky for stage 3, $>$0.33km^3/ky for stage 4. According the stepdiagram, the period from 0.7 to 0.4 Ma could be characterized by extremely low eruption rate and/or the presence of dormant stage.

Petrological features of the ejecta of Taisetsu volcano group can be distinguished among stages. All of the rocks are andesite and dacite, often containing mafic inclusions. These rocks contain plagioclase, clinopyroxene, orthopyroxene and Ti-magnetite as phenocrysts, associated with minor amounts of olivine, and quartz phenocrysts in some rocks. Although the rocks of stage 1 do not contain hornblende phenocrysts, those of stage 2 and 3 usually include hornblende phenocrysts. However, there rarely exist hornblende phenocrysts in the rocks of stage 4. The whole-rock SiO_2 contents range from 56.4 to 69.1 wt.% for host rocks and from 52.7 to 57.4 for the inclusions. Almost all the rocks are defined as medium-K in SiO_2 - K_2O and CA types in SiO_2-FeO/MgO diagrams, respectively. The host of the rocks from stage 1 is characterized by high Zr contents, compared with the rocks from other stages, whereas Zr contents in the mafic inclusions in the rocks from stage 1 are the same as those from other stages. Considering Zr contents and occurrence of hornblende phenocryst in andesite, magma type had changed largely during the possible long dormancy from 0.7 to 0.4 Ma. This would be related to the tectonic change at the junction between NE Japan and Kuril arcs.

Reconstruction accuracy of eruptive sequence inferred from the pyroclastic fall deposits of the Asama-Maekake volcano

YASUI, Maya[1*]

[1]Dept. of geosystem sciences, Nihon University

The pyroclastic fall deposits of the Asama-Maekake volcano, such as A (1783AD), B′ and B (12^{th} century), and C (4^{th} century), are mainly composed of pumice layers. On the other hand, ash fall derived from the recent vulcanian eruptions (e.g., 2004 and 2009 eruptions) is too small in scale to be preserved as a geologic unit. Ash particles from such small-scale eruptions are mainly lithic fragments originating from solidified lava in a shallow level of the conduit. After the 1783 eruption, repeated vulcanian eruptions have formed ash and soil mixtures on the flank of the volcano. Similar ash and soil mixtures are also recognized beneath A, B, C, and D pyroclastic fall deposits, respectively. These ash and soil mixtures contain lithic fragments as the ash component, indicating that vulcanian eruptions occurred repeatedly in the period between large-scale eruptions, similarly to the period after the 1783 eruption. Lithic ash layers are also interbedded with pumice fall layers of B′, B, and E pyroclasic fall deposits. There seem to be some cases of intermittent vulcanian and sub-plinian eruptions in the course of the large-scale eruption.

In the case of the 1783 eruption, detailed reconstruction of the eruptive sequence is possible on the basis of correlation between the stratigraphy of the eruptive products and old documents. The large-scale sub-plinian eruption is considered to be associated with the formation of a pyroclastic cone in a proximal area owing to vigorous fountaining. Subsequently, large-scale clastogenic lava flows are generated throughout its climactic eruption. On the other hand, little information is available for eruptions before 1783 because of limited exposure and few old documents. Although the reconstruction accuracy for the eruptions in the 12th century is not as good as that for the 1783 eruption, these eruptions might have occurred with a different sequence from the 1783 eruption. Intermittent events of ash and pumice fall occurred in the initial stage of these eruptions. Phreatomagmatic eruption also occurred in the early stage of the 1128 eruption, resulting in a B′ pyroclastic fall deposit. The existence of many units of pyroclastic flows in the 1108 eruption indicates that pyroclastic flow occurred on multiple occasions. Since the stratigraphic relationship between the B pyroclastic fall and these pyroclastic flows is unclear, the sequence of the eruption is still in question. Furthermore, little information is available for eruptions predating the 12^{th} century.

Comparative study of the distributions of pyroclastic fall deposits using isopach maps reveals that some fall units from B′ and B are larger in scale than that of the climactic pyroclastic fall deposit of the 1783 eruption. In addition, the A′ pyroclastic fall deposit is estimated to be comparable to or smaller than the preclimactic fall unit of the 1783 eruption. Although the isopach maps of A, B′, B, C, and E could be prepared, the accuracy of the isopach maps for the C and E pyroclastic fall deposits is insufficient. The preparation of an accurate map is difficult for deposits of older age. Consequently, at this point, the 1783 eruption is the only example in which the temporal variation in eruptive style and in eruptive volume can be discussed with high accuracy in the history of the Asama-Maekake volcano.

Polybaric crystallization of H_2O-saturated island arc low-K tholeiite magmas: A case study of the Izu-Oshima volcano

HAMADA, Morihisa[1*] ; OKAYAMA, Yuko[2] ; KANEKO, Takayuki[3] ; YASUDA, Atsushi[3] ; FUJII, Toshitsugu[4]

[1]Japan Agency for Marine-Earth Science and Technology, [2]National Museum of Emerging Science and Innovation, [3]Earthquake Research Institute, University of Tokyo, [4]Crisis and Environment Management Policy Institute

Introduction: The H_2O concentration of pre-eruptive melts, particularly that of primitive melts, provides information on the *P-T* conditions of their generation, their differentiation pathways, and their potential explosivity of eruptions. Consensus with regard to the H_2O concentration of island arc low-K tholeiitic magmas (melts) remains elusive. We investigated conditions of their crystallization differentiation, particularly the H_2O concentration in melts, using geochemical data of volcanic rocks from Izu-Oshima volcano in the Izu arc, along with the results of hydrous melting experiments.

Geochemistry and petrology of volcanic rocks: We selected 68 aphyric volcanic rocks which exhibit multiply saturated liquid compositions of the Izu-Oshima volcano. Among them, two magma groups are distinguished by the K/Zr ratio, a lower-K subgroup (K/Zr$<$60) and a higher-K subgroup (K/Zr$\geq$60). In this study, we focus on the higher-K subgroup liquids. Two endmember trends, referred to here as a higher-Al/Si trend and a lower-Al/Si trend, have been distinguished in the higher-K subgroup liquids. All the liquids are bracketed by these two endmembers, and thus may be mixtures of the two endmembers or may have been derived under intermediate conditions between those responsible for the two endmembers. An experimental study by Hamada and Fujii (2008, *Contrib. Mineral. Petrol.*) suggests that the higher-Al/Si and lower-Al/Si trends can be reproduced by upper crustal crystallization differentiation of primitive basalt under moderately hydrous ($\sim$3 wt % H_2O) and almost dry conditions, respectively.

Hydrous melting experiments on island arc low-K tholeiite magmas: Island arc low-K tholeiite magma is characterized by presence of Ca-rich plagioclase (An$\geq$90), with Ca-poor rim ($\sim$An75). Hydrous melting experiments on two volcanic rocks from the Izu-Oshima volcano, MA43 and MA44 (MgO$\sim$5 wt %), were conducted at 250 MPa to constrain the origin of Ca-rich plagioclase (Hamada and Fujii 2007, *Geochem. J.*). MA43 and M44 represent less differentiated liquid compositions on the higher-Al/Si and lower-Al/Si trends, respectively. In the melting experiments on MA43, plagioclase crystallized as the liquidus phase at all H_2O content (1$\sim$6 wt % H_2O), and anorthite content of the plagioclase increased from $\sim$An80 under nearly dry conditions to An$\geq$90 with $\geq$3 wt % H_2O in melt. In the melting experiments on MA44, plagioclase crystallized as the liquidus phase under low-H_2O ($\leq$2 wt %) conditions, but augite replaced plagioclase as the liquidus phase with more H_2O in melt. Anorthite content of plagioclase increased from about An70 under nearly dry conditions to An80 with $\sim$4 wt% H_2O in melt. Increases in anorthite content of plagioclase crystallized from the MA44 melt were suppressed compared with plagioclase crystallized from the MA43 melt. In short, Ca-rich plagioclase (An$\geq$90) can be crystallized from melts on the higher-Al/Si trend with $\geq$3 wt % H_2O, but cannot be crystallized from melts on the lower-Al/Si trend with any H_2O. Ca-poor rim ($\sim$An75) cannot be crystallized from melts on the higher-Al/Si trend, but can be crystallized from melts on the lower-Al/Si trend.

Summary: Geochemical variations in the liquids from the Izu-Oshima volcano are bracketed by two endmember trends, namely, the higher-Al/Si and the lower-Al/Si trends. Origins of the higher-Al/Si and the lower-Al/Si trends can be explained by crystallization differentiation under moderately hydrous conditions ($\sim$3 wt% H_2O) and almost dry conditions, respectively. We propose that polybaric crystallization of H_2O-saturated melts, at a depth range between the $\sim$4-km-deep magma chamber ($\sim$3 wt% H_2O) and near surface level (nearly dry) beneath the Izu-Oshima volcano, is a ubiquitous feature of island arc low-K tholeiite magmas.

The change time from magmatic to phreatomagmatic eruption, in the Hachodaira caldera eruption at Miyakejima Volcano

OIKAWA, Teruki[1*] ; GESHI, Nobuo[1]

[1]GSJ, AIST

The Miyakejima volcano formed the caldera in 2000. This volcano erupted Hachodaira Scoria and Hachodaira Ash at ca.3ka of Hachodaira caldera collapse. Many plant fossils (Miscanthus sp.) are recognized in Hachodaira Scoria and Ash. Based on plant fossils in these tephras occurrence, deposition late of soil in the Miyakejima volcano, and form of the boundary of Hachodaira Scoria and Ash, The change time from magmatic eruption (Hachodaira Scoria eruption) to phreatomagmatic eruption (Hachodaira Ash) is under 1 year, probably it is several days or less. Thus, there was no time gap almost between magma eruption and phreatomagmatic eruption. This eruption style change can be explained such as 2000 eruption (Geshi and Oikawa,2008:JVGR) as follows. The altitude of the summit part approached the sea level by caldera collapse; as a result, phreatomagmatic eruption occurred.

Pumice deposits of the pre-Ofunato stage distributed in northwest of the Miyake-jima volcano, northern Izu-Bonin Arc

NANRI, Shohei[1*] ; SUZUKI, Takehiko[2]

[1]Graduate student, Tokyo Metropolitan University, [2]Tokyo Metropolitan University

Miyake-jima Island, a volcanic island of the northern Izu-Bonin Arc, is located in the northwestern Pacific Ocean, approximately 180 km south of Tokyo. A pale-orange-tuff layer had been reported by Issiki (1960) on coastal cliff in the northwestern part of the island. The aim of this study is to clarify (i) distribution, (ii) stratigraphic position, (iii) sedimentary structure, (iv) petrological features, and (v) mineralogical features, for this pyroclastic deposit in more detail. The layer was re-defined as ”Miyake-jima Ofunato Pumice deposit: OFP”. The OFP is distributed from western to northern parts of the island. The OFP exists below the Aira-Tn tephra, erupted at 30 ka. The sedimental facies of OFP deposits suggest it formed as a pyroclastic flow deposit.

The relation between K_2O and FeO concentrations in the OFP is characterized by higher FeO wt.% and lower K_2O wt.%. Tsukui et al. (2006) and Saito & Miyairi (2008) showed that the chemical trends in the volcanic products of forearc of Izu-Bonin Arc such as Izu-Oshima and Hachijo-jima are characterized by high FeO wt.% and low K_2O wt.%, and those of the backarc Izu-Bonin Arc such as Nii-jima and Kozu-shima shows low FeO wt.% and high K_2O wt.%. Consequently, chemistry of the OFP suggests that it was originated from forearc of Izu-Bonin Arc.

This paper concludes that the activities of the Miyake-jima volcano around 30 ka are characterized by a production of pumice by the eruption at the northwestern part of the present island. The current stage of this study, it is not possible to discuss the source vent of the OFP in detail and specify the type of the volcanic eruption produced the OFP. In future, we attempt to find a clue to account for these two problems by the detailed study on the OFP with referring to its faces like a pyroclastic flow deposits.

Formation process of a volcanic island during the 2013-2014 eruption at Nishinoshima, Ogasawara, Japan

MAENO, Fukashi[1*] ; NAKADA, Setsuya[1] ; KANEKO, Takayuki[1]

[1]Earthquake Research Institute, Univ. Tokyo

New volcanic islets created by submarine eruptions are often observed around Japanese Islands. However, in most cases, such new islets are disappeared by wave erosion in short periods. To make a new volcanic island remaining for a long time, an amount of lava flows must occur and reclaim land from the sea. However, such relatively large-scale lava eruptions rarely occur. Therefore, the very initial stage of the formation process of a volcanic island has been poorly understood.

The submarine eruption off Nishinoshima, Ogasawara, has created a new volcanic islet since Nov 2013. The lava flow eruption continues for more than a few months, and the islet keeps growing. This eruption will give an opportunity to understand the birth and growth of a new volcanic islet. We studied variation of eruptive styles and sequences of this 2013-2014 eruption at Nishinoshima based on airborne observations and publicized aerial and satellite images (taken by JCG, GSI, and JAXA).

Nishinoshima forms a part of summit crater rim of a huge submarine volcano. The 2013-2014 eruption occurred inside the summit crater about 400 m off Nishinoshima with a depth of dozens of meters. In the first stage, Surtseyan eruptions repeated due to seawater entering a main crater of an islet. With the growth of the islet, the main crater was dried up and the eruption style changed to Strombolian with a scoria cone formation and lava flows that continuously effuse from the main crater over a few months. Lava flow front is brecciated by rapid cooling, or auto-brecciated, and eventually reclaimed the foreshore from the sea. The lava flows are then branched many times and extended to almost all directions. The continuous activity of Strombolian with lava flows suggests that magma is stably supplied from the deeper part of conduit.

Based on the change of outline of the islet and bathymetry data before the eruption, volume and discharge rate of lava flows are estimated. For the first 2.5 months by early Feb 2014, the volume of lava flow is estimated at about 6 M m^3. The discharge rate is estimated at 0.5-1$*10^5$ m^3/day with some fluctuations. This discharge rate is almost the same as that estimated for lava effusion in the 1934-1935 eruption at Showa Iwojima, southern Kyushu (1$*10^5$ m^3/day; Maeno and Taniguchi, 2006), which is one of the youngest remained volcanic islands in Japan. The volume of the 2013-2014 eruption is so far 1/4 of the total volume (24 M m^3) of the last 1973-1974 eruption, in which the volume of the last eruption was estimated based on bathymetry change before and after the eruption. The eruptive sequence and growth rate of the islet in 2013-2014 is different from the last eruption. This is probably because the eruption began at shallower depth than the last eruption. At the time of early Feb 2014, erosion signatures on lava flows are little, so that the new island is expected to further grow.

Petrological characteristics of volcanic materials ejected during 2012-2013 explosive events on Ioto Island

IKEHATA, Kei[1*] ; TAMURA, Tomoya[2]

[1]Faculty of Life and Environmental Science, University of Tsukuba, [2]Graduate School of Life and Environmental Sciences, University of Tsukuba

Ioto is an active volcanic island (8.5km long in NE-SW and 4.5km wide) located about 1250km south of central Tokyo. Since early February 2012, small explosive eruptions have repeatedly occurred at the Old Crater (Million Dollar Hole) in the western part of the island (JMA, 2013). Four (February 2012, March 2012, February 2013 and April 2013) ejected mud materials collected in the vicinity of the crater consist of free crystals (plagioclase, clinopyroxene, olivine, and Fe-Ti oxides), relatively fresh volcanic glass, altered volcanic glass, lithic fragment, altered lithic fragment and pyrite aggregate (Ikehata and Tamura, 2013). Among the mud samples, there is little difference in component of grains except for high abundance of altered lithic fragment in the mud ejected in February 2012.

Detailed SEM/BSE image observation of the relatively fresh volcanic glasses show that even these fresh glasses have pitted alteration and hydration features. The extent of hydration could be different among volcanic glass shards in geothermal field like Ioto because hydration rate depends on chemical compositions of volcanic glasses and groundwater, and soil temperature. To eliminate such hydration effects, heating (400 ℃-12h) is conducted for the relatively fresh volcanic glasses before analyzing. As a result of the chemical analysis, all of these volcanic glasses are trachytic, and their chemical compositions are homogeneous within the analytical error. In conclusion, no juvenile materials existed in the mud samples, suggesting these explosive events were not phreatomagmatic but phreatic eruption.

We would like to thank members of JMSDF Ioto Air Base weather team for sampling around the Old Crater and providing information on the studied area. Ministry of Defense, JMA and NIED are also thanked for their cooperation.

Compositions of minerals in volcanic products from pre- and the early stage of Aso-4 large-scale pyroclastic flow

KUROKAWA, Kiyoshi[1] ; YAMASAKI, Hideto[1] ; HASENAKA, Toshiaki[1*] ; MORI, Yasushi[2]

[1]Grad School Sci. & Tech., Kumamoto Univ., [2]Kitakyushu Museum of Natural and Human History

Formation of Omine scoria cone, Takayubaru lava flow, and Oyatsu pumice flow are a series of volcanic events just before and after the large-scale Aso-4 pyroclastic eruption. Compositions of volcanic products change from 62-66 SiO_2 wt.% for Omine scoria, 63-66 SiO_2 wt.% for Takayubaru lava, to 67-69 SiO_2 wt.% for Oyatsu pumice. The difference between Omine-Takayubaru compositional trend and Oyatsu trend is small but evident (Yamasaki et al., 2013). Common phenocrsyt assemblage is plagioclase, orthopyroxene, clinopyroxene, and opaque minerals. In addition, Omine scoria and Takayubaru lava contain hornblende microphenocrysts, whereas Oyatsu pumice contains phenocrysts of hornblende. Most plagioclase characteristically shows sieve texture among Omine-Takayubaru samples. Such texture is not so common among Oyatsu pumice samples. We analyzed these minerals using EPMA in order to characterize the change in magma supply system that lead to large-scale pyroclastic eruption.

In response to different compositional trends observed between Omine-Takayubaru and Oyatsu samples, different mineral compositions are also found. Plagioclase phenocrysts in Omine-Takayubaru samples are An50-An60 with uni-mordal peak, where as those in Oyatsu samples are An37-An56 with three peaks. Slight difference in Mg# are also found between orthopyroxene, clinopyroxene, and hornblende of Omine-Takayubaru and those of Oyatsu samples.

Estimated temperature for Omine scoria using Wells (1977) pyroxene thermometer is 950 ℃, and dry viscosity is 10^5.6 Pa • s. That for Tamaraigawa lava (SiO_2=61 wt.%) extruded before Aso-2 pyroclastic eruption was reported as 1120 ℃ and 10^3.9 Pa • s, respectively, by Kobayashi (2013). The difference in viscosity is reflected by different aspect ratio, i.e. 100 m thick and 7 km long for Takayubaru lava flow, and 10 m thick and 10 km long for Tamaraigawa lava flow.

Sieve texture and microphenocrysts in Omine scoria and Takayubaru lava make an important restriction for making models of magma supply system before and after the large-scale pyroclastic eruption. If sieve texture suggests melting process of plagioclase, it indicates temperature ascent and/or water vapor pressure increase. In contrast, growth of hornblende microphenocryst suggests temperature drop and/or water vapor pressure increase. Omine-Takayubaru samples do not contain mafic inclusions and mafic minerals with reverse zoning, thus possibility of magma mixing and temperature ascent is small. The change in physicochemical condition in Aso-4 magma supply system is yet to be solved.

Forming process of Minamidake stratovolcano, Sakurajima, inferred from paleomagnetic age and volume of lava flows

MIKI, Daisuke[1*]

[1]DPRI, yoto University

A paleomagnetic measurement was carried out on the Arimura lava, which consists uppermost part of the main body of Minamidake stratovolcano, Sakurajima volcano, Kyushu, Japan. A mean paleomagnetic direction, D=4.0 ^{o} E I=40.5 ^{o} down, was obtained from the Arimura lava. By comparison between measured paleomagnetic direction and the paleo-secularvariation of geomagnetic field, the age of the Arimura lava was estimated as about 3.1-2.7 ka, moreover the age of the Kannonzaki lava lying beneath the Arimura lava, was thought as about 3 ka. These two lavas are considerable to be formed by a sequence of intermittent eruption during several hundred years at around 3 ka. The volumes of individual lava that extruded in recent 4,000 years were estimated. The main body of Minamidake stratovolcano had grown rapidly at around 3 ka, since estimated lava volume. The volume of the Nagasakihana lava erupted in 764-766 AD was estimated as about 0.8km^{3}. The scale of 764-766 AD eruption may be greater than previously thought. The long?term magma effusion rate during historic time, particularly recent 240 years, was estimated as larger than earlier.

Morphology of microlite -projections of plagioclase microlite-

SANO, Kyohei[1*] ; TORAMARU, Atsushi[2] ; WADA, Keiji[3]

[1]Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, [2]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, [3]Hokkaido University of Education at Asahikawa

At Tokachi-Ishizawa (TI) rhyolite lava, Shirataki, Hokkaido, northern part of Japan, the interior structure transition can be observed, from the outer obsidian layer to the inner rhyolite layer. Thus TI lava is an appropriate target field for correlating textural characteristics with lava interior structure. In order to obtain insights into the magma ascent and outgassing process of viscous magma, we have analyzed oxide microlites of TI rhyolite lava, suggesting that dominant outgassing process is ductile permeable development (Sano et al.,2013 JpGU meeting). However, we have not examined the morphology of microlite. Morphology of crystal is considered to reflect the effective undercooling of the melt and provide the constraint for ascent process and water exsolution processes. In this study, we focused on the morphology of microlites, especially projections of plagioclase microlites. The projections mean localized growth of crystal from plagioclase surface.

In Shirataki, aphyric rhyolite lavas erupted ca. 2.2Ma and composed of 10 flow units. The TI lava is about 50 m in height and stratigraphic sequences from the bottom are a obsidian layer region, a boundary bounded region of obsidian and rhyolite, and rhyolite layer region. The obsidian layer region consists of a single vesicle-free obsidian about 7 m high. The rhyolite layer region consists of rhyolite layers with variable vesicularity, crystallinity and characteristic scales in layer thickness. The boundary banded region, which is located between the obsidian and rhyolite regions, consists of thin obsidian ($<$10mm in width) and rhyolite. In this study, we define the obsidian and rhyolite based on the differences in appearance of hand specimens and rock texture. Rhyolite has perlitic cracks in the glass and contains some amounts of crystalline materials, namely, spherulite and lithophysae. In boundary banded region, the fraction of obsidian decreases toward rhyolite layer region.

From the examination by scanning electron microscope (SEM) for thin sections from obsidian layer region, boundary banded region and rhyolite layer region, we found the projection texture in all samples. We measured projection length and number density (Nv) of plagioclase microlites for obsidian and rhyolite layer regions. The measurement results show that plagioclase microlites in obsidian and rhyolite layer regions indicate the similar number density. Nv for obsidian layer region is 1.8×10^{11} — 3.5×10^{11} [/m^3] and 8.2×10^{10} — 3.0×10^{11} [/m^3] for rhyolite layer region, respectively. However, the length of projection is remarkably different between two regions. The mean values are 2.3 μm in obsidian layer region, and 8.7 μm in rhyolite layer region. The transition of mean length can be observed in boundary layer region.

Since the difference of projection length reflects the growth rate (G [m/s]) and growth time (t [s]) according to the theory of crystal growth (Keith and Padden, 1963; Lofgren, 1971; Rao, 2002), we can estimate the degree of effective undercooling at the formation time of projections. Under the assumption that G is constant for the time, the length of projection can be given by Gdt. Assuming the constant growth rate and growth time, the difference in projection lengths indicate that in growth rate, namely, the undercooling. Using experimental values for growth rate and undercooling, it is found that the rhyolite layer region experiences higher undercooling than obsidian layer region by 30 — 70 K. The projection can be formed after the nucleation of plagioclase microlite, which indicate the similar number density in obsidian and rhyolite layer region. Thus projections reflect the different undercooling after the nucleation of microlites. Based on the quantitative analysis of crystal morphology of microlites, we can obtain the insights into the magma ascent process that rhyolite layer region experienced higher undercooling than obsidian layer region.

Differentiation process of arc magmas revealed by principal component analysis on trace element composition

UEKI, Kenta[1*]

[1]Volcanic Fluid Research Center, Tokyo Institute of Technology

Chemical composition of magma can be used to address state of the magmatic system and the processes during magma generation, ascendent and eruption. Various processes from the mantle to the crust in various pressure, temperature and chemical composition modify magma composition. Consequently, bulk chemical composition of erupted magma represents a sum of these processes.

Differentiation in terms of major element composition is controlled by non-linear thermodynamic relation. Major element composition of magma is modified by temperature, pressure and H2O content dependent saturation states of mineral phases, and partition between melt phase and mineral phases. In this sense, major element composition can be a proxy of physical state during magma generation and ascendent. However, the non-linarlity of major element processes and a small degree of freedom in compositional space prevent us from decomposition of processes that have derived compositional variation in terms of major element.

On the other hand, partition of trace elements between melt and mineral phase can be modeled with relatively simple equation, and can be considered as a linear process. Consequently, trace element composition of erupted magma represents a simple sum of a melting and differentiation processes. Trace element can be a tracer of the specific phase or reaction, because partition coefficients between various minerals melt show wide range of variation. Therefore, trace element can be used as a proxy of a specific chemical mass reaction process during magma generation and ascendent. In addition, trace element composition shows a large degree of freedom. Therefore, it is expected that nature and the number of processes during magma generation and ascendent can be decomposed by analyzing trace element composition of volcanic rock using multivariate statistics.

In this study, principal component analysis is used to analyze compositional variation of volcanic rocks in Northeastern Japan Arc.

Analysis based on a series of volcanic rocks from single volcanic activity has shown that the differentiation process and/or mantle melting process beneath each volcano (crystal fractionation and magma mixing) can be decomposed by using principal component analysis on trace element compositions. Consistent relationship between the trace element principal components, major element composition, and petrological information such as mineral composition is derived from the analysis.

In order to illustrate the differentiation process in terms of large scale spatial and compositional range, 262 samples from 17 different volcanoes in the Sengan region, northeastern Japan are analyzed with principal component analysis. Result of the analysis clearly demonstrates that differentiation processes in the arc crust, are the primary controlling factor to derive compositional variation of arc magmas. Only three principal components account for the compositional variation of 262 samples. It is estimated the three principal components represent magma mixing, relatively high pressure olivine fractionation, and relatively shallower pressure plagioclase differentiation, respectively. No strong mantle signature is identified by the analysis. This result shows intermediate-felsic magmas (SiO2>60 wt. %) can only be derived through magma mixing, not by crystal fractionation.

A preliminary estimation of water content of the mantle beneath Changbaishan Volcano, northeast China

KURITANI, Takeshi[1*] ; OKUMURA, Satoshi[2] ; YOKOYAMA, Tetsuya[3] ; ITO, Yoshinori[2] ; NAKAMURA, Michihiko[2] ; WEI, Haiquan[4]

[1]Osaka City University, [2]Tohoku University, [3]Tokyo Institute of Technology, [4]China Earthquake Administration

In northeast China, Cenozoic intraplate volcanic products are widely distributed. Geophysical studies have suggested that the underlying mantle transition zone is remarkably hydrous (Kelbert et al., 2009) and contains remnants of the subducted Pacific slab (Fukao et al., 1992); therefore, the Pacific slab stagnation and its relation to observed magmatism has received growing attention (e.g., Ohtani and Zhao, 2009; Richard and Iwamori, 2010). Beneath the Changbaishan volcanic field, a prominent low-velocity anomaly with a plume-like shape has been imaged in the upper mantle by P-wave tomography, which is suggestive of an upwelling of a mantle plume from the mantle transition zone (e.g., Zhao et al., 2009). In this study, to characterize the nature of the transition zone-derived mantle plume, the water content of the source mantle is estimated for basaltic products from the Changbaishan volcano.

Basaltic scoria samples were collected from a cinder cone, located about 20 km to the northeast of Tianchi volcano. One scoria sample was used for preliminary analysis of glass inclusions in some plagioclase phenocrysts. Basaltic lavas, which occur with abundant mantle xenoliths, were also collected from the outcrop near the cinder cone to know the primitive magma composition at the volcano. The MgO contents of the scoria and the lava are 5.1 wt.% and 9.1 wt.%, respectively. Major element compositions of quenched glass inclusions in the scoria sample were analyzed using EPMA, and the water contents were estimated by the difference of the analytical total of the major element analysis from 100 wt.%. Through calibration using an in-house standard glass sample of known water content, the water contents of the glass inclusions were obtained to be 0.15-3.4 wt.%. The FT-IR analysis was also performed for one glass inclusion of the estimated water content of 0.15 wt.% by EPMA, which yields the total water content of 0.2 wt.%.

Given that 3.4 wt.% represents the original water content of the melt without leakage, the H_2O/K_2O ratio of the melt of 0.90 is obtained. If we assume that the H_2O/K_2O ratio of the melt was not affected significantly by magmatic processes and the ratio is essentially constant in basaltic magmas at Changbaishan volcano, the water content of the primitive magma (2.4 wt.% in K_2O) is estimated to be 2.2 wt.%. The source mantle for the Changbaishan basalts may contain ˜0.5% sediment component (Kuritani et al., 2011), and the Ce content of the source mantle is estimated to be ˜1.1 ppm using the Ce content of the sediment component of 57.3 ppm (Plank and Langmuir, 1998) and that of the depleted mantle of 0.77 ppm (Salters and Stracke, 2004). If we assume that Ce and H_2O behave similarly during mantle melting (e.g., Michael, 1995), the compositions of the primitive basalt lava (Ce: 70 ppm, H_2O: 2.2 wt.%) yield the water content of the source mantle of ˜350 ppm. This estimated water content is significantly higher than that of the normal depleted mantle (˜120 ppm; Salters and Stracke, 2004), suggesting that the transition zone-derived mantle plume is hydrous compared with the surrounding ambient upper mantle.

In this preliminary study, we have analyzed only seven glass inclusions in a single sample, and therefore, the water content of ˜350 ppm may represent the minimum estimate. It is necessary to increase the number of data by EPMA and FT-IR analyses to more reliably estimate the source water content for the Changbaishan basalts.

Petrological and geochemical variations within an off-axial submarine large lava flow from the Oman Ophiolite

OTSUKA, Ryo[1*] ; KUSANO, Yuki[1] ; KANAYAMA, Kyoko[1] ; UMINO, Susumu[1]

[1]Department of Earth Sciences, Kanazawa University

Large submarine lava with thicknesses >100 m and volumes exceeding a few cubic kilometers are not uncommon volcanic constructs of mid-ocean ridges and around Hawaii Islands, yet details of the physical processes of eruption of these large lava flows are poorly understood. The V3 flow of the Oman ophiolite extruded at 90 Ma far off the paleospreading axis as thick lava flows with a minimum areal extent of >11 km by 1.5 km and the maximum thickness >270 m, yielding a minimum estimated volume >1.2 cubic kilometers. The V3 flow was fed by a thick feeder dike in the SW of the flow field and buried off-axial fault-bounded basins with a thick sedimentary cover in ˜40 days. The upper V3 flow field consists of compound lobes that merge upstream into larger and thicker sheet-like lava, which grew endogenously as a vast sheet lobe.

Low-T hydrothermal alteration and weathering slightly modified the bulk compositions as indicated by moderate albitization of plagioclase and partial replacement of titanomagnetite and clinopyroxene by titanite and chlorite, respectively. However, strong positive correlations among incompatible HFSEs and REEs and relatively good correlations with major elements besides LILEs and Pb show that these elements were less mobile and preserve primary characteristics. FeO and TiO2 show moderate increases with a decrease in MgO from 8 to 5 wt%, and then decreases with the decrease in MgO down to 4 wt%. 20-50 times enrichment in Th and depleted HREEs compared to primitive mantle of the V3 flow is similar to differentiated EMORBs.

Whole-rock major and trace element variations through a vertical transect at 8.7 km (T-21) from the feeder dike show fractional crystallization of clinopyroxene and plagioclase, the major phases in the groundmass of the lava, at a pressure of the paleowater depth. The stratigraphic variations show a notable enrichment in MgO and depletion in incompatible elements in the lowermost core, consistent with accumulation of olivine phenocrysts. Enrichment in incompatible elements in the uppermost core of the flow is in accordance with the model that the last solidified, residual melt resided in this horizon.

By contrast, samples collected from the basal crust every 0.5-1 km from the feeder dike, and vertical transects at 6.7 km (T-14) from the dike have whole-rock compositions spread over compositional spaces that could be explained by internal mixing of variably differentiated magmas. Interestingly, incompatible elements like Yb and Ti of the basal crust show increases downflow to ˜5 km from the feeder dike and decreases further downflow. Because the basal crust is the quenched lava that came to rest first at that place, samples farther away from the feeder were extruded and emplaced later in the eruptive event. The downflow variations show extrusion of differentiated lava in the middle stage of the eruption and less differentiated lava in early and late stages. Meanwhile, the transect at T-14 is differentiated in the upper and lower crust and less differentiated in the core.

These intraflow variations in the bulk geochemistry indicate supply of less differentiated magma in an early stage of the eruption, which was progressively replaced by mixed magmas of variably differentiated and less differentiated ones toward the end of the eruption. The eruptive sequence of less differentiated to differentiated magmas with increasing FeO suggests extrusion from a density stratified magma chamber with less dense and Mg-rich magma underlain by more dense Fe-rich magma. The internal mixing among variably differentiated magmas with the progress of the eruption and the extrusion of less differentiated magma toward the end of the eruption suggest a renewal of magma toward the end of the eruption caused mixing of newly supplied less differentiated magma with the differentiated magma within the conduit and the lava tubes.

Factors governing fragmentation of submarine lava - mechanism of hyaloclastite formation

UMEZAWA, Yumi[1*] ; UMINO, Susumu[1] ; KUSANO, Yuki[1] ; KANAYAMA, Kyoko[1] ; KITAMURA, Keitaro[1]

[1]Department of Earth Sciences, Kanazawa University

Hyaloclastite is water-lain volcanic breccia embedded in a matrix of glassy clasts by fragmentation of brittle lava under thermal stress. Fluidal basalt lava tends to form coherent flows like pillow lava and sheet flows. In contrast, viscous lava such as andesite and dacite is more likely to form hyaloclastite. This preference of hyaloclastite on lava composition indicates that mechanical response of solidified lava under stress is strongly dependent on composition. Fracturing of lava occurs when the rate of stress accumulation exceeds the rate of stress relaxation and ultimately reaches the mechanical strength of the lava. The rate of stress relaxation decreases with the increase in lava viscosity. Therefore, hyaloclastite is more common in viscous silicic lava.

However, the occurrences of pillow lava of dacite and rhyolite are known from the Ogasawara Islands, Unalaska Island, Oman Ophiolite, etc. Pillow lava is commonly associated with hyaloclastite of the same compositions. These examples demonstrate that factors other than lava composition determines fragmentation of lava. Then, the problem arises what are the governing factors that control the mechanical response of lava under stress. We will address these issues through comparative study on glass, quenched melt, of pillow lava and hyaloclastite of variable compositions spanning from basaltic andesite to rhyolite from the Eocene submarine volcanic strata in Chichijima, Ogasawara Islands.

Samples of glass from these sites were analyzed by EPMA for major elements and by SIMS for water contents. Eruption temperatures were estimated by clinopyroxene-liquid geothermometer of Putirka (2008). Crystal number densities of groundmass plagioclase and clinopyroxene were determined on COMPO images and modal abundance of constituent minerals were determined on element distribution maps of EPMA. Bulk viscosity of lava was estimated by the methods of Giordano et al. (2008) and Pinkerton and Stevenson (1992).

Dacite has phenocrysts of clinopyroxene, orthopyroxene, plagioclase and magnetite. Groundmass consists of clinopyroxene and plagioclase microlites and magnetite set in glass. In dacite glass, there is little difference in melt composition, eruption temperature, crystal number density between pillow lava and hyaloclastite. However, lower water content in hyaloclastite glass than in pillow margin glass yields higher bulk viscosity.

Andesite has phenocrysts of clinopyroxene, orthopyroxene, plagioclase and magnetite. Groundmass consists of clinopyroxene and plagioclase microlites and magnetite set in glass. Clinoenstatite xenocrysts enclosed by orthopyroxene rim are occasionally present. Hyaloclastite is higher in crystal number density and mode of groundmass plagioclase than associated pillow lava. Hyaloclastite glass is lower in Al2O3 than associated pillow glass, consistent with preferential crystallization of plagioclase. However, the cpx-saturated melt temperatures show little difference between pillow lava and hyaloclastite. Bulk viscosity estimated for the lava to become hyaloclastite is higher than the lava that formed pillows because of the larger crystal number density in hyaloclastite.

The above observations on dacite glass clearly indicate that water played an essential role in formation of hyaloclastite. Degassing either within the conduit or during flowage through lava tubes raised the bulk viscosity of lava and stress relaxation time, resulted in fragmentation of lava to form hyaloclastite. Although water content was not determined for andesite glass, higher crystal number density and modal amount of plagioclase in hyaloclastite with the same temperature as the coexisting pillow lava can be explained by volatile loss which raised the liquidus of plagioclase and its preferential crystallization, resulted in higher bulk viscosity and fragmentation of lava.

Eruption history and petrography of Akanfuji in the Me-akan volcano, eastern Hokkaido, Japan

SATO, Eiichi[1*] ; WADA, Keiji[2]

[1]Institute for Promotion of Higher Education, Kobe University, [2]Hokkaido University of Education at Asahikawa

Me-akan volcano is located in the Akan volcanic field, eastern Hokkaido, and ˜250 km inland from the Kuril trench. The volcanic activity of Me-akan volcano began at least a few tens thousand years ago, and eight volcanic bodies with different peaks have been formed.

Akanfuji (1476 m), which is the newest volcanic body in the Me-akan volcano, started its eruptions about 2.5 ka, and the volcanic activity continued for 1,500 years. The eruption products of Akanfuji are composed of scoria fall deposits and lava flows. The scoria fall deposits are distributed from northeast to south from present vent. We described the scoria fall deposits to interpret the complex depositional sequence. As a result, 17 scoria fall layers were recognized for 1,500 years.

Akanfuji had erupted basalts through its history. Two types of basalts (types I and II) are recognized on the basis of phenocrysts assemblage. Type I is orthopyroxene (opx) bearing olivine (ol)-crynopyroxene (cpx) basalt and Type II is cpx bearing ol-opx basalt. They were formed by mixing between different types of basaltic magmas on the basis of the textural and mineralogical evidences.

Evidence of eruption episodes before AD1741 of Oshima-Oshima Volcano, Hokkaido, Japan

YOSHIMOTO, Mitsuhiro[1*] ; NAKAMURA, Yugo[1] ; FUKUHARA, Genta[2] ; NISHIMURA, Yuichi[1]

[1]Faculty of Science, Hokkaido University, [2]Faculty of Science, Hokkaido University

We newly identified two eruption episodes of Oshima-oshima volcano below eruption products of the AD 1741 eruption at an outcrop on the summit of the volcano. The upper eruption product consists of alternating volcanic lapilli fall and ash fall deposits, and the lower one consists of scoria fall deposits. Tephra from those eruptions have not found in the other area including southern Hokkaido. We also identified two thin tephra layers between three eruption products of Oshima-oshima volcano with intercalating soil layers. They are correlating with well-known wide spread tephras such as Ko-d (AD 1640) from Hokkaido-Komagatake Volcano and B-Tm (ca. AD 940) from Changbaishan Volcano, China-North Korea, based on chemistry of volcanic glass shards. Considering the thickness of soil layers, those eruption episodes would occur at around AD 1450 and BC 600. It suggests that Oshima-Oshima volcano erupted at least 4 times in last 2500 years including 2 historical eruptions in AD 1741-1742 and 1759.

Compositional variation and magmatic differentiation at the northern Kita-Hakkoda volcanic group

KOMATSU, Sho[1*] ; OHBA, Tsukasa[1]

[1]Akita Univ.

Since 0.6 Ma, magmatic eruptions have occurred several times at Kita-Hakkoda volcanic group. This study focuses on the activity between 0.4 and 0.2 Ma. Magmatic differentiation process is investigated from whole-rock chemistry and mineralogy along with stratigraphy. This area consists of 12 geologic layers: Hakkoda 2nd Stage Pyroclastic Flow Deposit, Northern Kita-Hakkoda Basaltic Andesite Lavas, Lower Kansuisawa Pumice Flow Deposit, Lower Tamoyachi-dake Andesite Lavas, Upper Kansuisawa Pumice Flow deposit, the Upper Tamoyachi-dake Andesite Lavas, the Tashirotai Lacutrine Deposit, Narusawa Debris Flow Deposit, Maedake Lavas, Narusawa-daichi Andesite Lavas, Okuzuresawa Debris Flow Deposit and Okuzuresawa Pyroclasitic Flow deposit in stratigraphic order. Temporal variation of chemical composition in stratigraphic order is evaluated. The activity initiated with the effusion of differentiated tholeiitic basaltic magma around 0.4 Ma. After a dormancy the activity resumed around 0.2 Ma with effusion of andesitic magma (60wt% SiO_2), followed by a fluctuating activity between tholeiitic basalt and low-silica calc-alkaline andesite magmas. Then, the magma composition jumped to high silica (60wt% SiO_2) calc-alkaline andesite. No evidence for open system process is recorded in phenocrysts in the tholeiitic rocks. Previous studies accounted for the chemical variation of tholeiitic magma by crystallization differentiation, and our new data is consistent with the model. Disequilibrium mineral assemblages in calc-alkaline rocks, e.g., coexistences of magnesian olivine and embayed quartz, and of reversely zoned pyroxenes and normally zoned pyroxenes, implies open system processes. As indicated by linear trends between tholeiitic basalt and the high-silica andesite, magma mixing is a plausible process to produce the series. Stratigraphic chemical variation might be caused by temporal variation in mixing ratios.

The volcanic history and geological structure of Sanzugawa Caldera, Yuzawa, Akita prefecture

OKI, Fumiya[1*] ; OHBA, Tsukasa[1]

[1]Akita Univ.

Sanzugawa caldera, located in the southern part of Akita prefecture, was formed by collapses after eruptions of voluminous ash flows about >ca. 1 Ma. Torageyama Formation, deposited during the caldera formation, thickly infills the caldera depression. The Formation is divided into two members: Torageyama tuff member and Minasegawa tuff member. Torageyama tuff member consists of welded tuff, lapilli tuff, and alternation of tuffaceous sandstone, mudstone, and conglomerate. Thickness of Torageyama tuff member is approximatly 900m. Minasegawa tuff member consists of lapilli tuff, tuff and conglomerate. Thickness of Minasegawa tuff member is about 450m. In this study, on the basis of lithology, Torageyama Formation is divided into 10 layers, including pyroclastic density current deposits (PDC-1 to PDC-8), a debris flow deposit (DF-1) and a lacustrine deposit (LD-1). Stratigraphic order from the bottom is PDC-1, DF-1, LD-1 and PDC-2 to PDC-8. Approximate thicknesses of the layers are 20m, 80m, 140m, 50m, 250m, 200m, 340m, 160m, 90m and 30m, respectively. Pyroclastic density current deposits consist of massive lapilli tuff. The lapilli tuff contains pumice clasts and lithics, and minor amount of wood pieces. Bases of PDC-4 and PDC-6 consist of ground surge deposits. Low-angle cross-laminar and dunes are developed in the ground surge deposits. The ground surge deposit of PDC-6 is further underlied by a ground breccia layer. The ground breccia layer consists of matrix-supported conglomerate, containing lithics with a maximum grain-size of 2.5 m. Lapilli tuff of PDC-1, 3, 4, 8 include welded parts, developing degassing pipes and columnar joints. Welded parts often contain spherulites and exhibit eutaxitic texture. Debris flow deposit (DF-1) consists of clast-supported conglomerate with rounded clasts. The clasts are directed parallel to the bedding plane, showing coarse-tail reverse grading. Lacustrine deposit (LD-1) consists of alternation of tuffaceous sandstone, mudstone, and conglomerate. In mudstone, laminar is well developed. Laminar and bedding are well developed in tuffaceous sandstone. Conglomerate is massive. PDC-2 overlying the lacustrine deposit (LD-1) shows sedimentary structures that imply subaqueous setting. Pyroclastic density current occurred more than eight times, suggested by the number of pyroclastic density current layers. The source of PDC-4 is Takinohara vent, determined from paleocurrent estimated with dunes of a ground surge deposit. Presence of a lacustrine deposit (LD-1) in the middle of the Formation implies that caldera collapsed two times. Half-concentric distribution of strike surrounds Mt. Ishigami and their dips incline outward of the caldera. This structure implies a resurgent dome. This resurgent dome resulted in uplift of Oyasudake area where the center of the caldera. Presence of resurgent dome, thick pyroclastic density current deposits and ring fractures suggests that Sanzugawa caldera is classified as a Valles type caldera.

Stratigraphy and chemical compositions of eruption products in Umanose agglutinate activity, Zao volcano

KAWANO, Gen[1*] ; BAN, Masao[2] ; OIKAWA, Teruki[3]

[1]Graduate School of Science and Engineering, Yamagata University, [2]Faculty of Science, Yamagata University, [3]Geological Survey of Japan/ AIST

The newest stage of the Zao volcano, central part of NE Japan, began at about 30 ka and the activity has continued to present. The Zao newest stage eruption products are classified into Komakusadaira agglutinate, Umanose agglutinate and Goshikidake pyroclastics. In this study, we examined the stratigraphy of eruption products in the Umanose agglutinate activity (ca. 8-4 ka). Besides, we examined temporal change in chemical compositions of the products.

≪Tephra-stratigraphy≫ We re-examined the tephra-stratigraphy and recognized nine volcanic sand layers (Z-To 5a, 5b, 5c, 5d, 5e, 5, 6, 7, 8) during the Umanose agglutinate activity. The tephra (volcanic sand) layers younger than the Z-To 5e widely distribute around the summit area, while the others are found only in the northern part. Based on ^{14}C ages on paleosols and fossil leaf samples from the tephra-loam succession coupled with the stratigraphy, ages of Z-To 5a to 8, except for Z-To 5, are estimated to be ca. 8.9, 7.3, 6.0, 5.6, 5.3, 4.7, 3.9, 3.6 ka, respectively.

In addition, we found whitish yellow colored wide-spread tephra layer between Z-To 5e and 5d in the northern and bellow 5e in the southern part of the summit area. This tephra is mainly composed of pumice type volcanic glass. This layer can be correlated to To-Cu (Towada-Chuseri) tephra, based on the major element compositions of the volcanic glass and the stratigraphic horizon.

≪Stratigraphy of the proximal layers≫ The proximal layers are well exposed in the central part of the summit area. In this part, the Umanose agglutinate covers the Komakusadaira agglutinate, which include less-vesiculated volcanic bombs with glassy luster as well as scoria. Overlying products of the Umanose agglutinate are composed of alternation of agglutinate, scoria fall deposit, and pyroclastic surge deposit. More than ten layers are recognized by intercalating loam layers.

≪Temporal change in chemical compositions≫ The eruptive products are olivine +- pyroxene andesite (56.0-59.2% SiO_2) and belong to medium-K calc-alkaline series. All samples are plotted on same linear trends in SiO_2 variation diagrams. The silica contents increase gradually from the bottom to the middle part. Afterwards, the content drops to the lowest, and gradually increase upwards again.

Eruptive History of Post-caldera Stage, East-Azuma Volcano -Correlation between ejecta intra-caldera and boring core-

OZAKI, Mamoru[1*] ; FUJINAWA, Akihiko[2]

[1]Ibaraki Univ., [2]Ibaraki Univ.

Introduction

Azuma Volcano is one of the Quaternary stratovolcanoes located at the volcanic front of the Northeast Japan arc. The recent 7ka activities of this volcano are characterized by dominant fall out tephra (Yamamoto, 2005). Eruptive history occurred at the Jododaira explosion caldera (Fujinawa and Kamoshida, 1999) is built by comparing boring core of the Jododaira with the ejecta deposited the intra-caldera area.

Stratigraphy and lithofacies of boring core

Boring site is at about 500m NW from Azuma-Kofuji cone. This core was described most immediately after core-recovery, and stratigraphic sequence was outlined (CCPVE core analysis group, 2011). Layers of andesitic volcanic block and lapilli (11.20m-1.50m in depth) are lithologically correlated to the Azuma-Kofuji volcanic ejecta.

Andesite lava (100.55m-81.07m, sample No.19-17 near the bottom of the core) and welded tuff breccia / lapilli tuff (79.90m-14.20m, No.13-10) are to be the keys to reveal the eruption history. Andesite lava (19-17) is dark-gray in color with dominant plagioclase phenocrysts of 2˜3mm in diameter. Inclusions are rarely recognizable. Welded tuff breccia/lapilli tuff (No. 13-10) are characterized by dark-gray, highly deformed and elongated blocks/lapilli at the densely welded part.

Description of outcrops

3 lava flows and 1 pyroclastic flow deposit were newly found at the outcrops of intra-caldera area.

Lava flow1 (Lf1) does not show distinct lobe topography. This is exposed only at altitudes of 430m along forest road with about 5m thick. Lf1 is massive, dark-gray in color and characterized by dominant plagioclase phenocrysts of 2˜3mm in diameter. Rare cognate inclusion is also recognized.

Pyroclastic flow deposit (Pfl) intermittently cropped out around at altitudes of 470m along the route 126, showing a thickness about 2.5m. The Pfl is overlain by unconsolidated talus deposit. The stratigraphy of these deposits was not confirmed in the field observation. This Pfl includes dark-gray lithic fragments in weakly welded light-gray matrix.

Lava flow2 (Lf2) constitutes thick massive spreading widely on the floor of the Jododaira explosion caldera (Fujinawa and Kamoshida, 1999). Judged from topography, the Lf2 storatigraphically overlies the Pfl. At altitudes of 660m along forest road, the Lf2 of over 10m in thick showing an well-developed columnar joint is cropped out. The Lf2 is directly covered by Ak-Lf at this locality (Kamoshida, 1991MS). Lithology of Lf2 is massive, gray in color and pyroxene phenocrysts are secerned easily.

Lava flow3 (Lf3) is distributed in the southern part of the intra-caldera, well foamed and grey tinged with red in color. The Lf3 topographically overlies the Lf2, furthermore, and covered by Ak-Lf. The Lf3 consists of 3˜5 flow units, lobes and levees at its surface.

Comparison of lithofacies

The lava samples of the core (19˜17) are lithographically similar to those for the Lf1, but distinguishable to those of the Lf2 or Lf3. The core samples of the welded tuff (13˜10) is slightly different from Pfl in the degree of welding, but are similar to each other in terms of including dark-gray lithic fragments in light-gray matrix.

Eruptive history based on comparison of lithofacies

The welded pyroclastic deposits in boring core are as thick as 20m, suggesting that the deposit is the deposit of an enormous pyroclastic eruption. If such eruption occurs, a sort of depression would often be remained in the supply source area. Judging from topography, the Jododaira explosion caldera is the most plausible candidate. Because the Lf1 (=core 19˜17) lie beneath welded Pfl (=core 13˜10), this lava is promisingly erupted during pre-caldera activities. Because the Lf2 and Lf3 are topographically come above the Lf1, it is considered that these lavas erupted in the post-caldera stage.

Plagioclase phenocrysts and Opx-magnetite symplectite of the Sessho Lava of the Kusatsu-Shirane Volcano

OSHIO, Kazuki[1*] ; UEKI, Kenta[2] ; KAWANO, Munehiro[3] ; INUI, Mutsuko[3] ; NOGAMI, Kenji[2]

[1]Kokushikan University Graduate School of Engineering, [2]Volcanic Fluid Research Center, Tokyo Institute of Technology, [3]Kokushikan University

Chemical composition and crystal size distribution of plagioclase phenocrysts may represent the cooling rate and chemical heterogeneity of the magma chamber. Therefore, chemical and physical conditions in the magma storage before eruption can be constrained by analyzing the morphology and chemical composition of phenocrysts in lava.

For the purpose, we focused on the Sessho lava, a single lava flow erupted from Kusatsu-Shirane volcano. Kusatsu-Shirane volcano is a quaternary active volcano located in the Central Japan arc. According to Uto *et al.*(1983), the Sessho lava is estimated to have erupted from the Moto Shirane cone during an eruption about 3000 years ago. The Sessho lava shows andesitic composition (Takahashi *et al.*, 2010; Ueki and Terada, 2012). In this study, detailed descriptions in morphologies of phenocryst minerals have been carried out. We determined the modal composition of phenocrysts, and measured the aspect ratio and the crystal size distribution of plagioclase phenocryst. We also carried out the detailed description of opx-magnetite symplectite, which have been observed in several samples.

The phenocrysts assemblage of the Sessho lava is plagioclase, clinopyroxene, orthopyroxene, magnetite, and rare olivine. Groundmass shows glassy structure. Modal composition of phenocrysts shows homogeneous value in a single lava flow; 54.0 to 59.0 vol. % for groundmass, 33.4 to 38.1 vol. % for plagioclase, 2.1 to for 4.2 vol. % for magnetite, 3.0 to 6.4 vol. % for pyroxene. On the other hand, the aspect ratios of plagioclase phenocrysts show wide range of variation in a single lava flow. Fine grained plagioclase shows needle-like morphology whereas coarse grained plagioclase shows tabular morphology. Although the modal composition shows the homogeneous value, sizes of plagioclase phenocrysts show wide range of variation; samples rich in fine-grained phenocrysts and samples rich in coarse-grained phenocrysts are both present in the single lava flow.

Observations and quantitative analysis using EPMA and SEM show that the structure of plagioclase phenocrysts can be classified into following five groups; normal zoning, reverse zoning, oscillatory zoning, patchy zoning, dusty zoning. Plagioclase phenocrysts show a wide range of composition in the single lava flow. An# ranges 55-84 %. Olivine phenocryst is observed in some samples, its Mg# is -83, which is a non-equilibrium composition with its host rock.

Opx-magnetite symplectite have been observed in several samples. The symplectite show oval form. Its diameter ranges 2-4 mm. Magnetite shows lamella structure, and is concentrated at the central part of the symplectite. Orthopyroxene is 75-975 μm in diameter and distributes around the magnetite lamella. Orthopyroxene in the symplectite is characterized by its low birefringence than the typical orthopyroxene phenocrysts of the Sessho lava. This structure is estimated to be formed by the rapid oxidation of olivine, indicating that during the formation of andesite magma of Sessho lava, oxygen fugacity in the magma storage may have rapidly increased.

In conclusion, it is estimated that final temperature was homogeneous in the magma strage of the Sessho lava, because modal contents of phenocrysts in the single lava flow show homogeneous value. On the other hand, several types of the chemical composition and size of plagioclase have been observed in the lava flow, indicating rate of crystallization and cooling had variation in the magma storage of the Sessho lava. Existences of orthopyroxene-magnetite symplectite and non-equilibrium olivine indicate magma mixing and oxidization event had occurred during the formation of andesitic magma of the Kusatsu-Shirane volcano.

Boring Core Observation of the Izu Oshima Sembazaki Strain Meter Well.

KAWANABE, Yoshihisa[1*] ; ONIZAWA, Shin'ya[2] ; KOKUBO, Kazuya[3]

[1]Geol. Surv. Japan, AIST, [2]Meteorological Research Institute, [3]Japan Meteorological Agency

We report the boring core observations of strain gauge well that Japan Meteorological Agency has been installed in the Sembasaki, Izu Oshima. The location of the well is at 34 42' 20.5168 "N, and 139 21' 40.7016"E, and well altitude is 51.2m, and drilling depth is 100m. For deeper than about 70m deep, the core was recovered.

Depth from 70m to 86m is composed of volcanic breccia with thin layers of volcanic ash. Volcanic breccia is solidified and including fragments of various basalt, scoria and altered rocks. Some basalt fragments seems to be the essential with a quench rim. From the surrounding geology, this breccia can be compared to the Senzu Formation that is the product of explosive eruption at shallow sea in the first stage of Izu Oshima volcano.

The core, depth of 86m (below sea level 34.8m) or deeper, is made of fresh aphyric basaltic lava flow. At least 2 flow units can be identified. Both lava flows contain very small amount of plagioclase and clinopyroxene phenocrysts. There is no evidence that is water-cooled to the lava flow.

We performed the whole rock chemical composition analysis for basalt fragment of breccia and lava flows. All specimen have SiO_2 = 49.8 ˜52.9wt% and significantly lower K_2O content, about 0.2wt%, than the basalts of Izu Oshima volcano, except for one breccia fragment. The lower K_2O content than that of the rock of Izu Oshima volcano is consistent with the characteristics of the old basement volcanoes such as Fudeshima volcano.

In the sea floor of the west of the Izu Oshima, there are Semba spur accompanied by magnetic anomaly. Oshima et.al.(1987) pointed out that the Semba spur might be the older volcanic body and they named it Semba volcano. The height of the sea cliff is gradually increased from Sembazaki toward the north, and the highest around Tsuwai. The distribution of valleys around Tsuwai also shows the discordant rise in the foot of Izu Oshima volcano, and this discordant may lead to the Semba spur. The basalts from the Semba core indicate that the old basement volcano, Semba volcano, is also present in the Izu-Oshima southwest side.

Origin and deformation of the clastic flow bands in the Takanoobane rhyolite lava

FURUKAWA, Kuniyuki[1*] ; KANAMARU, Tatsuo[2] ; UNO, Koji[3]

[1]Faculty of Business Administration, Aichi University, [2]Department of Geosystem Sciences, College of Humanities and Sciences, Nihon University, [3]Graduate School of Education, Okayama University

In this study, we showed that the clastic flow bands, which are developed in the Takanoobane rhyolite lava, were formed by shear fracturing of the high viscous magma within the shallow conduit. The flow bands broke up into the small particle-rich flow lines, which are ubiquitously observed in obsidian lavas.

The Takanoobane rhyolite lava (TR lava) is located at the Aso caldera in the middle of Kyushu Island in SW Japan. The lava is effused at 51+/-5 ka (Matsumoto et al., 1991). The thickness, estimated volume, and bulk rock chemistry of TR lava are 60-90 m, 0.14 km^3 (Miyabuchi et al., 2004), and 71-72 SiO_2 wt.% (Furukawa, 2006), respectively. In this study, we examined two drill cores (AVL1 and AVL4) provided by the Aso Volcanological Laboratory. Both drill holes penetrated the proximal part of TR lava. TR lava is composed of an inner crystalline part and marginal glassy parts.

The black to dark gray colored flow bands within a few millimeters thick are concentrated around the boundary between crystalline part and basal obsidian. The bands are composed of clastic materials with a diameter below a few mm. The clastic materials are composed of glassy lithics and minerals. Some clasts are rounded and fluidal shapes and show different textural occurrences from the surrounding rhyolite. The chemical compositions of the glassy lithics and those of glassy matrix of the surrounding rhyolite are slightly different. Within the bands, the streak texture, which is defined by difference of clasts and microlite contents, is conspicuous.

The differences in texture and chemical compositions between the clasts in the bands and surrounding rhyolite indicate that the clastic bands were not formed by autobrecciation within the lava. These observations indicate that the clastic bands are likely to be formed by shear fracturing of the high viscous magma within the shallow conduit such as Tuffen et al. (2003). The fractures would become pathway of the volcanic gasses, and the clasts were transported by the gas transport. The streak texture within the bands is interpreted as sedimentary structures, which were formed by gas transportation of clasts through fracture system. The rounded and fluidal shapes of the clasts indicate that the fracturing occurred when the conduit magma was enough hot. The clastic bands consequently break up and disappear. The bands show progressive loosening along the individual streak, where will be the structural weakness. Consequently, the streak develops into the individual thin bands. The small particles, such as glass particles, microlites and lithics, are released from margin of the clastic bands to the surrounding rhyolite. Since the high viscosity of the lava inhibits their homogenization, the particles are likely to be aligned along the flow line. The clastic flow bands, originated from shear fracturing, will thoroughly break up via this process. Our results mean that the clastic flow bands developed within silicic lavas is important for understanding of the shallow conduit system of silicic magma.

Magma chamber processes revealed by textures in plagioclase phenocrysts through Taisho eruptions of Sakurajima volcano

YAMASHITA, Shunsuke[1*] ; TORAMARU, Atsushi[2]

[1]Department of Earth and Planetary Sciences, Graduate School of Sciences, [2]Department of Earth and Planetary Sciences, Faculty of Sciences

Textures in volcanic products record important information about the origin of the rock. Especially, plagioclase phenocrysts have been studied in order to understand the magma chamber processes because they are commonly included in various types of volcanic rocks. Two types of plagioclase phenocrysts are found in lavas by the 1914-1915 eruption of Sakurajima volcano, Southern Kyushu, Japan: (1) honeycomb plagioclase(H-Pl) with large melt inclusions in cores; and(2) clear plagioclase(C-Pl) without any melt inclusions. In Sakurajima volcano, magma mixing has been suggested by bimodal compositions of plagioclase phenocrysts. However, relationship between textures and chemical compositions has not been reported. In addition, the crystal size distributions (CSDs) also may provide essential information for the production environment of the crystals. Therefore, in order to obtain insights into magma chamber and magma mixing processes, we conduct chemical composition and crystal size distribution (CSD) analyses.

We carried out chemical compositional analysis by FE-SEM. As a result, it is found that H-Pl phenocrysts have heterogeneous mozaic cores with An75-90 and An55-70 and very low An#(An40-55) around melt inclusions. On the other hand, C-Pl phenocrysts are uniform in compositions while the An contents varies from grain to grain. The histogram of An contents in H-Pl cores shows narrow bimodal distributions around An78 and An86, whereas that of C-Pl cores shows the wide bimodal distribution around An62 and An86. We carried out CSD analysis. It is found that H-Pl and C-Pl phenocrysts showed different trends. CSD of C-Pl is strongly convex-downward showing crossover with two different slopes.

We revealed plagioclase are classified into three types: (1) type-H with an An-rich (An74-89) and heterogeneous core containing large melt inclusions; and (2) type-C-1 with an An62 and homogeneous core not containing melt inclusions; and (3) type-C-2 with an An-rich (An85) and homogeneous core not containing melt inclusions. The results of CSD suggest different formation pocesses between H-Pl and C-Pl, and crossover in the slopes of C-Pl CSDs suggest the mixing of two magmas from which two populations of phenocrysts originate (Higgins, 1996b). In Sakurajima, magma mixing has been suggested, therefore it is important to understand the temperature of magmas. So, we estimated temperature on equilibrium constants by plagioclase- and alkali feldspar-liquid thermobarometers (Putirka, 2008). The results show the temperature on equilibrium constants of the dacitic magma was about 850 ℃, and that of the basaltic magma was about 1050 ℃. Since the honeycomb plagioclases are generated by the skeletal growth under high supercooling condition, the H-Pl phenocrysts is formed in the basaltic magmas during cooling at mixing events. In summary, type-H is formed by skeletal growth due to the thermal interaction during mixing events in basaltic magma, type-C-1 is formed under magma chamber with mixed homogeneous magma, type-C-2 is formed under magma chamber with the basaltic magma before mixing, respectively.

Ground Deformation of Active Volcano in Kunashiri and Etorofu Islands using InSAR time series analysis

ANDO, Shinobu[1*] ; MIURA, Yuji[2] ; MATSUMORI, Toshiyuki[2]

[1]MRI, [2]JMA

ALOS has an L-band SAR (PALSAR), which is not affected by vegetation, and the interference is good even in mountainous areas. So these methods are effective for the crustal deformation observation of volcanic areas.

In previous studies, we have reported the analysis results about all domestic active volcanic areas, using D-InSAR of ALOS since 2007. However, ALOS has suspended the operation in May 2011. Therefore, we did not do D-InSAR analysis for the period thereafter. In recent years, InSAR time series analysis technique called PS-InSAR and SBAS has been developed, a number of cases have been reported.

There are 11 active volcanoes in the Kunashiri and Etorofu island, Southern Kuril Islands. It has still continued an active volcanic activity in the some volcanoes of them. In this report, we have take advantaged of the archive data of ALOS/PALSAR, and tried to analyze the ground deformation of around these 11 active volcanoes using *StaMPS* program was developed by the Stanford Institute of Technology. Note, we analyzed except for the data captured in the winter in order to remove the effect of the snow. Also, besides PS-InSAR and SBAS methods, *StaMPS* program has the analysis methods to merge these results. Therefore, we will also present about the difference of these results.

Some of PALSAR data were prepared by Japan Aerospace Exploration Agency (JAXA) via the Coordinating Committee for the Prediction of Volcanic Eruption (CCPVE) as part of the project ”ALOS Domestic Demonstration on Disaster Management Application” of the Volcano Working Group. Also, we used some of PALSAR data that are shared within PALSAR Interferometry Consortium to Study our Evolving Land surface (PIXEL). PALSAR data belongs to Ministry of Economy, Trade and Industry (METI) and JAXA. In the process of the InSAR analysis, we used ”the ASTER Global Digital Elevation Model” was developed jointly by METI and the United States National Aeronautics and Space Administration (NASA), and Generic Mapping Tools (P.Wessel and W.H.F.Smith, 1999) to prepare illustrations.

Preliminary result of resistivity modeling around Ponmachineshiri crater at Meakandake Volcano, Japan

TAKAHASHI, Kosuke[1*] ; MATSUSHIMA, Nobuo[2] ; TAKAKURA, Shinichi[2] ; YAMAYA, Yusuke[2] ; ARITA, Shin[1] ; NAGAMACHI, Shingo[1] ; OISHI, Masayuki[2] ; KAZAHAYA, Ryunosuke[2] ; FUJII, Ikuko[1]

[1]Kakioka Magnetic Observatory, Japan Meteorological Agency, [2]National Institute of Advanced Industrial Science and Technology

Meakandake Volcano, situated in Eastern Hokkaido, Japan, is an active volcano where a phreatic eruption occurs in every several years. Volcano-tectonic (VT) earthquakes mainly occurred below Ponmachineshiri crater which is one of active craters of the volcano (Japan Meteorological Agency, 2013). A source region of the tremors occurred before the 2008 eruption was estimated beneath the southern slope of the crater (Ogiso and Yomogida, 2012). Significant changes in the geomagnetic field were observed in 2008 and 2009 around the crater. Hashimoto et al. (2009) pointed out that the temporal variations of the geomagnetic field in 2008-2009 were due to the thermal demagnetization of the material beneath the southern slope of the crater.

These VT earthquake, tremor and rock demagnetization events probably associated with the movement of volcanic fluids such as hydrothermal water, gas and melt. Therefore, understanding of a hydrothermal system of the volcano is a key to reveal the mechanism of the tectonic events occurred there.

Resistivity of rock strongly depends on the fluid inclusion. Therefore, an electro-magnetic measurement is an effective method to image the fluid distribution. We conducted audio-frequency magnetotelluric (AMT) surveys in August 2013 on the western slope of the volcano. The objective of the survey is to reveal the resistivity structure around Ponmachineshiri crater and to infer the relationships among the fluid distribution, the seismic focal area, and the demagnetized area around the crater.

Since we have not finished the AMT survey on the eastern slope of the volcano yet, the resistivity structure around the Ponmachineshiri summit crater is not well-constraint. Therefore, we present the two-dimensional resistivity structure beneath the western slope of the volcano as a preliminary result. The characteristics of the resistivity distribution are described as follow.

1) A resistive (more than several hundred Ω m) layer locates at the top of the western slope of the volcano. Its thickness varies from 100 to 300 m on the profile. This layer can be regarded as a permeable lava or pyroclastic fall deposits.
2) Below the resistive surface layer, two conductive (less than 10 Ω m) bodies are found. One is located to the west of Ponmachineshiri crater at depths of 300-1000 m from the surface. This conductor corresponds to a hydrothermal reservoir which relates to the fumarolic activity in the crater. The second conductor is found beneath the western part of the profile at a depth of about 1000 m from the surface. The discharge of hot spring water at the west of our survey region suggests that this conductor can be explained by the presence of the hydrothermal fluid and/or the altered rocks.
3) A resistive area (more than several hundred Ω m) exists below the two conductors. Causes of this high resistivity are unknown yet.

Variation of Geomagnetic Total Intensity at Meakandake Volcano after the Eruptions in 2008

SHIMAMURA, Tetsuya[1*] ; ARITA, Shin[1] ; MASHIKO, Norimichi[1] ; FUJII, Ikuko[1] ; FUKUI, Keiichi[1] ; OGISO, Masashi[2]

[1]Kakioka Magnetic Observatory, JMA, [2]Matsushiro Seismological Observatory, JMA

This study reports on the geomagnetic total intensity change at Meakandake volcano and its relations with volcanic activity after eruptions in 2008.

Meakandake volcano is located in eastern Hokkaido and is a volcanic complex which consists of eight volcanoes, such as Ponmachineshiri, Nakamachineshiri, Akanfuji and so on. Ponmachineshiri has been active in recent years and minor phreatic eruptions repeatedly occurred in 1988, 1996, 1998, 2006 and 2008.

Kakioka Magnetic Observatory, Japan Meteorological Agency has carried out a repeat observation of the geomagnetic total intensity in one or two times a year since 1992 for the purpose of detecting geomagnetic field changes accompanying the volcanic activity of Meakandake volcano. Twelve repeat stations were installed on the east side of summit crators' edge and south slope of Ponmachineshiri in 1992 and since then we have improved the repeat station network step by step. About thirty stations are used recently. A continuous station of the geomagnetic total intensity (MEA) was installed on the south slope of Ponmachineshiri on October 16, 2003 in order to improve the time resolution of the observation. Then, a new continuous station (ME2) was installed between the 96-1 crater of Ponmachineshiri and MEA on September 28, 2013. The geomagnetic intensities are acquired every 5-minutes at MEA and ME2.

A significant decrease of the geomagnetic total intensity was observed at Meakandake volcano in July, 2013 and continues up to now (January, 2014). The total intensity varied with the eruptive activity in 2008, and no remarkable change of the total intensity was seen for thirty months from January 2011 to June, 2013. There has been no significant variations in volcano-tectonic earthquakes, tremors, volcanic smoke and tectonic deformation at Meakandake volcano since July, 2013 (Volcanic Observations and Information Center, Sapporo District Meteorological Observatory, JMA), which differs from the situation at the 2008 eruptions when significant variations of the total intensity and the other tectonic measurements were observed.

It is assumed that the decrease of the geomagnetic total intensity at Meakandake volcano in 2013 is due to the thermal demagnetization accompanying heating of the inside of the volcanic body. A source of the thermal demagnetization was estimated beneath the southern slope of the 96-1 crater at Ponmachineshiri by using geomagnetic total intensity changes at repeat stations for about 3 months from June to September, 2013. This source location is almost the same as that of the demagnetization in 2008. And it is inside the focal area of migrating volcanic tremors which occurred on November 16, 2008 reported by Ogiso and Yomogida (2012). We used MaGCAP-V (Seismology and Volcanology Research Department, Meteorological Research Institute, JMA, 2013) as a support software for the modelling of the demagnetization source.

It is indicated that the position of the thermal demagnetization source has not changed for last four months, because the difference of the geomagnetic total intensities at two continuous stations (MEA and ME2) has been almost constant since the end of September, 2013.

Only the geomagnetic total intensity detects a possible on-going heating process inside the Ponmachineshiri which commenced in July 2013. This case strongly suggests that the observation of the geomagnetic field is important to monitor heating or cooling of the volcanic body. The observation with two or more continuous stations is effective in order to monitor the source position of the thermal demagnetization. In addition, Hashimoto *et al.* (2009) suggested a possibility of the volcanic eruption prediction at Meakandake volcano, because a decrease of the geomagnetic total intensity was observed two days before the eruption on November 18, 2008 when the amplitude of the volcanic tremors had been increased.

Recent volcanic deformations observed by campaign GPS on and around Mt.Tokachi and Mt.Meakan

WADA, Sayaka[1*] ; MORI, Hitoshi, Y.[1] ; OKUYAMA, Satoshi[1]

[1]Hokkaido University, Institute of Seismology and Volcanology

Mt. Tokachi is one of the famous active volcanoes located in the central Hokkaido, Japan. In the recent 100 years, major magmatic eruptions at Mt. Tokachi occurred in 1926, 1962 and 1988-1989. Mt. Meakan sits in the eastern Hokkaido. It is also an active volcano and made phreatic eruptions in 1996, 1998, 2006 and 2008.

In this study, we will discuss the results of the campaign GPS on and around Mt. Tokachi and Mt. Meakan. Each broad area GPS observation had begun at Mt. Tokachi in 2007 and at Mt. Meakan in 2006. The campaign GPS observation for Mt. Tokachi made at 12 sites and that for Mt. Meakan at 8 sites, for several days to weeks in each year.

We used the data of our campaign observations since 2007 for Mt. Tokachi and after the 2008 eruption for Mt. Meakan. For evaluating spatial deformation pattern in more detail, we also used the data of several GPS sites operated by JMA (Japan Meteorological Agency) at the same time. Analyzing these data, annual movements at those stations were estimated. The regional tectonic movement and the coseismic step of Tohoku-oki earthquake on March 11, 2011 are included in those movements. We used the continuous data at GEONET sites by Geospatial Information Authority of Japan (GSI) around the volcanoes to make corrections for non-volcanic deformations. Using the GEONET data from 2007 to 2013, the regional tectonic and the seismic deformations were estimated by linear approximation in space. Seasonal changes should be taken into consideration to study the volcanic deformation. The discussion about deduced volcanic deformations will be made, after the corrections about the regional deformation, the coseismic step and the after slip of 2011 Tohoku-oki earthquake, and the seasonal variations.

Acknowledgements

In this study, JMA, Sapporo District Meteorological Observatory furnish their observation data to us. We would like to express our gratitude to them. Also, we used the data of GEONET sites of GSI with thanks.

The Volcanic activity of Tarumaesan Volcano in 2013 and Trial of Application to the Eruption scenario

NAGAYAMA, Hiroaki[1*] ; MIAYAMOTO, Masashi[1] ; FUJIMATSU, Jun[1] ; USUI, Yuji[1] ; FUSHIYA, Yuji[1] ; MIYAMURA, Jun'ichi[1]

[1]Sapporo Regional Headquarters, JMA

Continuous observation network with tiltmeter and strainmeter in Mt.Tarumae, which is located on the southeastern edge of Shikotsu caldera, operated by Japan Meteorological Agency (JMA) and Hokkaido University Institute of Seismology and Volcanology (ISV) detected volcanic ground deformation during June 19 to July 4, 2013. According to the Mogi model (Mogi, 1958), the ground deformation is interpreted as volume increase of about $10^5 m^3$ at about 3-4km in depth beneath sea level around Mt.Kitayama, is located in about 1.5km northwest from Tarumae summit. It is different from the deformation in shallow region (above the sea level) beneath the summit, reported by MRI (2008), the Meteorological Reaearch Insutitude, and ISV et al.(2011). According to the classification suggested by MRI (2013), it is correspond to slowly accumulation process of magma, as magma chamber or dike intrusion. B-type earthquakes, have been occurred in shallow region (˜sea level) beneath the summit, became active slightly in synchronization with the ground deformation. As a result of the process of volcanic fluid, the actual medium is unknown, rise to the volume increase area (depth 3-4km), it is interpreted as an increase in heat flux to shallow region beneath the summit.

Volcano-tectonic earthquake (VT earthquake) activated at a depth of 3-5km surrounding the deformation area in mid-July, after ground deformation, it is still ongoing. The VT seismicity was very active until August and maximum shock was M3.0 in late September. VT earthquakes have occurred in the relative high resistivity layer (50-500Ωm) of Resistivity imaging by Yamaya et al. (2005, 2012). Whereas, it have not occured in the deformation area and the path to beneath Tarumae summit, that is relative conductive area.

Order to carry out disaster prevention appropriately and promptly in the eruption, JMA has operated the eruption alert level on 31 volcanoes across the country. It is intended to share the consciousness of the local government by flow assuming the transition of volcanic activity, called the eruption scenario. For operating the level effectively, the eruption scenario, flow chart assuming the progress of the volcanic activity of each volcano, has been shared with the local government. As lastest magma eruption is in 1909, major volcanic activity had been occured in the very shallow part around lava dome for a long time. It is unknown what the phenomenon is observed when the magma is supplied to the shallow depth from the deeper. Therefore, the scenario that assumed the magma eruption is supplemented by the general knowledge that was observed at other volcanoes. The mechanism of the deformation and VT-seismicity is not clear. But, it can be considered of the distribution that related to the heat supply system or the geological structure beneath Tarumae. In this study, we tried to apply the interpretation of the ground deformation and VT-seismicity to the eruption scenario. However, our interpretation on the activity is unverifiable evidence so poor at present. In order to improve the eruption scenario certainly, elucidation of the magma supply system in Tarumae is essential, but it is not clear at present. To clarify the magma supply system, it is necessary to more information of geological structures and obseved results such as ground deformation and VT-seismicity in this time. However, we are at present able to investigate detection of the high attenuation region used natural earthquake and to estimate fault plane solutions of VT earthquake (P-axes) using P-waves, and would like to approach. In addition, it is necessary to operate new observation system to capture phenomena such as seismic activity and ground deformation more certainly due to magma rising from the deep.

Acknowledgment:In this study, we use the data of ISV, tiltmeter and strainmeter, and the waveform data. Thank you for permission to use data.

Volcanic activities of Hakkoda volcano after the 2011 Tohoku-Oki earthquake

YAMAMOTO, Mare[1*]

[1]Geophysics, Science, Tohoku University

The 2011 Tohoku-Oki earthquake of 11 March 2011 is one of the largest earthquakes in recent times, and it generated large displacements and deformation in and around the Japanese islands. Such large crustal deformation, especially the east-west extension exerted on Tohoku area, raises fear of further disasters including triggered volcanic activities as well as triggered seismicity. To assess the potential risks of triggered volcanic activities, understanding of the behavior of volcanic fluids in the crust and volcanic bodies would be a key. In this presentation, as examples of such possibly triggers volcanic activities, we report the recent seismic activities of Hakkoda volcano, and discuss the relation to the movement of volcanic fluids.

Hakkoda volcano is a group of stratovolcanoes at the northern end of Honshu Island, Japan. There are fumaroles and hot springs around the volcano, and phreatic eruptions from Jigoku-numa on the southwestern flank of Odake volcano, which is the highest peak in the main cones of Northern-Hakkoda volcanic group, were documented in its history. Since just after the occurrence of Tohoku-Oki earthquake, the seismicity around the volcano became higher, and the migration of hypocenters of high-frequency volcano-tectonic (VT) earthquake was observed.

In addition to these VT events, long-period (LP) events started occurring beneath Odake at a depth of about 2-3 km from February, 2013, and subtle crustal deformation caused by deep inflation source was also detected by GEONET GNSS network around the same time. The characteristics of LP events are summarized as follows: (1) The spectra of LP events are common between events irrespective of the magnitude of events, and they have spectral peaks at 6-7 sec, 2-3 sec, 1 sec, and so on. (2) The long-period component of LP events appears as a wave packet of a few cycles, and high-frequency ($>$1 Hz) signals sometimes overlaps it. (3) LP events sometimes occur like a swarm with an interval of several minutes. These characteristics of LP events at Hakkoda volcano are similar to those of LP events at other active volcanoes and hydrothermal area in the world, where abundant fluids exist. Our further analysis using far-field Rayleigh radiation pattern observed by NIED Hi-net stations reveals that the source of LP events is most likely to be a nearly vertical tensile crack whose strike is almost parallel to the direction connecting Odake summit crater and Jigoku-numa. The number of VLPs gradually decreased after September, 2013, and high-frequency VT earthquakes became more dominant in the seismicity around Hakkoda volcano. However, there were a burst of earthquakes beneath Southern-Hakkoda volcanic group, that includes a few low-frequency earthquakes, at the end of December, 2013.

These results suggest that the extensional steress field generated by the 2011 Tohoku-Oki earthquake causes the upward movement of volcanic fluids and heat from the deep, and results in an activation of hydrothermal activities at the pre-existent fracture zone at Hakkoda volcanic group.

New knowledge of eruptive sequence in Heian eruption of Towada volcano

HIROI, Yoshimi[1*] ; MIYAMOTO, Tsuyoshi[2]

[1]Grad.Sci.Tohoku Univ., [2]CNEAS.,Tohoku Univ.

1. Introduction

Heian eruption is the latest activity at Towada volcano, in Heian period (eruptive episode A : Hayakawa,1985). This eruption has been started from Nakanoumi caldera lake (Kudo,2010) filled with lake water, and repeated magmatic and phreatomagmatic eruption alternately. The details of the eruptive sequence have already been shown by Hiroi and Miyamoto (2010), however, we got and report new knowledge about the activity of first plinian phase and the occurrence mechanism of large pyroclastic flow unit.

2. Ash layers within unit OYU-1

The first plinian pumice fall unit OYU-1 has a SW dispersal axis and it achieves 50km farther. OYU-1 in distal shows very well sorting and uniform grain size distribution , but we found plural outcrops that OYU-1 accompanies with fine ash layers within 12km from source vent. Two kinds of ashes are observed, one is a beige colored ash in the lower part of OYU-1. The thickness is about 1-8 cm, and dispersal area is SW-SSE. Others are gray colored ashes and intercalated in the upper part of OYU-1. Their thicknesses are about 1-3 cm, and each dispersal area is SW-SSW.

All of ashes are intercalated in pumice layer, and the boundary between pumice layer and ash one is almost clear. Because OYU-1 without ash layers in distal shows uniform grain size distribution, the extent of these ashes deposit is limited in narrow area if their ash had been accumulated during the plinian column formation. The clear boundaries between pumice and ash suggest that ash layers are not fall deposit accumulated for a long period, but flow deposit piled in a very short time. Ash layers can be found not only a valley, but the little highland such as a mountain ridge line. This feature of distribution shows that they are regarded as surge deposit.

Because the ashes intercalated with pumice layer in OYU-1indicate the feature of density current, they are intra-plinian flow. As one of their origin these ashes are derived from small-scale density current by the partial column collapse. The dispersal area of the ashes is limited adjacent to source vent and just only the direction of dispersal axis. This tendency of distribution seems that it corresponds with the direction of strong wind of 22[m/s] blew.

On the other hand, the source vent within a caldera lake and the fine grain features of ashes indicate a possibility that ash layers are phreatmagmatic base-surge deposit. In that case the occurrence of magma-water explosion might be caused by satisfying a condition of magma-water ratio partially or temporarily on the surface of eruption collumn. Unit OYU-2, overlying OYU-1 pumice fall directly, is phreatomagmatic base-surge deposit. Thus these ash layers may be a precursor phenomenon of eruptive style transition.

3. Distribution and draining style of KPf

Kemanai Pyroclastic flow is the climax deposit of Heian eruption, the total volume is estimated about 5km3(Hayakawa,1985). KPf distributes only the south area of Towada caldera, except for Oirase River to east direction. The Towada caldera rim is lowest at southwest edge (630m above sea level). The highest outcrop of KPf on caldera rim is located in 760m. In spite of adjacent to the source vent KPf cannot be shown on Mt. Akaiwa(785m) on the south caldera rim. These distribution features suggest that KPf flew out over the lower part of caldera rim. KPf deposit has been regarded that it occurred by plinian column collapse of preceded unit OYU-3 (Matsu-ura et al.,2007,etc.). But the column collapse type pyroclastic flow can be accumulated in high-altitude, KPf seems to be piled on only lower portion. Thus KPf is not occurred by column collapse, but derived by currents over the lower caldera wall. This conclusion agrees with the new eruptive sequence by Hiroi and Miyamoto(2010), that the unit just before KPf is not plinian pumice fall OYU-3, but phreatomagmatic base-surge unit OYU-4 without higher eruption column.

Petrological study of northern part of ca. 300-100 ka volcanic edifices in Zao volcano.

TAKANO, Toru[1*] ; INOUE, Tsuyoshi[2] ; BAN, Masao[3] ; OIKAWA, Teruki[4] ; YAMASAKI, Seiko[4]

[1]Graduate School of Department of Earth and Environmental Sciences, Yamagata University, [2]Nippon Koei Co., Ltd., [3] Department of Earth and Environmental Sciences, Faculty of Science, Yamagata University, [4]Institute of Geology and Geoinformation, Geological Survey of Japan, National Institute of Advance

Zao volcano is a Quaternary stratovolcano located in the middle part of the volcanic front of northeast Japan arc. The volcanic activity started at about 800 ka, and has continued to present. During ca. 300 to 100 ka activity of the Zao volcano, several middle sized edifices were formed. These volcanic edifices can be divided into northern and southern parts. We performed petrologic study on eruption products of the northern part to reveal the variation of magma compositions along with the evolutionary history.

Eruption products are divided into 8 units from lower to upper: Yokokurayama lavas, Kanshodaira lavas, Jizosan west lavas, Kumanodake west eruption products, Kumanodake main edifice products, Jizosan east agglutinate and lavas, Kumanodake agglutinate and lavas, Umanose eruption products. Yokokurayama lavas, Kanshodaira lavas, and Jizosan west lavas are composed of andesitic lavas. Kumanodake west eruption products are consisted of andesitic lapilli tuff, tuff breccia, agglomerate, and andesitic lavas. Kumanodake main edifice products are consisted of alternation of andesitic lavas and pyroclastic rocks in the lower part, and andesitic tuff breccia and agglomerate in the upper part. Jizosan east agglutinate and lavas, Kumanodake agglutinate and lavas are consisted of basaltic andesitic agglutinate, agglomerate, and lavas. Umanose eruption products are mainly composed of basaltic andesitic lavas, with subordinate amounts of agglomerate.

The eruption center of the Yokokurayama lavas would be located westward from the main chain of eruption centers. The main eruption centers for the other units were located in between the Kumanodake-Jizosan area. Jizosan east agglutinate and lavas, Kumanodake agglutinate and lavas, Umanose eruption products are characterized by the agglutinate and/or agglomerate distributing near the eruption centers.

All of eruption products belong to medium-K calc-alkaline series. All units other than the Yokokurayama lavas are plotted on same general trends in most of the SiO_2 variation diagrams. The Yokokurayama lavas show a lower trend than the other units in K_2O diagram. Other than the Yokokura lavas, the lower four units are andesitic, whereas upper three units are basaltic andesitic. Looking at in detail, slight differences in compositions can be observed among units. Among the four andesitic units, Kumanodake main edifice products show higher trends in the Cr, Ni, Zr, Nb diagrams and a lower trend in Rb diagram than the others. The Umanose eruption products are plotted in higher part in Cr and Ni diagrams from the trends of the other products.

Characteristics of data observed by multi-component strainmeter installed at Senba, Izu-Oshima

YAMAMOTO, Tetsuya[1*] ; ANDO, Shinobu[1] ; KOKUBO, Kazuya[2] ; KOBAYASHI, Akio[1] ; KIMURA, Kazuhiro[1]

[1]Meteorological Research Institute, [2]Japan Meteorological Agency

Meteorological Research Institute installed a multi-component borehole strainmeter at Senba Station in Izu-Oshima, one of the most active volcanos in Japan, in February 2013. By the strainmeter, we aim to research on evaluation of volcanic activity by means of crustal deformation and also to monitor the activity of the volcano. In many cases, unavoidable drift were shown in data of strainmeter installed in a borehole from just after the installation for several years. In order to utilize the strainmeter for volcano monitoring effectively, it is important to grasp the drift and noise quantitatively from early stage of observation. We report a result of research about characteristics of the data observed for about a year.

The strainmeter has 4 sensors which measure linear strains in the horizontal plane in every 45 degrees. In data observed by the sensors, tidal variation of about a day or half day period over 500 nano-strains is obvious, as well as a long term variation. Generally only three components are independent in a plane, the strainmeter has redundancy and it makes us possible to evaluate quality of the data. Examining hourly mean values, all strain components look consistent in the period range of a day or half day. It suggests the data of strain are reliable in the period. On the other hand, the long term variation has an inconsistency as much as 4 micro-strains for 6 month. The inconsistency could be caused by only one sensor of the four, it is difficult to conclude what amount of volcanic deformation is observed at the present stage. In the periods shorter than a half day, almost all variation is less than 2-3 nano-strains. It indicates the accuracy of observation for a short interval.

Gravity changes during magma accumulation period in Izu-Oshima volcano

ONIZAWA, Shin'ya[1*] ; TAKAGI, Akimichi[1] ; FUKUI, Keiichi[2] ; ANDO, Shinobu[1]

[1]Meteorological Research Institute, JMA, [2]Kakioka Magnetic Observatory, JMA

Since March, 2004, we have been conducting series of campaign gravity measurements, in order to understand magma accumulation process and to detect eruption precursor of Izu-Oshima volcano. Here, we show calibration results of relative scale factors between gravimeters, and characteristics of temporal gravity changes observed in the volcano.

We have been measuring relative gravity changes in the volcano using three instruments; LaCoste & Romberg Type-D #109, Scintrex CG3M #454, and Scintrex CG5 #033. Gravity differences in our campaign network are about 180 mgal in maximum from the coastal sites to the summit sites. Such large differences easily induce systematic deviations between data obtained by different instruments, when gravimeter scales are not calibrated. Further, temporal changes in the scale factor of Scintrex CG3M have been reported by some previous gravity researches.

Since scale calibrations using absolute gravity networks had not conducted until 2012, we cannot absolutely calibrate for past data. However, we can check relative scales between gravimeters and their temporal changes by comparing campaign data obtained simultaneously. The scale factor for CG3M#454 relative to one for D#109 shows clear temporal decrease. One for CG5#033 also shows change at breakdown occurred in 2010. This can be explained by a parameter change done by the maker during repairing processes. Furthermore, we found a non-linear relationship between D#109 and CG5#033, which implies a non-linear scale factor of either instrument. Probably, the non-linearity occurs in LaCoste & Romberg Type-D, and we should calibrate further.

Although calibrations of each instrument are still not sufficient to discuss smaller gravity changes down to c.a. 10 micro-gal, we can find systematic temporal changes in relative gravity by correcting relative scale factors. Gravity increases at higher altitude sites relative to coastal sites are observed during a two-year period from July, 2008 to June, 2010. Temporal changes in relative gravities reaches up to 100 micro-gal in maximum. A spatial pattern of the changes suggests its center is at the northern caldera, which implies some relationship with ground deformation sources inferred by GPS data. However, both the amplitudes and phases of the relative gravity changes can never be explained by the ground deformation observed during the period. The change seems to be related to temporal changes in precipitation. Increase in water content in vadose zone may be one of possible factor of the changes. Apart from these candidates, we tentatively inferred source location and mass increase by assuming single point mass source. The best fit location after grid searches was at depth of 3 km b.s.l. beneath the northern caldera, where approximately coincides with the ground deformation source. However, the estimated mass increase is as much as 1.8×10^8 ton, which is equivalent to erupted materials of one large scale eruption of the volcano. It is difficult to accept easily such large amount of mass increase without any another significant signs. To detect signs of magmatic activities and to evaluate volcanic activities appropriately by gravity measurments, it is important to calibrate instruments further and to evaluate effects of environmental factors such as precipitations.

Preparation for the practical use of unmanned observation robots in the next Izu-Oshima eruption

SAIKI, Kazuto[1*] ; ICHIHARA, Mie[2]

[1]Graduate School of Science, Osaka Univ., [2]Earthquake Research Institute, Univ. of Tokyo

In the case of a volcanic eruption, in order to carry out evacuation guidance, it is important to observe the changing situation from just after the eruption to the completion of evacuation. In the 1986 eruption of Izu-Oshima, the explosive eruptions occurred at the unexpected points such as caldera floor and outside of a caldera. Therefore, volcanologists could not approach the vents and the opportunity of observation to gain the precious data for scientific understanding of the eruption phenomenon or disaster mitigation was lost. Moreover, during the evacuation from the island, the situation of the eruption had not been announced correctly to residents, and the mistaken information that the lava flow cut off the traffic between Okada-Motomachi was spread. Today, 20 years or more pass since a previous eruption in Izu-Oshima, and it has become the time to prepare the next eruption. In order to improve the situation at the time of the next eruption, development of the new observation robot which can respond immediately to an eruption and the establishment of an operation framework are required. From such a viewpoint, the author started Izu-Oshima Unmanned Observation Robot Symposium in 2009. This symposium is intended to bring together experts developing unmanned observation robots from different study fields such as volcanology, space engineering, and disaster relief to Izu-Oshima and to provide them the opportunity of field tests and exchange of knowledge to make them accelerate the development of the robots and the establishment of the operation framework. For these four years, many participants gathered to perform field test and to have an active information exchange. 8 UGV and 2 UAV from 9 research groups (2009), 5 UGV and 2 UAV from 5 groups (2010), 13 UGV and 3 UAV from 9 groups (2011), and 13 UGV and 6 UAV from 10 groups (2012) participated in the symposium. In the 2013 fiscal year, Izu-Oshima was hit by the 27th typhoon of the year just before the symposium. While an open lecture meeting was canceled, 5 UGV and 1 UAV from 6 groups performed field tests. In the 2013 fiscal year, we started to obtain an accommodation of the research funds for this activity from the specific joint research B of Earthquake Research Institute of the University of Tokyo. Furthermore, installation of volcano monitor cameras was also begun by inhabitants' cooperation. At the presentation, the results so far and a future view will be shown. For further detail of the symposium in the current fiscal year please refer to the following URL (http://www.volcano-robot.org/index.html). Izu-Oshima monitor camera can be accessed by the following URL (http://www.volcano-robot.org/oshima_camera/monitor_top.php) .

Pressure sources of Miyakejima volcano estimated from crustal deformation

FUKUI, Miyo[1*] ; MATSUSHIMA, Takeshi[1] ; OIKAWA, Jun[2] ; WATANABE, Atsushi[2] ; OKUDA, Takashi[3] ; OZAWA, Taku[4] ; MIYAGI, Yosuke[4] ; KOHNO, Yuhki[4]

[1]SEVO, Kyushu University, [2]ERI, University of Tokyo, [3]EVRC, Nagoya University, [4]NIED, Japan

Miyakejima volcano had deflated after the 2000 eruption. The deep region of the volcano has inflated since 2006 (JMA, 2013). It suggests magma accumulation for future eruptions. JMA, GSI, JCG and NIED independently observe crustal deformation using GPS. However, the observation networks are not enough to reveal the magma accumulation model.

A dense GPS campaign observation started in Miyakejima from 2011 associate with Kyushu University, University of Tokyo, Nagoya University and NIED. New GPS observation points have been established every year to improve spatial resolution of crustal deformation and estimation of the magma source parameter. In 2013, our observation network are constructed 21 points in total including new two points near summit crater where no observation after the 2000 eruption.

By assembling all the continuous GPS data that has been observed by each institution, and our observation data, integrated processing was made so as to measure the precise crustal deformation on the island for two years in 2011-2013.

As the result, the obtained deformation in this study indicates inflation in the south region of Miyakejima and deflation around the crater. The estimated magma sources are a shallow deflation sill source under the crater, a southern inflation dyke source and a deep inflation spherical source. Ozawa & Ueda (2011) estimated a flat source under the caldera using InSAR technique. The parameters of this model are consistent with our sill model. Further, only deep spherical inflation source estimated in prior studies cannot be described the observed deformation during this period. We think the supply of magma began to new inflation dyke source from deep spherical inflation source. In order to monitor the inflation source, it is necessary to enhance the southern observation network and obtain more detailed geodetic data.

The products of 2012-2013 mud eruption event at Million Dollar Hole crater, Ioto volcano

NAGAI, Masashi[1*] ; TANADA, Toshikazu[1] ; UEDA, Hideki[1] ; KOBAYASHI, Tetsuo[2]

[1]National Research Institute for Earth Science and Disaster Prevention, [2]Kagoshima University

Explosive eruptions occurred several times in the period from February 2012 to April 2013 at the Million Dollar Hall crater in Ioto (Iwo Jima) Island. The situation of eruptions and properties of the ejecta are summarized as follows.

At the eruption occurred in the duration from 7 to 9 February 2012, muddy volcanic ash were erupted from vents arranged NNW-SSE direction. The main vents were consist of follows. Vent A that occurred within the existing crater (25m in diameter, approximately 10m deep) at south-southeast side, vent C that was occurred in center of the existing shallow crater (30m in diameter) at north-northwest side, and vent B that was probably newly formed between the two. Thickness of ejecta layer was 30 or 40 cm on rim of each vent. Because isopach contours are irregularly shaped, tephra are estimated that were emitted directionally from each vent. Then, small scale muddy volcanic ash release and steam plume activities was followed.

The eruption on 17 to 18 February 2013 was the largest. Muddy volcanic ash were erupted from the location of vent A and B, and fell on the western side. Thickness of ejecta layer are 1 to 3 meter on vent rim. Cinders and minor man-made Objects there were possibility of ballistic ejecta reached distant point approximately 220m at the maximum from the vents. After the eruption, vent A and B were combined into a single crater (35m in diameter, 17m deep). In addition, the formation of collapse crater about 40m in diameter began at the location of vent C.

The eruption on 11 April 2013 was occurred at the collapse crater (vent C). Muddy volcanic ash deposited on the southern side. The maximum thickness of ejecta layer is 45 centimeter on the vent rim. Ballistic cinders were witnessed at the eruption, but the limit of distribution was not estimated. Vent C was combined with vents A. Therefore, the whole shape of the crater became a cocoon (60m in major axis, 17m deep). Thereafter, the crater has remained in calm state.

Volcanic ash that erupted in the series of eruptions were wet at the ejection and deposition. They are composed mainly of hydrothermal alteration clay consisting of smectite and kaolin minerals and also includes large amount of lithic fragments, free crystals and volcanic glass fragments that are altered varying degree. In addition, pieces of glass and iron piece of man-made weaponry, which is said to have been abandoned after World War II. In addition, pieces of glass and iron which were derived from weapons abandoned immediately after World War II are also included. Ballistic cinders consists of such as tuffaceous sandstone, tuff and altered trachyandesite.

Eruptive volume of each eruption are estimated approximately as follows. The eruption in February 2012 is 800 m^3, the eruption on 17-18 February 2013 is 11,000 m^3, and the eruption on April 11, 2013 is 2,000-4,000 m^3. Total volume is 14,000 to 16,000 m^3 approximately. On the other hand, total amount of subsidence in this peroid is 10,000 to 15,000 m^3, it is roughly equal to the eruptive volume.

These eruptions are considered phreatic explosion that blew off strongly altered rocks surrounding the hydrothermal reservoir and shallow non- or weakly altered tuffaceous rocks. It indicates that the hydrothermal activity under Million Dollar Hole crater became active in relation to rapid crustal deformation that occurred in Ioto from early 2011 to May 2012.

2013 eruption of Nishinoshima volcano, Ogasawara islands, Japan

ITO, Koji[1*] ; ONO, Tomozo[1] ; SASAHARA, Noboru[1] ; NOGAMI, Kenji[2]

[1]Japan Coast Guard, [2]Volcanic Fruid Research Center, Tokyo Institute of Technology

Nishinoshima volcano is a basaltic to andesitic maritime volcano on the volcanic front of the Izu-Bonin arc. For the first time ever, the submarine eruption including movement of vents and development and disappearance of new islands happened off the southeastern coast of the Nishinoshima island in 1973. The eruption stopped in May 1974 and the Nishinoshima island and the new volcanic islands were joined by sand drift in June. Then geographic changes was continued by erosion and sand drift till 1990s.

The eruption column and new volcanic island were firstly discovered by the airplane of Japan Defensive Force on 20 Nov. 2014. Then Japan Coast Guard found the new volcanic island with violent phreatomagmatic eruption. The following day, 21 Nov. 2013, phreatomagmatic eruption had occurred and volcanic edifice was developing. The eruption style changed into the Strombolian-type and lava started to flow from the vent on the eastern flank of main edifice on 22 Nov. 2013. In succeeding days, lava emerged from the western vent and pyroclastic cone was built up in the large crater in the center of main edifice. The vent of the pyroclastic cone effused blue-white volcanic gas consistently and spatter occasionally. On 24 Dec. 2013, new vent started to produce eruption colmun at the north of the central vent. These vents are located on the 1973 vents.

The new volcanic island consists of lava flow and water depth around eruption center may be almost constant, so growth rate of the island and magma supply rate should be equal. The growth rate estimated from the air photo is almost constant, hence the magma supply rate may be kept constant.

It is unclear that when did this volcanic activity start. But high temperature anomaly and difference of normalized water-leaving radiance within sea water are shown at the southern sea area in the satellite images published by the Earth Observation Research Center on Nov. 7. The volcanic activity may start on or before Nov. 7.

Future volcanic scenarios are uncertain, but volcanism is still active and shows no sign of end of eruption as of early-February.

The recent volcanic activities of Mt. Asosan

KATO, Koji[1*] ; NAGATO, Shinya[2] ; MATSUSUE, Shinichi[2] ; HIRAMATSU, Hideyuki[2]

[1]Japan Meteorological Agency, [2]Fukuoka District Meteorological Observatory

Mt. Asosan is one of the most active volcanoes in Japan.
In Mt. Asosan, volcanic tremor amplitude and volcanic earthquakes increased on September 2013. On November 2014, water level of crater lake decreased. On December 2014, volcanic tremor amplitude increased again and the emission rate of the SO2 increased. On January 2014, Mt. Asosan erupted. We report about recent volcanic activity of Mt. Asosan

Gravity variation near the crater of Aso volcano and gravity contribution of precipitation

HAYAKAWA, Hideaki[1*] ; KAGIYAMA, Tsuneomi[1] ; OHKURA, Takahiro[1] ; YOSHIKAWA, Shin[1]

[1]Graduate School of Science, Kyoto University

We investigated the gravity variation continuously measured near the active crater of Aso volcano. At the period of low volcanic activity, the gravity variation is dominated by a contribution of water mass movement arisen from percolation of rain water and discharge in a permeable layer under about 100m.

In this study, it is used a time series measured by a superconducting gravity meter, CT-200, which installed in Hondo tunnel under 30m located in about 1000m southwest of Nakadake first crater. An analysis period is for 3 years from February, 1998 to January, 2001. Aso volcano was quiet low active for this period. The hot lake in Nakadake first crater, Yudamari, which its state is an index of the volcanic activity, had been in high water level. There were no events of drying up and eructation of volcanic ash. The gravity variation removed tide and air response shows large seasonality, increasing 20 - 40 μGal at July and August after rainy season and decreasing gradually after that. It also has some minor changes in response to precipitation, for example, an increase of about 10 μGal after autumnal rain.

It is known that precipitation has an affect on gravity. However, the effect near the crater of Aso volcano did not well understand. We computed water flux by percolation into underground and water discharge from a permeable layer using a kind of physical model of storage function method known as tank model. Model input is amount of precipitation measured at Asosan meteorological station by Japan Meteorological Agency. The change of water volume contained in underground is computed from input-output difference of tank model. The gravity contribution is obtained from the corresponding density change in a region of 1400km in north-shouth and in east-west around the gravity meter with thickness from surface to 200m depth. It assumes that there is no gravity change by volcanic activity. Outflow resistance of a tank and permeable layer depth are decided so that the gravity contribution fits in the measured gravity variation as much as possible.

The gravity contribution of water mass movement by model computation is well coincident with the measured gravity variation in the case that rainwater percolates under 100m in vertically and is discharged horizontally from the permeable layer at 100 - 110 m depth. The model value correlates highly with the measured gravity value in the coefficient of 0.9. The root mean squares (RMS) are 10.5 μGal for the measured gravity and 11.4 μGal for the model computation, and 4.8 μGal for difference between the two. The model computation overestimates to a certain degree. It is considered for a reason of the discrepancy that percolation and ground water flow in general are complicate and non-linear phenomena in contrast to our linear model. However, the model computation represents sufficiently figures of the measured variation and explains it in accuracy of 14.4 μGal in 3σ RMS of the difference. The contribution of water mass movement in shallow underground to 110m depth is inferred to be main component of gravity change near the crater.

The water mass movement can be computed at any period of time. In this study, we obtained the gravity contribution under 30m where the gravity meter located in. Converting it to on ground, the model prediction is available for use in correction of values measured near the crater in the repeated gravity survey at Aso volcano area. A part of discharge from the permeable layer in the computing region is considered as a source of ground water flow into Yudamari. A seasonal peak of precipitation is for about a month from June to July, however the ground water flow continues for several months after rainy season. This is coincident with the seasonal water level change of Yudamari. It is expected to estimate a possible quantity of ground water flow into Yudamari as time variation.

Thermal activities of the Nakadake first crater at Aso volcano, Japan -Unusual heat discharge events in 2012-2014-

TERADA, Akihiko[1*]

[1]Volcanic Fluid Research Center, Tokyo Institute of Technology

Aso volcano is one of the most active volcanoes in Japan in terms of the persistent release of volatiles and thermal energy from the Nakadake first crater. Throughout most of the calm period, the crater emits significant amounts of volcanic gas, including 200 - 400 tonne/day of SO_2. The first crater contains a hot crater lake, locally referred to as Yudamari with a diameter greater than 200 m. Applying the model of Ryan et al. (1974), which involves the effects of free and forced convection, Terada et al. (2012) estimated that during the calm period, the heat discharge through the lake surface is almost constant, with a value of approximately 220 MW.

The water level falls rapidly preceding an active period. The disappearance of lake water is followed by the emergence of a red-hot crater bottom or wall and a phreatic-to-phreatomagmatic and strombolian eruption sequence that lasts several months. When the volcanic activity subsides to calm period levels, the lake reforms. These dramatic falls/rises in the lake water level are likely caused by increases/decreases in the input of high-temperature steam to the crater bottom (Terada et al., 2012).

In spring of 2012, an unusual event involving the increase in water temperature and rapid decrease in water level occurred at the Yudamari crater lake. The heat discharge rates approached the figure of 600 MW which is three times higher than the representative figure in a calm period. The computational results based on energy and mass conservation indicate that the event is caused by an increase in temperature and flux of fluid inputs from the lake bottom. Preceding the event, silica content in lake water clearly increased, indicating a rise in temperature of hydrothermal system beneath the Yudamari crater lake. The event was accompanied by slight increase in SO_2 emission rate, but seismicity around the crater did not change significantly.

After September 2013, the lake water of Yudamari almost disappeared. Consequently volcanic fluid emitting from the crater bottom ascended as a buoyant plume into the air without transportation of the heat to the lake water. To estimate the rate of heat discharge from the first crater, we applied the plume rise assumption (Briggs, 1969; Kagiyama, 1981). This assumption states that the height h of a given position in a fumarole increases proportionally with time t to the power of 2/3. Video records of surveillance camera operated by Japan Meteorological Agency are used to the analysis.

In September, 2013 and December, 2013 - January, 2014, seismicity including earthquake swarms and volcanic tremors were enhanced, which were accompanied by an increase in SO_2 emission rates up to 2,000 tonne/day. During the periods, heat discharge rates are estimated to be 800-1000 MW which is several times higher than the figure measured in a calm period. The ratio of H_2O/SO_2 has been roughly maintained whereas small amount of volcanic ash including juvenile materials were continuously emitted in January 2014. This may occur as a result of an increase in amount of degassing in the conduit beneath the first crater.

Acknowledgments: I would like to thank Yoshihiro Ushiroshoji, Shinya Nagato and the Fukuoka District Meteorological Observatory, Japan Meteorological Agency for sharing their data and for providing permission for the data to be published.

The temporal changes of the shallower resistivity structure associated with a small eruptions at Aso Volcano, 2014.

UTSUGI, Mitsuru[1*] ; KAGIYAMA, Tsuneomi[1] ; HAYAKAWA, Hideaki[1] ; INOUE, Hiroyuki[1]

[1]Graduate School of Science, Kyoto Univ.

On Aso volcano, many observations and research have been made to detect the subsurface structure and detailed information about the distribution of the subsurface hydrothermal system have been obtained from previous studies. From the high-density AMT survey, Kanda et al. (2008) found a low resistivity area is localized just beneath the Nakadake first crater. This area is considered as a chamber of the hydrothermal fluid which is formed by a part of the hydrothermal fluid which is supplied from the deeper magma. In recently, the activities of the Nakadake crater were often temporarily increased. Associated with these activities, it is expected that the distribution of the subsurface hydrothermal fluid is changed and subsurface resistivity structure is temporally changed. In order to detect such a temporal change of shallow resistivity structure according to these activities, we carried out the repeated control sourced electromagnetic survey around the Nakadake crater using ACTIVE observation system (Utada et al., 2007). In these observations, we installed electric current transmitter on 1 km NNE from the crater, and magnetic receiver was also installed on the 4 points around crater.

In Aso volcano, a small eruption occurred in January 2014, and this activity has continued after this eruption.

During this activity, we carried out the electromagnetic survey around Nakadake crater of Aso volcano. In our presentation, we will show the observation data and the resistivity structure obtained by the 1-D analysis of our data.

Crustal deformation associated with increase in VLP events activity in Aso Volcano

OHKURA, Takahiro[1*] ; YOSHIKAWA, Shin[1] ; INOUE, Hiroyuki[1]

[1]AVL,Kyoto Univ.

Aso Volcano, one of the most active volcanoes in Japan, is located in the central part of Kyushu and consists of an elliptical caldera with a diameter of 18km in E-W and 25km in N-S, and of central cones with more than 10 volcanoes aligned in E-W direction. Among central cones, Nakadake volcano is the only active cone and its recent activity is characterized by ash and strombolian eruptions and phreatic or phreatomagmatic explosions. The last strombolian eruptions ended in the beginning of the 1990s and after that, surface activities have been restricted to the fumarolic gas and ash emission from the northernmost crater of the volcano accompanying activity of long period tremors(LPT) or very long period (VLP) events.

Since 1990s, observations using broadband seismometers have revealed that the source of LPT is a crack-like conduit located at depths of 1-1.5 km beneath Nakadake, with a length of 1km and width of 2.5km. It is also revealed that at this depth a pressure was located and caused long-period displacements a few minutes before phreatic eruption which occurred in 1993 and 1994.

The Japan Meteorological Agency (JMA) raised the Volcanic Alert Level from 1 (Normal) to 2 (Do not approach the crater) based on rapid increase in numbers volcanic earthquakes and volcanic gas emission in September 2013, and based on increase in amplitude of volcanic tremors in December 2013, respectively.

Remarkable ground deformation was detected by water-tube tilt meters and super invar-rod extensometers which were installed in a 30m observation tunnel, 1km southwest from the active crater, in September 2013 and January 2014 associated with increase in VLP events activity.

By comparing the calculated deformation assuming a Mogi source and a dyke, is found that observed deformation can be attributed to the expansion of the crack-like conduit. At the beginning of the deformation, the radial component of the extensometer showed dilatation and converted to contraction, which indicates initiation of expansion at the deeper portion of the crack and propagation to the shallower part.

Remote temperature sensing on fumaroles in active volcanoes using stable isotopes of trace gases in volcanic plume

KOMATSU, Daisuke[1*] ; TSUNOGAI, Urumu[1] ; NAKAGAWA, Fumiko[2]

[1]Graduate School of Environmental Studies, Nagoya University, [2]Graduate School of Science, Hokkaido University

Molecular hydrogen (H_2) in a high-temperature volcanic fumarole (>400 degreeC) reach to the hydrogen isotope exchange equilibrium with coexisting fumarolic H_2O under the outlet temperature of the fumarole. In this study, we applied this hydrogen isotope exchange equilibrium of fumarolic H_2 as a tracer for the remote temperature sensing on the fumarolic area in the 1^{st} crater of Mt. Naka-dake (Aso volcano) where direct measurement on fumaroles was not practical, by deducing the hydrogen isotopic composition (dD value) of fumarolic H_2 remotely from those in volcanic plume. The reciprocal of H_2 concentration in the plume samples showed a good linear relationship with the dD values. The linear relationships suggested that both the concentrations and the dD values of H_2 in the plume samples can be explained by simple mixing between two end-members, both of which can be classified to a single category at least for the dD values of H_2. By extrapolating the linear relationship between $1/H_2$ and dD to $1/H_2$=0 to exclude the contribution of the tropospheric H_2 from the dD value of each sample, we estimated that the dD value of fumarolic H_2 to be -172+-16 per mil vs. VSMOW and the apparent equilibrium temperature (AET_D) to be 868+-97 degreeC. Although the estimated temperatures using the IR thermometers were much lower than the AET_D, we concluded that the AET_D represented the highest outlet temperature of the fumaroles in Aso volcano and that the dimensions of the fumaroles at surface smaller than the pixel of the IR thermometers was responsible for the temperatures lower than the AET_D. That is to say, temporal variation in the dimensions of fumaroles at surface, probably due to variation in the emission flux of fumarolic gases, was responsible for the temporal variation in the temperature determined by the IR thermometers, while the actual outlet temperature of the Aso fumaroles keeps the high temperature almost equal to the equilibrium temperature of fumarolic gases.

Strange seismic, infrasonic, and geodetic phenomena observed 3 days before the 2011 eruption of Shinmoe-dake volcano

ICHIHARA, Mie[1*] ; OIKAWA, Jun[1] ; TAKEO, Minoru[1]

[1]Earthquake Research Institute, University of Tokyo

Shinmoe-dake volcano started its climatic events on January 26 at 14:49. Some precursory phenomena have been found in petrologic studies. The ash from a phreatic eruption on January 19 contained fresh pumice fragments indicating ascent of new magma to a shallow depth (Miyabuchi et al., 2013; Suzuki et al., 2013). Petrologic analyses of the eruption products from the climatic events showed evidences of magma mixing in two stages before the eruptions; Suzuki et al. (2013) estimated the times of the first and second mixing to the eruption as >14 days and 0.7-15 hours, respectively, while Tomiya et al. (2013) conclusively proposed 0.4-3 days and several hours, respectively, and suggested that the first mixing likely triggered the eruption.

On the other hand, no clear precursory signals have been identified in geophysical observations. Considering the above petrologic studies, we reexamined the seismic, infrasonic, and geodetic data in a few weeks to the eruption, and particularly focused on a sequence of strange phenomena on January 23, three days before the eruption. It was the only notable phenomena recognized in several days to the eruption, but has not been reported elsewhere.

Nakada et al. (2013) referred to the JMA report (2012) that volcanic tremor was first recorded at 01:27 on 19 January and continued from the 19 January afternoon to the morning of 23 January. In fact, the tremor started to be recorded at stations around the summit of Shinmoe-dake at 12:45 on 18 January and increased significantly after the phreatic eruption at 01:27 on the 19th. If there was any sign indicating rise of new magma to the shallow depth before the phreatic eruption, the tremor could be the candidate.

On January 23, there was a clear infrasound signal continuing from 4:11 to 4:53 with an amplitude about 1 Pa and a sharp peak frequency at 1.8 Hz. The events was nearly aseismic and the regional seismic stations recorded infrasound shaking of the ground. The bad weather condition prohibited visual observation to see if any surface activity accompanied. At 6:00, the tremor power increased at stations on the north flank while it decreased at a station on the west flank, indicating some change of the source. The tremor power decreased from 8:00 to 8:30, stayed at the low level until 13:15, and then recovered to the previous level by 14:00. It was more distinct at stations close to the summit of Shinmoe-dake; the power decrease was more than an order of magnitude at the nearest station, SMN, 700 m from the summit. After the recovery the tremor stayed nearly same levels until the small eruptive event on the 26th before the main event. During the quiescent period of the tremor, gradual tilt up toward the summit was detected by a broadband seismometer at station SMN. Although, seismic activity except the tremor was low around the days, the quiescent period had more seismic events including relatively low-frequency ones.

Although causal relations among these events or their relation to the magma mixing are totally unclear, the sequence of phenomena on January 23 is potentially important to understand the processes leading to the climatic events of the Shinmoe-dake eruption.

Relationship between Infrasound Signals and Plume Heights by the JMA's Weather Radar, the Shinmoe-dake 2011 Eruption

TAKAGI, Akimichi[1*] ; SHIMBORI, Toshiki[1] ; YAMAMOTO, Tetsuya[1] ; FUKUI, Keiichi[2]

[1]Meteorological Research Institute, [2]Kakioka Magnetic Observatory

During the continuous sub-plinian eruption of the 2011 Shinmoe-dake eruption, the JMA's weather RADAR detected the sequential echoes from the volcanic plume (Shimbori et al., 2013). We report the brief result of basic analysis for the relationship between the plume heights and infrasound signals.

The eruption cloud echo data observed at the Kagoshima Airport Doppler RADAR (Kagoshima DRAW) were analyzed. While Kagoshima DRAW has the threshold of radar reflectivity factor, its time interval of the volume scan is shorter as 5 minutes. In this study, in order to improve the accuracy of time, the time of the plume top in a volume scan was identified by every scanning time of the antenna.

The relationship between the plume height and discharge rate of magma has the empirical power law, and its power index was estimated to be 0.259 (Sparks, 1997). Assuming that the discharge rate has the proportional relation with the integration of the infrasound signal generated by eruption (Takagi at al., 2013), we estimate the power law between the echo height and infrasound data for this eruption. In the result, the most appropriate power index was estimated to be 0.55, and the delay time and the time window of the infrasound data which make error smaller are 4 minutes and 6 minutes, respectively.

These time delay and window might be subjected to height and velocity of plume top. More advanced analysis for plume heights and infrasound signals would disclose the dynamics of volcanic plume.

Acknowledgements

We would like to thank Drs. Y. Tanaka, O. Suzuki, H. Yamauchi and E. Sato (MRI, JMA) for the use of their "Draft" radar analysis software.

Long-period seismic waves propagating over Kyushu as associated with the Sakurajima eruption of August 18, 2013

IKEDA, Ayami[1] ; KUGE, Keiko[1*] ; KAZAMA, Takahito[1] ; MATSUZAWA, Takanori[2]

[1]Dept. Geophysics, Kyoto University, [2]NIED

We found long-period seismic waves propagating over Kyushu after the explosive eruption from Showa crater of Sakurajima volcano at 16:31JST on August 18, 2013. The eruption is one of the most significant ones that Showa crater has experienced since 2006, and the volcanic plume rose approximately 5000 m high. Showa crater is currently very active, causing more than 1000 eruptions a year.

The broadband seismic network F-net recorded the long-period seismic waves traveling in a very wide area covering Amami and the whole Kyushu region. The dominant periods are longer than 5 s. The apparent propagation velocity is approximately 2.75 km/s. In data recorded by Hi-net tilt meters at shorter intervals of around 20 km, the long-period seismic waves arrived earliest at the station AIRH that is the closest to Sakurajima volcano, and propagated with the almost same apparent velocity as observed by F-net. The long-period seismic waves are, therefore, likely to have been radiated from Sakurajima volcano. Assuming that the source is located at Showa crater, we rotated two horizontal components of the F-net and Hi-net data to transverse and radial components. The long-period seismic waves were observed in the radial and transverse components, and the apparent propagation velocity is slightly faster in the transverse component than the radial one. The waves observed in transverse and radial components can be Love and Rayleigh waves, respectively.

For previous eruptions of Sakurajima volcano, we also examined whether or not long-period seismic waves were recorded by F-net. From 5057 eruptions in the period between 2006 and 2013, we selected 43 eruptions that have large amount and height of a volcanic plume as well as large deflation volume. Long-period seismic waves were found for five eruptions including ones from Minami-dake crater. The maximum distances with the observations of long-period seismic waves range from 150 to 331 km, which are much shorter than for the 2013 eruption. Therefore, the 2013 eruption could excite long-period seismic waves more remarkably, compared to the other five eruptions. Observations of long-period seismic waves, on the other hand, did not have clear dependence on the amount and height of a volcanic plume or the deflation volume.

We observed significant transverse components of the long-period seismic waves associated with the 2013 eruption, which are considered Love waves. We also had similar observations for the five eruptions accompanied by long-period seismic waves in F-net data. Eruptions of Sakurajima volcano have been explained by isotropic explosion and contraction of a vertical cylinder (Uhira and Takeo, 1994; Tameguri et al., 2002), and these models cannot excite Love waves. A model for explaining Love waves observed in the present study is to be investigated.

Comparison between areas of VT earthquakes around Sakurajima Volcano and a 3-D velocity model of the upper crust

YAKIWARA, Hiroshi[1*] ; HIRANO, Shuichiro[1] ; MIYAMACHI, Hiroki[1] ; TAKAYAMA, Tetsuro[2] ; ICHIKAWA, Nobuo[2] ; TAMEGURI, Takeshi[2]

[1]GSE, Kagoshima Univ., [2]SVRC, DPRI, Kyoto Univ.

Volcano-tectonic (VT) earthquakes associated with volcanic activities of Sakurajima Volcano also occur beneath Kagoshima Bay around the volcano (Hidayati et al., 2007). Not only seismic observations on land but also ones using Ocean Bottom Seismographs (OBSs) are need to detect micro VT earthquakes beneath the bay, and to improve accuracies of the hypocenter locations of the earthquakes. Authors therefore have performed OBS observations five times since 2009. In the present study, we summarize hypocenter distributions of the VT earthquakes obtained by OBS observations. We also compare the hypocenters and a three-dimensional seismic velocity model derived from regional earthquake data in order to extend knowledge for active area of the VT earthquakes.

The areas where the earthquakes occurred are summarized as follows: 1) Shallow VT earthquakes generated beneath Wakamiko Caldera. Most of the earthquakes were located shallower than or equal to 5 km depth. 2) Small number of VT earthquakes were also located at 5-10 km depth off the northeastern coast of the volcano. This activity may be steadily. 3) No earthquake was detected beneath the western half of Aira Caldera.

On the other hand, we also analyzed a three-dimensional seismic velocity model by use of regional earthquake data (Mera et al., 2013) to compare the hypocenter distribution and the velocity model. As a result of the 3-D inversions, we obtained reliable P- and S-wave velocities at the depth range of 5-12km under the area in and around the volcano. At shallower than 6 km depth, the model delineates an area of Low-Vp (5.3-5.4 km/s) and Low-Vs (3.0-3.1 km/s) beneath the area of south of Wakamiko Caldera. A peak of the low velocity area tends to close the volcano at the portion deeper than 6 km depth. At 10 km depth, a peak of Low-Vp (5.4-5.5 km/s) and Low-Vs (3.1-3.2 km/s) was imaged beneath an area off northeast coast of the volcano (beneath Shin-jima Island). Obviously low velocity areas also spread from the volcano to the area off the south coast of the volcano.

Because several recorder troubles happened among the five OBS observations, we selected the hypocenters of the VT earthquakes which were located using data recorded at common three OBS stations. As a result of the comparison between the hypocenters of the VT earthquakes and the 3-D velocity model, most of the VT earthquakes were located where intermediate velocities were estimated. Furthermore, some of VT earthquakes occurred in close vicinity of the peaks of Low-Vp and Low-Vs areas. The former suggests that the strains by crustal deformation hardly accumulate at areas of high and low velocities. The latter may reflect the increase of pore pressures and stress changes generated by existence of volcanic fluids.

The latest report on structural evolution and on effect of the density reduction in the seismic network will be presented through the sixth round of the repetitive seismic experiment in Sakurajima Volcano. Sakurajima Volcano locates in Kagoshima, south Kyushu, which is one of the most active volcanoes in Japan. The repetitive seismic experiment have been carried out since 2008 in order to detect and research structural evolution along volcanic activity, with using 4.5Hz sensors. This round has carried out as a part of the experiment which presented by Nakamichi et al. in this conference.

The detection and researching the structural evolution approach to magma movement under the ground along volcanic activity and will provide essential measure on development of volcanic activity. Extending its result into evaluation on flux and accumulation will bring significant informations on considering scenario about volcanic activity in progress. And the experiments should be sustainable method because of long time scale of the target.

The latest report about structural evolution will be presented. Details and results of the experiment rounds have been reported in these conferences since 2009. The seismic response along the line in the north flank have changed year by year. Two major sweet spots have been found at 4.9km depth in the northeastern Sakurajima and at 8km depth beneath northern flank of Kitadake, the northern edifice, through these experiments. The changes in seismic response are interpreted as a result of mass movement underground with going volcanic activity. Further change is expected associating with development of volcanic activity.

The effect of density reduction will be also discussed. Though the repetitive seismic experiments with two lines have been done with about 250 stations every December until 2012, the latest experiment with the most sensitive line with 74 stations on the northern flank was carried on December 2013. Discussions on the effect of density reduction in the seismic network is necessary in order to have a style of sustainable execution of the research.

We conducted active seismic experiment in and around Sakurajima volcano in December 2013, five years after the similar experiment that was conducted in 2008. We deployed 280 temporary seismic stations, 90% of which were located at the same locations of the experiment in 2008. Six explosive shots with 200 kg or 300 kg charges were detonated in December 5. The 2013 shot locations (S1, S2, S4, S5 and S6) are less than 60 m from the 2008 shot locations except for 1 shot (S3). We successively observed the explosions and volcanic events during nighttime nine hours continuous recording. The continuous records contain not only waveforms excited by the six shots but also by an explosive eruption and volcanic tremor. We evaluate cross-correlations of waveforms at the same station locations that obtained in 2008 and 2013 to detect temporal change of subsurface structure beneath Sakurajima volcano except for S3.

In 2012, in order to realize quantitative monitoring of magma transport process, we deployed the ACROSS (Accurately Controlled Routinely Operated Signal System) vibrator system composed of two vibrators in the site that is 3.6 km apart from the northwest of the Minamidake crater of Sakurajima.

On September 2012, we have started the full-scale operation under synchronized control of two vibrators with a frequency modulation, in which the modulation period is 50 seconds and the frequency range is 5 to 15 Hz, to produce broad frequency range of signal: one vibrator 'SKR1' with a signal frequency range of 7.510Hz +/- 2.50Hz and the other 'SKR2' with the range of 12.505Hz +/- 2.50Hz. The signal from the ACROSS source is routinely monitored with more than 20 permanent seismic stations in and around Sakurajima volcano. Five temporal seismic stations are also deployed to increase the spatial coverage of monitoring. The signals recorded at the seismic stations are deconvoluted with the source function to obtain the transfer function between the source and the receivers.

In this report, we estimated the daily transfer functions for the SKR2 vibrator at each station by every 5 days stacked data during a whole period (400 days from September 19, 2012 to October 23, 2013) of the operation. It is obviously found that these daily transfer functions vary temporally. To detect quantitatively the temporal variation of the transfer functions, we analyzed the variation of the transverse component (Tt) of the transfer functions at 7 seismic stations located in Sakurajima Island as folllows:

(1) We analyzed the transfer function obtained at temporal seismic station 'GOMI' located at about 50m apart from the ACROSS source to verify the stability of power of the seismic waves generated by the ACROSS source. According to the result, we rejected the transfer function evaluated during a period of the unstable power condition from a whole period of the operation.

(2) We visually inspected arrival times and amplitudes for the specific phases in the transfer functions at each station during the period of the stable power condition of the ACROSS, and obtained the quantitative temporal variation for the specific phases.

(3) On a simple assumption that the specific phases are SH waves (the transverse component of the transfer functions), we presumed the depth range where each specific phase propagated in the 5 horizontally layered model simplified from the results of the exploration seismic experiment (Miyamachi et al., 2013).

(4) We compared the temporal variation of the specific phases with activity of volcanic eruptions by JMA, the temporal change of the N-S and E-W horizontal distances (GPS data) in Sakurajima Island, and the temporal change of strain at the HAR station measured by Kyoto University.

In the presentation, we will show the observation results in detail. This ACROSS research project in Sakurajima volcano is still in a pioneering stage, and we have plans in the future to continue our project.

We conducted the precise leveling survey in Sakurajima volcano and around Aira caldera in October and November 2013, following the repeated leveling surveys to evaluate the vertical ground deformation associated with the recent eruptive activity of this volcano. The leveling routes measured in 2013 survey are about 117 km long in total, including Sakurajima coast route, Sakurajima western flank route, Sakurajima northern flank route, Kagoshima Bay western coast route (BM.2469 - BM.2474 - BM.J), Kagoshima Bay eastern coast route (BM.2500 - BM.J.2797) and Soo route (BM.J.2797 - BM.2785). These leveling routes were measured by the joint university team during the period of November 5-22 and by Geospatial Information Authority of Japan (GSI) during the periods from October 25 to November 7 and of November 13-26.

The obtained survey data are compared with those of the previous surveys conducted in October-December 2007 and November-December 2012, resulting in the relative vertical displacements of the bench marks. The resultant displacements show the ground uplift around Aira caldera as well as the ground subsidence near the central part of Sakurajima. From the analysis based on Mogi's model, the inflation and deflation sources are located beneath the center of Aira caldera and beneath the center of Sakurajima, respectively.

These results indicate that the magma storage at the magma reservoir beneath Aira caldera is still progressed. On the other hand, they also suggest the increase of the amount of ejected magma at the magma reservoir beneath the center of Sakurajima volcano, reflecting the recent increase of the eruptive activity at Showa crater.

Movement of pressure source at Sakurajima volcano after 2006 revealed by continuous GPS observation data

HOTTA, Kohei[1*] ; IGUCHI, Masato[2] ; OHKURA, Takahiro[1] ; YAMAMOTO, Keigo[2]

[1]Graduate School of Science, Kyoto University, [2]DPRI, Kyoto University

Ground deformation around Sakurajima has been mainly detected by precise leveling, and has been modeled with 2 spherical pressure sources at the center of the Aira caldera (about 10 km depth) and at beneath the summit crater (about 4 km depth) (Eto, 1989, Annuals of DPRI, Kyoto Univ.). The ground around the Aira caldera turned to uplift since 1993. After continuous GPS observation started at Sakurajima in 1995, explosive activity at summit crater temporally increased at the end of 1999, and Showa crater started eruptive activity at June 2006. Large deformation rate was obtained prior to these eruptive activities, and a pressure source was located at depths 6-8 km near the northern coast of Sakurajima by assuming a spherical source (Hotta et al., 2013, Annual of DPRI, Kyoto Univ.). It is thought that both of pressure sources at the center of the Aira caldera and at beneath the summit crater expanded, and a pressure source apparently moved toward northern coast of Sakurajima. Eruptive activity at Showa crater has increased since 2009. In this study, we analyzed GPS data to make clear process of magma movement accompany with eruptive activity of Showa crater.

GPS data observed by SVO (Sakurajima Volcano Observatory) and GEONET data during 2006-2012 were analyzed by using PPP-AR analysis of GIPSY OASIS II ver. 6.1.2. Although no significant deformations are found during 2006-2009, variable deformation rates are found after around 2009.

Here, we focused on the period of the largest deformation rate after eruptive activity at Showa crater started (from October 2011 to March 2012). At first, we searched average positions of pressure sources whole the period by using GA. Pressure sources located at the center of Aira caldera (8.3 km depth; source A) and beneath Sakurajima (2.9 km depth; source B). Next, fixing the position of source A at the average position (because previous studies also obtained pressure source at the center of Aira caldera around this average position), we set a time window with 4 month period, and shifted it by 10 days. Source B moved from around Kitadake toward the northern part of Sakurajima during 1st time window (October 1, 2011-January 31, 2012) to 6th one (November 21, 2011-March 21, 2012), and then moved toward beneath Minamidake at 7th one (December 1, 2011-March 31, 2012). During the period of November 26, 2011-March 25, 2012, which is middle of 6th and 7th time windows, source B located around Kitadake. Deformation pattern of GPS stations at the northern part of Sakurajima changed around the end of December 2011. Moreover, eruptive activity at Showa crater increased from December 2011. These suggest that magma migrated from Aira caldera toward Sakurajima at around December 2011.

The importance of hydrological disturbance corrections for relative gravity data: A case study at Sakurajima Volcano

KAZAMA, Takahito[1*] ; YAMAMOTO, Keigo[2] ; FUKUDA, Yoichi[1] ; IGUCHI, Masato[2]

[1]Kyoto Univ., [2]DPRI, Kyoto Univ.

An empirical water balance model was created to correct for hydrological disturbances in relative gravity data repeatedly measured at Sakurajima Volcano, southern Japan. This study aims to quantitatively monitor gravity signals due to magmatic activities of Sakurajima Volcano, and we here present the first applied results of the empirical model. The hydrological disturbances were simply calculated by the product of the instant gravity response to unit precipitation and land water storage, which were estimated using digital topography and observed meteorological data. The calculated hydrological disturbance was consistent with the observed absolute gravity data at Harutayama Station from 2010 to 2011 within 8 micro-gal (1 [micro-gal] = 1 E-8 [m/s2]), which was smaller than the typical accuracy of relative gravity measurements (˜10 micro-gal). In addition, after we subtracted (i.e., corrected) the calculated disturbances from the measured relative gravity data at Sakurajima Volcano, the average amplitude of the corrected gravity changes during 2007-2009 was reduced by 90 % compared with that of the original gravity data. Since gravity changes have been measured using both absolute and relative gravimeters at volcanic areas these days, hydrological disturbance corrections should be applied to the relative gravity data, not only to the absolute one. By sophisticating the effects of spatiotemporal variations in precipitation, evapotranspiration, and infiltration capacity, this model will enable us to robustly monitor long-period and wide-spread gravity variations associated with volcanic activities.

Automated sulfur dioxide flux observation at Suwanosejima volcano, Japan, and comparing to seismic data

MORITA, Masaaki[1*] ; MORI, Toshiya[1] ; IGUCHI, Masato[2] ; NISHIMURA, Takeshi[3]

[1]Geochem. Res. Center, Univ. of Tokyo, [2]DPRI, Kyoto Univ., [3]Dept. Geophys., Tohoku Univ.

Suwanosejima is a remote volcanic island located about 240 km south-southwest of Kagoshima city, Kyushu Island, Japan. This volcano has been erupting very frequently since early-1950s, and is one of the most active volcanoes in Japan. Previous studies on sulfur dioxide (SO_2) flux measurement of Suwanosejima are very limited and reported that daily average SO_2 flux from this volcano ranged about 5–15 kg/s [Mori et al., 2004; Hirabayashi et al., 2005]. Therefore, we conducted automated SO_2 flux measurement at Suwanosejima volcano to understand SO_2 flux variation with long-term observation at Suwanosejima volcano and to evaluate a relation between SO_2 flux and seismic data.

We developed automated SO_2 flux measurement system to conduct automated observation in such a remote island. The power consumption of the scanning instrument was significantly improved compared to that in the previous studies. The observation was conducted for January 21, 2013–May 7, 2013 (Period I) and November 5, 2013–the present (Period II). The observation system has been working without any trouble for more than 200 days in total showing robustness of the developed system.

SO_2 flux was calculated with a corrected differential optical absorption spectroscopy method for radiative dilution effect [Mori at al., 2006; Kern et al., 2009]. In the observation period of over 200 days, SO_2 flux was calculated for 40 days. The average SO_2 flux in the total observation period was 13.4 kg/s, which ranged from 5.9 kg/s to 34.5 kg/s. The average and the standard deviation in Period I were 16.9 kg/s and 6.2 kg/s, and those in Period II were 14.0 kg/s and 5.7 kg/s, respectively.

Since previously reported SO_2 flux in 2000s [Mori et al., 2004; Hirabayashi et al., 2005] were not corrected for the dilution effect, these values might be significantly underestimated. The average and the standard deviation of uncorrected SO_2 flux for the dilution effect in this study were 9.7 kg/s and 4.3 kg/s. This range was comparable to the range of the previous studies in 2000s. Considering above, SO_2 flux range has been stable since at least 2000s.

Surface and seismic activities in Period I (January 21–May 7, 2013) significantly differed from those in Period II (November 5, 2013–the present). Period I was in a continuous volcanic tremor period (September 2012–July 2013), and Period II was in an intermittent explosions and volcanic tremors period. In contrast to the surface and seismic activities, SO_2 flux variations in Period I and II were almost in the same range. This implies that degassing rate of magma for these two periods were similar. Therefore, the difference of surface and seismic activities which was observed in these periods needs to be explained considering the stable degassing magma rate.

Shallow active magma body beneath Taal Volcano Island, Philippines

KUMAGAI, Hiroyuki[1*] ; LACSON, Rudy[2] ; MAEDA, Yuta[1] ; FIGUEROA, Melquiades[2] ; YAMASHINA, Tadashi[3] ; BORNAS, Ma. antonia[2]

[1]Nagoya University, [2]PHIVOLCS, [3]Kochi University

Taal volcano, Philippines, is one the world's most dangerous volcanoes in view of its explosive eruption history and close proximity to populations. Electromagnetic, geodetic, and seismic studies have been extensively conducted at this volcano to reveal its magma system. Recent deployment of a realtime broadband seismic network has detected long-period (LP) and volcano-tectonic (VT) events that occurred beneath Taal. Our source location analysis of VT events using both onset arrival times and high-frequency seismic amplitudes points to the existence of a strong attenuation region with a shear-wave quality factor (Q) of around 10 near the surface at the eastern flank of Volcano Island in Taal Lake. This region is located just beneath the active fumarolic area and LP source and above inflation and deflation pressure sources, and is coincident with a low resistivity region. The attenuation region matches with that inferred from an active seismic survey conducted in 1993 at Taal volcano. These features strongly suggest that the attenuation region represents an active degassing magma body near the surface, which persistently existed for more than 20 years. Our study synthesized with previous studies clarifies the magma system beneath Taal, which further addresses volcanic risk at Volcano Island sitting on a shallow active magma body.

Waveform analysis on initial phases of explosion earthquakes at Lokon-Empung volcano, Indonesia

TAISHI, Yamada[1*] ; AOYAMA, Hiroshi[1] ; NISHIMURA, Takeshi[2] ; YAKIWARA, Hiroshi[3] ; NAKAMICHI, Haruhisa[4] ; OIKAWA, Jun[5] ; IGUCHI, Masato[4] ; MUHAMAD, Hendrasto[6] ; YASA, Suparman[6]

[1]Faculty of Sci., Hokkaido Univ., [2]Graduate School of Sci., Tohoku Univ., [3]Faculty of Sci., Kagoshima Univ., [4]DPRI, Kyoto Univ., [5]ERI, Univ. of Tokyo, [6]CVGHM, Indonesia

Excitation mechanism of explosion earthquake that often accompanies explosive Vulcanian eruptions is understood to be macroscopically explained by a downward single force acting in the vent. In the meantime, it is revealed that the excitation of initial phases of explosion earthquake occurs earlier than the explosion at the crater [e.g. Tameguri et al., 2002]. So the excitation of the initial phases of explosion earthquake can be regarded as one of the most important processes to understand the initiation of Vulcanian eruption. However, the researches focusing on the initial phases are not so common in spite of their scientific importance. In this study, we implemented temporary observation of Vulcanian eruption at Lokon-Empung volcano in Indonesia and estimated source parameters of the initial phases of explosion earthquakes to compare them to the previous works at Sakurajima volcano and Suwanosejima volcano.

Lokon-Empung volcano located in the northern part of Sulawesi island is known as one of the very active volcanoes in Indonesia. We deployed seismic and infrasound observation network around Lokon-Empung in September 2012. During about one-year-long observation, 46 events of explosion earthquakes associated with Vulcanian eruptions had been recorded. Seismograms of explosion earthquakes have common features in the initial phases at all stations; the compressional P phase arrives first, and a larger dilatational phase follows it. Comparison between seismic and infrasound record shows that the excitation of the P phase occurs about 1 second earlier than that of infrasound which is thought to be excited by the explosion at the crater. Particle motion analysis reveals that these initial phases consist of P wave and propagate from the direction of the active crater. Since signal to noise ratio of the first compressional wave (P phase) is not good at some distant stations, we focus on the second dilatational phase (D phase). We performed waveform fitting on the D phase using synthetic seismogram to estimate source depth, shape of source time function, contraction mechanism and seismic moment.

For most events, we obtained the best fitting solution with cylindrical contraction source located at 1 km below the crater. We compared the estimated seismic moment of D phase and the amplitude of seismogram and infrasound with those reported in the previous works, and found that the strength of the explosion of Lokon-Empung ranks between those of Sakurajima and Suwanosejima. At Sakurajima volcano, Tameguri et al. (2002) showed that the amplitude of infrasound is independent from the moment of D phase. On the other hand, Hirai (2013) reported a positive correlation between them at Suwanosejima volcano. Estimated focal depths of D phase at these two volcanoes are 2 km and 100 - 400 m, respectively. At Lokon-Empung volcano, we recognized a weak positive correlation between the amplitude of infrasound and the moment of D phase. The comparison suggests that the shallower focal depth of D phase becomes, the stronger the correlation between moment of D phase and strength of infrasound appears. This result we obtained here will provide a new insight into the unrevealed process between the excitation of D phase and the surface explosion.

Recent eruptive activity at Sinabung Volcano, Northern Sumatra, Indonesia

NAKADA, Setsuya[1*] ; YOSHIMOTO, Mitsuhiro[2] ; ZAENUDIN, Ahkmad[3] ; SUZUKI, Yuki[1] ; HOKANISHI, Natsumi[1] ; TAKAGI, Natsuko[1] ; HENDRASTO, Mochammad[3] ; IGUCHI, Masato[4] ; OHKURA, Takahiro[5]

[1]ERI, Univ. of Tokyo, [2]Grad. Sch. Sci., Hokkaido Univ., [3]CVGHM, Indonesia, [4]Disaster Res. Inst., Kyoto Univ., [5]Grad. Sch. Sci., Kyoto Univ.

Sinabung in the Northern Sumatra of Indonesia began its eruptive activity with phreatic events in August and September 2010. It resumed its activity in September 2013 with phreatic events. In November 2013, eruption columns stood about 5 km above the volcano. Volcanic ash issued since the middle November contained juvenile particles, and pumice fragments were ejected on to the NE flank of the volcano by the vulcanian event on 23 November 2013. Small-scale pyroclastic flows descended during the events. Though the eruptive activity had declined since early December, occurrence of low-frequency earthquakes replaced high-frequency events common during explosive events. Following partial collapse of the summit crater outer-slope repeated, lava appearance was confirmed in late December. Lava appeared in the summit crater grew as a dome and started its partial collapse on 30 December, generating pyroclastic flows which descended on the SE slope of the volcano. The lava dome grew into a lava flow moving to the SE, repeating its partial collapse. The horizontal length of the lava flow exceeded 1 km in late January 2014.

Several tens collapses occurred everyday in January 2014. Relatively large collapse (pyroclastic flows) generated on 7, 11 and 21 January and 1 February. Pyroclastic flows on 1 February traveled about 4.5 km, according to newspapers, and 15 local people who invaded into the danger zone, 5 km from the summit, were involved in the flows.

The present eruption at Sinabung is close to the eruption of 9 to 10th Century of this volcano in terms of both eruption site and scale. It is also similar to lava-dome eruptions at Unzen, Japan, in 1991-95 and at Soufriere Hills, Montserrat, West Indies, in 1995-present, where lava dome/flow growth associated with pyroclastic-flow events continued for several years.

Based on the chemical analyses of pumice of the Vulcanian event on 23 November 2013 and pebbles included in pyroclastic flow event on 11 January 2014, magma of this eruption (hornblende andesite) is similar to but a little poorer in SiO_2 (58-59%) than the magma of the 9 to 10th Century (59-60%).

Metal-silicate partitioning of U, Th, Nd, Sm at high P-T: Implications for heat and chemical budget in the core

NOMURA, Ryuichi[1*] ; HIROSE, Kei[1] ; KIMURA, Jun-ichi[2] ; CHANG, Qing[2]

[1]ELSI, Titech, [2]IFREE, JAMSTEC

The excess abundance of siderophile elements in the mantle has been proposed that the core was equilibrated with the mantle at ˜3500 K, ˜30GPa and fO2˜△IW-1 at the Earth ' s formation (e.g. Righter, 2011 EPSL). Much more severe condition (>6500 K) is supposed immediate aftermath the moon-forming giant impact based on the study of numerical simulation (e.g. Canup, 2012 Science). The occurrence of high-temperature equilibrium between the core and the mantle evoked that the early core had once incorporated heat-genic radionuclides (U, Th) and rare earth elements (e.g. Nd, Sm), which are know as highly lithophile elements, suggesting profound implications for the thermal history (Nimmo, 2007 Treatise on Geophysics) and early-formed geochemical reservoirs (e.g. sub-chondritic 142Nd/144Nd, Boyet and Carlson, 2005 Science).

However, partitioning of these elements between liquid metal and silicate melt has been investigated only up to 20 GPa and 2500 K using multi-anvil apparatus (Malavergne et al., 2007 GCA). Here, we extended pressure and temperature conditions up to 138 GPa and 5200 K at △IW-2˜-1 using laser-heated diamond cell (LH-DAC) and field emission-type electron probe microanalyzer (FE-EPMA, JXA-8530F, JEOL) and laser-ablation inductively coupled plasma mass spectrometry (LA-ICP-MS, Kimura and Chang, 2012 JAAS). K (4wt%) and trace elements (U, Th, Nd, Sm, Hf, W, Pb) doped pyrolitic gel, and pure iron were used as starting materials. Iron-free pyrolitic gel was used as a thermal insulator. After high P-T experiments using LH-DAC, recovered samples were analyzed by FE-EPMA and LA-ICP-MS for major and trace elements, respectively. Fe and Mg were used as internal standards for metal and silicate, respectively for LA-ICP-MS. The diameter of ablated area was about 10 um, small enough to measure each (silicate melt/liquid metal) phase.

The results are summarized as follows;

(1) Partition coefficient of U and Th are 10-3-10-2 at 3500-4000 K and △IW-1 to -1.5, resulting in 0.02-0.2 ppb (<0.03 TW) U and 0.08-0.8 ppb (<0.04 TW) Th into the core assuming that the abundance of U and Th are 22 and 83 ppb in the Earth ′ s mantle (McDonough and Sun, 1995). Total <0.1 TW (present-day) heat flow in the core has negligible effect on the thermal history of the Earth with <50 K change in the initial temperature at core-mantle boundary (Nimmo, 2007 ToG).

(2) The ratio of partition coefficients, D_{Nd}(metal/silicate)/D_{Sm}(metal/silicate), was always unity despite of large temperature dependence for each D, suggesting that the core could not be a candidate for an early-formed (with sub-chondritic 142Nd/144Nd) hidden reservoir.

Element partitioning between mantle minerals and melt under deep lower mantle condition

TATENO, Shigehiko[1*] ; SAKATA, Shuhei[2] ; HIRATA, Takafumi[2] ; HIROSE, Kei[3]

[1]Dept. Earth & Planetary Sciences, Tokyo Institute of Technology, [2]Dept. Earth & Planetary Sciences, Kyoto University, [3]Earth-Life Science Institute, Tokyo Institute of Technology

Melting is a primary mechanism of chemical evolution of our planet. Earth's mantle would have been completely molten due to moon-forming giant impact, leading to a global magma ocean. Resultant fractional crystallization by secular cooling progressively induced the chemical evolution of the Earth. As a consequence, remnant silicate melt left at the present day at the base of the mantle is a possible explanation for the seismically observed ultralow-velocity zones (ULVZs). The knowledge of melting phase relations and element partitioning between mantle minerals and partial melt is crucial to understand the chemical evolution in the early Earth and the nature of ULVZs. However, melting experiments under the middle to deep lower mantle conditions are quite limited.

Here we carried out the melting experiments on KLB-1 peridotite and basalt to deep lower mantle conditions up to 179 GPa by a combination of laser-heated diamond-anvil cell experiments and chemical analyses of recovered samples. Textural characterization and chemical analysis on major and minor elements were made by a field-emission-type electron microprobe (FE-EPMA). Trace element abundances were determined by a laser-ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). Typical crater diameter was 2 or 5 μm by using ArF Excimer laser.

Results shows that the liquids phase was $MgSiO_3$-perovskite at least above 34 GPa and further to post-perovskite in KLB-1 peridotite. The Fe-Mg distribution coefficients (K_D) between perovskite/post-perovskite and melt decreased considerably with increasing pressure, leading to strong Fe-enrichment in partial melts. It supports dense partial melts in a deep lower mantle, which migrate downward to the core mantle boundary (CMB). Furthermore, $CaSiO_3$-perovskite (CaPv) was found to be a liquids phase under whole lower mantle condition in MORB bulk composition. We then investigated the minor/trace element partitioning between CaPv and melt in basaltic composition. Partition coefficient of alkali elements such as Na and K increases with increasing pressure. In particular, potassium, known as highly incompatible element, become compatible with pressure, whose partition coefficient exceeded the unity at 90 GPa. Although pressure effect on D_{Sm} and D_{Nd} was not found even to 80 GPa, D_{Sm}/D_{Nd} decreases with increasing pressure and will reach to the unity at around 100 GPa. Our results shows that Sm and Nd was equally partitioned to partial melt and residual solids upon fractionation of CaPv from primordial deep magma ocean. This has profound implications for the origin of the super-chondritic $^{142}Nd/^{144}Nd$ for all terrestrial rocks.

Melting relation on FeO-SiO2 system at high pressure and the fate of the subducted banded iron formations

KATO, Chie[1*] ; NOMURA, Ryuichi[1] ; HIROSE, Kei[2] ; MIYAKE, Akira[3] ; OHISHI, Yasuo[4]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [2]Earth-Life Science Institute, Tokyo Institute of Technology, [3]Division of Earth and Planetary Sciences, Kyoto University, [4]Japan Synchrotron Radiation Research Institute

Subduction of banded iron formations (BIFs) may have played a significant role on the evolution of the core-mantle boundary (CMB) region and the chemical stratification at the topmost core. Almost all of the BIFs that had been deposited on the seafloor must have been subducted into the mantle and only a small portion was left at the surface today. Because of their high density, BIFs may have fallen down toward the CMB region. The amount of subducted BIFs is estimated to be $2*10^8$ km^3, which roughly matches with the total volume of the ultra-low velocity zones (Dobson and Brodholt, 2005, *Nature*). BIFs would be composed mainly of FeO and SiO_2 in the lower mantle because its oxidation state is close to iron-wustite buffer. We have performed melting experiments on FeO-SiO_2 system by laser-heated diamond-anvil cell technique at 25 - 140 GPa. FE-EPMA and FIB-SEM chemical analysis and observation of the texture of the recovered samples revealed that the liquidus phase was SiO_2 when starting from Fe_2SiO_4 fayalite, and compositions of the quenched melt suggested that the composition of the eutectic point was extremely FeO-rich ($<$0.6 wt% SiO_2). The solidus curve was constrained by observing the existence or no-existence of tiny quenched melt pools in each recovered samples. The solidus temperature at CMB pressure was 3,100 to 3,300 K that were lower than the solidus of pyrolite and the geotherm (Nomura et al., 2014, *Science*). These results imply that when the BIFs reach the CMB, they generate FeO-rich liquid that would be mixed with the basal magma ocean (Labrosse et al., 2007, *Nature*). This liquid would form a thin layer spread along CMB and react with the topmost core. Silicon content in liquid iron varies inversely to the oxygen fugacity when equilibrium with silicate melt (Ricolleau et al., 2011 *EPSL*). Assuming silicon-rich bulk core, exchange of silicon and oxygen would occur between the topmost core and FeO-rich silicate melt. This mechanism may account for the seismic wave speed anomaly observed at the topmost core which is thought to be honor to chemical stratification (Helffrich and Kaneshima, 2010 *Nature*; Buffett and Seagle, 2010 *JGR*).

Standardless determination of Nd isotope ratios in glasses and minerals using LA-MC-ICP-MS

KIMURA, Jun-ichi[1*] ; QING, Chang[1] ; KAWABATA, Hiroshi[2]

[1]JAMSTEC, [2]Kochi University

We investigated an appropriate instrumental setup for a laser-ablation multiple-collector inductively coupled plasma mass spectrometer (LA-MC-ICP-MS) and found that a reduced oxide setting allowed accurate and precise analysis of Nd isotope ratios in samples with or without concomitant interfering elements. We used an Aridus II solution?excimer laser dual-intake system. The ICP interface used normal sample and skimmer cones with torch shield switched off and an additional large interface rotary pump. The setting accomplished reduced oxide levels NdO+/Nd+ 0.01?0.05%, without significant sacrifice of the instrumental sensitivity (˜70%). Oxide molecular ions for the lighter elements were negligible and accurate internal mass bias corrections were achieved for both Sm and Nd using isotopic ratios derived from thermal ionization mass spectrometry measurements. This report reveals a novel setup that requires no external mass bias corrections (standardless analysis) for Sm and Nd isotope analyses by both solution- and LA-MC-ICP-MS methods. Solution analysis of La Jolla Nd standard gave a 143Nd/144Nd ratio of 0.511860 +/- 0.000026, which is in excellent agreement with the reference value (relative deviation (RD) = +6 ppm). JMC Nd standard solution yielded a 143Nd/144Nd ratio of 0.512216 +/- 0.000044 (RD = -14 ppm) while a Sm-doped JMC solution showed 0.512211 +/- 0.000030 (RD = -23 ppm). For LA analyses, the observed ratios and RDs were 143Nd/144Nd = 0.511921 +/- 0.000013 (RD = -12 ppm) for NIST SRM 610 glass standard (430 ppm Nd/453 ppm Sm); 0.512490 +/- 0.000018 (RD = +14 ppm) for Durango apatite (1121 ppm Nd/147 ppm Sm); 0.512200 +/- 0.000009 (RD = -26 ppm) for Fish Canyon Tuff sphene; 0.512232 +/- 0.000003 (RD = +65 ppm) for EDR monazite; and 0.512890 +/- 0.000147 (RD = +34 ppm) for groundmass of a St. Helena lava (22.7 ppm Nd/˜5.01 ppm Sm). All measurements were in good agreement with the reference values. Examinations on Sm/Nd elemental fractionation have also been made and we confirmed that this was originated from the ICP interface region rather than at laser ablation site.

Grain boundary diffusion of polycrystalline ice Ih under confining pressure of 100 MPa

NOGUCHI, Naoki[1] ; KUBO, Tomoaki[2*] ; DURHAM, William[5] ; SHIMIZU, Ichiko[4] ; KAGI, Hiroyuki[3]

[1]Graduate School of Engineering, Hiroshima University, [2]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, [3]Geochemical Laboratory, Graduate School of Science, University of Tokyo, [4]Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo, [5]Department of Earth, Atmospheric and Planetary Sciences, Massachusetts Institute of Technology

Ice I_h is a primary constituent of surfaces of the icy Galilean satellites and ice sheets at the Antarctica. Thus understanding rheological behavior of ice Ih will contribute to better knowledge about the dynamics and tectonics of the surface of the icy satellites and ice sheets. Stress applied by the tidal deformation to the surfaces of the icy satellites was predicted to be very low, ˜1 MPa (Sotin and Tobie 2004), and diffusion and grain-size-sensitive creeps probably control the deformation of the surfaces of the ice satellites. The deformation map under such a low stress condition can be constructed, based on two diffusion constants, grain boundary and volume diffusion coefficients, of polycrystalline ice I_h. The volume diffusion coefficient of ice I_h was determined from experiments using a single crystal of ice I_h (Ramseier 1967; Itagaki 1967), while the grain boundary diffusion coefficient has not been determined yet. Thus we carried out experiments to determine directly the grain boundary diffusion coefficient of polycrystalline ice I_h.

The diffusion couples have been composed of a pair of disks of pore-free polycrystalline H_2O and D_2O ices. The glass beads with a diameter of 2 μm were doped in the diffusion couples to prevent the grain growth during diffusion experiments by Zener pinning effect. The volume fraction of the glass beads was approximately 1 %. The diffusion experiments were carried out under the confining pressure of 100 MPa using a gas apparatus surrounded with a cryostat (Durham et al. 2001). Temperatures were set in the range from 235 K to 256 K. After keeping the diffusion couples in the deformation instrument for 20 ˜94 hours, we shaved off thin sections from the diffusion couples. Two-dimensional diffusion profiles of the thin section were determined with micro- and imaging- Raman spectroscopes and a cryo-stage. The Raman mapping or Raman imaging measurements were carried out with keeping the thin sections at -90 ℃. The concentration of deuteron can be determined from the relative intensity of Raman band of OH stretching mode to that of OD stretching mode using a quantitative curve. The two-dimensional distribution showed enrichment of deuterium at the grain boundaries near the H_2O/D_2O boundary. It indicates that grain boundary diffusion of ice I_h is rapid. The diffusion profiles obtained by the experiments enable to estimate the grain boundary diffusion coefficient of ice I_h which is essential to construct the deformation map.

Trace elements and Sr-Nd isotopic compositions of the pre-Komitake volcano

SHIBATA, Tomoyuki[1*] ; YOSHIMOTO, Mitsuhiro[2] ; FUJII, Toshitsugu[3] ; NAKADA, Setsuya[4]

[1]Institute for Geothermal Resarch, Kyoto University, [2]Faculty of Science, Hokkaido University, [3]Crisis & Environment Management Policy Institute, [4]Earthquake Research Institute, University of Tokyo

The chemical charecteristics of magmas from pre-Komitake Volcano, which is a buried and old volcanic body benarth the northeastern ?ank of Mt. Fuji, show the differences to those of Mt. Fuji (Yoshimoto *et al*., 2010). According to Yoshimoto *et al*. (2010), incompatible elements of former magmas increase with increasing SiO2, whereas those of later magmas increase at nearly constant SiO_2. They emphasized that those changes of the magma chemistry at this area from 250 ka to recent may have occurred due to a change in regional tectonics around 150 ka, although this remains unproven. To elucidate this problem, geochemical study for the magmas from pre-Komitake is essential. Therefore, we analyzed trace element and Sr-Nd isotopic compositions of those magmas.The samples are selected from the entire group, which are classified by lithology and chemistry (Group 1-3, Yoshimoto *et al*., 2010), and from 188-412m (core ERI-FJ2) and 426-624m (core ERI-FJ3) in depth. Trace elements are analyzed using by quadrupole inductively coupled plasma mass spectrometer following by the method of Chang *et al*. (2003). Sr-Nd isotopic compositions are measured by thermal ionization mass spectrometer following by the procedure of Shibata *et al*. (2007) and Yoshikawa and Shibata (2003). The enrichments of LILE's, Pb and Sr, which are general characteristics of island arc magma (eg. Wood et al., 1979), are observed from the analyzed samples in the primitive mantle normalized multi-element diagram. High Sr/Y ratios (70 in max.) and the weak positive Eu anomalies ($Eu^* = [Eu]_N/([Sm]_N/2+[Gd]_N/2$; N means condrite normalized value) are also found from several samples. The Sr and Nd isotope ratios show the variations from 0.703320-0.703476, and 0.512885-0.513087, respectively.

The Sr-Nd isotopic compositions of pre-Komitake volcano show a similar range of Mt. Fuji presented by Nagai *et al*. (2004), indicating that those magmas can be generated from the same source materials. Although the variations of Sr isotope compositions are small, significant differences are found. Most of the samples show similar Nd isotope ratios, whereas few samples show lower significant differences. These observations can be explained by 1) difference of slab derived fluid and 2) different degrees of crustal contaminations. It is unlikely that Nd isotope ratio of slab derived fluid is changed, because it is difficult keeping isotopic heterogeneity during the deep processes. Crustal rocks, which have similar Sr-Nd isotope ratios of Tanzawa tonalities (Kawate, 1996), are the candidate producing the whole isotopic variation of pre-Komitake volcano. Therefore, we prefer the contributions of crustal materials to explain the Sr-Ns isotopic variations of pre-Komitake volcano. The Eu∗shows positive correlation with Al2O3. This may indicate the plagioclase accumulation contributed the magma genesis of pre-Komitake volcano, and cause the elevation of Sr/Y ratios.

This study is supported by fund for collaboration from Earthquake Research Institute,The University of Tokyo.

Geochemical connection between HIMU-FOZO-PREMA: link to chemical and water content variation in oceanic crust

SHIMODA, Gen[1*] ; KOGISO, Tetsu[2]

[1]National Institute of Advanced Industrial Science and Technology, [2]Graduate School of Human and Environmental Studies, Kyoto University, Kyoto

One of fundamental concepts of the geochemistry is an existence of mantle reservoirs. Namely, isotopic composition of the ocean island basalts (OIBs) are explained by mixing of distinct and isolated reservoirs in the Earth (White, 1985; Zindler and Hart, 1986; Hofmann, 1997; Stracke, 2012). In early research on the mantle reservoirs, the isotopic composition of OIBs was mainly explained by the mixing of depleted MORB mantle (DMM) and three enriched reservoirs, those are HIMU (high-u: u = 238U/204Pb) EM1 (Enriched Mantle 1) and EM2 (Enriched mantle 2) whose isotopic compositions are enriched extremes. In addition to these reservoirs, importance of reservoirs whose isotopic compositions are common and intermediate has been pointed out, these are, FOZO (Focal Zone, Hart et al., 1992), C (common component; Hanan and Graham, 1996), PREMA (Prevalent Mantle, Zindler and Hart, 1986) and PHEM (Primitive Helium Mantle, Farley et al., 1992). Although the existences of these intermediate reservoirs are still in debated, the isotopic compositions of these reservoirs, in particular FOZO, have been frequently used to describe the isotopic distribution of OIBs. Therefore, elucidating the origin of these reservoirs should be important from the perspective of production of mantle heterogeneity (e.g., Hofmann, 1997; Stracke et al. 2005; Stracke, 2012).

To evaluate the origin of high-u (HIMU), focal zone; (FOZO) and Prevalent Mantle (PREMA), geochemical modeling was conducted from the perspective of chemical fractionation at mid-ocean ridges and subduction zones. For the modeling, MORB compositions from the Mid-Atlantic ridge are compiled for seven trace elements (Rb, Sr, Nd, Sm, Pb, Th and U) and used as representatives of oceanic crust compositions. Effect of chemical fractionation at a mid-ocean ridge is estimated based on magnesium number and frequency distribution. The results suggest that the chemical fractionation at a mid-ocean ridge can produce moderately depleted isotopic compositions those are suitable for PREMA if the age of recycled MORBs is1-2 Ga. It may follow that subduction modification is unnecessary for the production of PREMA, suggesting the importance of recycling of dry MORBs. Dehydration process at a subduction zone can produce FOZO isotopic signatures if degree of dehydration is high (4 %) that may represent maximum amount of dehydrated water. Thus, FOZO-PREMA isotopic array can be explained by mixing between recycled strongly dehydrated and dry MORBs. Consequently, PREMA-FOZO arrays could be produced by mixing between dry and dehydrated MORBs. For the production of HIMU, U and Th enrichment during crystal fractionation at mid-ocean ridge and Pb depletion owing to removal of sulfur during subduction is required in addition to FOZO production condition. As sulfur content in MORBs should be controlled by degassing process at a mid-ocean ridge, key processes that can differentiate HIMU from FOZO may be magma evolution process at mid-ocean ridge.

In recent years, particular attention has been paid to the ”REY-rich mud” (deep-sea sediment enriched highly in rare-earth and yttrium (REY)), because of its high potential as a REY resource. The REY-rich mud was originally reported from the central Pacific Ocean in 2011 (Kato et al., 2011). In January 2013, during KR-13-02 cruise, the mud was also discovered at southern part of the Minamitorisima within the Japanese exclusive economic zone (EEZ) (Kato et al., 2013; Fujinaga et al., 2013; Suzuki et al., 2013). Then, in the late 2013 and early 2014, we further conducted two more research cruises (MR13-E02 Leg2 and KR14-02 cruises) in the northern and eastern part of the Minamitorishima EEZ. During the cruises, we performed an acoustic survey using sub-bottom profiler (SBP), together with mud sampling by piston coring. In this presentation, we report the distribution and characteristics of the REY-rich mud in the northern and eastern part of Minamitorishima EEZ inferred by the SBP survey.

Recently, deep-sea sediment enriched in rare-earth elements and yttrium (REY) (called REY-rich mud) has been reported from a central part of the Pacific Ocean (Kato et al., 2011). Due to its great potential as a completely new REY resource, the REY-rich mud attracts particular attention from a wide field of scientists and non-scientists. In 2013, we have discovered the deep-sea sediments that are extremely enriched in REY (˜6,600 ppm) from the south region of the Minamitorishima within the Japanese exclusive economic zone (EEZ) (Kato et al., 2013; Fujinaga et al., 2013; Suzuki et al., 2013). In 2014, in order to investigate the detailed distribution of REY-rich mud in the EEZ of Minamitorishima, we further conducted research cruises (MR13-E02 Leg. 2 and KR14-02) in the north region of the Minamitorishima. Here, we report the distribution, mineral composition, and geochemical features of the REY-rich mud from the north region of the Minamitorishima EEZ.

Independent component analysis to decouple geochemical components of REY-rich mud in the Pacific and Minamitorishima EEZ

YASUKAWA, Kazutaka[1*] ; TAKAYA, Yutaro[2] ; OTA, Junichiro[1] ; FUJINAGA, Koichiro[1] ; NAKAMURA, Kentaro[1] ; KATO, Yasuhiro[2] ; IWAMORI, Hikaru[3]

[1]Sys. Innovation, Univ. of Tokyo, [2]FRCER, Univ. of Tokyo, [3]JAMSTEC

Rare-earth elements and yttrium (REY) are essential for state-of-the-art devices and green technologies including electric vehicles, fiber optics, smart phones, wind power generation etc. Recently, the deep-sea sediments enriched in REY (termed as "REY-rich mud") have been discovered in the Pacific Ocean, which have great potential as a completely new REY resource (Kato et al., 2011). In 2013, the presence of REY-rich mud was also confirmed within the Japanese exclusive economic zone (EEZ) around Minamitorishima (Fujinaga et al., 2013; Suzuki et al., 2013). The maximum total REY content in the REY-rich mud from Minamitorishima EEZ reaches as high as 6,600 ppm, although typical REY-rich mud in other regions of the Pacific Ocean contains less than 2,230 ppm of total REY.

In order to elucidate a component contributing to REY-enrichment in the sediments, Kato et al. (2011) performed independent component analysis (ICA) on the geochemical data set of Pacific deep-sea sediments. ICA is a relatively new multivariate statistical method established in 1980s, which can extract original independent source signals or factors from observed signals based on an assumption that the observed multivariate data are mutually independent but do not form a multivariate normal (Gaussian) distribution (Hyvärinen et al., 2001).

Four independent components (ICs) were found by Kato et al. (2011): two diluting components corresponding to biogenic carbonate and silica, and two components toward high REY contents with Fe and Al values, respectively. Kato et al. (2011) interpreted that the Fe- and Al-rich ICs that are responsible for the REY-enrichment of the mud correspond to end-member minerals of Fe-oxyhydroxide and phillipsite, respectively. Recently, however, X-ray absorption fine structure (XAFS) analysis and μ-XRF elemental mapping using high-energy synchrotron radiation revealed that most of REY are directly bonded to apatite in the REY-rich mud (Toda, 2013; Kashiwabara et al., 2014).

Here, we analyze a new comprehensive geochemical data set of deep-sea sediments from the Pacific Ocean and Minamitorishima EEZ by ICA. In this calculation, we utilize the new chemical composition data of individual crystals of phillipsite and apatite measured by LA-ICP-MS as new end-members for the ICA analysis. We will discuss the results and interpretation of our new analysis.

The KR13-02 cruise was conducted in the southern part of the Minamitorishima to explore rare-earth elements and yttrium-rich mud (REY-rich mud) within Japanese Exclusive Economic Zone (EEZ) on January 2013. During the cruise, seven sediment cores were successfully collected. The results of bulk sediment analyses showed that one of the cores (PC05) has an extremely REY-concentrated layer with 6,596 ppm total REY (Kato et al., 2013; Suzuki et al., 2013) which is three times higher than the maximum concentration in the mud previously reported for the eastern South and central North Pacific Ocean (2,230 ppm; Kato et al., 2011). In addition to REY, P concentration in the layer is also noticeably high (Kato et al., 2013; Suzuki et al., 2013), suggesting that Ca phosphate (apatite) is mainly responsible for the REY-enrichment in the layer, as in the case for the mud presented in other areas (Kashiwabara et al., 2014). However, factors contributing the extreme enrichment of REY, which in turn might provide important insights into the genesis of REY-rich mud, are still uncertain. In the present contribution, we report mineralogical features of Minamitorishima REY-rich mud including the extremely REY-concentrated layer and discuss about its genesis.

Helium and halogen compositions in MORB vesicles

KAGOSHIMA, Takanori[1*] ; TAKAHATA, Naoto[1] ; SANO, Yuji[1]

[1]Atmosphere and Ocean Research Institute, University of Tokyo

Degassing behavior of halogens through submarine volcanism is not well understood. We determined helium and halogen compositions of MORB vesicles to constrain halogen flux at ridges. Samples collected at 8 sites (13oN-17oS on EPR; 15oN-37oN on MAR; 24-25oS on CIR) were crushed in dilute NaOH or NH_3 solution at liquid nitrogen temperature and volatiles were extracted from vesicles. Helium isotope compositions were determined with a VG-5400 MS and F and Cl contents were measured with ICS-2100 ion chromatography. For glass matrix, concentration of F and Cl were determined with a NanoSIMS.

For vesicles, the average ^{3}He concentration was (4.5+/-2.1)x10^{-15} mol/g of sample and the average F/^{3}He and Cl/^{3}He ratios were (1.4+/-0.5)x10^6 and (2.9+/-0.6)x10^7. This provides F and Cl flux of (7.1+/-2.8)x10^8 mol/y and (1.5+/-0.4)x10^{10} mol/y at ridges calibrating against the known ^{3}He flux of 530 mol/y. They may be defined as lower limits of MOR flux because F and Cl contents in glass matrix are $>$7000 and $>$100 times higher than those in vesicles and dissolution of only a small part of volatiles staying in oceanic crust into the ocean will increase volatile flux significantly. The large difference between F/Cl ratios in vesicles and glass matrix reflects difference in vesicle/glass partition coefficients of these elements, which suggests that they have significantly different degassing behavior at ridges. From the data of the noble gas method on MORB in literature, Br/Cl and I/Cl ratios in vesicles were calculated to be (1.8+/-0.1)x10^{-3} and (5.4+/-0.1)x10^{-5} which are almost equivalent with those in glass matrix [1], suggesting their vesicle/glass partition coefficients are similar in submarine basaltic magma. Br and I flux at ridges were calculated to be (2.7+/-0.8)x10^7 mol/y and (8.3+/-2.4)x10^5 mol/y based on the Cl flux estimated in this study. They are the first estimate of Br and I flux obtained by indirect calibration against ^{3}He flux and may be lower limits of MOR flux by the same reason as Cl. Combination of the method in this study and the noble gas method on the same sample will give us new insight into degassing behavior and geochemical cycles of halogens.

Magmatic process of Cretacious plutonic complex in Ikoma mountains, SW Japan

KOIZUMI, Naoko[1*] ; OKUDAIRA, Takamoto[1] ; OGAWA, Daisuke[1]

[1]Osaka City University

The Ikoma gabbroic complex is one of the largest Cretaceous mafic pluton in SW Japan are exposed at Ikoma mountains, consisting of mafic rocks (the Ikoma gabbroic rocks) and intermediate to felsic rocks, the Fukihata tonalites and the Kyuanji quartz diorites. These rocks show three modes in whole-rock compositional relation, 1) as Plagioclase (Pl) cumulate, 2) as Hornblende-plagioclase (Hbl-Pl) cumulate and 3) as Hornblende (Hbl) gabbronorite.

The SiO_2 contents of the Ikoma gabbroic complex show 44 to 63 wt.%. Plagioclase cumulate and Hbl-Pl cumulate with SiO_2<50wt.%, their major oxide contents change widely for SiO_2 contents. Hbl gabbronorite are mafic to intermediate with SiO2>50wt.%, major oxide contents show linear trends with respect to SiO_2 contents on compositional variation diagrams.

Plagioclase cumulate shows cumulus structure and consists of mainly Ca-rich plagioclase (An_{85-90}). On the compositional variation diagrams, plagioclase compositions included in Plagioclase cumulate is located to the end-member on the trend of Plagioclase cumulate. Moreover, their plagioclase mode are shown by a positive trend with respect to the variation of CaO contents. It suggests that Plagioclase cumulates were associated with the accumulation of plagioclase. On the other hand, plagioclase compositions in Hbl-Pl cumulate and Hbl gabbronorite are Ca-poor (An_{70-75}). It suggests Hbl-Pl cumulate and Hbl gabbronorite occur after forming Plagioclase cumulate. Whole-rock compositions of the Ikoma gabbroic complex vary linearly with increasing SiO_2 contents, and their $^{87}Sr/^{86}Sr$ initial ratios at 82 Ma show a positive trend with variation of SiO_2 contents. These characteristics suggest a mixing of mafic magma and felsic materials. The mafic end-member is mafic magma of Ikoma gabbroic complex. Granitoids occurred at the same time of the activity of the Ikoma gabbroic complex are plotted on the extrapolation of the compositional trend of Hbl gabbronorite, but their $^{87}Sr/^{86}Sr$ initial ratios at 82 Ma is too low as the felsic end-member in a mixing. It is suggesting that the felsic end-member may not be the granitoids, but other crustal materials.

Volatile compositions of apatite grains from pyroclastic flow deposits of Aso volcano

DOKYU, Marie[1*] ; KOGISO, Tetsu[1]

[1]Graduate School of Human and Environmental Studies, Kyoto University

Water in the Earth is important for life and mantle dynamics. The amount of water in the early Earth is one of the most essential constraints for revealing the origin of the Earth's water.

An important clue to the water budget in the early Earth is apatite inclusions in ˜4.4 Ga zircon from Jack Hills in Australia. Because apatite has volatile components, it is expected to determine the amount of water in the interior of the early Earth from OH composition of the Jack Hills apatite. However, partitioning of OH between apatite and melt is unclear.

We analyzed volatile compositions of apatite grains from pyroclastic flow deposits of Aso volcano in order to reveal the relationship between OH composition of apatite and H_2O composition of melt. The H_2O concentrations in the host magma have been estimated from those of melt inclusions in plagioclase phenocrysts. It shows that mafic melt contains more H_2O than silicic melt does. F concentrations in apatite in each sample show large variations while Cl concentrations are constant, suggesting that F and OH substitute for each other. OH concentration in apatite of mafic sample was larger than that of silicic one, that is, OH concentration in apatite and amount of H_2O in melt show negative correlation.

The negative correlation would have been caused by difference in Ca content between mafic and silicic samples. It is possible that Ca in melt combines F and affect partitioning F between apatite and melt (Mathez and Webster, 2005). Mafic melt contains more Ca than silicic melt and Ca may disturbed partitioning F for apatite and OH concentration can be increase in apatite. Another possibility is that the water compositions of melt inclusions do not represent those in the host melt. The melt inclusions have many bubbles, and the more bubbles they have, the less H_2O they contain. It means that H_2O in melt inclusions was lost to the bubbles, resulting in underestimation of water contents in the host melt. Actually another study calculated the amounts of H_2O in the mafic and silicic melts of the Aso pyroclastic flow and results were 4.1-7.7wt% and 4.1-5.7wt% respectively (Kaneko et al., 2007). If these results are correct, then OH concentration in apatite and the amount of H_2O in melt are positively correlated.

Range of the amount of F and OH in each sample could mean that melt composition gradually changed by degassing or/and crystallization differentiation. For precise determination of OH partitioning between apatite and melt, it is necessary to reveal the effect of Ca or other components to partitioning behavior of volatile components between apatite and melt.

Measuring osmium isotopic composition of natural polycrystalline diamond (carbonado) and implications for its origin

SHIRAISHI, Noriko[1*] ; SENDA, Ryoko[2] ; KAGI, Hiroyuki[1] ; SUMINO, Hirochika[1] ; SUZUKI, Katsuhiko[2]

[1]Geochemical Research Center, Graduate School of Science, University of Tokyo, [2]Institute for Research on Earth and Evolution, Japan Agency for Marine-Earth Science and Technology

The origin of natural polycrystalline diamond, carbonado, has long been enigmatic. Carbonado is characterized as high porosity, no genetic relations to kimberlites, light carbon isotope ratio, and lack of mantle-derived mineral inclusions. Based on these observations, several hypotheses about the origin of carbonado have been proposed: transformation of subducted organic carbon into diamond in a cold slab (Robinson, 1978); shock metamorphism of organic carbon by meteorite impact (Smith and Dawson, 1985); radiation-induced diamond formation by spontaneous fission of uranium in crustal environment (Ozima *et al*., 1991); formation in an interstellar environment (Garai *et al*., 2006); crystallization from C-O-H fluid in cratonic upper mantle (Ishibashi *et al*., 2012). However, no conclusive evidence has been provided to settle a controversy about the origin of carbonado. In this study, we first tried to measure Os isotopic composition of carbonados collected from placer deposits in the Central African Republic in order to identify its origin.

Natural samples have a wide variety of Os isotopic ratios, $^{187}Os/^{188}Os$, depending on their origin because ^{187}Re, the parent nuclide of radiogenic ^{187}Os, is a mildly incompatible element during mantle melting whereas Os is a strongly compatible element. $^{187}Os/^{188}Os$ ratio of upper continental crust ranges from 1.0 to 1.4 (Peucker-Ehrenbrink and Jahn, 2001), whereas that of primitive upper mantle is about 0.13 (Meisel *et al*., 1996). Os isotopic ratio of the micro diamond crystal itself can reflect the environment where diamond grains crystallized. Carbonado is a porous aggregate of micrometer-size diamond crystals and original chemical characteristics of the grain boundaries could be heavily altered after the diamond growth.

This study was designed to determine Os isotopic ratios within diamond crystals of carbonados and in the grain boundaries separately. Two-step sample chemical leaching was carried out by Carius tube method (Shirey and Walker, 1995). First, carbonado samples were crushed to submillimeter grains and were sealed in a Carius tube with spike solutions and inverse aqua regia (HCl + 3 HNO_3). The solution was heated at 220 ℃ for 24 hours. This procedure was for extract Os in the grain boundaries. Second, the residue of solid samples was heated in a vacuum chamber to convert diamond to graphite. A graphitized sample was decomposed in acid solution in the same way as the first leaching process. The second process was to extract Os within diamond grains. Osmiums in the both solutions were purified with the solvent extraction (Cohen and Waters, 1996) and microdistillation (Roy-Barman, 1993). Osmium isotopic compositions of the samples were determined using thermal ionization mass spectrometry (TIMS). Blank levels of Carius tubes and inverse aqua regia solutions prepared from several chemical regents were checked. As a result, a quartz glass tube was found to have the lowest blank level compared with other glass tubes made from borosilicate glass.

In the presentation, we will report preliminary results of Os isotopic ratios of the carbonado, which have the potential for a decisive evidence to close the debate on the origin of carbonado.

High-pressure high-temperature phase transitions in $ZnTiO_3$

ABE, Kohei[1*] ; KOJITANI, Hiroshi[1] ; AKAOGI, Masaki[1]

[1]Department of Chemistry, Gakushuin University

It is widely accepted that perovskite-type $MgSiO_3$ is the most abundant mineral in Earth ' s lower mantle. Ilmenite-type $MgSiO_3$ transforms to perovskite at 23 GPa and 1600 ℃. It was reported that ilmenite-type $ZnTiO_3$, an analogue to ilmenite-type $MgSiO_3$, decomposes into ZnO and TiO_2 at about 20-25 GPa (Ito and Matsui, 1979). However, phase relations in $ZnTiO_3$ have not been studied yet in detail. Therefore, we investigated the phase relations in $ZnTiO_3$ by high-pressure high-temperature experiments.

A starting material of ilmenite-type $ZnTiO_3$ was synthesized by heating a mixture of ZnO and TiO_2 with 1:1 mol ratio at 800 ℃ for 32 hours in air. High-pressure phase relation experiments were made by using a Kawai-type 6-8 multi-anvil apparatus in the pressure and temperature ranges of 13-35 GPa and 1000-1400 ℃, respectively. After keeping the starting sample at desired conditions for 1-2 hours, the samples were quenched, and then decompressed to ambient pressure. Recovered samples were identified by using the powder X-ray diffraction method.

We found that the recovered samples which were compressed between 15 and 20 GPa at 1000-1400 ℃ had the $LiNbO_3$-type (LNO) structure. The ilmenite-LNO phase boundary was determined as P(GPa)=19.9-0.0038T(℃). $FeTiO_3$ ilmenite which is an analogue to ilmenite-type $MgSiO_3$ transforms to perovskite above 15 GPa, and the perovskite transforms to the LNO-type structure during decompression (Ming et al., 2006). The ilmenite-perovskite phase boundary in $FeTiO_3$ has a negative slope which is caused by a positive entropy change for the transition due to increase of coordination number of divalent cation from 6 to 8. If the LNO-type $ZnTiO_3$ is a stable phase, the slope of the boundary should be positive because of no change in the coordination number of the divalent cation. Therefore, the negative slope of the boundary implies that the recovered LNO-type $ZnTiO_3$ was originally perovskite-type at 15-20 GPa.

The recovered samples synthesized above 20 GPa were identified to be an assembly of wurtzite-type ZnO and α-PbO_2-type TiO_2. The post-perovskite phase boundary in $ZnTiO_3$ is determined as P(GPa)=9.5-0.010T(℃). Wurtzite-type ZnO transforms to NaCl-type at about 6 GPa (Kusaba et al., 1999). Also, α-PbO_2-type TiO_2 transforms to baddeleyite-type at about 17 GPa (Tang and Endo, 1993). Therefore, we suggest that the phase assembly of NaCl-type ZnO and baddeleyite-type TiO_2 is stable above 20 GPa.

Quantitative multi-element imaging of geological materials by femto-second LA-ICP-MS

CHANG, Qing[1*] ; KIMURA, Jun-ichi[1]

[1]Japan Agency for Marine-Earth Science and Technology

Elemental mapping analysis of geological materials using X-ray related methods (EPMA, XRF) or SIMS suffers from insufficient sensitivity and poor quantification. LA-ICP-MS has advantages of high sensitivity and less matrix effect, therefore has been developed for elemental and isotopic imaging analyses over the last decade. However, quantification problem by this method remains unsolved because of the lack of a suitable sampling volume correction method and necessity of matrix-matched standard. This work presents multi-element imaging/mapping analysis of orthopyroxene and plagioclase minerals by femto-second LA-ICP-MS using a novel normalization process. Laser sampling volume is corrected for by analyzing ten major elements (SiO2, TiO2, Al2O3, FeO, MnO, MgO, CaO, Na2O, K2O, and P2O5) followed by normalization of the analyzed total sum to 100 wt% to obtain correction factor. This correction method is free from any external analysis (e.g., EPMA) for at least one internal standard element (e.g. Ca), and can be applied for both spot and line scanning LA mode. This allows LA-ICP-MS method standalone and liberates from errors inherited from any local heterogeneity of the samples picked up differently by the different analytical techniques used. Use of USGS basalt glass as a standard eliminates matrix effect in the levels less than 10% RD for these silicate minerals. Two-dimensional elemental distribution images of 43 elements were acquired from 4-6 μm depth of the sample surface with a ˜40 μm lateral resolution. An area of 500$\times$500 μm can be scanned simultaneously for 43 elements in less than 2.3 hours. Trace elements in silicate minerals can be imaged at sub-ppm concentration level, while major elements were mapped at sub-percent concentration.

Key words: femto-second LA-ICP-MS, elemental mapping, minerals

Applicability of fictitious domain method in data processing of marine CSEM exploration

KUSUDA, Kei[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1]

[1]Graduate School of Engineering, Kyoto University

Marine controlled-source electromagnetic (CSEM) survey, one of the electro-magnetic (EM) sounding methods, is considered as a technique in practice for the exploration of hydrocarbon resources including methane hydrate (MH). In the analysis of EM field acquired in CSEM survey, forward modeling is used to model sub-seafloor structure. In the forward modeling, transforming the diffusive Maxwell equation to a fictitious wave domain reduces CPU time (Mittet, 2010). Phase velocities of electromagnetic waves are a function of material properties, i.e., electric conductivity and magnetic permeability. In the fictitious domain, the difference in the phase velocity as a function of materials is exaggerated so that EM field could propagate in the earth with much slower apparent phase velocity compared to the other field propagating through materials above seafloor. However, such character of the fictitious wave domain has not been well exploited for the estimation of subsurface resistivity structure. In the present study, we examine whether the received waveforms in the fictitious wave domain could highlight MH responses better than in the diffusive domain. We conduct numerical simulations using a three-dimensional resistivity model composed of seawater and earth layers, and a thin MH zone of a rectangular shape. Our results show that the sensitivity to the MH response in the received waveform is improved in the fictitious domain. It is mainly due to the separation of EM waves travelling with different phase velocities through the sub-seafloor layers and seawater in the fictitious domain. We then tested to see if the transform from the diffusive domain (e.g., observed EM field) to the fictitious wave domain is possible or not for further utilization of the transform. As a result of the singular value decomposition method to achieve the transform, the transforming EM waves in the fictitious domain indicated that the sensitivity to MH becomes about twice as much than the original EM field in the diffusive domain.

Subsurface imaging with EM migration of magnetic fields from multiple frequencies

HYODO, Daisuke[1*] ; GOTO, Tada-nori[1] ; MIKADA, Hitoshi[1] ; TAKEKAWA, Junichi[1]

[1]Kyoto University

These days, the supply of water is facing a crisis due to the dramatic growth of population, industrialization, etc. As a result, the groundwater demand is becoming more and more stronger than before. Electrical prospecting is a method usually attempted for groundwater exploration, but setting the observation equipment in desert regions, where water shortage is a serious problem, causes us difficulty using this method there, since there is nothing that assures electrical contact between electrode and the earth. In these circumstances, some other methods that do not require any contact of electrode are needed. VLF or ULF is the method that satisfies the condition. However, none of these methods could provide information necessary to locate groundwater and it is strongly necessary to locate water head of survey areas. There is some shortcomings in the present processing of these VLF and ULF data. In this study, the phase-shift method, which is used in seismic migration, is applied to the horizontal magnetic components with multiple frequencies in order to image subsurface resistivity structures to locate groundwater. The survey is conducted more easily and shortly, if only the magnetic sensors above the surface are enough for estimating the structures. As in the seismic migration, both upward/downward imaging and the exploding reflector concepts can be applied to the horizontal magnetic components. The synthetic data examples show that the migration method is effective for imaging the conductive anomaly. However, it is necessary to select appropriate frequency bands in order to estimate correct subsurface structures. We conclude that this technique gives an approximate resistivity structures quickly and that the migration of magnetic components is expected to provide information on the subsurface. This method is also useful for geological interpretations and for an initial model of the more complicated inversion method.

Application of particle method to forward modeling of marine controlled-source electromagnetic survey

IMAMURA, Naoto[1*] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1] ; MIKADA, Hitoshi[1]

[1]Kyoto University, Graduate School of Engineering

A new marine controlled-source electromagnetic (MCSEM) forward simulation is presented in this study. The benefit of the method is the better treatment of complicated seafloor topography and/or buried structures than before. Here, we focused on the moving particle semi-implicit (MPS) method. In our method, the Maxwell ' s equations are discretized with particle arrangement without grid structure, which is usually used in finite-difference method (FDM). Each particle denotes the three components of electromagnetic fields at each particle. MPS method has some advantages over the other methods such as finite-element method (FEM), FDM, integral method (IE), etc. An obvious advantage of this approach is a numerical model that can flexibly form arbitrary topography shapes. Although FEM is sometimes employed to treat the topographic structure, especially for MCSEM, pre-process for creating grid or mesh structures require a time-consuming procedure especially in three-dimensional cases. A second advantage is that the three components of electric field and electric current as well as magnetic field and source are defined at the same location of every particle, while not at the same location in the case of Yee ' s grid.

We tested our three dimensional MCSEM forward simulation using the particle method and confirmed that the accuracy of the forward simulation with the simple tilted layered model would be improved. Our forward modeling results show the accuracy sufficient to discuss with the analytical results. The local and arbitrary refinement of particle is conducted to obtain more accurate result using the same model. The local refinement is applied only near the transmitter and receiver dipoles. The accuracy of MPS becomes higher in the local refinement than in the use of isodiametric particles. Our results suggest that the method using MPS with locally refined particles is useful for the forward simulation of electromagnetic field with arbitrary topography in the MCSEM modeling.

Simultaneous inversion of self-potential for estimating hydraulic parameters and streaming current coefficient

OZAKI, Yusuke[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1]

[1]Graduate School of Engineering, Kyoto University

In this study, we develop an inversion scheme for the simultaneous estimation of hydraulic conductivity, streaming current coefficient and specific storage, using transient self-potential (SP) data. SP is a natural electrical potential, which is thought to be caused by subsurface fluid flow through the electro-kinetic coupling. Recently, several SP measurements are performed during pumping tests to characterize the parameters of the aquifer. Almost of all SP analysis methods are adaptable to the static SP data, but a huge amount of the transient SP data is not used efficiently. Therefore, we develop an inversion scheme for the analysis of transient SP data. The electrical conductivity, streaming current coefficient, hydraulic conductivity and specific storage are parameters effectively influencing the SP profile on the surface, and can be solved in the inversion. The distribution of electrical conductivity structure can be used if the electrical resistivity tomography (ERT) or other EM measurements are performed with the SP measurement. We employ the relationship between hydraulic conductivity and streaming current coefficient to decreases the number of estimating model parameters, and to enable the simultaneous estimation of hydraulic conductivity and streaming current coefficient. First in this study, we check the sensitivities of the hydraulic conductivity and specific storage obtained at different times. The sensitivities of the hydraulic conductivity and specific storage are different with respect to the phase. The simultaneous inversion of hydraulic conductivity and specific storage from the transient SP profile is turned out possible from the difference in phase. Finally, we apply our inversion scheme to a synthetic SP profile, and reconstruct the subsurface structure of hydraulic conductivity, streaming current coefficient and specific storage simultaneously. As a result, our inversion technique allows us to obtain the hydraulic parameters from SP data on the ground surface, although the conventional hydraulic tomography strongly relies on the borehole data.

Numerical study for failure behavior of rock masses including complex free-surfaces using a particle method

TAKEKAWA, Junichi[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1]

[1]Kyoto Univ.

Failure of rock mass including complex free surfaces is of importance in many engineering and scientific fields. This paper applied an advanced discretization approach to simulate quasi-static failure of rock mass within a Hamiltonian particle method (HPM) framework. In HPM, a free surface is introduced in a simple way, just by removing or ignoring outer particles. This potential can be developed to discretize numerical models including complex free surfaces without the increment of time for pre-processing. In the present study, we developed the numerical simulator based on HPM with a staggered particle technique for simulating brittle failure and AE activities in rock mass with incorporating the elasto-plastic damage model. We, first, conducted uni-axial compressive tests for validating the effectiveness of our approach. Next, we adopted rectangular and circular disc specimens with a hole as complex free surface models. Our numerical results had good agreement with those from laboratory experiments. This suggests that HPM would be a method to simulate failure behavior of rock mass without time-consuming pre-processing.

Forward calculation of Magnetotelluric responses with MPS method

TANI, Masanori[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1]

[1]Graduate School of Engineering, Kyoto University

In this research, we developed a new 2-D magnetotelluric (MT) forward simulation method based on the MPS (Moving Particle Semi-implicit) method framework. Our final purpose is to calculate MT response with arbitrary three-dimensional topography.

The MPS method is a particle method and was first developed for the simulation of incompressible fluid flow (Koshizuka and Oka, 1996). Recently, the MPS method is used the digital reproduction of failure of materials,for the simulation of elastic wave propagation, etc. We use the MPS method for the simulation of electromagnetic induction.

In our forward calculation, electric and magnetic fields are defined at each particles in a calculation model. MT responses are calculated on the surface of the ground with topography with a horst-graben shape. Our simulation results indicate that MT forward calculation with the MPS method is suitable for free surface like topography, because the MPS method does not require the mesh configuration such as for FDM and FEM, particles in the MPS method could form any shape. The results of MT forward calculation (TE-mode and TM-mode) based on MPS method is reliable enough to calculate MT responses on models with topography. Based on the inherent character of MPS method, the expansion of our code from two-dimension to three-dimension will be easily achieved.

Fluid-physical simulation of silicate scale formation using lattice Boltzmann method

MIZUSHIMA, Akihiro[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1]

[1]Graduate School of Engineering, Kyoto University

Scaling behavior has an important role in various geosciences fields. For example, precipitation of silica can cling to pipes and wells, and prevent the geothermal power generation. Silica precipitation strongly affects the circulation of hydrothermal systems by changing the permeability structure, which is related to the nucleation of seafloor massive sulphide. Self-sealing is of importance in the understanding of long-term radionuclide mobility and the safety of deep geological repositories of radioactive waste.

The deposition of amorphous silica is controlled probably by many processes. There have been a number of experimental studies made on the chemical kinetics of silica deposition as a function of the degree of super-saturation. However scaling estimated by the simple chemical precipitations cannot explain the measured features in laboratory and field experiments. On the other hand, a high rate of deposition could be found where fluid flow stagnates. Although it has been empirically observed that the fluid flow structure can influence silica scaling, relatively little research have been conducted to investigate hydrodynamic effect on silica scaling. The aim of this work is to evaluate the importance of both chemical kinetic and hydrodynamic effects on silica scale growth with a method of numerical simulation.

Here using the lattice Boltzmann method, we calculated velocity, temperature and concentration of dissolved silica in the 2D parallel plate channel and predicted the silica deposition of both chemical kinetic and hydrodynamic deposition processes. The laboratory results by Hosoi and Imai (1982) can be as the reference. We also predicted the silica deposition along the channel with sudden expansion of width. For the latter case, the similar field example in the production pipes of the geothermal well was reported (Mercado et al., 1989).

In our numerical simulations, the silica deposition predicted by the kinetic process has the magnitude extremely lower than the amount of laboratory experiment, but shows the similar magnitude if the hydrodynamic process is considered for scaling. In addition, at the another channel model with the sudden expansion scaling predicted by the hydrodynamic process can explain the observed feature at the geothermal well.

It is found that consideration of the simple kinetics process solely is not sufficient for explanation of the real silica deposition. Therefore, we emphasize the importance of hydrodynamic effect on silica scaling. To predict the silica deposition more quantitatively, an advanced-simulation including behaviors of colloid silica particles in flow.

Distinct element method for solid-fluid coupled interaction in the application of hydraulic fracturing

NAGASO, Masaya[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1]

[1]Graduate School of Engineering, Kyoto University

The hydraulic fracturing is of great interest in many scientific and engineering fields in hydraulic fracturing, such as the hot dry rock geothermal power(HDR). However, the natural fractures have significant influence on the nucleation and growth of fractures created in hydraulic fracturing. In addition, the viscosity of fluid used in hydraulic fracturing also influences the geometry of hydraulically created fractures. Although the influence of both natural fracture and fluid viscosity has been intensively investigated on the distribution of hydraulic fractures, none of the studies has dealt with natural fractures and fluid viscosity at the same time and the interaction between them has not been revealed yet. We, therefore, performed a series of numerical simulations for hydraulic fracturing in naturally fractured rock using a 2D flow-coupled DEM code to examine the influence of the fluid viscosity on the interaction between hydraulic and natural fractures. In this study, a low viscosity fluid of 0.1 m^2/s and a high viscosity fluid of 100.0 m^2/s are used. Our model is a square block with a borehole at the center under a stress field whose maximum and minimum stresses are 10 and 5 MPa, respectively. We apply the hydraulic pressure to the borehole wall, and observe how induced hydraulic fracture would propagate in the presence of a single natural fracture located adjacent to the borehole. The viscosity of fluid and the angle between the maximum stress direction and fracture orientation are the parameters of the numerical simulation. The results show that the lower the oblique intersection angle is, the less linearly the induced fracture crosses the pre-existing fracture. However, when a high viscosity fluid is used, the interruption of natural fractures decreases and the induced fracture tends to go straight along the direction of maximum compression. Our numerical example implies that high viscosity fluid could be used in hydraulic fracturing to reduce the influence of a natural fracture when the hydraulic fracture intersects the pre-existing fracture with certain angles .

Unsteady fluid dynamics in Newtonian and non-Newtonian fluid is the main concern of aeronautical engineering, mechanical engineering, chemical engineering, resource engineering and civil engineering. It is also true to the oil industry because the amount of oil production in the world is decreasing recently, it is of importance to seek the technological development for enhanced oil recovery (EOR) in place in the subsurface. Recently, many laboratory experiments and field tests have been performed such as water, gas, chemical, or thermal injections to attempt the enhancement of oil production. Seismic stimulation is known as one of the EOR methods and unsteady flow problem. Numerous observations show that seismic stimulation of oil reservoir may improve oil production. However, for effective usage of seismic EOR, we need to understand the characteristics of changing apparent viscosity under oscillating solid-phase. In this study, we attempt to demonstrate the apparent viscous change in laminar flow under oscillating boundary condition with the models of single pore throats and porous media.

We use Lattice Boltzmann method (LBM) describing Boltzmann equation. We use 2-dimensional 9-velocity (2d9v) model to simulate 2-dimensional incompressible viscous flow. We assume that the background pressure difference between inlet and outlet is constant. The flow is generated by a constant pressure difference.

We discuss the apparent viscosity of a single pore throat and porous media.

First, we discuss four characteristics of an incident elastic wave: amplitude, frequency, angle, and pressure disturbance (P wave). The characteristics of amplitude, frequency and angle are largely related with the amount of changing apparent viscosity. The flux increases under cases with large amplitude, high frequency, and large angle (S wave) of incident to the wall. On the other hand, the pressure disturbance (P wave) is not effective for changing apparent viscosity. We then discuss the possibility of changing apparent viscosity in terms of fluid properties. Wall oscillation can cause improving relative permeability. So, if the rock has water wettability, the oil flux largely increase with wall oscillation. After that, we examine the possibility of changing apparent viscosity in terms of pore scales or shapes under the oscillating boundary condition with LBM. The models of single pore throat consists of two half pore and one pore throat. The models of porous media consist of several pore spaces connected by pore throats from one pore to the others. The shapes of single pore throats are also largely related with changing apparent viscosity. The apparent viscosity decreases with increasing length of the pore throats and radius of the pore throats, and with decreasing width of the pore throats and large pore radius. Comparing single pore throat model and porous media model, we find the apparent viscosity change in porous media models cannot be replaced by linear combination of the apparent viscosity changing in single pore throat models.

Our numerical results imply: i) the flow resistance under oscillating condition increases because the velocity difference between the wall and the center of flow is larger than that in steady flow, ii) the effect of the advection term in oscillating boundary condition is larger than that in steady flow, iii) fluid extrusion is generated by partial pressure gradient near the wall and pore throat, and iv) the oscillating boundary may cause improving pressure loss.

Estimation of stress change in ductile part of the crust inferred from seismic scattering

OKAMOTO, Kyosuke[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1]

[1]Graduate School of Engineering, Kyoto University

In the past, stress field in the subsurface has been measured by various techniques. For example, the borehole-breakout, the stress release method, the hydraulic fracturing, the strain gauge buried in the ground are used to measure the stress field after costly drilling the subsurface. Beside the techniques requiring direct access to the subsurface, the stress field is also measured indirectly. The Electro Distance Meter, the Global Positioning System, etc. are used to measure a surface deformation in time, from which the subsurface stress change is estimated. However, the estimated stress change in the subsurface is largely affected by near-surface inhomogeneities. Thus, information on the stress field should be obtained from other indirect techniques.

Here, we focus on seismic scattering wave, particularly the coda-Q value, to measure spatial and temporal variations of subsurface stress field. The coda-Q, derived from the attenuation of coda envelope, is perceived to be an indicator of the inhomogeneity in the subsurface. Meanwhile, it has been proposed that the coda-Q has a proportional relationship with the magnitude of stress using a numerical simulation. In this study, we hypothesize that the coda-Q, obtained from seismic waves traveling over a wide range of the crust, indicates stress change in a deep subsurface. At first we numerically calculate a relationship between the coda-Q and the magnitude of stress using a homogeneous crustal model, and show that the coda-Q systematically increases against the magnitude of the stress. Then we confirm the relationship using a heterogeneous numerical model, which has a low velocity zone near the surface. It is revealed that the coda-Q indicates the magnitude of the stress change in the deep subsurface, beneath the inhomogeneity, while the surface strain distribution is largely affected by the low velocity zone near the surface. For the next step, using real seismic data acquired at the regions of the 2008 Iwate-Miyagi Nairiku earthquake and the 2004 mid-Niigata prefecture earthquake, we examine whether the coda-Q indicates stress change in the deep subsurface. The stress change estimated from the coda-Q corresponds with the theoretical one in the ductile part, calculated by a fault model acquired by a seismic wave analysis, whereas the estimated stress change dose not correspond with the inferred one from GPS measurement. It means that the coda-Q can indicate stress change in the deep subsurface, which could give more accurate investigation than the GPS measurement.

2D simulation of seismic wave propagation for time lapse monitoring of heterogeneous structure and near-surface effects

KAMIMURA, Aya[1*] ; KASAHARA, Junzo[1] ; MURASE, Kei[1] ; TAZAWA, Oshie[1] ; NISHIYAMA, Eiichiro[1] ; KUBOTA, Ryuji[1] ; FUJIMOTO, Osamu[1] ; OHMURA, Takeshi[1] ; NOGUCHI, Shizuo[1] ; OHNUMA, Hiroshi[1]

[1]Kawasaki Geological Engineering Co.,Ltd.

For the time lapse study in CCS and EOR, we have proposed the method using the seismic ACROSS (Accurately Controlled and Routinely Operated Signal System) and geophone array. However, it is considered that the near-surface effects and their temporal changes caused by water content changes, temperature and surface wave generation, might have very large effects for time lapse estimation, and we would like to evaluate and reduce the near-surface effects by the comparison of surface and borehole geophone records. We have carried out simulation studies to evaluate the effects of near-surface and heterogeneities such as the man-made cavities in the green tuff layers (Vp ˜2.5 km/s). We also evaluate the near-surface effects by changing geophone depths. The results of the simulations are as follows.

At the simulation of surface hypocenters, seismic waves passed through the man-made cavities attenuated and seismic waves scattered at the man-made cavities. This shows that there will be a heterogeneous structure like man-made cavities when observed seismic waves were attenuated, and the man-made cavities will become a secondary hypocenter.

As the results of simulation of surface hypocenters, the amplitude of scattered waves observed by borehole geophones were larger than that of surface geophones. This means that the borehole geophones are suitable for time lapse monitoring of heterogeneous structures. The amplitude of scattered waves observed by horizontal components of geophones was larger than that of vertical components of geophones. This means that the horizontal components of geophones are suitable for time lapse monitoring of heterogeneous structures.

At the simulations of deep hypocenters (15Hz, 2Hz) as assumed natural earthquakes, seismic waves scattered by the man-made cavities. Observation of natural earthquakes will be helpful to look at the wide seismic structure.

In order to estimate the physical property changes in the subsurface, the time-lapse measurement is quite useful for various cases such as CCS (Carbon Capture and Sequestration) zone, EOR, shale gas exploration, and oil production. The authors have carried out the time lapse experiment at the water pumping area in Kingdom of Saudi Arabia using a very accurate and extremely stable seismic source called ACROSS (Accurately Controlled and Routinely Operated Signal System).

Because this seismic ACROSS has been installed semi-permanently at the Saudi test field, it is not easy to bring to any places. Instead, we alternatively used a much conventional electro-magnetic vibrator for this field test in the green tuff area in Japan.

We used the vibrator for 12 hours a day during five days in 2013. We also used 110 geophones and two borehole geophones placed just above the green tuff miming area with 2km x 3km. We used sweep signal from 10 Hz to 50Hz during 100 second.

We repeated 32 sweep during an hour. 32 stacking of waveforms of 100s second time-windows improved the S/N, and we can identify arrivals up to 3 km distance by this one-hour stacked data. If we look the 12 hours waveforms, it is difficult to find the change of those with time.

Using the subtraction of waveforms every day with 12-hour stack data from the first day, we generated residual waveforms. If we use residuals waveforms from the first day, we can clearly identify the change of waveforms with time. In conclusion we can use the time lapse method during five days by the use of residuals waveforms though the period is short. We can use conventional seismic vibrator(s) for the time lapse for several days.

A Reflectivity Guided Elastic Full Waveform Inversion

JAMALI HONDORI, Ehsan[1*] ; MIKADA, Hitoshi[2] ; GOTO, Tada-nori[2] ; TAKEKAWA, Junichi[2]

[1]JGI, Inc., [2]Kyoto University

Full Waveform Inversion (FWI) of seismic reflection data has become a common technique for producing subsurface images based on local minimization of least squares misfit between observed data and calculated model. Usually, an initial model that is close to the global solution of the problem is needed to obtain satisfactory results without being trapped in a local minimum of the misfit function. Due to the limitations in quantity of the observed data, e.g. using seismic traces from surface receivers to make an image of earth model, the full waveform inversion problem is ill-posed and underdetermined. The problem becomes even worse when dealing with elastic waveforms which require increased number of model parameters, i.e. P wave velocity, S wave velocity, density etc. In order to overcome this problem, inserting a priori model information in to the inversion process helps the algorithm to converge to a solution in the vicinity of the global minimum. This kind of information could be included in the gradient of the misfit function by adding model terms, when using conjugate gradient method to iteratively update the model parameters.

On the other hand, producing reliable velocity model is a key for successful Pre Stack Depth Migration (PSDM) of seismic data. Assuming an available depth section of seismic reflection data, e.g. by time to depth conversion of time migrated section, we estimate the P wave velocity from seismic section by first extracting reflectivity and then using Gardner equation (Gardner 1974) as stated by Hondori et. al 2013. This will produce a P wave velocity model which is used in full waveform inversion as a priori information. Our frequency domain elastic full waveform inversion is developed using finite difference method and perfectly matched layers are used on the boundaries of the computational area. A preconditioned conjugate gradient method is used together with improved pseudo Hessian matrix for updating the model parameters. At each iteration the gradient is calculated using adjoint state method, and then l_2 norm of the model term is added to the gradient to constrain the inversion. We suggest that this method not only improves the full waveform inversion results, but also resulting FWI models provide a good velocity model for pre stack depth migration of seismic data.

3D-FDFD simulation for high resolution eddy-current testing method

SAITO, Takuya[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1]

[1]Kyoto University

The applicability and the feasibility of eddy-current testing method for the measurement of wall thinning and surface crack of steel structure have been practically confirmed by field and laboratory experiments. Where and how large the cracks would be are roughly understood by this method. However, it is difficult to estimate the exact size and shape of them. For more accurate inspections, there has been a growing demand to quantitatively evaluate the cracks. Therefore, we have developed a numerical simulator for the high accuracy eddy-current method. Eddy-current method measures excitation magnetic and induced magnetic fields, the latter of which is caused by the eddy-current in the inspecting material. In order to calculate induced magnetic field deformed by the cracks, we used three-dimensional finite-difference frequency domain technique to solve Maxwell's equations numerically. As a simulation model, two-layer structure consisting of seawater and steel plate including cracks is used. We simulated a variety of cracks to estimate characteristic of the induced magnetic field, and compared the results in terms of what kind of difference in the induced field would appear. As a result, the effect of surface cracks of steel plate on receiving magnetic field intensity was confirmed as follows: the induced magnetic field intensity increases near the edge of cracks and decays above the cracks with the distance to the edge. The deeper and wider cracks are, the more the magnetic field intensity becomes attenuated. Due to the limitation of our simulation schemes, the response of magnetic field intensity whose detectable scale of cracks was no smaller than mm order. We are introducing a method that could allow us to confirm much finer detectability.

Elastic parameter estimation in full waveform well-to-well tomography

TERANISHI, Keisuke[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1]

[1]Graduate school of Engineering, Kyoto university

Seismic full-waveform inversion (FWI) method has been used to estimate velocity and density structures in the subsurface. The waveform analysis is a powerful tool to investigate the properties in the areas of interest, and the importance to use the waveform is widely recognized in the seismic explorations. As the wave propagation is influenced by elastic parameters, Vp, Vs, density, it is necessary to include these parameters in FWI (Virieux and Operto 2009). However, there are few previous studies dealing with density as a parameter in the application of elastic FWI. Density is usually estimated using an empirical formula such as Gardner's relationship (Gardner et al., 1974), or is fixed to a constant value. Almost all elastic FWI studies have neglected the influence of approaches how density parameter is estimated. The objective of this study is to investigate how difficult the estimation of density structure is, and propose a new approach to overcome the problem. We employ 2D numerical simulations in order to investigate the important factor in the inversion of density structure. Our results show that it is difficult to estimate density structure because density structure is less sensitive to waveform than Vp and Vs. Therefore, we hypothesize that the simultaneous inversion of Vp and density structures, using a selected dataset can improve the accuracy of the FWI. For testing this hypothesis, various ways for estimation of Vp, Vs and density using different datasets and approaches. We conclude that Vp and density structures should be estimated simultaneously in the elastic FWI, in which P-wave data separated from the seismic records is used as the input data.

Estimation of fluid contact in terms of attenuation

ISHIKURA, Kazuki[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1]

[1]Kyoto University graduate school of engineering

Sonic logging has been widely used for many years to acquire physical properties of formations in the vicinity of hydrocarbon reservoirs. When gaseous phase exists in the formation fluid, the compressional waves traveling through the formation could be strongly attenuated due to low bulk modulus of gas in the fluid, while the shear waves are not. For acquiring physical properties of fluid in the formation, Biot physics or poroelastic analysis would be the best method. Among the available technologies, quality factors based on the Biot's equation could be used. Although the Biot's theory considers the viscous attenuation induced at the interface between pore wall and fluids, the intrinsic attenuation caused by the internal friction in the matrix is ignored.

In the present study, adding the intrinsic attenuation we investigate if we take the effect of the viscous attenuation from the acquired quality factor, and then, on the basis of the result, if we estimate the fluid contact (e.g. gas-oil contact and oil-water contact). We employ a 2D finite-difference scheme to simulate seismic wave propagation in a poroelasic medium. The intrinsic attenuation is included in our model using a filter for frequency-independent quality factor (constant-Q). We then achieve the results of compressional and shear wave in our numerical simulations. Our results show that on compressional and shear waves, obtained the quality factors different from each other. We acquire the effect of the viscous attenuation by subtracting the quality factor of shear wave from the quality factor of compressional wave. We conclude that the effect of viscous attenuation is extracted and the gas-oil contact is estimated.

AVO waveform inversion for estimating the fluid contact with fluid transition zone

IWAKI, Yunosuke[1] ; MIKADA, Hitoshi[1*] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1]

[1]Graduate School of Engineering, Kyoto University

The fluid distribution in the hydrocarbon reservoir affects waveforms acquired in reflection seismic method. A reflected wave changes its waveform at the transition zone of the interface of two different fluids as a function of volume fraction of the two. AVO is in general used to estimate the difference in the P and S wave velocities for the interfacing two media at the interface without any assumptions on the existence of the transition zone. The consideration of the effect of the volume fraction of a fluid to the other in the waveform could be a key for evaluating the fluid mixture around the fluid contact in the reservoir. Therefore, we try to use the waveform directly to estimate fluid distribution in the transition zone that has not been done in the practice of AVO.

In our research, we consider the effects of the transition zone at a gas-water contact (GWC) in a horizontally stratified medium on seismic waveforms. The numerical simulation reveals that the fluid distribution of transition zone distorts the seismic waveform both in amplitude and in phase. Then we use the difference in amplitude and in phase for estimating some necessary parameters expressing the fluid-mixture. We apply a waveform inversion method to the fluid substitution problems to see if the method is applicable to estimate the fluid contact with the transition zone, while the conventional AVO only utilizes the amplitude derived from observed data. Our numerical approach uses full waveform and the results imply the advantages in the estimation of the parameters including the thickness of the transition zone under that assumption of linear trend in the volume fraction in a contrast porosity condition. We suggest that the phase information should be used simultaneously for the inversion process to get the closer contact image.

The insulation effects caused by the scattering of electromagnetic waves by fine spheres against insolation heating

HORIE, Jun[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1] ; TANIGUCHI, Kiyoshi[2] ; ASHIDA, Yuzuru[3]

[1]Kyoto University, [2]West Nippon Expressway, [3]NPO EEFA

The temperature of materials rises when they are exposed to the sunlight (insolation heating). Insolation heating could be suppressed when the materials are coated with paint admixed with fine silica spheres (insulating paint). By coating buildings' walls and roofs with such paint, the temperature in the subjacent rooms could be kept lower thanby coating with regular one. The temperature of the former could be enough low so that no air-conditioning becomes necessary even in the mid summer. These phenomena are well known in a practical manner and have been widely utilized. However,the cause of the phenomena has hardly been analyzed theoretically yet. Moreover, micron-scale ceramic spheres have been known as the best commixture than the other metallic commixture of the same size. Theoretical analysis would greatly enhance the effects of the suppression of insolation heating. We focus on the light scattering by fine spheres under the assumption that the scattering of lights, i.e., electromagnetic waves, attributes to suppression of insolation heating and that the imaginary part of scattering coefficients of the spheres is a key to explain the observed phenomena. In this study, we therefore consider commixture sphere materials to be (i)silica, (ii)aluminum and (iii)copper, distributed in a paint layer coating an iron material, and calculate transmission, reflection and absorption coefficient using the Monte Carlo ray tracing method based on the Mie theory. Using these coefficients, the rise in temperature of surface of the iron layer would be estimated. We finally investigate how the structure of the paint attributes to the insulating effects.

We assume three layers: air, paint, and iron, and commixed fine spheres in the paint layer using Distinct Element method (DEM). A number of photons vertically incident to the paint at random position from the air. We then count the number of photons that reaches the iron to estimate the intensity of the transmitted wave, and count the number of photons that are absorbed by spheres to estimate the intensity of the absorbed wave energy. Fresnel Equations are used to identify photons' behavior stochastically using a random number. Moreover, Mie theory is used to calculate the radiation pattern of scattering at each sphere when a photon incident to the sphere. As a result, it is estimated that the transmission coefficient would be less than 0.1 forthe commixture material of silica whose radius is smaller than ca. 0.7 micrometers. On the other hand, the transmission coefficient could be much less than 0.1 if we use conductive spheres. However, in the latter case, the absorption coefficient would be approximately 0.5, which could cause the rise in temperature of the spheres and the paint.

We estimate the rise in temperature of iron layer using coefficients calculated above. Near-infrared radiation of the sunlight is assumed to be the incident wave. As a result, whereas the temperature would be 63 degrees Celsius if no paint is coated. On the other hand, the temperature would be suppressed to 39, 59 or 56 degrees Celsius, respectively, if we use silica, aluminum or copper spheres of the same radii of 0.5 micrometers. The metallic commixture could lower the temperature rise but the absorption of the energy seems deteriorate the efficiency of the insulation.

In conclusion, silica is one of ideal material for insulating paint in contrast with conductive ones such as aluminum and copper, mainly due to the absorption phenomena of electromagnetic waves by spheres.

Three-dimensional joint inversion of gravity and magnetic anomalies using fuzzy c-means clustering

TERANISHI, Yosuke[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1] ; TADA, Ryohei[2]

[1]Kyoto University, [2]INPEX CORPORATION

The gravity and magnetic surveys have been widely carried out over the years, especially for the exploration of metallic mineral deposits and geothermal resources. These intensity data of gravity and magnetic fields could be acquired in much quicker and simpler ways than the other geophysical or geological surveys. The inversion of such potential field data, however, has been known as a non-uniqueness problem expressed in the Green's equivalent layer theory. Because of this problem, gravity and magnetic data have no inherent resolution in depth. We, therefore, would like to develop a way to make use of high exploration efficiency that takes the advantages of the convenience to conduct gravity and magnetic surveys.

We present a 3D joint inversion method to estimate two physical parameters, density and magnetization of subsurface materials. In the method, we introduce the fuzzy c-means (FCM) clustering technique in our joint inversion algorithm to consider the petrophysical relation between density and magnetization of subsurface materials. The fuzzy c-means clustering technique we introduce does not necessitate any empirical equations but deals with a linear combination of the influence from multiple clusters given a piece of data to belong to plural clusters in the parameter space formed by the petrophysical parameters. Adding the simple FCM clustering scheme, we introduced the smoothness constraint to a weight for membership to each clusters, instead of the conventional smoothness constraint to model parameters. Numerical studies using synthetic data indicate the effectiveness of FCM clustering in the joint inversion: the joint inversion results using gravity and magnetic data sets show higher accuracy and resolution than the individual ones.

As the field example, we focus on submarine volcanoes located at Mozambique Channel, because the world-class gas fields were discovered around that area and it is necessitated to estimate structure of submarine volcanoes near gas fields. We apply our inversion method to the real field gravity and magnetic data of the submarine volcanoes at Mozambique Channel. We conclude that our joint inversion method gives the reliable and detailed density/magnetization structures inside the submarine volcanoes in term s of the gravity and magnetic anomalies.

Stress field and fracture propagation due to the change of injection pressure

OKUBO, Kurama[1*] ; MIKADA, Hitoshi[1] ; GOTO, Tada-nori[1] ; TAKEKAWA, Junichi[1]

[1]Kyoto University

Hydraulic fracturing is an indispensable scheme to stimulate fluid production in hydrocarbon reservoir development in conjunction with various well testing methods such as drill stem, buildup tests, etc. In recent years, it is also well known that hydraulic fracturing plays a major role in the development of shale oil or gas reservoirs.

The extension length and the orientation of fractures induced by hydraulic fracturing are strongly influenced by the crustal stress field under which any reservoirs are located. Therefore the propagation of fractures is controlled by the regional stress field. It is, in general, necessary to get some understanding of regional stress field before the application of hydraulic fracturing as well as acquiring the rock physical properties of reservoir formations.

However, hydraulically induced fractures may not be created as planned and could cause some environmental issues such as pollution, induced seismicity, etc. It is, we think, very important to estimate how fractures are induced under various crustal conditions to cope with unexpected behavior of fracture propagation.

We focused the effects of the in-situ stress on the stress field around the pre-existing fracture and the fracture propagation with both steady and non-steady hydraulic pressure conditions. To simulate failures in crustal materials under the complicated stress field, we use an extended finite element method (X-FEM) in this study, which can retrieve the stress distribution affected by fractures effectively and estimate the fracture propagation based on linear elastic fracture mechanics (LEFM). Numerical simulations are conducted for a 2D elastic medium having a borehole and a pre-existing fracture. We put the pre-existing fracture around the borehole initially and simulate the propagation of this fracture by applying the hydraulic pressure. The velocity of fracture propagation and the interval of the stress recovery from the stress drop caused by the propagation are set uniformly for the kinetic simulation.

We first simulate the fracture propagation around the borehole under different steady hydraulic pressures with regional stress field. Then we try to see how the fracture could propagate with the non-steady hydraulic pressure during the propagation.

We confirmed that the orientation of the fracture propagation converges to that of the principal stress. Moreover, the convergence speed could be inversely related to the hydraulic pressure. We also found the time delay of the influence of the hydraulic pressure change to the fracture propagation with non-steady hydraulic pressure condition.

From the results of our numerical simulations, we would like to have two conclusions. First, the curvature of the fracture trace depends on hydraulic pressure, but no matter how the fluid pressure is, the orientation of fracture propagation converges to that of principal stress. Second, the transition of the stress field involves the time delay, which leads to the delayed response of the fracture propagation in the non-steady hydraulic pressure condition.

When we develop a hydrocarbon reservoir using hydraulic fracturing, the orientation of maximum in-situ principal stress and the fluid pressure for fracturing should be quantitatively taken into account for the environmental safety and for the stimulation efficiency. It might be also necessary to consider the time delay of the transition of the stress due to the non-steady hydraulic pressure.

Estimation of the Dispersion Curve for Soil Layers with Lateral Heterogeneity Using Continuous Wavelet Transform

TSAI, Pei-hsun[1*]

[1]Department of Construction Engineering, Chaoyang University of Technology

The MASW method is the normal method regarding surface wave testing, but it requires 12 or more receivers to measure the phase velocity for statistical redundancy. Therefore, the SASW method has potential for use because only two receivers are required. A time-frequency domain analysis is used to extract a dispersion image of Rayleigh waves and select a dispersion curve from the seismic signals of two receivers during surface wave testing. The signals are transformed by continuous wavelet transform, and the products of the transformed signals of the two receivers are summed at the same slowness over the intercept time to construct a dispersion image. This method is unnecessary empirical judgment in the unwrapping of phases and a significant number of receivers. To examine the applicability of the method on evaluating the dispersion curve for soil layers with lateral heterogeneity, three synthetic examples and an experience example of surface wave testing are discussed. The method is applicable for extracting a dispersion image for lateral heterogeneity soil layers. A high-resolution dispersion image is generated in this study by increasing the interval of the receivers. The result of the experience example was in accordance with that of the borehole data.

Issues and Countermeasures for the Geophysics Investigation of Contaminated with Chlorinated Hydrocarbon

LIU, Hsin-chang[1*] ; LIN, Chih-ping[1] ; WANG, Tzu-pin[2] ; DONG, Tian-xing[3]

[1]Disaster Prevention and Water Environment Research Center, National Chiao Tung Univ., [2]Chien Hsin University of Science and Technology, [3]APOLLO TECHNOLOGY CO., LTD.

Environmental geophysics survey has the advantages of survey rapidly, high resolution result and less affected by the surface topography and objects. It is suitable to either a wide range of general survey or a small-scale precise survey. Recently, non-invaded technologies such as geophysical technology have been introduced to provide the plane and space information of pollution in subsurface by integrating few bore-hole dates. The most common used geophysical technologies are ground-penetrating radar method (GPR) and electrical resistivity tomography (ERT). The electrical resistivity tomography (ERT) is one of the most widely used geophysical methods in geological, hydro-geological, and geo-environmental investigations.This study would first discuss how DNAPL and its soluble-phase components invade into the low permeable layer based on the field observation. Then, the importance of geophysical technology is introduced with comparing to the limitations of bore-hole investigation. Last, the case studies on using geophysical technologies including geophysical well logging are introduced to snapshot the complex profile of DNAPL distribution for improving future application.

Development of a laser strain gradiometer and reduction in its thermal noise.

DEGUCHI, Takehiro[1*] ; ARAYA, Akito[1]

[1]Earthquake Research Institute, University of Tokyo

An earthquake is essentially a shear slip on a fault. Because the rupture velocity is roughly constant for most earthquakes, the length, the width, and the slip distance of a fault are respectively proportional to the duration of the rupture, and therefore an earthquake follows the scaling law that its seismic moment is proportional to the cube of its duration. In addition to the ordinary earthquakes, slow earthquakes have been discovered recently. Slow earthquakes include short-term and long-term slow slip events, non-volcanic tremors, low-frequency earthquakes, and very low-frequency earthquakes. They are known to be also shear slips but have slower rupture velocity than the ordinary earthquakes (see the reference [Beroza and Ide, 2011]). Ide et al. (2007) proposed that every slow earthquake has the same mechanism with a new scaling law that its seismic moment is proportional to its duration.

However, no middle-term slow earthquakes with duration of 200 s to 1 day have been reported so far. To understand the reason, we conducted analytical calculations including comparisons of expected signals of slow earthquakes and background seismic noise. It was shown that the middle-term slow earthquakes cannot be observed by a single accelerometer, a strainmeter, or a tiltmeter due to the background seismic motion.

AIST's synthetic analysis using the network of strainmeters, tiltmeters, and groundwater pressure gauges [Itaba et al, 2009] detected smaller slow slips.

Let us take the second spatial derivative of displacement, "the strain gradient". Analytical calculations showed that the signals of slow earthquakes with duration of 200 seconds to 1 day can directly be detected from the strain gradient of the ground. The spatial scale of the background ground motion is larger than the typical distance between a hypocenter and an observatory and the typical size of the fault. Taking spatial derivative emphasizes the small-scale crustal deformation, and makes the detection of local slow earthquakes easier. Thus, measuring the strain gradient will be effective to detect them.

We made a prototype instrument of measuring the strain gradient, "strain gradiometer," with laser interferometry. Before installing it on the ground, we measured its instrumental noise in the atmosphere and found the noise following power spectral density of 10^{-12}[m^{2}s] at 10^{-5}Hz and tendency of 1/f^2 below 0.1Hz. This noise was caused by changes in optical path lengths due to the fluctuation of air pressure. Subsequently, the noise of the interferometer in vacuum was measured; the noise was reduced by 1/10 and had the tendency of 1/f below 0.1Hz. This noise could be reduced by adjusting the optical path difference because it was estimated to be caused by frequency fluctuations of the laser source, which was frequency stabilized by the two-mode method. After the adjustment, there remained noises that had the power spectrum of 1/f^6 in the period between 5000s and 20000s and same power in the period longer than 20000s. This noise had similar waveform to temperature in time-domain. This noise was estimated to be caused by thermal expansion of the optical devices and the optical breadboard. Assuming this noise will be reduced in proportion to the square of the baseline length in terms of the strain gradient, the necessary baseline will be more than 300m. In the presentation, analyses of the noise of the interferometer with thermal insulation by ceramics and the future development will be explained.

Compact Ocean Bottom Cabled Seismic and Tsunami Observation System Using ICT and Installation Plan

SHINOHARA, Masanao[1*] ; YAMADA, Tomoaki[1] ; SAKAI, Shin'ichi[1] ; SHIOBARA, Hajime[1] ; KANAZAWA, Toshihiko[2]

[1]Earthquake Research Institute, University of Tokyo, [2]National Research Institute for Earth Science and Disaster Prevention

The Pacific plate is subducting below the northeastern Japan islands arc. The 2011 Tohoku earthquake occurred at the plate boundary between the Pacific plate and the landward plate below landward slope of the Japan Trench. In 1996, Earthquake Research Institute (ERI), University of Tokyo had installed seismic and tsunami observation system using seafloor optical fiber in the off-Sanriku area. The continuous real-time observation has been carried out since the installation. The system observed seismic waves and tsunamis generated by the 2011 Tohoku earthquake, and the data from the system are indispensable to estimate accurate position of the source faults and the source process of the 2011 event. However, the landing station of the system was damaged by huge tsunami 30 minutes after the mainshock, and the observation is discontinued. Because the data from the real-time system on seafloor are important, we decide to restore the existing system and install newly developed Ocean Bottom Cabled Seismic and Tsunami (OBCST) observation system off Sanriku for additional observation and/or replacement of the existing system. In this paper, we present a system of the new OBCST in detail, and installation plan.

Until 2010, we had already developed and installed the new compact Ocean Bottom Cabled Seismometer (OBCS) system near Awashima-island in the Japan Sea. After the installation, the OBCS system is being operated continuously and we have continuous seismic data for more than 3 years at the present. The new OBCST system for off-Sanriku area is based on this system, and is characterized by system reliability using TCP/IP technology and down-sizing of an observation node using up-to-date electronics. The new OBCST has three accelerometers as seismic sensors. Signals from accelerometers are 24-bit digitized with a sampling rate of 1 kHz and sent to a landing station using standard TCP/IP data transmission. A precise pressure gauge is also equipped as a tsunami sensor. The tsunami data with a sampling rate of 1ms are also transmitted by TCP/IP protocol. In addition, an observation node can equipped with an external port for additional observation sensor instead of a pressure gauge. Additional sensors on seafloor are supplied the power using Power over Ethernet technology. Clock is delivered from the GPS receiver on a landing station using simple dedicated lines. In addition, clocks in observation nodes can be synchronized through TCP/IP protocol with an accuracy of 200 ns (IEEE 1588). The data will be stored on the landing station and sent to ERI in the real-time. A simple canister for tele-communication seafloor cable is adopted for the observation node, and has diameter of 26cm and length of about 1.3m. This small size of the canister has an advantage for burying the system below seafloor.

At the present, we are producing the observation nodes of the new OBCST. The new system has three observation nodes; two have three-component seismometer and a pressure gauge, one has seismometers and an external port by using the PoE technology. We have a plan to connect a pressure gauge and hydrophone via the PoE external port of the third observation node. Total length of the practical system is approximately 100 km and an interval of the observation node is about 30 km. We have a plan to install the practical system in 2015.

Long-period duration of the teleseismic events reported to ISC from Syowa Station since 1967

KANAO, Masaki[1*]

[1]National Institute of Polar Research

Phase identifying procedure for teleseismic events at Syowa Station, East Antarctica have been carried out since 1967 after the International Geophysical Year (1957-1958). From the development of INTELSAT telecommunication link, digital waveform data have been transmitted to the National Institute of Polar Research for utilization of phase identification. Arrival times of teleseismic phases, P, PKP, PP, S, SKS have been reported to the International Seismological Centre (ISC), and published by JARE Data Reports from NIPR. In this paper, hypocentral distribution and time variations for detected earthquakes are demonstrated over the last four decades in 1967-2010. Characteristics of detected events, magnitude dependency, spatial distributions, seasonal variations, together with classification by focal depth are demonstrated. Besides the natural increase in number for occurrence of teleseismic events on the globe, a technical advance in observing system and station infrastructure, as well as the improvement of procedure for reading seismic phases, could be efficiently combined to produce the increase in detection number in last few decades. Variations in teleseismic detectability for longer terms may possibly by associate with meteorological environment and sea-ice spreading area around the Antarctic continent. Recorded teleseismic and local seismic signals have sufficient quality for many analyses on dynamics and structure of the Earth's as viewed from Antarctica. The continuously recorded data are applied not only to lithospheric studies but also to Earths deep interiors, as the significant contribution to the Federation of Digital Seismological Network from high southern latitude.

Seismic observation on Greenland Ice Sheet by the Japanese GLISN team (2011-2013), and a plan for the 2014 season

TOYOKUNI, Genti[1*] ; KANAO, Masaki[2] ; TONO, Yoko[3] ; HIMENO, Tetsuto[4] ; TSUBOI, Seiji[3]

[1]RCPEVE, Tohoku Univ., [2]NIPR, [3]JAMSTEC, [4]Seikei Univ.

Melting of the Greenland ice sheet is now in progress accompanying the global climate change. Recently, a new type of seismic event called ”glacial earthquakes”, which are generated by the movement of a large mass of ice within the glacial terminus, has been realized as a new way to monitor current ice sheet dynamics. In 2009, the multinational GreenLand Ice Sheet monitoring Network (GLISN), a large broadband seismological network in and around Greenland was initiated to monitor these events.

Japan, a partner country of the GLISN project, has been sending a field team every year since 2011. The joint U.S. and Japanese team first constructed a seismic station (station code: ICESG) on the Greenland ice sheet. In 2012, we serviced two ice sites (ICESG, DY2G) and one rock site (NUUK). In 2013, the same team spent 11 days on ice for maintenance of ICESG and DY2G, and helped rogistics for another ice site (NEEM). This presentation summarizes our field activities on the GLISN project for three years, and show a plan for the 2014 season.

Our activity is supported by JSPS KAKENHI 24403006.

This paper is devoted to present an operation system to acquire, to transfer and to storage data for world-wide observation networks, which is named as WONM (Wide-area Observation Network Monitoring) system, developed in NICT (National Institute of Information and Communications Technology). This system provides us with easier management of data collection than legacy systems by means of autonomous system recovery, periodical state monitoring, and dynamic warning procedures. We have equipped world-wide observatories for space weather prediction and research works with this system connected with the NICT Science Cloud. Demonstration and discussion will be presented concerning with this challenging system, especially from the viewpoint that we easily operate world-wide observatories on a web application.

Development of hypocenter location method using envelopes: Application to B-type earthquakes at Miyakejima volcano

UCHIDA, Higashi[1*] ; NISHIMURA, Takeshi[2] ; NAKAHARA, Hisashi[2] ; YAMASATO, Hitoshi[1] ; FUJITA, Eisuke[3]

[1]Japan Meteorological Agency, [2]Geophysics, Science, Tohoku University, [3]NIED

B-type earthquakes are frequently observed in active volcanoes, but it is difficult to locate them by using traditional phase picking methods because most of B-types show emergent onsets of P- and S-waves. We applied the envelope correlation method of Obara (2002) to B-type earthquakes at Miyakejima volcano, but the located hypocenters shifted towards the south-east by 0.5 - 1 km compared to those determined by phase picking method. Such systematic difference is caused by some assumptions such as that the envelope waveforms at each station are all the same. Actually, the envelope waveform broadens as hypocentral distance increases because of the scattering, or the waveform strongly depends on the site condition. In this study, therefore, we develop a new envelope correlation method in which a small number of the B-type earthquakes whose S-wave arrival times are manually picked are used as reference events. The method estimates S-wave arrival times by taking cross-correlations between envelopes of reference events and that of target event at each station. To find appropriate reference events effectively, we use the similarity of concatenated envelopes: the envelopes of all stations are connected in order keeping the amplitude ratios and time differences of envelopes between stations. The similarity of the concatenated envelopes means that the hypocenters and path effects on the envelope waveform at each station are almost the same with those of the reference events. By applying this method to B-type earthquakes at Miyakejima volcano observed from August 2010 to April 2011, we determine 71 % of the observed ones in an automated way. The B-type earthquakes are located within a 1 km diameter centered on the southern part of the summit caldera, where continuous gas emission occurs. On the other hand, A-type earthquakes, which show clear onsets of P- and S-waves, are distributed from southern part to western part of the summit caldera. To check the reliability, we also compare the result to the hypocenters located by picking P- and S-onset times, and there is no systematic difference between them as seen in the comparison to the result of Obara (2002) method. Our new method is applicable to volcanic earthquakes recorded at other seismic networks that consist of at least several stations surrounding hypocenter regions, which will help us to monitor and understand volcanic activity.

The annual variation in the teleseismic detection capability at Syowa Station, Antarctica

IWATA, Takaki[1*] ; KANAO, Masaki[2]

[1]The Institute of Statistical Mathematics, [2]National Institute of Polar Research

Kanao et al. [2012a, 2012b] have pointed out the annual variation in the teleseismic detection capability at Syowa Station located in Antarctica. The main cause of the variation is considered to be the increase in area and/or thickness of sea ice in winter, which restrains the generation of sea waves around Antarctica; consequently the noise level in seismic records changes annually [Grob et al., 2011; Kanao et al. 2012c].

This implies that environmental parameters relevant to climate, sea ice, and so forth affect the teleseismic detection capability. To investigate the relationship in detail, a quantitative evaluation of the annual variation in the detection capability is dispensable because the aforementioned studies have revealed the annual variation only qualitatively on the basis of the time history of the minimum magnitude of detected teleseismic events at the station. Therefore, we conducted the following analysis in this study.

The dataset analyzed in this study is the same as the examined one in Kanao [2010] and Kanao et al. [2012]. The data period ranges from 1987 to 2007 and the magnitudes of the events are measured with the body-wave magnitude (Mb) scale. The number of analyzed earthquakes of which magnitudes are determined is 19,044. Because the main interest of this study is to quantify the annual variation, the earthquake sequence is divided into periods of one year and these one-year sequences were stacked.

For the quantification of the detection capability, the model representing a magnitude-frequency distribution of earthquake covering the entire range [Ogata & Katsura, 1993] is used with a small modification. In this model, the distribution is assumed to be the product of the Gutenberg-Richter (GR) law [Gutenberg and Richter, 1946] and the detection probability of earthquakes at magnitude M. As mentioned above, the magnitudes in the examined dataset are given as Mb, which saturates at its large value. Therefore, instead of the original GR law, we introduced a modified type of the GR law, which is suggested by Utsu [1974], that contains the maximum magnitude of earthquake potentials as a parameter. The detection probability was represented by the cumulative distribution of a normal distribution, following the suggestion of Ringdal [1975] and its accompanied studies [e.g., Ogata & Katsura, 1993; Iwata, 2008, 2012, 2013a, 2013b, 2013c]. This formulation results in the introduction of a parameter μ, which corresponds to the magnitude at which 50% of earthquakes are expected to be detected, and this parameter quantifies the quality of the earthquake detection capability.

Then, the annual variation in μ was estimated by adopting a Bayesian approach used in Iwata [2013a, 2013b]. In this approach, the annual variation is represented by a piecewise linear approximation of which breaking points were taken at each of the occurrence times of each events. We determined the variation in μ with a smoothness constraint.

The result of the estimation is summarized as follows. The significance of the existence of the annual variation was evaluated with ABIC [Akaike, 1980]; the value of ABIC in the case with the annual variation is 54.9 smaller than that in the case without the annual variation, suggesting high significance of the variation. The maximum (i.e., the worst detection capability) and minimum (i.e., the best) values of μ appear around the end of December and the middle of August, respectively. The difference between the maximum and minimum values is 0.13. Because the maximum and minimum of the average temperature at Syowa Station also appear in those periods, this result reinforces the relationship between the environmental parameter and teleseismic detection capability.

Towards Detection of Hydraulic Fracturing Induced Earthquakes Using Neural Network

KIM, Ahyi[1*] ; IIDA, Shuhei[1] ; FUJIHARA, Satoru[2]

[1]Yokohama City University, [2]Itochu Techno-Solutions Corporation

Detection, location and determination of focal mechanism of low frequency and hybrid events such as volcanic and non-volcanic events have been extensively studied. Recently, Das and Zoback (2011) found unusual events which has relatively low frequency in the seismic activity induced during hydraulic fracturing in a gas shale reservoir. Those events were observed in limited frequency band similar to tectonic tremor sequences. It is important to understand the mechanisms of those events for clarifying the fracturing process during the hydraulic stimulation. In this study, we introduce a method to detect the band-limited waveform using neural network. The results of the initial numerical test indicate that the harmonic function waveforms could be identified when they have clear features in shape. As the next step, we will add realistic noise to the synthetic data and perform the synthetic analyses. After we verify the applicability of our method, we will apply the method to real seismic data observed during fluid injection.

Background noise characteristics of F-net broadband seismograms

KIMURA, Takeshi[1*] ; MURAKAMI, Hiroshi[2] ; YANO, Tomoko elizabeth[1] ; KIMURA, Hisanori[1] ; KAZAKAMI, Tomoe[1] ; MATSUMOTO, Takumi[1]

[1]NIED, [2]ADEP

National Research Institute for Earth Science and Disaster Prevention (NIED) has operated a broadband seismometer network, F-net. F-net consists of 73 stations in Japan and a broadband seismometer, STS-1/2/2.5 or CMG-1T/3T, has been installed at each station. The seismometers are installed in 30-50 m vault to prevent effects of the temperature and air pressure changes. All the data are openly available on the web, and rapid automated data processing systems, such as AQUA system [Matsumura et al., 2006], have used these data. To evaluate the data quality continually is important for the operation of the observation network, the earthquake monitoring, and the automated analyses. In order to assess the F-net data quality, we investigated the characteristics of their background noise.

To quantify the background noise of F-net waveform data, we used probability density functions (PDFs) of power spectral densities (PSDs) [McNamara & Buland, 2004]. For 1996-2013 continuous waveform data with the interval of 1 sec, PSDs of ground acceleration were computed from overlapping (50 %) 1-day time-windows. Each time-window was divided into 13 time segments (6 hours) overlapping by 75 %, and the 1-day PSD estimate was calculated as the average of the 13 segment PSDs. These 1-day PSDs were gathered by binning periods in 1/8 octave intervals and binning power in one-dB intervals.

We calculated a new noise model for F-net, based on the statistical mode of the obtained PDFs for vertical component of all the F-net stations [McNamara & Buland, 2004]. The noise model was constructed from the minimum PDF mode value among all the stations at each period. The values of the F-net model is ˜5 dB higher than ones of the mode noise model of the continental United States [McNamara & Buland, 2004] around periods of 4 sec and 40 sec. The F-net noise model is mainly defined by the STS-1 mode values. The STS-2 values are ˜5 dB larger than STS-1 ones at the periods of 200-800 sec, and the CMG-1T/3T are ˜15 and ˜10 dB larger than STS-1 at 30-2000 sec and 100-2000 sec, respectively.

Recently, we have equipped a styrofoam cover on the broadband sensor for temperature shielding. This cover has reduced the PDF mode values for vertical component of STS-2 by ˜5 dB at the periods longer than 500 sec, and is useful to obtain such long-period signals with a good signal/noise ratio.

Long-term ocean-bottom seismometers in MRI/JMA and some related problems

HIRATA, Kenji[1*] ; TSUSHIMA, Hiroaki[1] ; YAMAZAKI, Akira[1] ; KATSUMATA, Akio[1] ; MAEDA, Kenji[1] ; BABA, Hisatoshi[2] ; MATSUBARA, Tadayasu[3] ; ITOU, Tatsuya[3] ; SUGITA, Tomoya[3] ; HORI, Katsuhiro[4] ; SHIRAKO, Takeshi[4]

[1]Meteorological Research Institute, JMA, [2]School of Marine Science and Technology, Tokai University, [3]Tokyo Sokushin, [4]NiGK Corporation

In 2011 to 2012, seismology and volcanology research department/MRI introduced eight long-term ocean-bottom seismometers (OBSs) by converting existing short-term ones so that we were able to conduct one-year-long, three-component seismographic observation. The conversion was made by changing the control circuit, the AD convert, and the data storage device into low-power consumption ones.

In November 2011, four long-term OBSs were deployed off Boso Peninsula, about 40 km east of Tokyo, to test them and to investigate seismicity in this region that adjoins the southern end of the mainshock rupture area of the March 11, 2011 Tohoku earthquake (Mw9.0). In September 2012, we tried to recover the four long-term OBSs that were deployed in 2011 and re-deploy other four long-term OBSs. However, all transponder units of four long-term OBSs to be newly deployed got out of order soon after the vessel left the port. So we declined to newly deploy other four long-term OBSs. Also, we could not recover two long-term OBSs among four that were deployed. We confirmed that two recovered long-term OBSs recorded ultra-micro earthquake activity successfully.

After the cruise, the OBS transponder units that became out of order were tested in manufacturer's laboratory so that the cause of the trouble was inferred to be (1) possible opening within the housing of transducer unit of OBS transponder due to thermal expansion/contraction thorough high temperature in summer and low temperature in winter, and (2) cavitation in silicon-oil within the housing of transducer unit of OBS transponder due to hull vibration. Countermeasures were devised as follows; (a) overhaul of electric circuits and transducer unit housing filled with silicon oil, (b) use of base-isolation floor-mat on which OBSs should be placed. Both of manufacturer's laboratory tests and actual onboard tests suggest that these countermeasures are effective.

Value change of ocean bottom pressure gauge (Paroscientific depth sensor) by inclination of the sensor

OGATA, Naoki[1*] ; SATO, Toshinori[1] ; YAMADA, Tomoaki[2] ; SHINOHARA, Masanao[2]

[1]Graduate School of Science, Chiba Univ., [2]ERI, Univ. Tokyo

Introduction

Ocean bottom pressure gauges (OBP) using depth sensor of Paroscientific Inc. are used for observation of up-down crustal movement at ocean bottom (e.g. Inazu et al., 2012). Observation error of this sensor is about 0.5 hPa (about 5mm in water) (e.g. Kono et al., 2012). So, this sensor is expected to detect coseismic movements and movements with large slow slip events such as the Boso slow slip events. But , it is known that this sensor shows incorrect values when the sensor is inclined. This suggests the possibility that this sensor can not obtain correct value because OBP itself may be inclined by coseismic crustal deformation. This presentation shows measurements of value change by inclination of the sensor, and discusses limits of inclination based on the observation error.

Measurements and results

We used an intelligent depth sensor 8CB2000-I, Paroscientific Inc. We set the sensor upright, then incline it, hold it for some time, then return it upright. We measured differences of the values between upright position and inclined position. We found that if we incline the sensor very fast, it shows very large transient values after inclined. So, we need slow inclination (a few ten seconds par 10 degree inclination) of the sensor. After the measurements, we fit the data using a spherical harmonic function.

The observed data show 2 hPa at 10 degree inclination, 6 hPa at 20 degree, and 12 hPa at 30 degree. The data is not symmetrically with respect to the upright position, but symmetrically at a point which is inclined about 15 degree from the upright position. The reproducibility of the values for inclination is within about 0.3 hPa (STD). From this result, inclination limit of OBP is about 5 degree if OBP sits on the ocean bottom flat. If OBP touches down at steeper inclined bottom, the limit become narrower. If OBP is inclined at 20 degree, the limit is about 2 degree.

Evaluating performance of automatic earthquake detection and location system for the nationwide seismic network(2)

NAKAYAMA, Takashi[1*] ; HIRAHARA, Satoshi[1] ; KONO, Toshio[1] ; NAKAJIMA, Junichi[1] ; OKADA, Tomomi[1] ; UMINO, Norihito[1] ; HASEGAWA, Akira[1] ; HORIUCHI, Shigeki[2] ; HORIUCHI, Yuko[2]

[1]Graduate School of Science, Tohoku University, [2]Home Seismometer Corporation

The number of seismic stations has tremendously increased by many temporary seismic networks recently deployed in various areas, in addition to dense routine seismic networks such as the nationwide Kiban seismic network. Effective automatic earthquake detection and location system is anticipated, because the ability of data processing is limited. Manually picking P- and S-wave arrival times etc. from a huge amount of seismic waveform data observed by such many seismic stations is considerably time consuming work.

Horiuchi et al. (2012, 2013) have developed such an automatic seismic waveform processing system. This system was set up at Tohoku University on December 2012, and automatic detection and location processing of the nationwide seismic network data has been operating since then. The system can detect and locate many earthquakes which are difficult to be located by the routine processing based on manual pickings. However, sometimes earthquakes cannot be correctly discriminated by the system: for example, when more than two earthquakes occur almost simultaneously. In order to consider the application of automatic earthquake detection and location system to the actual seismic network, we need to know its performance.

Nakayama et al. (2013) tried to evaluate performance of this earthquake detection and location system for the application to the nationwide seismic network. Results showed that the automatic system could detect and locate earthquakes about 1.5 times more than those in the JMA unified catalogue. The automatic system extended the lower limit of the detection capability to much smaller magnitude range than that by the JMA unified catalogue. The evaluation also showed that S-wave arrival times picked by the automatic system were systematically delayed by ˜0.05-0.1 sec compared with those by the manual pickings of the unified catalogue. Based on this performance evaluation, Horiuchi et al. (2014 this meeting) have tried to improve the system by developing a new algorithm to better pick S-wave arrivals.

We have evaluated performance of this presently improved automatic processing system by using the waveform data for the same period as those in the previous evaluation. Results show that the systematic delay of S-wave arrivals by the automatic pickings is considerably improved and the difference in S-wave arrivals between the new automatic system and the unified catalogue has become nearly the same as that between the manual pickings by Tohoku University and those in the unified catalogue. This indicates that the S-wave arrival times, as well as P-wave arrival times, picked by the automatic system almost stand comparison with those by the manual picking. Moreover, the evaluation shows that the new system also improved the rate of correct discrimination of earthquakes: the percentage of events that were missed to be correctly located decreased from 19% to 14% (most of these events are those located in and around the Izu-Bonin Islands and the Ryukyu Islands), and the percentage of events that were incorrectly defined as earthquakes decreased from 3.1% to 2.5%. This is because of the improvement of algorithm to correctly discriminate more than two earthquakes that occurred nearly simultaneously.

W-phase analysis with 1Hz GNSS data

UENO, Hiroshi[1*] ; KATSUMATA, Akio[1] ; KAWAMOTO, Satoshi[2] ; YAHAGI, Toshihiro[2] ; MIYAGAWA, Kohei[2]

[1]Meteorological Research Institute, [2]Geospatial Information Authority of Japan

The Japan Meteorological Agency analyze W-phase inversion solution and CMT solution when big earthquakes occur. Now we can analyze W-phase solution with broadband seismograms in Japan after 6 minutes of earthquake occurrence. These W-phase solution are one of information for performing grade changes or cancel of TSUNAMI warning.

Broadband seismic records is used by integrating for W-phase analysis. Because when big earthquake occur, the waveform data recorded at near site from source area may be unstable, it might be difficult for analyzing W-phase solution. On the other hand, the GNSS data to be recorded directly displacement, it can be used as a stable displacement.

In this study, using 1Hz GNSS data of Geospatial Information Authority of Japan(GSI), we analyzed W-phase solutions of Great Tohoku earthquake in 2011, its aftershock, and Tokachi-oki earthquake in 2003.

Automated event identification of aftershocks(2)

KATSUMATA, Akio[1*]

[1]Meteorological Research Institute, JMA

We are developing a seismic event identification technique for a quick grasp of aftershock activities of great earthquakes. For the case of the 2011 off the Pacific coast of Tohoku Earthquake, a number of onsets of aftershocks were not clear due to successive occurrence of aftershocks. Envelops of seismic waves are used to make it possible to estimate source locations of events without clear onsets.

The method is based on peak amplitudes and their times as

(1)A band pass filter is applied to the seismic waves.

(2)Envelop of seismic wave is obtained.

(3)Peak amplitudes and times are checked.

(4)Possible events are searched for the data of envelop amplitudes and times.

Formerly we tried to estimate source parameters by searching a solution in five-dimensional space of (origin time, latitude, longitude, depth, magnitude) by the shuffled complex evolution (SCE-UA) method. However, good solutions were seldom obtained because a combination of noise data often show a high score.

We changed the source estimation method. At the first, a group with high S/N data is searched for. We select a key data with highest S/N from the group. Then we estimate the best source parameter which is consistent to the selected data. While searching for the source location, the focal depth is fixed and epicentral distance and azimuth are changed. The origin time is obtained from the time of the envelop peak and epicentral distance, and the magnitude is estimated from the peak amplitude and epicentral distance.

Noise is often selected as the key data. Noises are usually rejected because they do not form a group of consistent data. Data of noise and identified events are removed from dataset to be checked. Data search is continued until no candidate is left.

Events are successfully identified and source locations are properly estimated for the events with a number of data. However source locations are not properly estimated for events with a small number of data.

We used seismic data from the National Research Institute for Earth Science and Disaster Prevention, Hokkaido University, Hirosaki University, Tohoku University, University of Tokyo, Nagoya University, Kyoto University, Kochi University, Kyushu University, Kagoshima University, the National Institute of Advanced Industrial Science and Technology, Aomori prefectural government, Tokyo metropolitan government, Shizuoka prefectural government, Kanagawa prefectural government, the City of Yokohama, the Japan Marine Science and Technology Center, and the Japan Meteorological Agency.

Construction of the seismic observation network around Shimokita Peninsula

SEKINE, Shutaro[1*] ; SAWADA, Yoshihiro[1] ; KASAHARA, Keiji[1] ; SASAKI, Shunji[1] ; TAZAWA, Yoshihiro[1] ; YAJIMA, Hiroshi[1]

[1]Association for the Development of Earthquake Prediction

Introduction

Seismic activity in the Shimokita region is not well grasped, because the distribution of the seismic stations is not dense compared with that of Southern Tohoku region. So, it is not enough to estimate the depth of the seismogenic zone. Accordingly, the Association for the Development of Earthquake Prediction (ADEP), determined to newly construct a high-density seismic observation network (AS-net) in the region in question, as a part of its investigation and research into seismic activity in the Shimokita Peninsula. An outline of the observation network is presented below.

Outline of the network

The AS-net consist 36 seismic observation stations. 20 stations were made before the end of 2013. And the other stations will make in 2014.

The sensors of each station are installed in boreholes at a depth of about 20m. We set the short period three dimensional velocity sensors by Lennartz, and accelerometers by Japan Aviation Electronics Industry ltd. And A/D converter is LS-7000XT made by Hakusan Co.

The data of the each station send to ADEP using with Internet, and relay to other facility for research.

Future works

It is anticipated that useful data will be obtained regarding detailed velocity and attenuation structures in the area surrounding the seismic observation network, as well as micro earthquake activity in the regions. The number of the earthquakes we estimate in January, is twice as that of JMA.

Regional Airborne Survey for the Evaluation of Geothermal Potential in Japan

SHIMADA, Tadaaki[1*] ; TAKAI, Katsumi[1] ; MIYAKE, Kazuhiro[1] ; HISATANI, Koichi[1] ; TOSHA, Toshiyuki[1]

[1]Japan Oil, Gas and Metals National Corporation

Japan Oil, Gas and Metals National Corporation (JOGMEC) supports smooth development of geothermal resources in Japan by providing assistance to geological, geophysical, and well-drilling surveys, equity capital or liability guarantees, and information and data on geothermal resources.

As part of them, we planned to conduct evaluation of geothermal potential with airborne technique of gravity gradiometer method and time-domain electromagnetic method.

The gravity gradiometer method measures the differential of gravity, and provides information of much detailed geological structures. The time-domain EM method provides deeper penetration data than the frequency-domain EM method.

Since these methods are state-of-the-art techniques, we demonstrated them first in a couple of area with relatively high geothermal potentials and a lot of surveys conducted.

We carried out airborne survey with the technique of the gravity gradiometer method in the Kuju and the Kirishima areas in 2013. We would like to introduce the result of the airborne survey.

The authors thank local municipalities and related organizations for their understanding and cooperation to conduct the airborne survey.

Study on the prediction of the deep catastrophic landslide using the Airborne Electromagnetic Survey

KAWATO, Katsushi[1*] ; KINOSHITA, Atsuhiko[2] ; TAKAHARA, Teruyoshi[2] ; ISSHIKI, Hiromitsu[2] ; ISHIZUKA, Tadanori[2] ; OKUMURA, Minoru[1] ; UCHIDA, Koichi[1]

[1]Nippon Engineering Consultants Co.,LTD., [2]Public Works Research Institute

Recently, the deep catastrophic landslides were occurred frequently including the disaster of the Kii peninsula by typhoon 12 in 2011. The risk evaluation is demanded to be carried out the measures that we can assume at the both sides of the method constructing sabo dams and evacuation method. Recently, the airborne electromagnetic survey is performed a close-up to evaluate the risk of them. Merits of the airborne electromagnetic survey include that a geological feature border in conjunction with the deep catastrophic landslides having possibilities to become clear, hydrological properties may become clear. On the other hand, there is the uncertain element such as the decision method of the ratio resistance level of the geological feature border and the groundwater not being clear. In this study, we have arranged the results such as in the airborne electromagnetic survey, a geological survey, the hydrological investigations for the points where the deep catastrophic landslides were occurred and where airborne electromagnetic survey was carried out so far. The study areas are Byutano river basin (is about 4.4km2), Fujikawa river basin (about 3.7km2), Himekawa basin (about 15.2km2), and Kumano river basin (about 10.1km2). In these areas, in the past, the deep catastrophic landslides were occurred and the airborne electromagnetic surveys were carried out.

First, we have examined ratio resistance properties every area by the airborne electromagnetic survey. The range of the ratio resistance level to appear in the area for showed 1-2400 Ω-m in 1-1200Ω-m, the Kumano river basin in the Himekawa river basin whereas it was 1-400Ω-m in Byutano river basin and the Fujikawa river basin, and the distribution of the ratio resistance level knew that there was a difference by a geological feature and an area. And we have found that there were three patterns of the distributions of the resistance when we have paid our attention to the ratio resistance pattern of the plumb directions from the surface of the slope at the point with the fear of the deep catastrophic landslides to the deep part. From this, the depth that a ratio resistance level changes in the plumb direction may become the fundus of the deep catastrophic landslide. Boring investigations were carried out in Byutano river basin, Fujikawa river basin, Himekawa river basin, and a weathering department and the geological feature border of the virginity part are authorized by the observation of the boring core. The ratio resistance level corresponding to this geological feature border indicates 100Ω-m in Byutano river basin, 70Ω-m in Fujikawa river basin, and in Himekawa river basin indicates 500Ω-m, 680Ω-m, 1000Ω-m.

From these, it was confirmed that the ratio resistance level to correspond to appearance frequency and the geological feature border of the ratio resistance level varied according to an area and a geological feature. Therefore, it is necessary to carry out the risk evaluation of the deep catastrophic landslide after carrying out a boring investigation in addition at a representative point when we carry out the airborne electromagnetic survey, and having arranged a geological feature and the relations of the ratio resistance level.

In addition, at the deep catastrophic landslide point of Kumano river basin, consecutive low ratio resistance zones and the low ratio resistance zone of the plumb direction are common to the valley part from the ridge and are confirmed and agree with the groundwater situation by the hydrological investigation. We need to accumulate data about the ratio resistance structure in conjunction with the deep catastrophic landslide and want to examine the extracting method of the point with the fear of the deep catastrophic landslide, an estimate method of the collapse depth and collapse volume in future.

In the lower basins of the active volcanoes, there are always the risks that sediment disasters are occurred. Especially, when large landslides are occurred at the time of heavy rains, the landslide sediment become a debris flow and makes a big damage by the sedimentation and the flooding in a lower basin. In late years,the Airborne Electromagnetic Survey is performed a close-up of as means to predict these large-scale landslides. It is necessary to estimate establishing technique to estimate a collapse side, the water sentence process in the slope to predict the slope where there is possibility of the collapse in at the time of heavy rains, but is the situation that is hard to say to be considered about these enough currently.Therefore, in this study, we havetaken Mt. Azuma and Mt. Fuji examples and examined the estimate technique of the collapse side and technique to predict a water sentence process from the result of a geological survey and the quality of the water investigation that we carried out the airborne electromagnetic survey in addition.

First, we performed the documents investigation into the characteristics of the topography, the geological feature, results of the sediment disasters, volcanic activity history there. Next, we performed a field work and confirmed the quality of soil structure in conjunction with the landslides, hydrothermal alteration situation causing the landslides and the hot spring gush situations. We examined areas of the airborne electromagnetic survey in reference to these results.We decided that the top of the mountain body and the representative craters were included and did the investigation object with the area including inclines more than 15 degrees that landslides were possible.The exploration area of Mt. Azuma was about 18km2 and the exploration area of Mt. Fuji was about 120km2.We have arranged themevery depth two-dimensionally so that we could recognizethe result of the helicopter electromagnetic explorationregionally.And, at the area where sediment disasters were easy to be occurred, there were some craters and water level under the ground were high, we have arranged them every depth two-dimensionally so that we grasped ratio resistance levels of the depth direction for running. We have verified the result of the airborne electromagnetic surveyby Comparing with the investigation results of the topographic and geological features.In addition, we investigated hydrology and water quality of the water at 10 neighboring streams in Mt.Azuma for the purpose of confirming the result of the airborne electromagnetic survey in detail.The investigation items werewater discharge, electric conductivity, pH, water temperature and ion silica concentration. In addition, we have carried out the boring investigation for the purpose of checking the ratio resistance levels by the airborne electromagnetic survey and the relations with the geological feature in Mt.Fuji.

We have found that by using the airborne electromagnetic survey in volcano area we could roughly grasp the geological features and underground water levels.From this, wecouldroughly predict the slopes that may collapse at the time of a heavy rain by using the airborne electromagnetic survey. On the other hand, we cannot estimate the collapse depth and the collapse volume in detail when it is only the airborne electromagnetic survey.It is necessary to supplement the results of the in the airborne electromagnetic survey by carrying out other investigations which arethe boring investigations and physics explorations on the ground, the waterquality and hydrological investigation to estimate these.In the near future, we will carry out the investigations including the airborne electromagnetic survey for models in some volcanoes and want to establish the estimate technology of the collapse dangerous points in the volcano areas, estimate technique of the collapse depths and collapse volume by accumulating data.

Verification of the tunnel geological structure based on the helicopter-borne magnetometry data analysis

OKAZAKI, Kenji[1*] ; ITO, Yoshihiko[1]

[1]CERI, PWRI

1. Introduction

More detailed geological information of tunnel ground is very important for its construction. Especially, geological complicated area, such as accretionary complex, is needed more accurate information for process control and avoidance of risk during construction of tunnels. The authors carried out helicopter-borne magnetic survey to verify its applicability for geotechnical evaluation of a mountainous planned road tunnel in east Hokkaido, Japan. We describe corresponds with the results of the geological profiles estimated from the outcomes of tunnel construction records and its analysis results of magnetic anomalies which was obtained by helicopter-borne magnetometry data.

2. Outline

The geology of the study area is mainly consists of greenstone, pyroclastic sedimentary rock and hyaloclastite, and is mixed with pillow lava, chert and limestone. Many faults are formed in the area around the survey site due to tectonic movements at the time of formation of the accretionary complex and after that. Surveyed tunnel is planed to 910 m long and maximum overburden is 150 m. The magnetic intensity was measured from a helicopter at low altitude using a cesium magnetometer, and a magnetic intensity map was compiled based on the scalar volume of the magnetic force after reduction to pole magnetism. The probable geological model of the tunnel profile was analyzed using the magnetic anomaly pattern. The forward modeling process for the magnetic data was conducted using Mag2dc software (Cooper, 2003) based on the Talwani algorithm for calculation anomalies. The forward modeling was carried out according to the type of magnetic anomaly over blocks/steps, dependence of anomaly on width, depth, susceptibility contrast and dip angle. The tunnel geological models that estimated using the magnetic anomaly pattern were verified by the geological properties from tunnel construction records.

3. Results of survey

Results of this survey, executed in a mountainous area where accretionary complexes are distributed, are summarized as follows:

1) Helicopter-borne magnetic survey was carried out for a tunnel in northeastern Hokkaido and magnetic intensity map was figured. By the correlation to the other results such as the geological survey or the observation of rock type and fracture shear and conditions in advanced core, high magnetic intensity zone corresponded to the sedimentary rock and the fracture and shear zone of hyaloclastite and massive basalt.

2) Two geological models were made by combining helicopter-borne magnetic survey results with geological survey results and magnetic intensity model. The models were correlated to the detailed data obtained by advanced boring core observation, and these distributions are roughly confirmed by advanced boring core observation.

3) In this case study, helicopter-borne magnetic survey provided useful information for effective interpretation. To analyze geological structure by helicopter-borne magnetic survey is very effective to evaluate potential geotechnical issues when excavating a tunnel.

Magnetic structure of the tsunami inundation area of the 2011 off the Pacific coast of Tohoku Earthquake

OKUMA, Shigeo[1*] ; UEDA, Takumi[1] ; NAKATSUKA, Tadashi[1] ; MITSUHATA, Yuji[1] ; JINGUUJI, Motohara[1] ; UCHIDA, Toshihiro[1]

[1]Geological Survey of Japan, AIST

In June 2012, the Geological Survey of Japan (GSJ) conducted an airborne EM and magnetic survey over the inundation area by the tsunami of the 2011 off the Pacific coast of Tohoku Earthquake, northeast Japan. The purpose of the survey was mainly to map the resistivity of the subsurface structure associated with sea water invasion by the tsunami. Airborne EM data were successful for revealing the subsurface resistivity distribution as an aid for groundwater assessment of the study area.

Aeromagnetic data were also observed by the survey and processed (Okuma et al., 2013). However, it turned out that the magnetic data seem to be contaminated by artificial noise with amount of ˜20nT probably caused by the survey helicopter. To mitigate directional errors (Herringbone effect), the generalized mis-tie control method (Nakatsuka and Okuma, 2006) was applied to the observed magnetic data and magnetic anomalies were reduced onto a smoothed observation surface. According to the compiled aeromagnetic anomaly map of the Southern Sendai Plain, magnetic highs lie over the Cretaceous granitic rocks with high magnetic susceptibilities (˜10^{-2} SI; PB-Rock 21) outcropping on the north-trending Wariyama Mountains, which may constrain the groundwater flow system. The magnetic highs also extend NE and reach the Pacific coast, implying the existence of Cretaceous granitic rocks. In a map of the Matsukawaura area, an obvious magnetic high lies over the northern edge of the lagoon without any signatures of magnetic sources on surface. To better understand the subsurface structures of the survey areas, we applied 3D imaging (Nakatsuka and Okuma, 2013) to the observed magnetic anomalies. The preliminary results of the imaging indicate magnetization highs lie below the Wariyama Mountains and coastal regions between the Torinoumi Lagoon and Ushibashi river mouth in the Southern Sendai Plain. An obvious magnetization high is present below the northeastern edge of the Matsukawaura Lagoon, corresponding to granitic rocks with high magnetic susceptibilities (˜10^{-2} SI; PB-Rock 21) at a depth of around 300m below the surface in a hot spring exploration well. The details of the 3D imaging will be shown in the presentation.

Repeated aeromagnetic surveys in Shinmoedake volcano, Japan, by using an unmanned helicopter

KOYAMA, Takao[1*] ; KANEKO, Takayuki[1] ; OHMINATO, Takao[1] ; WATANABE, Atsushi[1] ; TAKEO, Minoru[1] ; YANAGISAWA, Takatoshi[2] ; HONDA, Yoshiaki[3]

[1]Earthquake Research Institute, University of Tokyo, [2]Institute for Research on Earth Evolution, Japan Agency for Marine-Earth Science and Technology, [3]Center for Environmental Remote Sensing, Chiba University

After the 2011 eruptions of Shinmoedake volcano in Japan, we conducted three repeated aeromagnetic surveys around this area, by using an autonomously driven unmanned helicopter. Shinmoedake volcano had sub-Plinian eruptions in the end of January 2011 and its vent was filled by uprising intrusive lavas. After that, some Vulcanian eruptions followed, and then volcanic activities were decreasing gradually up to the beginning of April 2011.

After these events, we conducted aeromagnetic surveys in the end of May 2011, the beginning of November 2011, and the end of October 2013. The Yamaha RMAX-G1 unmanned helicopter was used for our surveys, which was usually used to spray the agricultural chemicals to fields, and can make flights following the programmed tracks within about 1 m precision. Availability of precise flights are a great advantage for repeated surveys in order to detect easily the changes of circumstances, such as, geomagnetic changes due to volcanic activities by measuring at the same positions. Almost 85 km flights in total were made in every survey with a flight speed of about 10 m/s. Flight heights above the ground were almost kept in 100 m.

As the result of some data processing, we clearly detected the change of the magnetic fields around the vent of Shinmoedake, which has a kind of a dipolar pattern with positive changes in South and negative changes in North. This indicates a region around the vent got magnetization due to cooling. The intrusive lava is supposed to be the source of magnetization, and 2.0x10ˆ7 Amˆ2 magnetization of lava is evaluated at the second survey (0.5yr) and 4.8x10ˆ7 Amˆ2 is evaluated at the third survey (2.5yr), compared with the first survey. This means the magnetizing rate is almost related to a square root of the elapsed time and it leads to an implication the lava cooling is dominantly made gradually by thermal diffusion, not by other cooling processes such as thermal convection. The common thermal diffusivity of rocks, however, is too small by one order of magnitude to explain this cooling rate, and intrusion of water in lava, say, rainfall water, may play an important role to raise the effective thermal diffusivity to make the lava cool.

The 3D magnetic imaging using the L1 regularization and variable selection procedure.

UTSUGI, Mitsuru[1*]

[1]Graduate School of Science, Kyoto Univ.

Recently some new method to obtain 3D subsurface structure from the gravity or geomagnetic data were proposed. Some of them have a goal to obtain a stable and most simple model which reproduce the observed data in high accuracy. This is because, in generally, most of the traditional way of inversion for the potential data provides distorted or unfocused mages of real gravitational or magnetic structures. In this study, we propose a new method introducing a L-1 penalized least square procedure and tried to obtain a simple, and therefor high- resolution model.

Lasso(Tibshirani,1995) is a linear regression and variable selection procedure based on the L1 penalized least square. L1 penalty has a effect of shrinkage the value of regression coefficients which has only weak contributions to be 0. So, the Lasso does both continuous shrinkage and automatic variable selection simultaneously. On the other hand, Lasso has some limitations and restrictions. One of them is, at most Lasso algorithm can select nonzero variables of same number of observed data. So, in the case of p <<n problem, i.e. in the case of number of unknown regression coefficients (p) is larger than the number of observations(n), this algorithm cannot be adopted or overly shrinkage model will be obtained.To overcome this limitation, Zou and Hastie (2005) proposed a new L-1 penalized method named Elastic Net.This method is a compromise of the L-1 and L-2 regularization method with two control parameters. Using this method, we can treat p <<n problems in the framework of L-1 penalized method.

In our presentation, we will show the results of applying this method to the synthesized and real magnetic data.

Magnetic structure of the north part of Deception Island based on the aeromagnetic survey by a small unmanned airplane

SAKANAKA, Shin'ya[1*] ; FUNAKI, Minoru[2] ; HIGASHINO, Shin-ichiro[3] ; NAKAMURA, Norihiro[4] ; IWATA, Naoyoshi[5] ; OBARA, Noriaki[6] ; KUWABARA, Mikio[7]

[1]Akita Univ., [2]NIPR, [3]Kyushu Univ., [4]Tohoku Univ., [5]Yamagata Univ., [6]Robotista, [7]RC Service

Aerial magnetic survey was carried out in the part of the flight project of the autonomous unmanned aerial vehicles (UAV). The project was incorporated with National Institute of Polar Research (Japan), Korea Polar Research Institute, Chile Antarctic Institute, Bulgarian Antarctic research and Spanish Antarctic team. Magnetic anomaly data were aquired over the northern part of Deception Island (within South Shetland islands) in Bransfield Strait. It was the first time to succeed to get the geophysical data by a long-flight unmanned aerial vehicle (UAV) in the area of Antarctica as already reported by our team. Due to the severe weather the flight was canceled over the southern half of the Deception Island and its surrounding sae area.

The flight altitude is about 780m averaged. The main survey lines are directed east-west and the intervals of the lines are about 1000m. Longest length of the main survey line is about 18km. Probably due to the unstable atitude of the UAV body by strong wind, some east-west lines are shortcuted regardless of pre-programmed 18km length courses. The flight courses were overlapped on the survey lines along the latitude of 62 degree 53 minute and the longitude of -60 degree 28 minute. On these lines each direction of the flight is opposite. Some unnatural unduration was seen around overlapped lines. These kinds of unduration are occurred due to the difference of the observed magnetic field on each line. These differences have to be corrected, now we have the torerable data for estimate the structure of the Deception Island.

Outstanding high magnetic anomaly is recognized over the eastern peak of the island. Preparing topographic digital data of the Deception Island and bathymetric data on surrounding sea area, we estimated the distribution and the intensity of magnetization.

Three dimensional inversion for the Grounded Electrical-Source Airborne Transient Electromagnetic (GREATEM) data

ABD ALLAH, Sabry[1*] ; MOGI, Toru[1] ; KIM, Hee[2] ; FOMENKO, Elena[3]

[1]Institute of Seismology and Volcanology, Hokkaido University, [2]Departments of Environmental Exploration Engineering, Pukyong National University, Busan, Korea, [3]Nova Scotia Community College, Halifax, NV, Canada

Previous studies conducted by the Grounded Electrical-Source Airborne Transient Electromagnetic (GREATEM) have shown that, this system is a promising method for modelling 3D resistivity structures in coastal areas, in addition to inaccessible area such as volcano, mountainous area covered by deep forest. To expand the application of the GREATEM system in the future for studying hazardous wastes, sea water incursion,geothermal exploration and hydrocarbon exploration, a 3D-resistivity modelling that considers large lateral resistivity variations is required in case of large resistivity contrasts between land and sea in surveys of coastal areas where 1D resistivity model that assumes a horizontally layered structure might be inaccurate. In this abstract we present the preparation for developing a consistent three dimensional electromagnetic inversion algorithm to calculate the EM response over arbitrary 3D conductivity structure using GREATEM system. In forward modelling the second order partial differential equations for scalar and vector potential are discretized on a staggered-grid finite difference method (Fomenko and Mogi, 2002, Mogi et al., 2011). In the inversion method the 3D model discretized into a large number of rectangular cells of constant conductivity and the final solution is obtained by minimizing a global objective function composed of the model objective function and data misfit. To deal with a huge number of grids and wide range of frequencies in air borne datasets, a method for approximating sensitivities is introduced for the efficient 3-D inversion. Approximate sensitivities are derived by replacing adjoint secondary electric fields with those computed in the previous iteration. These sensitivities can reduce the computation time, without significant loss of accuracy when constructing a full sensitivity matrix for 3-D inversion, based on the Gauss?Newton method (Han, N.et al., 2008).

Firstly, we started testing the algorithm in the frequency domain electromagnetic response of synthetic model considering a 3D conductor embedded in uniform half space. In the second step we tested more complex synthetic model, considering vertical contact between two different high and low resistivity quarter-spaces and a conductor embedded in a high resistive quarter-space. Frequency-domain computation is executed at frequencies of five equal logarithm spacings in one decade in the frequency range of (10^{5}-10^{-2}) Hz. After the computation, we transformed into time domain using FFT and compared forward value with inverted value.The inverted results in case of the simple model, appear to highlight a conductive zone of potential interest within the resistive region. In addition, in case of two quarter spaces model, it was able to the reveal the clear resistivity contrast between the two quarters spaces and highlight a conductive zone within the high resistive quarter space. Both of the forward and inverted models have almost the same EM response which can confirm the accuracy of the inverted method. The next step for preparing this algorithm will be using the field data from previous GREATEM surveys to demonstrate this technique

An Advanced Method of Data Analysis for Gravity Exploration System on a Mobile Vehicle

OGURA, Yumiko[1] ; MATSUDA, Shigeo[2] ; YOKOI, Isamu[3] ; SUDA, Haruo[3] ; KIMA, Sadaharu[3] ; MORIKAWA, Hitoshi[1*] ; SAEKI, Masayuki[4] ; SUZUKI, Takuya[4] ; KOMAZAWA, Masao[5]

[1]Tokyo Institute of Technology, [2]Clover Tech . Inc., [3]Tokyo Sokushin Co.,Ltd.,, [4]Tokyo University of Science, [5]OYO Corporation

A model of ground structure is very important to estimate earthquake ground motions. Gravity survey is one of exploration methods. We can estimate ground structure by using information of gravity anomaly which comes from heterogeneous density structure of the ground. Generally speaking, there are high correlation between density and velocity structure of the ground. Thus, the gravity survey is comparatively easier than other exploration method to estimate the ground structure, so that it is very suitable for the aspect of the seismic hazard projection.

For gravity survey, spring-type relative gravimeter is usually used. This type of gravimeter can provide accurate data, however, it is very expensive and difficult to handle. Furthermore, it takes much time to obtain adequate data. We, thus, began to develop a simple and inexpensive sensor which can measure gravity anomaly on a moving vehicle, such as air, land, and sea vehicles, that is, airplanes, motor vehicles, and ships. In a case where a gravimeter is used with a moving vehicle, we may survey the gravity over larger area in shorter time than using conventional survey techniques.

Generally, the gravity should be measured with resolution of 10 micro Gal at least for survey to estimate ground structure. However, the signal obtained from sensor is contaminated by various noise such as vibration of a moving vehicle etc. This means that a sensor with high resolution and large dynamic range is required. This is difficult to realize because resolution and dynamic range are conflicting requirement. To solve this problem, we have developed a sensor with a new feedback system, which has high resolution and large dynamic range.The performance of this sensor is examined in this study, and we also propose a technique of data processing based on the combination of second order blind identification (SOBI) and Hilbert Huang transform (HHT) technique.For this two different type of observations are carried out.

First, we set the sensor statically in a tunnel to confirm whether the sensor can respond to the gravitational effects caused by earth tides. From this observation, it is found that the sensor is affected by atmosphere. The effect is can be removed by applying second order blind identification (SOBI).

Second, the ship survey is carried out.Through a technique of data processing based,the observed data provide quite good agreement with theoretical gravity in phase and period of the signal.

DEM accuracy evaluation in mountain area by utilizing topographic corrected products of high-resolution TerraSAR-X data

NONAKA, Takashi[1*] ; OKAJIMA, Yuki[1] ; TSUKAHARA, Koichi[1]

[1]PASCO CORPORATION

The commercial high-resolution Synthetic Aperture Radar (SAR) sensors have been developed during past few years and became essential source of information in Earth Observation. The production of the maps is examined in the various fields, such as the damaged area caused by disaster, paddy field area, and forest etc. The interpretation of the objects from the images and the positional accuracy of the images are highly important for the map creation and several basic studies for such issues are also conducted by applying high-resolution SAR data.

TerraSAR-X is one of the commercial SAR satellites, and has acquired data worldwide after it was launched in June 2007. Furthermore, TanDEM-X (TerraSAR-X add-on) was launched in 2010. Both satellites are currently acquiring land surface of Earth for creating global and homogeneous Digital Elevation Model (DEM) of very high precision. TerraSAR-X has several processing level products, and the Geocoded Enhanced Ellipsoid Corrected (EEC) is amplitude data projected to the digital elevation model (DEM), which makes possible for users to integrate other optical data and GIS data. Pre-geocoded Single Look Slant Range Complex (SSC) product is complex data with two axes in the azimuth-slant range plane, and used for interferometric and polarimetric analysis.

It was reported that the geometric accuracy of SSC product was better than 1 m in several previous studies, however there are no reports stating details for the validation results of the EEC product using the actual TerraSAR-X data though it is utilized by the most of users. Therefore the authors evaluated the geometric accuracy of the EEC product by performing in-situ experiment using reflectors on the flat area, simultaneously conducted during satellite passed over. The results showed that the accuracy satisfied several meters in case of utilization of SRTM DEM. In the next stage, we developed the model showing the relationships between the geometric accuracy of range direction, DEM accuracy, incidence angle, and it was revealed that the accuracy of the model was about 1 m in the flat area.

The purpose of this study was to evaluate the accuracy of utilized DEM for the topographic correction by applying the model to TerraSAR-X data in the mountain area. The utilized TerraSAR-X data were 2 data sets of high-resolution SpotLight mode (about 2 m resolution) with the different incidence angles, and the DEMs were produced by ASTER with the mesh of 30 m and SRTM with 90 m. We also used the airborne optical data with a geometric accuracy (Digital topographic level of 2,500 scales) for a validation.

Firstly we selected 25 validation points from the intersections and curves of roads easily interpreted both from TerraSAR-X and airborne data. The average, standard deviation, and Root Mean Square Errors (RMSE) value of the difference between TerraSAR-X and reference optical data were evaluated for X-, Y-, and X-Y plane. In the next stage, we examined to apply the model to data in the mountain area. We estimated DEM's errors by assuming that the variation of the differences of the X-direction was corresponded to the errors of the topographic correction since the range direction was almost same for X direction. The results were summarized based on the evaluations of both flat and mountain areas.

Pi-SAR-L2 observation of the landslide caused by Typhoon Wipha on Izu Oshima island

WATANABE, Manabu[1*] ; DAN, Risako[2] ; MOTOHKA, Takeshi[1] ; OHKI, Masato[1] ; SHIMADA, Masanobu[1]

[1]Japan Aerospace Exploration Agency, [2]RESTEC

On October 16, 2013, Typhoon Wipha struck Izu Oshima island, and a large-scale landslide was induced by the heavy rain. Six days after the disaster, Pi-SAR-L2 observation was carried out in four different observation directions (L203201?L203204). One Pi-SAR-L observation (L03801) was carried out before the disaster on August 30, 2000 in same observation direction of L203201. The observation data were used to determine which parameters and directions are preferable to detect landslide areas. Several full polarimetric parameters, including Sigma_0, polarimetric coherence, four-component parameters, and eigenvalue decomposition parameters were obtained using PolSARPro and a self-produced programs. As pointed out by Shimada et al. [1], the change of the land cover from a forest before the disaster to bare soil after the disaster was well detected by the coherence between HH and VV. In addition to this parameter, the eigenvalues and four-component decomposition parameters have the potential to detect landslide areas. The data from observations of the bottom to the top of the landslide detect the landslide well, whereas the observation of the opposite side are not as useful.

Soil from the landslide intruded into the town areas, but none of the full polarimetric parameters show any significant difference between the landslide-affected town areas and the unaffected areas.

Shoreline change analysis using JERS-1/SAR and ALOS/PALSAR amplitude images

ASAKA, Tomohito[1*] ; IWASHITA, Keishi[1] ; KUDOU, Katsuteru[1] ; AOYAMA, Sadayoshi[1] ; SUGIMURA, Toshiro[2]

[1]Nihon University, [2]Remote Sensing Technology Center of Japan

Aerial photo analysis and bathymetric survey are commonly conducted to investigate the actual conditions and temporal variation in beach transformation. In recent years, satellite-based optical imagery has been more widely used to evaluate coastal erosion. However, defining shoreline edges using optical imagery is difficult because the sand under seawater near the shoreline can often be seen through clear water. On the other hand, synthetic aperture radar (SAR) imagery can be used to interpret the boundary between a sandy beach and seawater; this is possible because the incident radio waves are not transmitted through water, and SAR images can be compared to trace the shoreline. In this work, we examine the potential of shoreline change analysis by using Japanese Earth Resources Satellite 1 (JERS-1)/SAR and Advanced Land Observing Satellite/Phased Array type L-band Synthetic Aperture Radar (ALOS/PALSAR) amplitude images. We consider Kujy?kurihama beach in Chiba Prefecture as our test site; along this beach, the shoreline is almost perpendicular to the SAR antenna beam orientation for the descending orbit.

We propose a three-step automated shoreline-tracing method to assess the temporal variation of the shoreline in the study area; the HH-polarized JERS-1/SAR amplitude image captured on February 22, 1993, and the HH-polarized ALOS/PALSAR amplitude image captured on May 20, 2010 were used for this purpose. In our method, a shoreline is traced as vector data. In the first step, edge pixels in SAR images are identified by using the Laplacian of a Gaussian filter. In the second step, unwanted edge pixels are masked on the basis of a discriminant analysis in which candidate shoreline edge pixels are estimated by using statistical information within a moving window. The criteria for identifying shoreline edge pixels is decided on the basis of previously gathered data, the backscattering average, and the standard deviation, in the training area (30 by 10 pixels) encompassing the sea, shoreline, and land. In the third step, shoreline vector data are generated from continuous candidate shoreline edge pixels by an automated shoreline-tracing algorithm.

The results were verified in two ways. We first verified the location of the shoreline edge in the SAR amplitude images by overlaying multispectral images acquired on dates close to the acquisition dates of the earlier mentioned JERS-1/SAR data and ALOS/PALSAR data: the JERS-1/Optical Sensor (OPS) color composite image acquired on May 3, 1993, and the ALOS/Advanced Visible and Near Infrared Radiometer type 2 (AVNIR-2) color composite image acquired on January 8, 2011, were used for this analysis. Next, we calculated the statistical information of the backscattering data in the JERS-1/SAR and the ALOS/PALSAR amplitude images for our selected training area. It is noteworthy that the backscattering average and standard deviation in the shoreline training area is a unique than anything training area.

Our proposed method reproduces the temporal variation of the shoreline by using JERS-1/SAR and ALOS/PALSAR amplitude images. However, a part of the shoreline extracted using the JERS-1/SAR amplitude image was inaccurate. The speckle noise in the JERS-1/SAR amplitude image and the low spatial resolution of the raw data may have caused these errors. In our future work, we intend to improve the algorithm for JERS-1/SAR data and accumulate backscattering information of shoreline edge areas using SAR amplitude images.

Glacier observations by airbourne synthetic aperture radar, PiSAR2, at Tateyama, Japan

FURUYA, Masato[1*] ; FUKUI, Kotaro[2] ; SUGIYAMA, Shin[3] ; SAWAGAKI, Takanobu[4]

[1]Hokkaido University, Graduate School of Science, [2]Tateyama Caldera Sabo Museum, [3]Institute of Low Temperature Science, [4]Hokkaido University, Graduate School of Environmental Science

Fukui and Iida (2012) reported that three snowy gorges at Tateyama, Japan, were flowing at a rate of 10-30 cm/month and hence could be identified as glaciers. Fukui and Iida's observations are based on ground-based GPS observations. Because glacier flow velocity data sets are one of the fundamental physical quantities to better understand the dynamics, conventional geodetic techniques have been applied, and the measurement accuracy has significantly improved. However, due to the severe environment and logistic problems, SAR-based velocity mapping has been performed with successful results at large glaciers and ice sheets over the past decades. The velocity mapping technique is so called pixel-offset (or feature) tracking. Thus, applying the same technique to the fore-mentioned newly discovered glaciers, we should also be able to detect the spatial distribution of glacier velocities. However, the presently available satellite-based SAR data set does not have enough spatial resolutions to resolve the velocities. In this regard, the 30-cm resolution of Pi-SAR2 seems promising to perform the pixel-offset tracking. Here we report the first observation images of the Japanese glaciers acquired by Pi-SAR2, and will discuss the preliminary report of velocity mapping.

Monitoring of Ice sheet marginal zone using multi-frequency SAR data

YAMANOKUCHI, Tsutomu[1*] ; DOI, Koichiro[2] ; NAKAMURA, Kazuki[3] ; AOKI, Shigeru[4]

[1]Remote Sensing Technology Center of Japan, [2]National Institute of Polar Research, [3]Nihon University, [4]Institute of Low Temperature Science, Hokkaido University

Environment of Antarctic continent and ice sheet marginal zone is quite important for understanding the mass balance of ice, formation of deep ocean water and other cryospheric phenomena.Previous study showed the usefulness of SAR data to understand what is happen on the bounary area between ice sheet and ice shelf by SAR data analysis, and achieved the mapping of ice sheet surface velocity mapping. In recent, many kinds of satellite equipped SAR sensor plan to launch and these data are available trough the scientific Research Announcement (RA) or Announcement of Oppotunitty (AO).

Based on these facts, this study focuses on the use of multi-frequency SAR data for ice sheet marginal zone monitoring. Especially, we focus on the use of InSAR analysis for grounding line extraction, ice flow velocity mapping by offset tracking, and understanding the image feature difference through the interpretation of X-, C- and L- band SAR data. We use X-band data by TerraSAR-X, C-band data by ENVISAT and ERS-1/2, and L-band data by ALOS/PALSAR data. Then, we will try to describe the applicability and prospectives of ALOS-2 / PALSAR-2 data

TerraSAR-X data were provided by DLRs' AO project (Proposal No. HYD1808), ERS-1/2 and ENVISAT data were provided by ESA Cat-1 AO project, (project C1P.7657) and ALOS/PALSAR data were provided by Research Announcement by JAXA PI project (PI No. P1418002).

Evaluation of surface roughness, magnetic permeability and dielectric permittivity using polarimetric SAR data

KOIKE, Katsuaki[1*] ; MASUDA, Takayuki[1] ; SAEPULOH, Asep[2] ; URAI, Minoru[3] ; OMURA, Makoto[4] ; DOI, Koichiro[5]

[1]Graduate School of Eng., Kyoto Univ., [2]Bandung Institute of Technology, [3]Geological Survey of Japan, AIST, [4]Dept. Cultural Studies, Univ. Kochi, [5]National Institute of Polar Research

Synthetic Aperture Radar (SAR) systems have great advantages of observing the Earth surface regardless of meteorological conditions and detecting crustal deformations by Interferometric processing. Another latest technique, polarimetric SAR has also been widely used through its principle that backscattering intensity differs with polarization mode. However, most applications are limited to image classification. In addition, the evaluation method for surface physical properties has not yet been investigated well. To achieve this evaluation from the viewpoints of geological identification and water-content estimation of soils, this study adopts mdPSAR (**m**agnetic permeability and **d**ielectric permittivity from **P**olarimetric **S**ynthetic **A**perture **R**adar) proposed by Saepuloh *et al*. and tries to evaluate roughness, relative magnetic permeability, and relative dielectric permittivity of the surface materials using the HH, VV, and HV mode SAR data.

As the first step of mdPSAR, the surface roughness is calculated from the backscattering coefficient data at the HV mode and an empirical equation based on an assumption of fractal property of the topography (Campbell and Shepard, 1996). Next, using the Small Perturbation Model (Fung and Chen, 2010) of backscattering coefficient and the Nelder-Mead Simplex method (a method of nonlinear optimization), the relative magnetic permeability and the relative dielectric permittivity are calculated by minimizing the difference between the model and the backscattering coefficient data at the HH and VV modes.

The areas around the Tottori sand dunes were selected as a case study of mdPSAR using two scenes of ALOS PALSAR data acquired on 25 October and 27 April 2009. As the result, the average calculation errors were small as about 1% for both the HH and VV modes and the errors were uniform in general over the scenes. The relative dielectric permittivity values of the Tottori sand dunes were evaluated as 13.4 and 10.6. These values correspond with those of wet sands. It is noted that the value is higher in the scene after raining. Higher values of relative magnetic permeability were evaluated in the sand dunes than the surroundings, which is a reasonable trend because the sands are originated from the weathering of granitic rocks containing magnetite. Consequently, the effectiveness of mdPSAR is demonstrated. However, an improvement is necessary for the surface-roughness estimation of the areas occupied by artificial structures such as buildings. This is because the HH mode intensity becomes strong in them.

Application of mdPSAR to the PARSAR data around Syowa Station, Antarctica is in progress. Its purposes are to clarify distribution of outcrops and snow ice areas, melting state of ices, and development of crevasse topography from the spatio-temporal changes of surface roughness and relative dielectric permittivity.

Four global mosaics of Advanced Land Observing Satellite (ALOS) Phased Arrayed L-band Synthetic Aperture Radar (SAR) HH and HV polarization data were generated at 25 m spatial resolution using data acquired annually from 2007 to 2010. Variability in L-band HH and HV gamma-naught for forests was observed between regions, with this attributed to differences in forest structure and vegetation/surface moisture conditions. Region-specific backscatter thresholds were therefore applied to produce from each annual mosaic, a global map of forest and non-forest cover from which maps of forest loss and gain were mapped. Using a combination of Degree Confluence Project (DCP), Forest Resource Assessment (FRA) and Google Earth images as ground data, the overall agreement was 85 %, 91 % and 95 % respectively. Using 2007 as a baseline, decreases of 0.040 and 0.028 dB (with a 0.006 dB confidence level) were observed in the HH and HV gamma-naught respectively suggesting a decrease in forest area and increased smoothing of the global surface at the L-band radar observation. The maps provide a new global resource for documenting the changing extent of forests and contributing to ongoing monitoring through integration with historical (1992-1998) Japanese Earth Resources Satellite (JERS-1) SAR and forthcoming (from 2014) ALOS-2 PALSAR-2 data.

Recent progress in InSAR and PolSAR signal processing

HIROSE, Akira[1*]

[1]The University of Tokyo

This invited talk reviews latest technology in synthetic aperture radar (SAR) signal processing, in particular interferometric SAR (InSAR) and polarimetric SAR (PolSAR), by focusing on the works on adaptive processing made by the author's group. This field attracts more attention because of its usability in solving serious social problems through, e.g., disaster monitoring and mitigation, water resource management, and prevention of global warming. We discuss a radar-physics-based adaptive processing framework, namely complex-valued neural networks, to increase variety of observation functions and/or improve the accuracy. We also introduce a new phase-unwrapping method to discuss its recent progress.

Uplift and reverse fault rupture of the 2013 Bohol earthquake (Mw 7.2), Philippines, revealed by SAR pixel offset analys

KOBAYASHI, Tomokazu[1] ; TOBITA, Mikio[1*]

[1]GSI of Japan

Applying a pixel offset analysis using RADARSAT-2 SAR data to an inland crustal earthquake that occurred in Bohol Island, Philippines on 15 October, 2013, we succeeded in mapping a ground displacement associated with the earthquake. The most concentrated crustal deformation is located in the northwest of the island with ground displacement exceeding 1 m. The crustal deformation is zonally distributed with the length of approximately 50 km in the ENE-WSW direction. The ground in the mountainous area moves toward the satellite, while in the northern coastal zone the ground moves away from the satellite. A clear displacement discontinuity with the length of about 5 km, probably corresponding to earthquake surface faults, can be identified in the northeastern part. Our fault model that consists of two rectangular planes shows nearly pure reverse fault motions on south-southeast-dipping planes with moderate dip angles. A local rupture located in the northeast occurs at shallow depths, causing appearance of surface ruptures. Applying an additive color process using SAR amplitude images, significant changes in the backscatter intensity are detected along the coast from Maribojoc to Loon, suggesting that the seafloor uplifted and the shoreline shifted seaward resultantly. The area showing the shoreline change is in good spatial agreement with the locally-distributed large ground uplift predicted from our fault model. We can identify a good correlation between the ground upheaval produced by the reverse fault motion and the elevation in the mountainous area, consistent with the idea that the historically-repeated reverse faultings have developed the present-day topography.

Estimate of error in ALOS/PALSAR interferograms

HASHIMOTO, Manabu[1*]

[1]DPRI, Kyoto University

Large deformation is generated by the subduction of the Philippine Sea plate in Shikoku. GNSS observation reveals a WNW ward horizontal motion and a velocity gradient from south to north. This velocity field is suitable for the observation with SAR, which is sensible to the E-W ward displacement field. Based on these facts, we have conducted to derive average velocity in Shikoku using ALOS/PALSAR. We mainly analyzed ascending images acquired during 4 years, but anomalously large displacements (peak-to-peak displacement ˜50 cm) were often observed possibly due to ionospheric disturbances. We discarded interferograms with such disturbances with visual inspection, and stacked rest of them. However we found E-W velocity gradient in Shikoku that is inconsisntent with GNSS observations, when stacked interferograms are superposed from 4 paths. Furthermore, discontinuities between paths are evident in the Chugoku district. Therefore we made error estimate in order to clarify its magnitude and spatial distribution, comparing line-of-sight displacements derived from InSAR and GNSS.

The procedure is as follows:

(1) Calculate displacements of GNSS stations between the acquisitions of master and slave images for a specific pair from the F3 solution of GEONET and convert them to LOS displacements.

(2) Extract LOS displacements at GNSS sites from the interferogram.

(3) Take differences of LOS displacements between interferogram and GNSS.

(4) Examine dependence of latitude, longitude and height, and interpolate differences of LOS displacements with Surface function of GMT.

(5) Add interpolated differences of LOS displacements to the original interferogram.

One typical example is interferogram for the pair of April 11 and May 27, 2010 for the path 419. Since the time difference is 46 days, little motion is expected. However, we observe LOS changes of ˜40 cm in the E-W direction. We also find a tong-shaped region of LOS decrease in the Chugoku district. Applying the above procedure, we obtain interpolated differences of LOS displacement with the opposite sign to the original interferogram. The standard error of difference of LOS displacements for 36 GNSS sites is 7.8 cm. However, the dependences of longitude and latitude are obviously different at 34 N. Therefore we use the Surface function instead of a simple linear function for the interpolation. Finally, we obtain a fairly flat interferogram consistent with the GNSS result. There still remain displacements with shorter wavelength than 20 km, however.

Applying to other pairs, we evaluate standard errors. The minimum is 1.2 cm (Jan. 6 - Feb. 21, 2009), while the maximum is 18.9 cm (May 27 - Jul. 12, 2010). In total 24 pairs, 4 is less than 2 cm, 7 for 2 ˜4 cm, 6 for 4 ˜6 cm, 3 for 6 ˜8 cm, 2 for 8 ˜10 cm, and 2 is larger than 10 cm. The median is 4.5 cm. For the neighboring path 418 (30 GNSS sites), the minimum is 1.5 cm, while the maximum is 19.8 cm. The median is 4.7 cm. These estimates may give a rough idea of error of PALSAR interferograms including ionospheric disturbances.

We apply this procedure to other paths (417, 418 and 420) and obtain corrected interferograms that cover the entire Shikoku (Attached figure). This map is fairly consistent with the GNSS velocity field, but there is a discontinuity between the paths 417 and 418. We use interferograms with a rather long perpendicular baseline, which causes decorrelation in mountains. We use only GNSS displacements in plain areas for such interferograms, which results in systematic error.

Persistent scatterer SAR interferometry using multi-polarimetric SAR interferograms

ISHITSUKA, Kazuya[1*] ; TAMURA, Masayuki[1] ; MATSUOKA, Toshifumi[1]

[1]Graduate School of Engineering, Kyoto University

Persistent scatterer SAR interferometry (PS-InSAR) is a method to estimate surface deformation using a number of SAR interferograms, and has been applied to aseismic fault slip, volcano and land subsidence as a practical monitoring tool. In recent years, more and more satellites that are equipped with SAR, which can acquire multi-polarimetric data has been operated. In this study, we propose a method to processing PS-InSAR analysis using multi-polarimetric SAR interferograms, and show that the estimation accuracy of surface deformation increases.

In this study, we increase estimation accuracy by processing multi-polarimetric SAR interferograms simultaneously. Since, the amount of noise ratio would differ in different multi-polarimetric SAR interferograms depending on the geometry or electromagnetic characteristics of targets, we determine the weighting coefficient between polarimetric SAR interferograms from observed phase based on maximum likelihood method.

We applied the method to ALOS/PALSAR data acquired in multi-polarimetric mode. First, we processed HH-HH and VV-VV interferograms simultaneously. As a result, weighting of HH-HH and VV-VV interferogram was almost identical, suggesting that decorrelation-induced noise in HH-HH and VV-VV interferograms was almost same. In this case, the accuracy of estimated deformation rate would increase twice. On the other hand, when we processed HH-HH and HV-HV interferograms simultaneously, the weighting of HH-HH interferograms are larger than that of HV-HV interferograms, suggesting that HH-HH interferograms has less amount of noise compared with HV-HV interferograms. Nevertheless, we found that the estimation accuracy increases by using both HH-HH and HV-HV interferograms compared with the standard analysis using HH-HH interferograms.

Correction by GNSS data for wide area InSAR analysis

MORISHITA, Yu[1*]

[1]GSI of Japan

InSAR results include not only deformation signals but also noises caused by orbital inaccuracies, tropospheric delay and ionospheric delay. Orbital inaccuracies yield a residual orbital phase ramp. As spatial wavelengths of tropospheric and ionospheric noise are typically long, the effect is trivial for a small area but it can be significant for a large area.

Tropospheric noise can be mitigated by estimating the amount of tropospheric delay from a numerical weather model. However, the mitigation does not always work because of the limitation of spatial and temporal resolution of the numerical weather model. There is no common and effective technique to correct ionospheric noise so far while several techniques have been proposed. The ionospheric noise remains a big problem because, in particular, L-band is greatly affected by ionospheric noise. A residual orbital phase ramp can be reduced by flattening the phase in an area with no deformation. Another effective correction method is estimating model parameters (e.g. bilinear surface) to fit other deformation data such as GNSS continuous observation (Tobita et al., 2005; Fukushima and Hooper, 2011). This method works even if the deformation extends the entire area (Kobayashi, 2011). However, if the area is wide, a bilinear surface model is not sufficient because of noises with long wavelengths. A spline interpolation method has been proposed to overcome this problem (Fukushima, 2013).

In this presentation, I will report a GNSS correction technique using a natural interpolation method for scattered points. This technique can mitigate not only residual orbital phase ramps but also noises with long wavelength. Adjusting correction steps enables realistic extrapolations while conventional steps sometimes result in outliers in extrapolated areas. The results of wide area time series InSAR analysis using ALOS/PALSAR data show less noise and more apparent phase changes with shorter wavelength than the interval of the GNSS stations.

Research on the characteristics of ionospheric disturbance around Japan by GPS-TEC for ionospheric correction to InSAR

NAKAGAWA, Hiroyuki[1*] ; MUNEKANE, Hiroshi[1] ; KUROISHI, Yuki[1] ; KAMIHARA, Masashi[2]

[1]GSI of Japan, [2]Pascalia Co.,Ltd

In the monitoring surface deformation using SAR interferometry (InSAR), it is a serious problem that the long-wavelength noise caused by ionospheric disturbance degrades accuracy of the detection of deformation. Since 2013, Geospatial Information Authority of Japan (GSI) have conducted a research project on the method for ionospheric correction to satellite InSAR based on TEC information obtained from two-wavelength observation data of GEONET.

For the first step, in order to understand the characteristics of ionospheric disturbance around Japan, we identified ionospheric disturbance of the period between 2000 and 2011 by GPS-TEC of GEONET and estimate characteristic values of each event.

In the manner in Munekane (2013), we first estimate zenith TEC and TEC gradient in north-south and east-west component every thirty second during the period from GEONET thirty-second RINEX data. Then, we adopted high pass filter of 3600s to remove low frequency component.

Next, based on this GPS-TEC time series, we identified ionospheric disturbance event in the period. In this step, we focus rather on revealing overall trend of ionospheric disturbance than inspecting accuracy of the characteristic value of each event.

The process of identification is as follows. First hourly RMS of TEC was calculated every hour, and, if the number of sites which hourly TEC-RMS is over threshold is more than a certain criterion, regard the epoch as a part of ionospheric disturbance event. Then, viewing the ”GEONET GPS-TEC maps over Japan” on the web site of NICT, each disturbance event was divided visually into three category according to the pattern of TEC distribution, ”traveling ionospheric disturbance (TID) ”, ”plasma bubble” and ”other”.

After the identification of event category, we decided characteristics such as event start and end time, affected area and its temporal transition based on ten-minute RMS of TEC. Also, we estimate characteristic values associated with event category such as wavelength of a TID or northernmost latitude of a plasma bubble etc. Finally, we derived characteristics of the ionospheric disturbance around Japan statistically.

We identified 8,815 ionospheric disturbance in the period, reaching maximum of 967 events in 2001, decreasing gradually to minimum of 471 in 2007, and having increasing tendency afterwards. This trend is consistent with solar cycle. The occurrence of TID and plasma bubble is found to be consistent with solar cycle, too.

Also, it appears that TID occurs commonly from May to August, in summer season. TID occurrence also concentrates before and after two hours around 22 o’clock in local time. As for plasma bubble, the occurrence is high from the sunset to midnight in local time. These results are consistent with earlier studies.

APPLICATION OF DINSAR TIME SERIES ANALYSIS USING ALOS PALSAR TO EXTERIOR DEFORMATION MONITORING OF DAMS

HONDA, Kenichi[1*] ; MUSHIAKE, Naruo[1] ; SATOH, Wataru[1] ; SATOH, Hiroyuki[2] ; KOBORI, Toshihide[2] ; SASAKI, Takashi[3] ; YAMAGUCHI, Yoshikazu[4] ; SHIMIZU, Norikazu[5]

[1]Kokusai Kogyo Co., Ltd., [2]Public Works Research Institute, [3]National Institute for Land and Infrastructure Management, [4]Japan Dam Engineering Center, [5]Yamaguchi University

The number of aging civil engineering structures is rapidly increasing in Japan. As for dams, it is estimated that 58% of existing dams in the year 2020 will be 50 years old or over after completion. This situation increasingly requires not only efficient deformation monitoring systems for safety management of civil structures but also safe and rapid methods in case of emergencies such as earthquakes.

Remote sensing techniques, especially Synthetic Aperture Radar (SAR), can play an important role to conduct deformation monitoring of civil structures such as dams. Differential Interferometric SAR (DInSAR) analysis using SAR satellite data can be suitable to deformation monitoring in broad areas.

To investigate the applicability of DInSAR analysis for the deformation monitoring, the Taiho Subdam, which is located in the Okinawa Prefecture, Japan, was selected as a study area because the deformation monitoring using GPS have been rigorously conducted since the completion of the dam from December 2006. In this study area, at maximum 114 mm of deformation was measured from December 2006 to December 2010, which corresponds to the observation period by SAR satellite. ALOS PALSAR data, L-band SAR, was used for DInSAR analysis and the results of deformations calculated by DInSAR analysis were compared with the results of the GPS deformation measurements. 28 scenes of ALOS PALSAR data were used: 14 scenes of descending data from December 6, 2006 to December 17, 2010, and 14 scenes of ascending data from January 12, 2007 to January 23, 2011, respectively.

The values of deformations calculated by DInSAR analysis were about 70 or 80% of those measured by GPS during observation period about four years. Although the DInSAR analysis results were expected to have some errors and were different from the GPS measurement results to some extent, DInSAR deformation monitoring is sufficient enough to monitor few-centimeter deformations. Additionally time series changes by DInSAR analysis can well reproduced the tendency of the settlement of the dam. This indicates a possibility that DInSAR analysis is useful for the deformation monitoring for civil structures.

Approach for monitoring ground deformation around the active volcanoes in Japan by InSAR time series analysis

MIURA, Yuji[1*] ; ANDO, Shinobu[2] ; NAKAMURA, Masamichi[1]

[1]Volcanological Division, JMA, [2]MRI

In previous studies, we have reported the analysis results about domestic active volcanic areas using D-InSAR of ALOS since 2007. In recent years, InSAR time series analysis technique has been developed. Therefore various studies have been reported for monitoring ground deformation using InSAR time series analysis. In this study, we have applied this procedure to the analysis of the data of ALOS/PALSAR for monitoring ground deformation of the active volcanoes in Japan.

As a result, we can detect ground deformations associated with volcanic activities of Tokachidake, Azumayama, Izu-Oshima, Miyakejima, Satsuma-Iojima and others. These obtained ground deformations by InSAR time series analysis were basically consistent with the results of GPS.

Surface displacement around Hachobaru geothermal field inferred from persistent scatterer SAR interferometry

ISHITSUKA, Kazuya[1*] ; TSUJI, Takeshi[2] ; MATSUOKA, Toshifumi[1] ; FUJIMITSU, Yasuhiro[3] ; NISHIJIMA, Jun[3]

Fluid migration around geothermal field can cause surface displacement. Leveling campaign and GPS measurement has been used to estimate surface displacement and shown the usefulness for reservoir monitoring at geothermal field. Recently, persistent scatterer SAR interferometry (PS-InSAR) analysis has been developed as a practical tool for surface displacement monitoring. By making use of the advantage of wide data coverage of satellite image, the analysis enables us to estimate surface displacement at the whole geothermal field with high spatial density. In this study, we applied PS-InSAR analysis on areas around Hachobaru geothermal field, the largest geothermal field in Japan, located Kyushu Island. For the analysis, we used 18 ALOS/PALSAR images acquired from July 2007 to December 2010 from an ascending orbit.

As a result of the analysis, we estimated secular surface displacement with the maximum rate of 15 mm/year opposite to satellite direction, which can be inferred as ground subsidence. We also found temporally irregular displacement along with the secular displacement. This irregular displacement has occurred all of Mt. Kuju, suggesting that displacement at Mt. Kuju has influenced displacement at the geothermal field. Moreover, we found that the secular displacement has decayed over time and has clear boundaries which possibly correspond to fault locations.

The Steady Crustal Deformation Analysis in Tokai region by InSAR

ANDO, Shinobu[1*] ; IWAKIRI, Kazuhiro[2] ; AOKI, Gen[2]

[1]MRI, [2]JMA

ALOS has an L-band SAR (PALSAR), which is of help to understand of a ground surface state, and its interferometric coherence is highly effective for the crustal deformation observation.

We analyzed the ALOS/PALSAR data around Omaezaki and Kakegawa cities in Shizuoka Prefecture, and tried to detect steady crustal deformation due to the subduction of the Philippine Sea plate. In this study, in order to obtain steady-state deformation (time series), we subjected to interference processing on the image pairs of a number of different imaging date interval. Then, using a variation of the satellite line-of-sight direction in the interference each images and we were calculated the average variation of the 46 days (stacking process). However, to reduce noise, we analysed except for some interferograms with obvious noise. This method can be expected to improve detection accuracy, because of able to reduce the influence of noise caused by the ionosphere.

We used 23 ascending data acquired from January 2007 to October 2010 and 19 descending data acquired from October 2006 to September 2010. Before solving for the displacement time series, we corrected the atmosphere phase delay by Japan Meteorological Agency nonhydrostatic model (JMA-NHM), and calculated the displacement of the satellite line-of-sight direction of the pair of all. The average displacement of the satellite line-of-sight direction of the 46 days was calculated under the assumption that the variation in the period of each pair is constant. The distance between the imaging date is different for each pair, but we did not weight during the averaging process.

As a result, steady-state deformation was hardly observed in the analysis of the ascending orbit data, but in the analysis of the descending orbit data, were observed the steady-state deformation the away from the satellite in the radar line-of-sight direction. This crustal deformation was significant in Omaezaki area, especially. These results are consistent with the displacement vector by GNSS. In this report, we also reported about InSAR time series analysis using *StaMPS* program was developed by the Stanford Institute of Technology.

Some of PALSAR data were prepared by the Japan Aerospace Exploration Agency (JAXA) via the Geospatial Information Authority of Japan (GSI) as part of the project ”ALOS Domestic Demonstration on Disaster Management Application” of the Earth Working Group. Also, we used some of PALSAR data that are shared within PALSAR Interferometry Consortium to Study our Evolving Land surface (PIXEL). PALSAR data belongs to Ministry of Economy Trade and Industry (METI) and JAXA. We would like to thank Dr. Shimada (JAXA) for the use of his *SIGMA-SAR* software. In the process of the InSAR, we used ”the digital elevation map 50m-mesh” provided by GSI, and Generic Mapping Tools (P.Wessel and W.H.F.Smith, 1999) to prepare illustrations.

Monitoring of Sakurajima Volcano using Cosmo-SkyMed

MIYAGI, Yosuke[1*] ; OZAWA, Taku[1] ; SHIMADA, Masanobu[2]

[1]National Research Institute for Earth Science and Disaster Prevention, [2]Japan Aerospace Exploration Agency

Sakurajima volcano is located in southwestern part of Japan, and currently a most active volcano in Japan. Eruptive activities from Showa-crater have activated since 2009, and several explosive eruptions occurred in 2012. On July 24, 2012, another large eruption occurred from Minamidake-crater after a lapse of 18 months. To understand current condition and future unrest of Sakurajima, periodic monitoring is required. Although it is generally difficult to make a field observation in dangerous active volcanoes, a satellite remote sensing can make observations of even ongoing volcanoes periodically. Especially, Synthetic Aperture Radar (SAR) sensor is well-suited for monitoring active volcanoes because it can penetrate ash clouds and can observe targets like an active vent. Moreover, SAR data are applicable to use a Differential Interferometric SAR (DInSAR) technique to detect crustal movement associated with the magmatic activities. In this study, we used COSMO-SkyMed data for monitoring Sakurajima volcano and tried DInSAR processing. Monitoring using high-resolution amplitude images revealed changes of backscattering intensity probably due to some kind of surface change within or around the crater. DInSAR processing suffered from low coherence, therefore we acquired quite limited geodetic information.

Volume Increase of Lava within the Kirishima, Shinmoe-dake Crater, Detected by TerraSAR-X/DInSAR

MIYAGI, Yosuke[1*] ; OZAWA, Taku[1] ; KOZONO, Tomofumi[2] ; SHIMADA, Masanobu[3]

[1]National Research Institute for Earth Science and Disaster Prevention, [2]Department of Geophysics, Graduate School of Science, Tohoku University, [3]Japan Aerospace Exploration Agency

Shinmoe-dake in the Kirishima volcano group is located in southwestern part of Japan. In January 2011, eruptive activities started from the Shinmoe-dake crater with a rapid accumulation of lava within the crater. The eruption phase ceased by the beginning of September, and the post-eruptive inflation also ceased by November 2011. After the 2011 eruption, monitoring by TerraSAR-X have continued and revealed a continuous shortening of satellite-ground distance even after the end of the main activity. This LOS shortening means uplifts of the lava surface. We estimated the volume increase of the lava after November 2011, using DInSAR processing of TerraSAR-X data, and concluded that the volume increase still continued in January 2014. The volume change rate has exponentially decreased with a small fluctuation as an overall trend. PSInSAR and long-term DInSAR results show LOS elongation including a subsidence in the northeast flank of the crater. It is interpreted that the subsidence is caused by deflation of a shallow deformation source located just beneath the crater. A total amount of effused lava after November 2011 is comparable to a volume decrease of the shallow source estimated from the deflation deformation. This long-term continuous lava extrusion suggests a possibility of an additional injection from the deeper source.

Crustal deformation in Izu-Oshima Island detected by PS-InSAR analysis and estimation of volcanic deformation source

HASEGAWA, Yuichi[1*] ; TABEI, Takao[2] ; OZAWA, Taku[3]

[1]Grad. School Int. Arts Sciences, Kochi Univ., [2]Fac. Science, Kochi Univ., [3]National Research Institute for Earth Science and Disaster Prevention

Mt. Mihara in Izu-Oshima Island have erupted 21 times in the last 800 years. The latest eruption occurred in 1986 inside the caldera. Though spatially and temporally dense observation network is desired to continuously monitor volcanic activities, it is not easy to construct such a network in a mountainous region. In this study, we conduct time-series analysis of ALOS/PALSAR images over Izu-Oshima Island using persistent scatter interferometric SAR (PS-InSAR) method to detect volcanic deformation.

From the analysis of 20 images collected from ascending track during the period from October 2007 to February 2011, we detect distance change of about 15 cm extension in the line-of sight (LOS) direction inside the caldera. Similarly the extension of about 14 cm is detected at the same location from the analysis of 18 images from descending track during the period from January 2007 to March 2010. Next we compare the LOS distance changes with those converted from GPS coordinate time-series at four continuous sites in the island. The RMS between them are as large as 1.3-3.2 cm, implying that SAR results are good enough to monitor volcanic deformation over the island.

Combining the LOS distance changes from the ascending and descending tracks, we derive quasi-vertical and quasi-east-west components of the displacement. The most remarkable is the vertical displacement of the caldera where the subsidence of about 16 cm is detected during 2007-2010 with small occasional uplifts. Moreover uplift of about 11 cm is recognized in the eastern coastal area of the island during the same period. Based on the quasi-vertical component of the displacement, we estimate a spherical pressure source model (Mogi, 1958) below the island. We assume two sources with different depth and estimate the optimum model using a grid search method. Horizontal position of the shallower source is fixed to coincide with the location of the caldera and its depth is varied every 0.5 km in a range of 2.0-4.5 km. Horizontal position of the deeper source is varied every 2 km and its depth is checked every 0.5 km in a range of 5.0-10 km. The optimum model shows that the shallower source is located at a depth of 3.0-4.5 km where inflation and deflation are occurring alternatively while the deeper source is located at a depth of 6.0-9.0 km where nearly constant inflation rate of about 8 million m3 per year is expected. These results can be interpreted that the deeper magma reservoir continues to expand due to magma supply from the mantle while the shallower reservoir is affected by magma supply from the deeper source and gravitational load of lava that spreads within the caldera.

Flow velocity measurements of ice streams in the southern part of Soya Coast, Antarctica, by DInSAR

SHIRAMIZU, Kaoru[1*] ; DOI, Koichiro[2] ; AOYAMA, Yuichi[2]

[1]The Graduate University for Advanced Studies, [2]National Institute of Polar Research

Differential Interferometric Synthetic Aperture Radar (DInSAR) is an effective tool to measure flow rate of ice streams on Antarctic continent. In this study, we applied the DInSAR technique to L band (wavelength 23.6cm) SAR data acquired by ALOS/PALSAR, and tried to measure flow velocity around Skallen, in the southern part of Soya Coast, East Antarctica. We used 9 scenes (Path633, Row 571-572), observed during the period from November 23, 2007 through January 13, 2010. In order to remove topographic fringes in the interferograms, we used a digital elevation model ASTER GDEM.

According to the analysis, ice flow rate of up to 3.5cm/day was obtained in the line of sight direction. Although no displacement is expected in areas of outcrops in general, we found displacements up to 37cm in the outcrops of obtained displacement maps. These displacements are considered to be apparent ones and must contain errors induced in the process of analysis. Therefore, it is possible to use apparent changes as a measure of the error contained in ice flow rate estimation.

In this presentation, we will show the results of flow rate estimation of the ice streams, and discuss the errors included in the flow rate estimation.

Flow measurements of ice sheets in Arctic region by differential SAR interferometry

DOI, Koichiro[1*] ; YAMANOKUCHI, Tsutomu[3] ; NAKAMURA, Kazuki[4] ; SHIRAMIZU, Kaoru[2]

[1]National Institute of Polar Research, [2]The Graduate University for Advanced Studies (SOKENDAI), [3]RESTEC, [4]Nihon University

Rapid ice sheet mass losses from ice sheets have been found in Greenland and the Canadian Arctic Archipelago on and after 2000 from the observations by the satellite gravity mission GRACE (Svendsen et al. 2012, Gardner et al. 2011). It is considered to be one of the causes that flow rate of ice sheet and ice stream was accelerated and ice mass outflow into the sea increased.

We aim to measure flow rates of ice sheet and ice streams in the Arctic region by applying differential Synthetic Aperture Radar (SAR) interferometry (DInSAR) with a digital elevation model ASTER GDEM to satellite SAR data. In addition, we intend to explore whether changes in the flow rate happen or not.

We obtained displacement maps along line of sight direction for 46 days of three regions in north eastern Greenland and Ellesmere Island of northern Canadian Arctic Archipelago observed by ALOS/PALSAR by applying differential SAR interferometry. We will show the obtained displacement maps in the presentation, and will also intend to discuss changes in the flow rates by applying three or four pass interferometry.

Spatial distribution and classification of rock glaciers in Kyrgyz Ala-Too Range, Central Asia

YAMAMURA, Akiko[1*] ; NARAMA, Chiyuki[1] ; TOMIYAMA, Nobuhiro[2] ; TADONO, Takeo[3]

[1]Niigata University, [2]RESTEC, [3]JAXA

In the arid and semi-arid region of Central Asia, Tien Shan Mountains is known as important water tower in Central Asia. Although the current situation of mountain glaciers and permafrost should be researched for estimate of water resources, mountain permafrost is not clarified in the Tien Shan (Marchenko et al., 2007; Sorg et al., 2012). In recent years, landslides caused by the melting of mountain permafrost in Ak-Shiyrak mountains, show that recent changes of mountain permafrost begin to influence to mountain environment including the disaster. In this study, to clarify mountain permafrost environment, we researched spatial distribution and classification of rock glaciers in Kyrgyz Ala-Too Range, Tien Shan Mountains. In addition, we applied InSAR analysis to the ALOS PALAR data obtained in 2007-2010, to research moving of rock glaciers. We extracted polygon data of rock glaciers based on aerial photo interpretation and ALOS PRISM, using ArcGIS. Rock glaciers were classified an active and inactive-fossil types by NDVI (Normalized Difference Vegetation Index) of ALOS AVNIR-2 and field observation in the summer 2013. The distributions of active rock glaciers show the lower limit of mountain permafrost is 3300m in the northern part and 3500m in the southern part of the Kyrgyz Ala-Too Range. We confirmed moving of some rock glaciers in this mountain area using InSAR analysis. In particularly, the moving of rock glaciers in the southern part of the range is remarkable. The most of these active rock glaciers developed from glacier ice. We report the results in detail in JpGU meeting.

Development of InSAR processing tools in NIED ?Part3?

OZAWA, Taku[1*]

[1]National Research Institute for Earth Science and Disaster Prevention

Synthetic aperture radar (SAR) became one of the useful tools for crustal deformation detection. Recently, InSAR processors which can be used freely in scientific research (e.g., ROI_PAC, GMTSAR, and Doris) were released, and enabled anyone to do crustal deformation detection by InSAR. Especially, algorithm of two-pass differential InSAR analysis matured, and it enabled anyone to obtain almost same results. On the other hand, advanced InSAR analysis methods, e.g., time-series analysis, have been recently used to detect precise crustal deformation. However, many issues to improve remains in such analyses. In order to research on improvements for such analysis, we are developing InSAR processor.

In this InSAR processor, general procedure is adopted. (1) Format conversion of SLC and creation of parameter files. (2) Rough co-registration of two SLCs considering parallel shift only. (3) Estimation of affine transformation coefficients. (4) SLC resampling. (5) Generation of the initial interferogram. (6) Simulation of a SAR intensity image and estimation of translation tables between geodetic and radar coordinates based on DEM. (7) Co-registration between simulated and observed SAR intensity images. (8) Correction of translation tables. (9) Simulation of the orbital and the topographic phase components. (10) Generation of differential interferogram. (11) Applying interferogram filter. (12) Geocoding.

In JPGU meeting 2013, we showed comparison between results from our processor and from GAMMA SAR processor. Although their results were roughly the same, it indicated that many improvement points remained. In 120th meeting of the Geodetic Society of Japan, we presented about improvement of coherence by the spectrum shift filter (Gatelli et al., 1994), improvement of calculation speed, and correspondence to skewed images. After that, this processor corresponded to the InSAR processing with FBS-FBD image pair of ALOS/PALSAR using SLC over-sampling and band-pass filter. We added DEM resampling function by over-sampling method and by the bi-cubic spline interpolation. Furthermore, we are attempting to improvement of the image matching now. After this correspondence, the first step of this development will be finished. In next step, we will attempt more improvements and additions of other advanced algorithms.

Creating future of solid Earth science with high performance computing (HPC): Introduction

HORI, Takane[1*] ; HINO, Ryota[2] ; HONKURA, Yoshimori[3] ; KANEDA, Yoshiyuki[1] ; ARIKAWA, Taro[4] ; ICHIMURA, Tsuyoshi[5] ; TODORIKI, Masaru[5]

[1]JAMSTEC, [2]Tohoku University, [3]Tokyo Institute of Technology, [4]Port and Airport Research Institute, [5]University of Tokyo

In Japan, high performance computing (HPC) had been driven by computer science community (HPC developer). However, recently, computational science community (HPC user) has been expected to contribute to the planning and development of the next generation HPC showing the scientific and/or social issues to be solved for the next 10-20 years using HPC. In various filed of science using HPC, scientists has started to discuss scientific and/or social issues to be solved in each field. Hence, in this session, we aim to examine such issues in solid Earth science, which HPC can contribute to solve. For social issues, we will focus on earthquake and tsunami disaster mitigation. For scientific issues, we would like to discuss construction of the next generation of solid Earth model based on the big data of seismic waves and crustal deformation obtained by high-density observation networks. We will introduce the contents of the ”white paper” of the future plans for computer science in various fields including solid Earth science.

Keywords: HPC, hazard mitigation

The K Computer and Japan Plan for Exascale

HIRAO, Kimihiko[1*]

[1]AICS RIKEN

At the end of September 2012, official operation of the Kcomputer has started. Already in many areas we see many great results. Users of K are actually very much impressed having experienced using K. The K is Japanese supercomputer jointly developed by Fujitsu and Riken and everything is made in Japan. The K computer won the top position on TOP500 in 2011 achieving a LINPACK benchmark performance of 10 petaflops - becoming the first supercomputer ever to reach this milestone. The K fell behind China and US machines on the latest TOP500. We believe that the K is still one of the most powerful and user-friendly machine in the world. K demonstrates an extraordinary level of stability. K is capable of sustained performance of 1 PF on real applications in a wide range of science. K is the strong science machine.

Computer simulation is becoming more and more important for contemporary science and engineering. Nobel Prizes 2013 in chemistry and physics show how computing is changing every field of research. Particularly simulations performed on the supercomputer will drive progress in science and technology and play an important role in solving difficult problems that we face as a society. There are very critical issues that need to be solved - global warming, alternative energy, disaster mitigation, new materials, healthcare, security, etc. The role of simulations will become increasingly larger, and the results that they provide will undoubtedly greatly affect society. The new frontiers opened up by the K computer will be presented.

The post K project will be lauced from April 2014. MEXT selected RIKEN AICS to develop a new exascale supercomputer by 2020. The post K is 100 times faster than the current K computer. Architecture is hybrid of general-purpose plus accelerator components. We will push the state of the art in power efficiency, scalability & reliability. Power consumption is limited in the range of 30-40MW.Total project cost is ca. JPY140 billion with about JPY 110 billion coming from the government’s budget (JPY 1.2 billion for 2014)

Computer simulation will dramatically increase our ability to understand the world around us. With exascale computing, we are reaching a tipping point in predictive science. Its success will have lasting impact on the planet and people all around the world and for generations into the future. With a planned deployment in 2020, the new system is expected to keep Japan at the leading edge of computing science and technology.

The application of simulation studies using HPC to disaster management: current status and future.

YOKOTA, Takashi[1*] ; TAIRA, Yutaro[1]

[1]Cabinet Office

In Central Disaster Management Council, estimations of damage by anticipated earthquakes have been conducted to plan measures for disaster management(preparedness, emergency response and recovery). Also, when a large earthquake occurs early assessments of the damage have been carried out immediately to grasp the situation of the disaster and to support decision-making for emergency response operations in central government. These estimations and assessments require high accuracy to develop more effective measures and to decide more appropriate operations.

It is indisputable that the sophistication of forecasting techniques of natural phenomena is necessary to mitigate human damage by encouraging residents to evacuate.

In this presentation, we will introduce our approaches described above, and would like to talk about what to expect from the application of simulation studies using High Performance Computing to the disaster management of earthquakes and tsunamis in particular.

Development of Integrated Earthquake Simulator on K-computer

ICHIMURA, Tsuyoshi[1*] ; HORI, Muneo[1]

[1]Earthquake Research Institute,The University of Tokyo

Earthquake simulation with high-resolution and high-accuracy could have significant contribution on making rational and effective contour measures against earthquake disaster. Such earthquake simulation must consider whole process from a fault rupture to city responses, since each process has significant effects on the resulting responses. We are now developing such earthquake simulation system on K-computer, which is called Integrated Earthquake Simulator (IES). IES combines spatial data and earthquake simulation with a high-fidelity model to simulate the whole process. The target domain of earthquake simulation is typically very large, making it difficult to prepare sufficient data to construct a high-fidelity model. Even if a high-fidelity model can be constructed, it is difficult to resolve the computational expense due to the discretization of such models. Thus, simplified analyses or analytical methods are typically used in earthquake simulation. However, the construction of high-fidelity models has become popular with recent increases in available spatial data, and a considerable volume of data from high-density observation networks is now available for checking their validity. The realization of analyses using high-fidelity models is desirable. Several examples of analyses using such models can currently be found on the K-class supercomputer, although the resolution is not yet adequate. In this presentation, we discuss the following earthquake simulations (parts of IES) on the K computer, together with problems to be solved: non-linear wave simulation with high resolution, crust deformation analysis with island-scale and the seismic response analysis of soil-structures system.

Consideration to the resiliency of protective structures against tsunami by using High Performance Computer

ARIKAWA, Taro[1*] ; OIE, Takayuki[1] ; TOMITA, Takashi[1]

[1]Port and Airport Research Institute

The Committee for Technical Investigation on Countermeasures for Earthquakes and Tsunami Based on the Lessons Learned from the ”Great East Japan Earthquake” (2011) of the Central Disaster Management Council has responded to the Great East Japan Earthquake by proposing that basically, two levels of tsunami must be hypothesized to build future tsunami countermeasures. One is a tsunami hypothesized to build comprehensive disaster prevention countermeasures centered on evacuation of residents. It is set based on a survey of tsunami deposits formed over an ultra-long period and observations of crustal movement, and it is a maximum class tsunami which, although it occurs extremely rarely, causes devastating damage when it does occur. One more is a tsunami which is hypothesized to build coastal protection facilities such as breakwaters and other structures which prevent tsunami from inundating inland regions. It is a tsunami which occurs more often than the maximum class tsunami, and although it is a low type of tsunami, it causes severe damage. At such times, technological development of structures which are capable of resiliently providing effects even under tsunami height which is the object of the design must continue for coastal protection facilities etc. to be improved. So, in this research , the protective effectiveness is considered by using STOC-CADMAS(Arikawa and Tomita, 2005).

Determination of Earth structure using waveform inversion and Spectral-Element Method

TSUBOI, Seiji[1*] ; MIYOSHI, Takayuki[1] ; OBAYASHI, Masayuki[1] ; TONO, Yoko[1]

[1]JAMSTEC

Recent progress in large scale computing by using Spectral-Element Method and the Earth Simulator has demonstrated possibilities to perform full-waveform inversion of three dimensional (3D) seismic velocity structure inside the Earth. Specifically Liu and Tromp (2006) have shown that it becomes feasible to compute finite frequency kernel for seismic velocity structure based on adjoint method. We apply their method to obtain 3D velocity structure beneath East Asia. We take one chunk from global mesh of Spectral-Element Method and compute synthetic seismograms with accuracy of about 10 second. We use GAP-P2 mantle tomography model (Obayashi et al., 2009) as an initial 3D model and try to use as many broadband seismic stations available in this region as possible to perform inversion. We then use the time windows for body waves and surface waves to compute adjoint sources and calculate adjoint kernels for seismic velocity structure. We use the earthquakes, which occurred in East Asia since 2001, with magnitude greater than 5.5 and selected 161 events for this inversion. One iteration of the waveform inversion using 256 cores of massively parallel supercomputer, such as K-computer, requires 0.1 million CPU hours. We have performed several iteration and obtained improved 3D velocity structure beneath East Asia. The result demonstrates that waveform misfits between observed and theoretical seismograms improves with the iteration proceeds and it now becomes feasible to perform waveform inversion within practical computational time. We will use much shorter period in our synthetic waveform computation and will try to obtain seismic velocity structure for basin scale model in our future study.

Acknowledgements: We used F-net seismograms of the National Research Institute for Earth Science and Disaster Prevention. This study was supported by the strategic Programs for Innovative Research ”Field 3” Advanced prediction Researches for Natural Disaster Prevention and Reduction.

In this presentation, we will discuss (a rather personal view of) the possible
directions of the advanced numerical studies of mantle dynamics in concert with the progress of high-performance computing in the next era. We will start with a brief overview of the research targets and outcrops of the numerical modelings of mantle convection to date from a viewpoint of geosciences. Then we will discuss the scientific goals which the mantle dynamics researchers are to tackle with in coming years, together with the technical issues in terms of both software and hardware developments.

Cloud Services to Release Techniques of Data Assimilation

NAGAO, Hiromichi[1*] ; HIGUCHI, Tomoyuki[2]

[1]Earthquake Research Institute, The University of Tokyo, [2]The Institute of Statistical Mathematics

Data assimilation (DA) is a fundamental technique to integrate numerical simulations and observation data in the framework of the Bayesian statistics. The purpose of DA is to provide an assimilation model that enables us to predict the future state and/or to determine parameters in the given simulation model. A sequential Bayesian filter, e.g., Kalman filter and particle filter, alternatively estimates probability density functions of one-step-ahead prediction and filtering, which respectively mean the states conditionally given the past observation data and given both past and present observation data. DA seems to be hard to implement due to complex programing of the procedure and needed numerous computation, which essentially requires High Performance Computing (HPC). Cloud service (CS) can be a solution for this through an implementation of the DA procedure on a parallel computing environment.

We have developed and released several CSs related to DA such as CloCK-TiME (Cloud Computing Kernel for Time-series Modeling Engine) and DA system for seismoacoustic waves. CloCK-TiME enables us to carry out a multivariate time-series analysis using the particle filter through the Internet. Users can, via the user interface, construct observation and system models, and specify optional parameters to control the analysis in detail. DA system for seismoacoustic waves enables us to determine hypocentric parameters through DA based on a numerical simulation related to seismoacoustic wave propagation using the normal model summation and observed infrasound data obtained at Shionomisaki and Sugadaira.

We will discuss the importance and availability of CS for DA researches through introduction of CSs we have developed.

Techniques of Big-Data Processing on the NICT Science Cloud

MURATA, Ken T.[1*] ; WATANABE, Hidenobu[1] ; UKAWA, Kentaro[2] ; MURANAGA, Kazuya[2] ; YUTAKA, Suzuki[2] ; TATEBE, Osamu[3] ; TANAKA, Masahiro[3] ; KIMURA, Eizen[4]

[1]NICT, [2]Systems Engineering Consultants Co., LTD., [3]University of Tsukuba, [4]Ehime University

This paper is to propose a cloud system for science, which has been developed at NICT (National Institute of Information and Communications Technology), Japan. The NICT science cloud is an open cloud system for scientists who are going to carry out their informatics studies for their own science.

The NICT science cloud is not for simple uses. Many functions are expected to the science cloud; such as data standardization, data collection and crawling, large and distributed data storage system, security and reliability, database and meta-database, data stewardship, long-term data preservation, data rescue and preservation, data mining, parallel processing, data publication and provision, semantic web, 3D and 4D visualization, out-reach and in-reach, and capacity buildings.

In the present study, we examine performance of parallelization of I/O on the NICT Science Cloud system. We examine an I/O performance of data file system; distributed file system (Gfarm). The Gfarm file system shows a tremendous fast I/O, as fast as 23 GB/sec using only 30 servers. We should pay attention to this I/O speed (23GB/sec is 184 Gbps) from the viewpoint of network speed. We also discuss that the distributed file system shows high scalability: Parallelization efficiency in the present examination is higher than 90% in case of parallel file system. We finally discuss high-performance data processing on the NICT Science Cloud. We have already archived several examples using our technique for both Earth and Space observation data and simulation data. The speed up of the data processing is more than 60 times for scientific big-data.

How the evolution of High Performance Computing (HPC) contributes to progress in earth sciences? We will develop a perspective in the next 10 to 20 years based on comprehensive discussion provided in the session including invited talks. Especially, we will discuss what is necessary for solving the social issues such as improvement of hazard maps, tsunami warning system, long-term forecast, etc. The aim of the concluding discussion is to integrate the opinions of attendees, both speakers and non-speakers, into a proposal for development of next generation HPC as a solution to important problems in terms of scientific break through and social relevance.

Parallel Performance of Particle Method in Many-Core System

FURUICHI, Mikito[1*] ; NISHIURA, Daisuke[1]

[1]Japan Agency for Marine-Earth Science and Technology

We present a computational performance of the smoothed particle hydrodynamics (SPH) simulation on three types of current shared-memory parallel computer devices: many integrated core (MIC: Intel Xeon Phi) processor, graphics processing units (GPU: Nvidia Geforce GTX Titan), and multi-core Central Processing Unit (CPU: Intel Xeon E5-2680 and Fujitsu SPARC64 processors). We are especially interested in the efficient shared-memory allocation methods with proper data access patterns on each chipset. We first introduce several parallel implementation techniques of SPH code for shared-memory system. Then they are examined on our target architectures to find the best algorithms for each processor unit. In addition, the computing and the power efficiency, which are increasingly important to compare multi device computer systems, are also examined for SPH calculation. In our bench mark test, GPU is found to mark the best arithmetic performance as the standalone device and the most efficient power consumption. The multi-core CPU shows the best computing efficiency. On the other hand, the computational speed by the MIC on Xeon Phi approached to that by two Xeon CPUs. This indicates that using MIC is attractive choice for the existing SPH codes parallelized by OpenMP to gain the computational acceleration by the many many-core processors.

Numerical investigation of efficient parallelization of large scale quasi-dynamic earthquake generation cycle simulation

HYODO, Mamoru[1*] ; ANDO, Kazuto[1] ; HIYOSHI, Yoshihisa[1] ; HORI, Takane[1]

[1]Japan Agency for Marine-Earth Science and Technology

Recently, Ohtani et al. (2011) applied an efficient compression method of full matrix to the problem of earthquake cycles. Since an original full matrix is approximated by a set of sub-matrices with the hierarchical structure, a compressed full matrix is called as H-matrices. By multiplying H-matrices to a column vector, they found that the required floating-point operation reduces to O(N)-O(NlogN) where N means the number of discretization of the model fault, though the original multiplication operation using the full matrix is $O(N^2)$. Owing to H-matrices, required memory and computation time are largely reduced for the problems of M8 earthquake cycles with $N=10^5$-10^6, and it enables us to execute capacity computing consisting of many earthquake scenarios using massively parallel computers like the K computer. However, for more realistic simulation with multi-scale earthquakes and their interactions, we must use 100 times larger N at least, and capability computing with massively parallel CPUs will be indispensable.

Following Ohtani et al. (2011), we have implemented MPI parallelization of earthquake cycle simulation with H-matrices. First, we applied a 1D division in the row direction to H-matrices. Then, each MPI process took charge of a divided row band region of H-matrices. Since the original H-matrices have a hierarchical structure consisting of many sub-matrices with large variation in size, it is difficult to divide all sub-matrices into MPI processes without overlapping through the 1D row division. Hence, we arrowed the overlapping sub-matrix to be calculated in both adjacent MPI processes for the simplification of parallelization. Then, through the simulation with $N=3\times10^5$, we confirmed a gradual speed-up with the increase of MPI processes up to about 100. However, further increases of MPI processes caused stagnation of speed-up, because the overlapping operation that is not reduced by the increase of MPI processes became dominant.

Accordingly, for more large-scale simulation with many MPI processes, it is necessary to reconsider the parallelization. At first, based on the current 1D division code, we limit the division number in the row direction so as not to increase the ratio of operations with respect to overlapping sub-matrices to the total operations. Then, each row region is divided into further small sub-regions in the column direction, thus we will apply the 2D division of H-matrices. In dividing a particular row region into further sub-regions, we introduce a reference size for the division, B (Block size). The column directional division of H-matrices requires data transfers between sub-matrices. Moreover, depending on the value of B, we also need data transfer inside the large sub-matrix. Though such 2D division increases the data transfers between neighboring MPI processes, the appropriate choices of B and division number in the column direction will realize the equal load balancing among MPI processes in row bands. Accordingly, parallel implementations with 2D division of H-matrices may overcome the overhead due to the increase of data communications.

As tentative results, for $N=1.3\times10^6$ problem, we implemented parallel calculations with both 1D and 2D divisions. Though the 1D parallelization cannot reduce the computational time with the increase of MPI processes, 2D parallelization successfully achieves speed-up with the increase of the number of parallelization. For the same number of MPI processes (1024 processes), the 2D implementation is more than two times faster than that of 1D.

In the presentation, we will show the more detail of our parallelization algorithm and its dependencies on the values of N, B, and division numbers.

Acknowledgement: Part of the results is obtained by using the K computer at the RIKEN Advanced Institute for Computational Science (Proposal number hp120278). We thank the Fujitsu tuning team for helping us to develop the parallelization of simulation codes.

The Van, Turkey Earthquake of October 2011: Seismicity, Mechanism and its Aftershocks

KALAFAT, Dogan[1*]

[1]Bogazici University Kandilli Observatory and ERI Cengelkoy, Istanbul Turkey

On 23 October 2011, a strong earthquake (Mw=7.1) occurred east of Van Lake. The earthquake destroyed damage along the Van Fault Zone. Generally, it is caused significant damage in the city of Van with Ercis town, as well as in many villages. The epicenter of the main shock was located in Tabanli Village between Van city and Ercis town. Shortly afterwards the November 9, 2011 earthquake (Mw=5.6) occurred southeastern part of Van Lake, Edremit town area. The main shock and second shocks caused significant damage and deaths of 644 people.

After the main shock 11 important earthquakes ($5.0 \leq M \leq 6.0$) were occurred in the region which has hypo-central distances of 8-38 km. from the main shock location. The main shock triggered mass movement, spreading, and local liquefaction. The important earthquakes and the aftershocks distribution showed that the E-W and NE-SW oriented fault segments caused the earthquake activities. The distribution of the aftershocks supported the presence a rupture of approximately 70 ∓ 10km. Aftershocks occurred within an area of approximately 2300 km^2.

Fault mechanism solution has supported 23 October 2011Van Earthquake was a reverse fault with a northward dipping fault plane. The fault plane solutions of about 225 important earthquakes ($M \geq 4.0$) were calculated using MT inversion solution technique by this study.

In addition, the stress tensor analysis was completed using the focal mechanism solutions. The stress tensor values of the region were calculated using the azimuth and plunge pairs of P and T axes for 225 earthquakes. The maximum principal stress (P-compressional) of the main shock is aligned in an N-S (NNW/SSE) direction and the tensional axis (T-dilatation) is aligned in an E-W (ENE-WSW) direction. The results of the focal mechanism and stress analysis solutions show that earthquakes have occurred on the reverse faulting and the seismic activity has been continuing under the compressional regime in the region. The Van earthquake activity initiated and caused an increase in seismic activity of the region. This may be explained by the triggering of small faults by the Van Earthquake. The Van earthquake is a good example of compressional deformation and the activity of blind reverse faulting.

This study was supported by Bogazici University Research Projects Commission under SRP/BAP project No. 6671.

Microstructural observation of quartz and K-feldspar in quartzo-feldspathic granulite in Sri Lanka

ATHURUPANA, Bhathiya madhura bandara[1*] ; FUKUDA, Jun-ichi[1] ; MUTO, Jun[1] ; NAGAHAMA, Hiroyuki[1]

[1]Department of Earth Science, Tohoku University, Japan

Sri Lankan basement has been considered as high grade terrains which have suffered poly phase deformation and also upper amphibolite to granulite facies metamorphism during Pan-African amalgamation. In order to illuminate the rheological properties of felsic granulite in deep crustal level associated with high grade metamorphism, microstructural and petrographic observations were conducted.

A quartzofeldspathic gneiss sample (Quartz$\sim$40%, K-feldspar$\sim$55% and plagioclase $<$5%) contains highly elongated ribbon quartz which demarcate lineation, in K-feldspar matrix. The sample was collected from the hinge zone of kilometer scale large upright cuspate antiform between two large synforms named Dumbara and Huluganga in Sri Lanka.The lineation as maximum elongation direction is N35^{0}W/horizontal. Thin sections were made parallel and perpendicular to the lineation for petrographic and microstructural observations. Based on energy dispersive X-ray spectroscopic (EDS) measurement, most of K-feldspars in the matrix are sanidine [$(K_{0.59}Na_{0.41})AlSi_3O_8$]composition. Plagioclase is albite (An 0.1) composition and occurs in clusters and exsolution lamellas in K-feldspar. The grain size of sanidine is from $\sim$50 μm to 2 mm. Large sanidine porphyroclasts are partly recrystallized and show core and mantle structures. Grain boundaries of sanidine are sub polygonal to amoeboid shapes with increasing grain size, while plagioclase grains in clusters show perfect polygonal boundaries with grain size ranging from 50 to 200 μm. Around the plagioclase clusters, scapolite reaction corona exists with crosscutting elongated ribbon quartz. Sericite presents in the same region as very low temperature alteration of plagioclase and scapolite. Most importantly ribbon quartz grains are boudinaged in K-feldspar matrix. Any sign of undulatory extinction or dynamic recrystallization is absent in both boudinaged and large ribbon quartz. Measured average axial ratio of ribbon quartz grains is 21:7:1 with respect to X, Y and Z directions.

The crystallographic orientations of both quartz and sanidine were measured by electron backscattered diffraction (EBSD) method, including large ribbon quartz and boudinaged quartz and also matrix sanidine. The lattice preferred orientation (LPO) patterns of sanidine manifest (010)$<$001$>$as a dominant slip system with a minor activation of (010)$<$100$>$slip system. The quartz LPO indicates the activations of prism$<$a$>$and rhomb$<$a$>$slip systems.

According to the presence of K-feldspar as sanidine and their slip systems, we can point out that the sample has prevailed high grade conditions ($\sim$550-800^{0}C and $\sim$0.4-0.8 GPa) during deformation [e.g. Menegon et al. 2008]. Scapolitization which occurs at granulite facies could be indicative of peak metamorphism. Also, reaction coronas of scapolite crosscutting ribbon quartz can be interpreted as strong deformation prior to the peak metamorphism. Exsolution of K-feldspar indicates the post dated cooling relative to the strong deformation and the peak metamorphism.

Multiple events of metamorphism in lenses of eclogite within marbles of Maykhan Tsakhir Formation, Lake Zone, Mongolia

JAVKHLAN, Otgonkhuu[1*] ; TAKASU, Akira[1] ; BAT-ULZII, Dash[2] ; KABIR, Md fazle[1]

[1]Department of Geoscience, Shimane University, Japan, [2]School of Geology and Petroleum, Mongolian University of Science and Technology, Mongolia

The eclogite-bearing Alag Khadny metamorphic complex in the Lake Zone, SW Mongolia located in the central part of the Central Asian Orogenic Belt, consist mainly of orthogneisses which interleaving with marbles including lenses of garnet-chloritoid schists of Maykhan Tsakhir Formation. Eclogites have two modes of occurrence, i.e. lenses and boudins *eclogite-1* in orthogneisses and *eclogite-2* in marbles. Thermocalc calculations for the peak eclogite facies metamorphism for *eclogite-1* with the assemblage of Grt + Omp + Brs ± Ph ± Ep yielded 570-630 ℃ and 22-25 kbar (Javkhlan et al., 2013a). In contrast, pressure conditions of the garnet-chloritoid schists (10-11 kbar) are distinctly lower than those of the eclogite-1, whereas temperatures (560-590 ℃) are similar (Javkhlan et al., 2013b).

Eclogite-2 in marbles consists of small grains of garnet (<0.1 mm) and omphacite with minor amounts of amphibole, epidote, paragonite, plagioclase, chlorite, calcite, biotite, quartz, titanite and rutile. The matrix of *eclogite-2* shows a pseudomorpous texture, where small grains of garnet crowd cemented by titanite forming isomorphic round shape. Some of cores of garnet grain contain relics of garnet (X_{Ca}=0.32-0.42; X_{Mg}=0.06-0.08) indicating previous mineral were larger porphyroblastic garnet. In addition, small grains of omphacite forming rectangular prismatic nature surrounded by garnet grains.

Garnet grains have compositionally zoning with core (X_{Ca}=0.08-0.20; X_{Mg}=0.10-0.16), mantle (X_{Ca}=0.24-0.39; X_{Mg}=0.08-0.17), rim (X_{Ca}=0.22-0.26; X_{Mg}=0.18-0.23) and outer-rim (X_{Ca}=0.20-0.22; X_{Mg}=0.12-0.18). Few omphacites preserved their core (X_{Jd}=0.27-0.31; Fe_2O_3=1.34-2.22 wt%) whereas most of grains have compositional heterogeneity with X_{Jd} from 0.34 to 0.48 (Fe_2O_3=0.04-2.31) and locally with rims of higher Fe_2O_3 (3.79 wt%)-bearing omphacite (X_{Jd}=0.32). Omphacites partially replaced by symplecites of Pl (An=15-17), amphibole (Ed, Act, Mg-hbl) and Ep. Three types of amphibole are distinguished by their texture, amphibole (Amp1) [zoned with Act (X_{Mg}=0.79-0.81) core, Brs (X_{Mg}=0.54-0.69) mantle and rims with Ts, Mg-Trm and Prg in compositions] coexisting with Grt and Omp, poikiloblastic barroisitic amphibole (Amp2) (X_{Mg}=0.65-0.75) containing eclogitic minerals of Grt and Omp with their symplectitic assemblage and finally actinolitic amphiboles (Amp3) partially replacing Omp and Grt.

Based on the textures we distinguished two metamorphic events, i.e. eclogite facies metamorphism and poikiloblastic barroisitic amphibibole metamorphism. The peak eclogite facies metamorphism characterized by assemblages of Grt (mantle) + Omp + Amp1 (Brs) + Ep + Pg + Rt. Thermocalc calculation yielded 487 ± 46 ℃ and 19.7 ± 2.1 kbar (sigfit=1.80). Thermocalc calculation of Grt (rim) + Omp (rim) + Amp1 (Mg-Trm) + Ep + Pl yielded 666 ± 45 ℃ and 13.7 ± 1.6 kbar (sigfit = 2.11) suggesting a decompression stage after the eclogitic metamorphism. The poikiloblastic barroisitic Amp2 shows decreasing Si (7.01-6.69 pfu) and increasing NaB (0.61-0.70 pfu) from core to rim, suggesting that the Amp2 grew after the peak eclogite facies metamorphism, and probably during the second prograde metamorphic event. Approximate P-T conditions of the poikiloblastic barroisitic Amp2 are estimated as 5-7 kbar at c. 450 ℃.

$^{40}Ar/^{39}Ar$ muscovite ages for eclogites (543 ± 3.9 Ma) in marbles (probably eclogite-2) and the garnet-chloritoid schists (537 ± 2.7 Ma) were determined (Stipska et al. 2010). K-Ar ages for eclogite-1 [603 ± 15 Ma, 602 ± 15 Ma (Amp) and 612 ± 15 Ma (Ph)] within orthogneisses have been obtained (Javkhlan et al., 2014). These ages are interpreted as the exhumation ages for the eclogites (-1 and -2) and the garnet-chloritoid schists.

The peak temperature conditions of eclogite-2 considerably lower than eclogite-1 whereas the pressure conditions are similar. The peak P-T conditions garnet-chloritoid schists are correlated with the poikiloblastic Amp2 metamorphism of the eclogite-2.

Multiple exhumation episodes recorded in orogenic garnet peridotites from the Bohemian Massif (Czech Republic)

NAEMURA, Kosuke[1*] ; SVOJTKA, Martin[2] ; ACKERMAN, Lukas[2] ; SHIMIZU, Ichiko[1] ; HIRAJIMA, Takao[3]

[1]Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, [2]Geologicky ustav Akademie, Czech Republic, [3]Department of Geology & Mineralogy, Faculty of Science, Kyoto University

Presence of garnet peridotites in *HP/UHP* metamorphic terranes is taken as evidence for interaction between crust and mantle during orogeny. In order to constrain the timing of interaction, *P-T* paths for both peridotites and crustal rocks have been constrained, which demonstrated that there are significant gaps between peak pressure of peridotites and host continental crust. In this contribution, we will show an evidence for multiple exhumations recorded by clinopyroxene (*Cpx*) megacryst discovered in the garnet peridotite from the Bohemian Massif, and will constrain the timing of crust-mantle interaction in the light of the new data.

The Gföhl Unit experienced the highest metamorphic grade in the Moldanubian zone of the Bohemian Massif, and it mainly consists of quartz-feldspathic garnet-kyanite granulite with peak condition at 2.2-2.3 GPa and 1000 ℃ (Vrana et al., 2013, *J. Geosci.* **58**, 347-378), although Kotková et al. (2011, *Geology* **39**, 667-670) recently found diamond and coesite from the Saxony-type granulite. Gföhl granulite occurs as tens km-sized isolated blocks and contains garnet peridotites whose peak conditions were estimated as 2-6 GPa and 850-1350 ℃ (Medaris et al., 2005, *Lithos* **82**, 1-23). We studied *P-T* path for the garnet peridotite at Lom pod Libínem quarry in the Prachatice granulite massif in the south Bohemia. Lom pod Libínem (*LPL*) peridotite generally displays granoblastic texture consisting of mm-sized (0.1-5.0 mm in diameter) garnet, pyroxenes, olivine, and most garnet grains are transformed to kelyphite and are replaced by phlogopite. *LPL* peridotite includes a lot of cm-size Cpx megacrysts. Among them, the largest megacryst (3×5 cm) shows a strong chemical zoning consisting of three zones (Fig. 1), namely, core, mantle and rim: (1) the " pale-green core " is poor in Ca-Tschermak (CaTs.˜6 mol.%) and rich in Enstatite (En.˜9 mol.%) (components after Simakov, 2008, *Lithos* **106**, 125-136) and includes phlogopite and orthopyroxene, (2) the " mantle " is lower in CaTs. (4-5 mol.%) and En. (4 mol.%), and includes hornblende, chlorite, apatite, titanite, andradite, olivine, and celsian, and (3) the " rim ", rich in CaTs. (7-9 mol.%) and En. (9 mol.%), includes olivine, phlgopite, and hornblende, respectively. The mm-size Cpx has identical composition to the megacryst-rim, and (4) the smaller Cpx is richer in CaTs. (12 mol.%) and poorer in En. (7 mol.%). Four mineral stages can be identified: **Stage 1** is defined by megacryst-core coexisting with phlogopite, orthopyroxene. Assuming the co-existence with garnet, the equilibrium condition was estimated at ˜4 GPa and 1000 ℃ by use of the single Cpx geothermobarometer (Nimis & Taylor, 2000, *Contrib. Mineral. Petrol.* **139**, 541-554), **Stage 2** is defined by the " mantle " coexisting with hornblende, chlorite, orthopyroxene, and andradite, which were equilibrated at ˜700 ℃, $P<2.5$ GPa. **Stage 3** is defined by the core of mm-size pyroxenes, garnet and olivine that were equilibrated at ˜3.0 GPa and 1000 ℃ in the garnet lherzolite facies. **Stage 4** is defined by the matrix spinel lherzolite assemblage equilibrated at T˜800 ℃ at 1-2 GPa.

We envisaged the following juxtaposition mechanism: *LPL* peridotite originally came from the upper mantle (4 GPa) that exhumed to the depth of <2.5 GPa and was partially transformed to chlroite peridotite. Assuming that *LPL* peridotite was entrained in the crust at Stage 2, peridotite and host continental crust could have shared the Variscan *UHP* metamorphism at 3 GPa (Stage 3), followed by final exhumation. Although the peak *P-T* condition of Stage 3 is still higher than that of country granulite (<2.3 GPa), this could reflect different degree of retrogression during the final exhumation. Our study suggests some orogenic peridotites were exotically derived from the *UHP* mantle (>4 GPa), where continental crust have not subducted more than 3 GPa. This will give an another solution to the observed pressure gaps between orogenic peridotites and host continental crust.

Modelling of the Phase Relations in High- and Ultrahigh-pressure Metabasic Rocks

WEI, Chunjing[1*]

[1]School of Earth and Space Sciences, Peking University

Pseudosections calculated with THERMOCALC predict that for glaucophane- lawsonite eclogite facies conditions (500-600 ℃ and 18-28 kbar), MORB compositions in the NCKMnFMASHO system will contain glaucophane, garnet, omphacite, lawsonite, phengite and quartz, with chlorite at lower temperature and talc at higher temperature. In these assemblages, the pyrope contents (Xpy) in garnet is mostly controlled by variations in temperature, grossular content (Xgr) is strongly controlled by pressure, and the silica content (Si-) in phengite increases linearly with pressure. As the P-T conditions for these given isopleths are only subtly affected by common variations in bulk-rock compositions, the P-T pseudosections potentially present a robust geothermobarometric method for natural glaucophane-bearing eclogites. The maximum Xpy content may define the temperature peak (Tmax) and the minimum Xgr content constrains the pressure peak (Pmax) conditions. An isothermal decompression of these lawsonite-bearing assemblages would result in epidote- bearing assemblages through dehydration reactions such as lawsonite + omphacite = glaucophane + epidote + H2O, releasing a large amount of bound fluid. Thus, most natural HP epidote eclogites may have experienced a metamorphic stage of lawsonite stability.

Under low-T UHP conditions (>28 kb, 550-650 ℃), basic rocks are predicted to contain garnet, omphacite, lawsonite, phengite, coesite and talc. In this assemblage, the Xpy contents steadily increase as temperature rises and the Si-in phengite increases linearly with pressure. However, the Xgr content is very sensitive as pressure changes, showing slowly decrease as pressure rises. The peak P-T conditions for low-T UHP eclogites can be determined using the isopleths of maximum Xpy and Si-in phengite in P-T pseudosections. An isothermal decompression of these low-T UHP eclogites at temperature i.e. 600 ℃ would result in disappearance of lawsonite and talc in the peak stage, but appearance of glaucophane, epidote and kyanite, forming the mineral assemblages involving garnet + omphacite + glaucophane + epidote ? kyanite + quartz/coesite + phengite commonly observed. Moreover, garnet in the low-T UHP eclogites is characteristic of growth zoning with its rims containing lower Xgr and higher Xpy contents.

Under Medium-T UHP conditions (>28 kb and >650 ℃), basic rocks are predicted commonly to contain garnet + omphacite + lawsonite + phengite + coesite. In this assemblage, the Xpy in garnet mostly depends on bulk compositions, whereas the Xgr in garnet and the Si-contents in phengite regularly increase, respectively, as temperature and as pressure rise, and thus, can provide robust thermobarometric constraints. Decompression of the eclogites with lawsonite in the peak stage is inferred to be dominated by lawsonite dehydration, resulting in increase in the mode of anhydrous minerals, or further eclogitization, and formation of epidote porphyroblasts and kyanite-bearing quartz veins in eclogite. As lawsonite dehydration can facilitate evolution of assemblages under fluid-present conditions, the UHP eclogites with lawsonite are hard to memorize their real peak P-T conditions.

DEHYDRATED FLUID AND SEISMIC DEFORMATION IN DEEP SUBDUCTION ZONE ?constraints from lawsonite eclogite and olivine-opx sp

OKAMOTO, Kazuaki[1*]

[1]Saitama University, [2]Joint Graduate school, Tokyo Gakugei University

Introduction: It has been considered that there is a correlation between the double seismic zone and metamorphic dehydration reaction in deep slab. The location of the upper limits of the upper seismic plane correspond to metamorphic facies boundary where H2O contents change in subducting crust; nu-merous earthquakes from 60 to 110 km depths in the lawsonite-blueschist facies, many earthquakes in the lower crust of the slab from 110 to 150 km depths in the lawsonite-amphibole eclogite facies and few earthquakes in the lawsonite eclogite facies. It was considered that the dry eclogite is distributed in the area where there is few earthquake [1] . However, ultrahigh pressure experiments and thermodynamic calculation are both demonstrating that the lawsonite eclogite is stable [2] in the area. In order to unravel relation between dehydration and seismic defor-mation, we have investigated dehydration process of natural metamorphic rocks recording very cold geo-thermal history in the crust and lithosphere in the slab.

Lawsonite eclogite (Alpine Corsica): Alpine Corsica is the best representative field area exhibit-ing lawsonite eclogite and blueschist as a coherent high pressure, low temperature metamorphic belt. Ophiolite sequence (oceanic plate structure) is also well-preserved, and the pillow structure is clearly recognized in the lawsonite eclogite. Recent petro-logical researches have revealed that both blueschist (rims of the pillow) and lawsonite eclogite (core of the pillow) are stable in the same pressure and tem-perature condition [3] because chemical variation including water content creates both law-sonite-amphibole eclogite and lawsonite eclogite in different portion of suducted crust. We carefully observed microtexture of the lawsonite eclogite and blueschist and have found that omphacite vein and lawsonite vein in mylonitized blueschist matrix.

Olivine-opx spinifex in serpentinite (Cerro del Almirez, Nevado complex): Metamorphic olivine after antigorite has been de-scribed in Italian Alps and also from the Mt. Shiraga, Japan. However, the olivine was formed with talc and fluid by antigorite breakdown reaction in pressures lower than 1.5 GPa. Spinifex olivine with opx in the Cerro del Almirez, is the product at pres-sures (P >1.5 GPa) relevant to the lower seismic plane beneath Northeast Japan. In Cerro del Almirez, olivine-opx rocks underlie an-tigorite schist by a contact[4]. In the olivine-opx rocks, the blade-like, elongated olivine and opx were grown, representing spinifex texture. It clearly indi-cates the presence of large amount of water facilitate crystallization of elongated olivine with opx.

Discussion and conclusion: In the lawsonite eclo-gite in the Alpine Corsica, blueschist and lawsonite coexist together reflect-ing chemical difference in pillowed structure or lithology. Omphacite and law-sonite veins are observed along the shear band in mylonitized blueschist. It suggests that decomposi-tion of glaucophene causesd hydro-fracturing and precipitate omphacite and lawsonite vein. Garnet was grown statically close to the vein.

Olivine-opx spinifex in the serpentinite, Cerro del Almirez, were probably recrystallized in the presen-ce of large amount of water. The estimated dehydra-tion reaction has a negative P-T slope at pressures higher than 1.5 GPa. The reaction is volume reduc-ing reaction and the olivine-opx spinifex texture was formed under volume reducing reaction.

Ultrahigh-pressure eclogites: paleo-environment indicators

UR REHMAN, Hafiz[1*]

[1]Department of Earth and Environmental Sciences, Graduate School of Science and Engineering, Kagoshim

Ultrahigh-pressure (UHP) eclogites generally form by the metamorphism of mafic lithologies (gabbros or basalts) at depths greater than 90 km (minimum stability field of coesite) indicating P-T conditions of >2.7 GPa and 600-800 ∘C. At such conditions most minerals reequilibrate their chemical elements (e.g. major and trace and even isotopes) and new minerals crystallize or grow at the expense of other minerals formed during the magmatic crystallization. Some chemical elements, considered as relatively less mobile or immobile (e.g. Sm, Nd, Lu, Hf), are widely used for the extraction of past records the rocks have evolved through. Besides those elements, oxygen, the major component of silicates and oxides, impart important information related to protolith formation of rocks and their metamorphism. In general, most basaltic rocks show a narrow range of δ^{18}O (ca. +5.7 $\pm$ 0.3 ‰ relative VSMOW) and values for altered basalts vary from 0 to +12 ‰.

In this paper, I discuss the origin of low or negative δ^{18}O values; recently we found in the Himalayan UHP eclogites of Kaghan Valley and explain the mechanism how these low values were acquired. These eclogites are formed during Eocene by the India-Asia collision and their protoliths were the Panjal Trap basalts which were emplaced in Permian when Indian Plate was part of Gondwana. The δ^{18}O values are as low as — 2.25 ‰ in the fresh parts of eclogites and increase towards more positive in the retrogressed or amphibolitized parts. The unusually low δ^{18}O values in eclogites are interpreted to have resulted from the hydrothermal alteration of the protoliths by meteoric water interaction when Greater India was still at southern high latitudes (>65 degrees S) during the Permian indicating glacial paleo-environment. These low δ^{18}O values were frozen-in in the protolith rocks and did not change during subduction-related UHP metamorphism. However retrogressive process, due to infiltration of ^{18}O-rich fluids during exhumation, shifted these values towards more positive range.

Role of the second continent

KAWAI, Kenji[1*] ; ICHIKAWA, Hiroki[2] ; YAMAMOTO, Shinji[4] ; TSUCHIYA, Taku[2] ; MARUYAMA, Shigenori[3]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [2]Geodynamics Research Center, Ehime University, [3]Earth-Life Science Institute, Tokyo Institute of Technology, [4]Department of Earth and Astronomy, Graduate School of Arts and Sciences, The University of Tokyo

It has been thought that granitic crust, having been formed on the surface, must have survived through the Earth's evolution because of its buoyancy. Recent geological studies have suggested that a significant amount of crustal material has been lost from the surface due to delamination, continental collision, and subduction at oceanic?continental convergent margins (von Huene and Scholl 1991; Yamamoto et al. 2009; Ichikawa et al. 2013a). If so, then the subducted crustal materials are expected to be trapped in the mid-mantle due to the density difference from peridotitic materials induced by the phase transition from coesite to stishovite (Kawai et al. 2013). In order to study the effect of the subducted granitic materials floating around the mantle transition zone, we conducted two-dimensional numerical experiments of mantle convection incorporating a continental drift with a heat source placed around the bottom of the mantle transition zone. We found that the addition of heat source in the mantle transition zone considerably enhances the onset of upwelling plumes in the upper mantle, which further reduces the time scale of continental drift. The heat source also causes massive mechanical mixing, especially in the upper mantle. The results suggest that the heat source floating around the mantle transition zone can be a possible candidate for inducing the supercontinent cycle (Ichikawa et al. 2013b).

Where had the primordial continent gone?

MARUYAMA, Shigenori[1*] ; KAWAI, Kenji[2] ; TSUCHIYA, Taku[3]

[1]ELSI Tokyo Institute of Technology, [2]Tokyo Institute of Technology, [3]Ehime University

There are no Hadean rocks on the Earth ' s surface. This indicates (1) there was no continents on the primordial Earth, or (2) continents were present in the Hadean but lost afterwards. It is well-known that Moon surface was covered by anorthositic continental crust with KREEP basalts with ca. 50-60km thickness. Those rocks are the fractionated final residues of magma ocean after the giant impact at 4.56Ga.

The Earth must have been completely melted if giant impact was correct, but due to 6 times larger gravity, the thickness of anorthositic continents must be 21 km. Moreover, during the consolidation of magma ocean, bulk of anorthositic blobs could be transformed into (1) zoisite+kyanite+quartz, (2) grossular+kyanite+quartz, (3) grossular +kyanite+coesite, (4) grossular +kyanite+stishovite, in 300km depth.

Absence of TTG rocks in the Hadean and nearly absent in early Archean less than 5% among the surface of present continents must be caused by extensive tectonic erosion by subducting slabs which are present even today at trench. Therefore, it is wrong to believe that low-density granite must have accumulated on the surface once formed on the surface of the Earth.

Density calculation of anorthosite, MORB, harzburgite, and pyrolite using first principles calculation showed that anorthosite was heavier if it convected at depth in mantle transition zone. If it turns into lower mantle, it becomes to be heaviest among those as mentioned above, suggesting the stability field at D " layer on the bottom of mantle which is right above CMB.

However, it depends on the geothermal gradient on which phase change of Al2O3 occurs to determine whether or not the heaviest among all rocks at CMB. Depending on cooling the CMB, meta-anorthosite could have been buoyant particularly after the mantle overturn at 2.7-2.6Ga.

Before the overturn, if the basal magma ocean was present in the Archean, the lost primordial continents musty have been melted into basal magma ocean where anorthosite-KREEP basalts mixed with FeO-enriched primordial basal magma ocean. The possible bulk chemistry can be estimated, though qualitatively; it must be super-enriched in anorthositic component. It can be expressed in Ca-Pv, Mg-Pv, Ferro-periclase as major components.

When, mantle overturn occurred at 2.7-2.6Ga, low-temperature materials of upper mantle must have cooled down the basal magma ocean to consolidate to crystalize Ca-Pv rock, bi-mineral Ca-Pv + Mg-Pv rock, and the tri-mineral Ca-Pv + Mg-Pv + FM periclase rock. According to the formation of these rocks, those three rocks would have been behaved differently, although depends on not only density but also mass.

Assuming the enough volume of Ca-Pv rocks, those rocks may be floating in mid-depth of lower mantle.

Subduction origin for UHP chromitite from the Nishisongi metamorphic rocks, Western Kyushu, Japan

NISHIYAMA, Tadao[1*] ; MORIBE, Yousuke[1] ; ISHIMARU, Satoko[1] ; ARAI, Shoji[2] ; MORI, Yasushi[3] ; SHIGENO, Miki[3]

[1]Graduate School of Science and Technology, Kumamoto University, [2]Department of Earth Sciences, Kanazawa University, [3]Kitakyushu Museum of Natural History and Human History

Ultrahigh-pressure (UHP) chromitite from the Luobsa Ophiolite in non UHP terrane has been an enigima because of its peculiar occurrence. We newly found a UHP chromitite from serpentinite in the Nishisonogi metamorphic rocks (NMR), a member of the Nagasaki Metamorphic Rocks, in Western Kyushu, following our finding[1] of it from the Higo Metamorphic Rocks (HMR), Central Kyushu. The UHP chromitite from NMR documents well a fluid -chromite interaction, showing partial graphitization of microdiamond. Such a fluid - chromite interaction is not observed in HMR chromitite. The NMR are high P/ T (epidote-glaucophane schist subfacies) metamorphic rocks of Cretaceous in age, mainly consisting of pelitic and psammitic schists intercalating with minor basic schists[2]. The peak metamorphic condition of the crystalline schists is estimated as 1.4 GPa and 520 ^{o}C by an assemblage of garnet with inclusions of chloritoid and omphacite, glaucophane, paragonite, and phengite in a garnet galucophanite[3]. Serpentinite and serpentinite melanges occur as elongated bodies or lenses concordant with schistosity trending N-S of the country schists[1]. Jadeitite and omphacitite occur as tectonic blocks in the serpentinite melange, showing the peak condition of 1.5 GPa and 500 ^{o}C by coexistence of jadeite and quartz[4]. Microdiamond - bearing chromitite was found from serpentinite in a melange at Ooseto Town, Saikai City. Chromitite occurs as a thin layer several cm thick and meter-size long in a serpentinite with numerous magnesite (or ankerite) veins. The layer is strongly deformed to show a schlieren - like structure. The serpentinite consists of fine-grained antigorite with no relics of olivine and pyroxenes. The chromitite consists of an aggregate of rounded and fractured chromite crystals with small amounts of talc and magnesite as a matrix and veins. Microdiamond occurs as aligned crystals in narrow zones ranging from a few μm to several tens of μm in chromite. Chromite is zoned, consisting of Mg-rich core $(Mg_{0.33}Fe^{2+}{}_{0.65}Mn_{0.03})(Cr_{0.84}Al_{0.12}Fe^{3+}{}_{0.04})_2O_4$ and Fe-rich rim $(Mg_{0.06}Fe^{2+}{}_{0.89}Zn_{0.02}Mn_{0.03})(Cr_{0.85}Al_{0.12}Fe^{3+}{}_{0.04})_2O_4$. The microdiamond - bearing zones are conspicuously richer in Fe_2O_3 [$(Mg_{0.03}Fe^{2+}{}_{0.94}Mn_{0.04}Zn_{0.01})(Cr_{0.67}Ti_{0.01}Fe^{3+}{}_{0.31}0)_2O_4$], observed as a brighter zone in a BSE image, than other part of chromite in the same grain. The network -like distribution of the zones clearly indicates fluid infiltration associated with the following exchange reaction of trivalent cations between chromite and the fluid: Cr^{3+} + Al^{3+}(in chromite) = Fe^{3+}(in fluid)

Microdiamond occurs either as polyhedral or as platy crystals, 1 to several μm across. Identification of diamond was carried out with an energy dispersive X-ray spectroscopy (EDS) analysis (carbon peak) and Raman spectroscopy with a He-Ne laser. We observed a broad Raman peak at 1331 cm^{-1}, which is comparable to the peak (1332 cm^{-1}) characteristic of diamond. Graphite peak at about 1600 cm^{-1} is also observed, showing partial graphitization of microdiamond. These lines of evidence shows that the fluid infiltration may have occurred after inclusion of microdiamond.

It is quite astonishing that microdiamond is preserved in such a completely serpentinized ultramafic rock. Chromite can be a good container of microdiamond to prevent graphitization during geologically long duration of exhumation and serpentinization. Our finding suggests the subduction origin of UHP chromitite from NMR rather than mantle migration origin[5] in the case of the Luobusa Ophiolite.

Melt-Peridotite Reactions In The Upper Mantle: Geochemistry Of Peridotite And Pyroxenite From The Beni-Bousera Massif

CHETOUANI, Kamar[1*] ; AMRI, Isma[1] ; TARGUISTI, Kamal[1]

[1]departement de geologie, Faculte des sciences de Tetouan. Maroc

The Beni-Bousera massif contains ubiquitous pyroxenites of various types, organized into conspicuous layers ranging from 0.5 to 100 cm in thickness, hosted by peridotites. Integrated field features, petrographic observations, and geochemical analyses from 92 samples (whole rock major and trace elements data: 55 samples, microprobe data for minerals: 48 samples, and mineral trace elements data: 30 samples) from pyroxenites provide information to classify the rock types into four different groups typified as: (1) garnet pyroxenites, (2) spinel-garnet websterites, (3) spinel websterites, and (4) spinel chromium websterites. Type 1 rocks, occurring at the base of the massif, are considered as the most primitive type, garnet pyroxenites layers represent the vestiges of an old veined subcontinental lithosphere. They generally indicate temperatures <970∘C (based on two-pyroxene thermometry) and a low to very low Mg# (<76%). Trace element contents show enrichment in heavy and middle rare earth elements but strong depletion in light rare earth elements (LREE). Paradoxically, the host peridotites show enrichment in LREE, which give new insights into their genesis history. Based on our field observations and geochemical results, we suggest that garnet-pyroxenite layers metasomatised the host peridotite successively by the partial melting as a consequence of subsequent heating phase(s) of the lithosphere. The magmatic event that led to the diversity and zoning of mafic layers was caused by melting of the base of thinned subcontinental lithosphere by upwelling asthenosphere, followed by infiltration of asthenospheric melts. The different groups of mafic layers record several stages of this event.

Petrology and geochemistry of the ultramafic metamorphic rocks from the Masora domain, east-central Madagascar

ICHIKI, Takashi[1*] ; ISHIKAWA, Masahiro[1] ; KIMURA, Jun-ichi[2] ; SENDA, Ryoko[2]

[1]Yokohama National University, [2]JAMSTEC IFREE

Madagascar is located within the interior of the Neoproterozoic East African Orogen (Jacobs and Thomas, 2004) that marks the join between East and West Gondwana. In the east Madagascar, the Paleo-Mesoarchean Antongil-Masora domains are exposed (Collins, 2006; Tucker et al., 2011). In this study we report the petrological and whole rock and REE geochemical characteristics of the ultramafic metamorphic rocks exposed within the Masora domain and we discuss their origin and tectonic settings. The Masora domain is mainly composed of the Paleo-Mesoarchean felsic metamorphic rocks with subordinate amounts of metasedimentary rocks (e.g. Randriamananjara, 2008; Tucker et al., 2011). This domain was intruded by Neoproterozoic granitoids and mafic-ultramafic rocks (e.g. Smith et al., 2008).

The ultramafic metamorphic rocks are exposed in the north and south Masora domain. Three types of ultramafic metamorphic rocks are identified in the north: peridotite, pyroxenite and hornblendite. The peridotite is mainly composed of olivine and anthophyllite with subordinate amounts of serpentine, magnesite and magnetite. The pyroxenite is mainly composed of clinopyroxene and hornblende with subordinate amount of magnesite and magnetite. The hornblendite is mainly composed of hornblende with subordinate amount of actinolite and magnetite. Some of the hornblendite has spinel. An ultramafic metamorphic rock body occurs as a lens within metasedimentary rock in the south. This metasedimentary rock is kyanite+biotite+muscovite schist. The mineral assemblage of the ultramafic lens differs between core and rim. It is mainly composed of olivine, tremolite, actinolite and chlorite with subordinate amounts of serpentine, magnetite and altered minerals in the core. The rim is mainly composed of tremolite, actinolite and chlorite with subordinate amount of magnetite and ilmenite.

The ultramafic metamorphic rocks except for the hornblendites have SiO_2 = 42.7-51.7 wt.%, Al_2O_3 = 1.5-7.5 wt.%, MgO = 19.8-35.4 wt.%, and CaO = 3.5-16.5 wt.%. They have high Mg# (molar ratio of $Mg^{2+}/(Mg^{2+} + Fe^{2+})$) of 0.76-0.83. On the basis of bulk rock CIPW normative Ol-Cpx-Opx composition, the ultramafic metamorphic rocks except for the hornblendites plot in the field of the lherzolite, olivine websterite and websterite (Streckeisen, 1976). Compared with the geochemical characteristics of abyssal peridotites (Niu, 2004), the ultramafic metamorphic rocks shows lower MgO, higher TiO_2 and CaO than those in the abyssal peridotites. On the MgO-Ni diagram (Pfeifer, 1990 in Katzir et al., 1999) one of the samples plot in the typical abyssal lherzolite field whereas the others plot in higher-Ni (orogenic) field. Chondrite normalized REE patterns of the ultramafic metamorphic rocks show flat HREE with variable LREE patterns. One of the samples shows enriched LREE pattern and the others show depleted LREE patterns. The depleted LREE samples have flat HREE with about twice amount of chondritic HREE abundances. This is typical characteristic of an orogenic lherzolite such as Ronda massif in the southern Spain and Lanzo lherzolites in the Italian Alps (Bodinier and Godard, 2003). Enriched LREE pattern is also a typical characteristic of pyroxenites occurring in orogenic peridotites (Bodinier and Godard, 2003). On the basis of petrological and geochemical characteristics, their protoliths are orogenic lherzolite, websterite and pyroxenite.

Zircon Nano-SIMS U-Pb dating from the country gneiss beside Horoman peridotite, Hokkaido, Japan

SUZUKI, Ryosuke[1] ; OKAMOTO, Kazuaki[1*]

[1]Saitama university, Japan

Hidaka Metamorphic Belt, Hokkaido, Japan includes the youngest granulites and the Horoman peridotite complex in the highest grade zone. Age of the Hidaka gneiss and amphibolite have been determined by various methods (e.g. K-Ar, U-Pb, Rb-Sr and etc). However, the age of Horoman peridotite complex has not been determined yet. Only Yoshikawa et al (1993) reported the cooling age of the complex as 23 Ma based on whole rock Rb-Sr isochron method. This study performed U-Pb dating of zircons from the paragneiss surrounding the Horoman peridotite complex in order to determine the intrusive age of the Horoman peridotite complex from the upper mantle into the lower crustal conditions. The zircons have detrital cores and thin rims (<20 microns). Therefore we used Nano-SIMS because it is possible to focus the secondary beam diameters down to submicrons for the analysis. As a result of this measurement, rim ages of the zircons show that 238U-206Pb age are 7-11Ma (n=7) and detrital core ages show 25.6 Ma, 34-35 Ma, 78 Ma and 150 Ma (n=8). The rim ages are the youngest in Hidaka metamorphic rocks and there is a discrepancy with zircon rim ages (19Ma) from the granulite (Kemp et al. 2007; Usuki et al. 2006). The present rim ages (7-11 Ma) fit well with the tectonic scenario of the collision process of Hokkaido Island proposed by Yamamoto et al. (2010). It is considered that the Horoman peridotite complex was juxtaposed onto the Hidaka metamorphic belt at 7-11Ma by the subducting Pacific plate after the collision between North American and Eurasian plates.

3 types of Ca-Amp found from Nove Dvory UHP eclogites and their origin, Moldanubian Zone of the Bohemian Massif

YASUMOTO, Atsushi[1*] ; HIRAJIMA, Takao[1]

[1]Department of Geology and Mineralogy, Graduate School of Science, Kyoto University

The upper-stability limit of Ca/Na amphibole (Amp) in meta-mafic rocks are considered to be around 2-3 GPa in pressures (Schmidt & Poli, 1998). Thus, most Ca-Amp in (ultra)-high pressure metamorphic rocks have been considered as retrograde products. The peak metamorphic conditions of Nové Dvory eclogites are estimated to be 4.5-4.9 GPa and 1050-1150^{o}C. However, some Ca-Amp inclusions in Grt are likely to be interpreted as prograde relicts survived the ultra-high pressure metamorphism. This paper reports the mode of occurrence and the chemical compositions of Ca-Amp and the coexisting minerals in Nové Dvory eclogite, and discusses when Ca-Amp crystalized. Investigated two eclogite samples, ND0107 and ND120, collected from the same outcrop, are composed mainly of garnet (Grt) and Omphacite (Omp) with minor amounts of apatite (Apt) and rutile (Rt) at the UHP stage, and suffered hydration reactions, represented by Ca-Amp and plagioclase (Pl) formation, with various degree during the exhumation stage.

Ca-Amp in studied eclogite can be classified into 3 types based on their modes of occurrence; Type 1 Amp occurs in sporadic euhedral shaped polyphase mineral aggregates (PMAs) in Grt along with Omp, Rt, and Apt. Type 1 Amp is identified only from ND0107, and is classified as pargasite (Prg) or kaersutite (Krs). Omp inclusions associated with Type 1 Amp are homogeneous and have high X_{Jd} of 40-45, suggesting that the associated Omp did not suffer retrogressive reactions. On ACF diagram, Type 1 Amp is plotted between the associated Omp and host Grt. It suggests that Type 1 Amp could be a relict of the following reaction, Amp=Omp+Grt+W, during the subduction stage. Type 2 Amp is identified as a member of PMAs in Grt along with spinel (Spl) and diopside (Di). Those PMAs with Type 2 Amp show unidiomorphic shapes and straight alignment in Grt. They are classified as Prg or magnesio-hastingsite (Mg-Hs). Type 3 Amp is a member of the symplectite along with Omp. Di, Spl, and Pl developed at Grt rim. These facts suggest that Type 2/3 Amp were formed during the exhumation stage reacted with infiltrated fluids to the host eclogite.

The different stage origins of Type1/2 Amp mentioned above is supported by F and Cl contents in them. Type 1 Prg contains 0.21-0.30 wt% of F, but is almost free from Cl (<0.01wt%). Type 2 Prg contains 0.43-1.17wt% of Cl. Type 2 Prg in ND0107 with Type 1 Amp contains 0.05-0.29wt% of F. On the other hand, Type 2 Prg in ND120, which is free from Type 1 Amp, is scarce in F (<0.05wt%). Type 3 Amp is free from Cl.

It is generally considered that Ca-Amp enriched in $(Na+K)^{A}$, ^{IV}Al, and $^{VI}Fe^{2+}$ can incorporate more Cl (Makino, 2000). However, Type 1/2 Amp have a similar major element compositions such as $(Na+K)^{A}$=0.79-0.95 pfu (for O+OH+F+Cl=24 basis), ^{IV}Al=2.01-2.45 pfu, and $^{VI}Fe^{2+}$=0.56-0.97 pfu, in spite of a scarce but significant difference in Cl content among them. Cl-free Type 3 Amp contains similar amount of $(Na+K)^{A}$ (0.75-0.96 pfu) and ^{IV}Al (1.95-2.38 pfu), but less in $^{VI}Fe^{2+}$ content (<0.47pfu) compared with those of Type 1/2 Amp.

As a present stage conclusion, Type 1 Amp crystalized under F-bearing and Cl-poor environment during the prograde stage, and Type2/3 Amp crystalized during the retrograde stage along with supply of Cl from outside of the rock. F identified in Type 2 Amp in ND0107 with F-bearing Type 1 Amp could be supplied from the Type 1 Amp through the retrogressive reactions.

carbon and helium in faulted-seismogenic areas

SANO, Yuji[1*]

[1]Atmosphere and Ocean Research Institute, University of Tokyo

Carbon and helium have been discharging for a long time from the Earth's mantle to the atmosphere through volcanic and hydrothermal activity. In addition they are derived from faulted-seismogenic areas. It is obvious that volcanic fluxes are originated in magma source even though they may be partly contaminated by crustal material. In contrast, it is difficult to estimate how deep they are derived in non-volcanic and tectonically active regions. Irwin & Barnes [1] reported that CO_2-rich springs occur worldwide along major zones of seismicity. They further suggested that much of the CO_2 is derived from the mantle and that other important sources are the metamorphism of marine carbonate-bearing sedimentary rocks and the degradation of organic material. Carbon isotopes may provide information of the origin. When the delta13C value of spring gas in faulted-seismogenic area shows -6permil, it is explained by either mantle carbon or a mixing of marine carbonate (0permil) and sedimentary organic matter (-30permil). Thus it is difficult to estimate the origin of carbon. If the data are combined with helium isotopes, however, we can deconvolve the mantle contribution quantitatively [2]. There are several evidences of mantle carbon and helium degassing from active fault. Kennedy et al. [3] suggested the mantle helium flux in the San Andreas fault system located at boundary between the Pacific and North American plate. The bottom may extend the upper mantle. Significant CO_2 discharges were observed at the same time. A part of CO_2, up to 3.3% may be derived from the mantle [4]. Similar discharges have been observed in the North and East Anatolian fault zones [5,6]. These are examples of steady-state degassing from active fault. Non steady-state, catastrophic degassing of carbon and helium were reported in the 1995 Kobe earthquake, even though they are originated in shallow crust [7,8]. On the other hand, increase of helium isotopes in bottom seawater in the trench region after the 2011 Tohoku-oki earthquake suggested substantial input of mantle helium [9]. There may be a fluid flow induced by the earthquake, which would carry helium and methane from the mantle wedge to the trench through the entire plate boundary.

Volatiles in kimberlites:an indicator of possible deep mantle origin

KANEOKA, Ichiro[1*]

[1]Earthquake Research Institute, University of Tokyo

Kimberlites are well known to bear diamonds and their magmas are regarded to have been derived from a depth of at least more than 150km. They are found only in old continental areas and the exposed areas at the surface are quite limited to a diameter of less than 2km in most cases. Although their distributions are quite sparse, they have quite unique characteristics in their chemical and isotope compositions.

In spite of ultrabasic properties, they bear abundant volatiles such as H2O, CO2, halogens, sulfur and they also contain relatively abundant LIL elements. On the other hand, they show more abundant concentrations of Os and Ir compared to those of other kinds of lavas such as MORBs (mid-oceanic ridge basalts) and OIBs (oceanic island basalts). Their magmas are generally regarded to have been produced in relatively less oxidized environments compared to MORBs, OIBs and IABs (island arc basalts). Hence, it is a quite significant issue to clarify the origin of volatiles in kimberlite magmas, which might be related to the chemical circumstances of deep mantle.

Based on Sr-Nd isotope systematics, kimberlites are classified in two groups (Smith, 1983). In the 87Sr/86Sr-143Nd/144Nd diagram, Group I kimberlites are relatively concentrated in an area which is close to the Bulk Earth value. In contrast, Group II kimberlites are located in an area of typical enriched character and widely scattered. Most kimberlies are regarded to belong to Group I. Since Group II kimberlite magmas show the effect of recycled materials with an enriched character, volatiles in Group II kimberlites might have been also affected from them.

On the other hand, distribution of data of Group I kimberlites on the Sr-Nd isotope diagram implies that the magma source of Group I kimberlites is less fractionated from the assumed Bulk Earth material than those of MORBs. Further, Ne isotopes in kimberlites from Russia indicates that its magma source is similar to those of OIBs isotopically and different from those of MORBs (Sumino et al. 2006). Noble gas signatures of OIBs indicate the occurrence primordial components in the OIB source (e.g.Kaneoka, 2008). The magma source of MORBs has been generally assigned to be located in the upper mantle, while those of OIBs are located at a deeper part than those of MORBs. These signatures suggest that volatiles in Group I kimberlites would probably reflect those of the deep mantle. In effect, some diamonds are regarded to have been derived from the upper part of the lower mantle. Thus, at least Group I kimberlites might contain volatiles including carbon of the lower mantle origin which has not always been recycled.

Further, kimberlite magmas are conjectured to have been erupted directly from a magma reservoir located below the thick continental lithosphere within a few hours so that captured diamonds might not be decomposed during the rise of a kimberlite magma. Hence, it is inferred that chemical contamination for a kimberlite magma might be less compred to that for a OIB magma which would take much longer time to be transported to the surface from a magam reservoir. If so, Group I kimberlites might keep more primary information on the chemical state of the lower mantle compared to OIBs.

Carbon isotope systematics during carbonated silicate melting under upper mantle conditions

MADHUSOODHAN, Satish-kumar[1*] ; MIZUTANI, Shogo[2] ; YOSHINO, Takashi[3]

[1]Niigata University, [2]Shizuoka University, [3]Okayama University

Carbon isotope fractionation between graphite and carbonated silicate melt was determined at 5 GPa and in the temperature range between 1400 and 1900 ^{o}C. High pressure experiments were carried out in the carbon-saturated model harzbergite system (Enstatite-Magnesite-Olivine-Graphite), where carbonated silicate melt and graphite were the two stable carbon-bearing phases in the run products. Carbonated silicate melting resulted in an isotopic fractionation between graphite and carbon in the silicate melt, where the carbon in the melt is ^{13}C enriched than co-existing graphite (Mizutani et al., 2014). ^{13}C enrichment in carbonate melt were further confirmed in experiments where redox melting between olivine and graphite produced carbonate melt as well as carbonate reduction experiments to form graphite.

According to the results of carbon isotope fractionation obtained in this study between graphite and carbonated silicate melt, heavier carbon will be selectively partitioned to the melt and graphite will be lighter than the melt in the order of 1 to 2 permil. If locally oxidative or reductive domains are present or melt extraction and a Rayleigh fractionation process dominate in the upper mantle, then carbonate silicate melt-graphite carbon isotope partitioning at upper mantle conditions will have larger effect on carbon isotopic composition. It is possible that carbonate melt will progressively enrich in carbon isotopes, which corresponds to the primary igneous carbonatite values (-5 to -8 permil) and even rare carbonatites having the more enriched ^{13}C (-2 to -5 permil) may be explainable in term of the existence of more reductive environment. Conversely, the graphite coexisting with such melts will have delta13C values corresponding to main mantle carbon reservoir. Recent experiments have shown that carbonate melts can be a medium for the efficient crystallization of diamonds in Earths mantle. Therefore, redox reaction at lower upper mantle is likely to yield the range of carbon isotope variation of mantle derived diamond. Moreover, carbonated mantle melting according to redox melting at upwelling mantle can be an alternative explanation for the formation of ^{12}C enriched diamonds in the deep mantle

3He/4He distributions near the Tancheng-Lujiang faults zones, at Liaoning, NE China

ZHENG, Guodong[1*] ; XU, Sheng[1] ; NAKAI, Shun'ichi[2] ; WAKITA, Hiroshi[3] ; WANG, Xianbin[1]

[1]Institute of Geology and Geophysics, Chinese Academy of Sciences, [2]Earthquake Research Institute, The University of Tokyo, [3]Faculty of Science, The University of Tokyo

Chemical and isotopic compositions have been measured for natural gases near the NNE trending Tancheng-Lujiang Fault Zones (TLFZ) at Liaoning Province, NE China, including hydrocarbon-rich natural gases from Liaohe basin (121oE-124oE, 40.5oN-42oN) and nitrogen-rich geothermal gases from the eastern Liaoning Mountains. Observed 3He/4He ratios show two orders of magnitude variability from 0.04 RA to 3.5 RA where RA is atmospheric 3He/4He ratio 1.4x10-6. The following geochemical observations are noted: (1) at Liaohe basin and the adjacent geothermal fields, 3He/4He ratios show positive correlations with He contents; (2) in Liaohe basin, the 3He/4He ratios are largely variable (0.04-3.5 RA), generally high in the eastern depress and low in the western depress; (3) in the eastern Liaoning mountains, geothermal 3He/4He ratios are generally low (0.2-0.7 RA) but have closed relationship with distribution of seismic activity and heat flow; and (4) overall there is a spatial distribution pattern that 3He/4He ratios gradually decrease from the TLFZ eastwards and westwards. Such a 3He/4He distribution feature shows strong evidence that the TLFZ played an important role on mantle-derived helium transform from mantle upwards and groundwater circulation along the deep major faults.

Heterogenous carbon reservoir in sublithospheric mantle: variations of carbon isotopic composition in diamonds from Sao-

ZEDGENIZOV, Dmitriy[1*] ; KAGI, Hiroyuki[2] ; SHATSKY, Vladislav[3] ; RAGOZIN, Alexey[2]

[1]V.S.Sobolev Institute of Geology and Mineralogy, Novosibirsk, Russia, [2]University of Tokyo, Tokyo, Japan,, [3]A.V.Vinogradov Institute of Geochemistry, Irkutsk, Russia

The Juina kimberlite field in Brazil is a well-known source of alluvial sublithospheric diamonds as identified by their properties and mineral inclusions. Taking advantage of the rather common occurrence of superdeep mineral inclusion assemblages in diamonds from Sao-Luis river alluvial deposits (Juina, Brazil), we carried out a study of variations of C isotope in diamonds from this locality.

Diamonds from Sao-Luis are characterized by rough morphologies and have complex growth histories. Episodic growth, plastic deformation and breakages are visible in these crystals and most diamonds have experienced a final episode of resorption before exhumation. Total nitrogen content in studied diamonds reach 1200 ppm and more. Only several studied diamonds are nitrogen-free (type IIa). Some diamonds consist of domains that are also nitrogen-free but other parts may contain nitrogen. Many diamonds have very low (>10 ppm) but still detectable nitrogen impurity. Extremely high nitrogen aggregation state and overall platelet degradation detected in the majority diamonds from Sao-Luis are suggested they have stored at considerably higher temperatures that are typical for continental lithosphere.

Syngenetic inclusions in 59 diamonds from Sao-Luis were represented by phases of superdeep paragenesis as it was described previously. The dominated inclusions are majoritic garnets, ferropericlases, CaSi- and CaSiTi-perovskites, MgSi-perovskites, TAPP, SiO_2 phases, kyanites, AlSi-phases, olivines and Fe-sulfides. Rare inclusions of clinopiroxenes, KFsp (K-hollandite?), CF, NAL, grossular, native iron, magnesite, $CaCO_3$+$CaMgSi_2O_6$ (composite inclusions) have been found in separate diamonds. All majoritic garnets we found are of metabasic affinity and in some cases associated with omphacitic clinopyroxenes.

The studied diamonds from Sao-Luis display wide variations of carbon isotopic compositions (δ^{13}C) ranging from 2.7 to -25.3 ‰. The diamonds with inclusions of ferropericlase have very narrow range of δ^{13}C values from -2.1 to -7.7 ‰, which are closely similar to the normal mantle values [Cartigny, 2005; Stachel et al., 2009]. From this observation, it may be suggested that their formation may proceed from isotopically homogeneous mantle reservoir that do not support the model of large primordial isotopic variability of carbon isotopes in primitive Earth's mantle with a predicted pyrolite composition. Diamonds with inclusions of majoritic garnet and CaSi- and CaSiTi-perovskites in many cases show marked differences from the expected normal mantle values of δ^{13}C values. Low δ^{13}C values (-10 to -25 ‰) have been observed exclusively in a series of superdeep diamonds with calcic-majorite garnets, Ca-silicates, aluminous silicates and SiO_2 from Sao-Luis.

The δ^{13}C measurements in core to rim traverses within some individual crystals varied substantially, indicating multi-stage growth histories. The variations in δ^{13}C within individual diamonds may be attributed to either different source of carbon or fractionation effect during diamond growth. No correlation of carbon isotope composition and nitrogen content has been found in individual diamonds. It therefore appears that the cores and rims of the Sao-Luis diamonds precipitated from different fluids/melts with variable N/C ratios and/or under different growth conditions. The highly negative δ^{13}C values in the core (-20 to -25 ‰) potentially represent organic matter in sediments or altered basalts, and the lower δ^{13}C values may represent mixing trends towards normal mantle compositions [Schulze et al., 2004; Harte, 2011]. In this study, we have also described a series of diamonds which show opposite trend of change carbon source from primordial mantle to subducted/crustal (either biotic or abiotic carbon).

Chemical composition of nano-inclusions in supe-deep diamonds and implications to the growth condition

KAGI, Hiroyuki[1*] ; ISHIBASHI, Hidemi[2] ; OHFUJI, Hiroaki[3] ; ZEDGENIZOV, Dmitry[4] ; SHATSKY, Vladislav[4] ; RAGOZIN, Alex[4]

[1]Graduate School of Science, University of Tokyo, [2]Graduate School of Science, Shizuoka University, [3]Geodynamic Research Center, Ehime University, [4]Russian Academy of Science

Superdeep diamonds originating from the mantle transition zone and the lower mantle were found from alluvial deposits of Sao-Luis river (Juina, Brazil). We investigated carbon isotopic variations and chemical compositions of nano-inclusions in the superdeep diamonds which can give a clue for the growth condition.

We found syngenetic inclusions of superdeep paragenesis from 59 diamond samples from Sao-Luis. The dominant inclusions in diamonds from studied here are CaSi-perovskite and AlSi-phases. MgSi- and CaTi-perovskites, ferropericlase, native iron, coesite and zircon have also been found. Our SIMS analysis showed the wide variations of carbon isotopic compositions ranging from 2.7 to -25.3 ‰ in δ^{13}C. The details on the carbon isotopic analysis will be reported by Zefgenizov et al. in this session.

Some samples contained microinclusions and FTIR analyses showed that water and carbonates were not major components of these tiny inclusions. To identify the microinclusions, TEM observations were carried out on a foil of carbonado (0.1 micron thick) made from a polished diamond specimen after Au-coating. The foil was fabricated with a Ga ion beam using a focused ion beam (FIB) instrument (JEOL JEM-9310FIB). The foil was observed with a TEM (JEOL JEM-2010) under an accelerating voltage of 200 kV. We found that the microinclusions were euhedral inclusions of several tens nanometers in size. The TEM observations revealed that the nano-inclusions have a negative cystal shape suggesting the syngenetic origin directly related to the diamond growth. In this study, chemical composition of the nano-inclusions were conducted by synchrotron X-ray fluorescence analysis using X-ray micro-beam as an incident light at BL-4A, Photon Factory, KEK. The obtained results clarified that the nano-inclusions contain S, Cr, Mn, Fe, Co, Ni, Cu Zn, and so on. The present study suggests that the growth media of the superdeep diamonds are composed of sufilde melt.

High-pressure melting experiments on magma genesis in Hawaiian plume: effect of volatiles

GAO, Shan[1*] ; TAKAHASHI, Eiichi[1] ; IMAI, Takamasa[1] ; SUZUKI, Toshihiro[1]

[1]Earth and Planetary Sciences, Tokyo Institute of Technology

Introduction: Compared with OIB, Hawaiian tholeiitic basalt is thought to be relatively drier (about 0.5 wt.% H2O content; Muenow, 1979). In front of the plume core, overlying mantle is metasomatized by hydrous partial melts derived from the Hawaiian plume. Downstream from the plume core, lavas tap a depleted source region similar to enriched Pacific mid-ocean ridge basalt (Dixon & Clague, 2001). Magma genesis model has been proposed by some authors (Hauri, 1996; Takahashi & Nakajima; 2002; Sobolev et al., 2007) that magma produced near the axis of the plume head may be mixtures of two types of melts 1) basaltic andesite melt formed by melting of eclogite and 2) picritic melts formed by the reactive melting of eclogite and peridotite. A series of high temperature high pressure experiments were conducted to explore the genesis of tholeiite magma from Hawaiian plume and investigate the role of volatiles in magma genesis.

Experiments: A series of experiments were conducted under dry and slightly hydrous conditions at 2.85GPa for 1, 3 to 9 hours and from 1460 to 1520C with a piston cylinder by making basalt peridotite sandwich which using MgO-rich CRB72-180 (Takahashi et al 1998) and a fertile peridotite KLB-1 (Takahashi 1986) as starting materials.

Results: Three factors that might affect melting progress and chemical reaction among minerals – temperature, duration and water content –were examined, respectively.

1) Temperature: (1460˜1520C and every 20C as an interval.)

Basalt went partial molten at 1460C and completely molten when temperature went above 1500C. Orthopyroxene reaction rim formed on the border area due to the reaction between high Si-rich melt and olivine in the peridotite matrix. The opx film becomes more visible and thicker with the increasing of temperature. Partial melting degree of peridotite is also related to the increasing of temperature but the change is not very sensitive when 20C as an interval. The higher temperature, the more peridotite molten. The area of the peridotite near the opx film has a higher degree of partially melting than areas away from the boundary.

2) Duration: (1, 3 and 9 hours.)

Longer time do accelerate the speed of chemical reaction between basalt and peridotite in this study. Basalt molten completely as the running time longer than 3 hours. The orthopyroxene reaction rim on the boundary between peridotite and basalt becomes thicker. Large clinopyroxene crystals formed on the border (the minerals on the border from melt to peridotite are cpx, opx, garnet) momentarily yet faded away as the chemical reaction went on with time.Partial melting of peridotite is also positively related to duration. When the melt of peridotite is too much and unable to support the weight of basalt and it would got rid of the crack and finally went to the basalt side and mixed with the basalt melt.

3) Water content

Basalt layer melted completely, and large orthopyroxene crystallized in the basalt side. Peridotite layer also melted considerably at the same time than its anhydrous counterparts owing to the reason that the join of water could lower the peridotite liquidus line and finally made it more partial melted than in hydrous condition.

Discussion: Under dry conditions below peridotite solidus, melting is limited in eclogite layers and chemical reactions with ambient peridotite is hindered by opx film. On the other hand, under slightly wet conditions, water could accelerate the melting process of both eclogite and peridotite layer. As a result, melts formed under wet conditions are saturated with oliv+opx whereas those formed under dry conditions could be saturated with only opx. Changing nature of Hawaiian magma during the shield building stage will be discussed in the light of present melting experiments.

Partitioning of carbon between metallic- and silicate-liquids in magmaocean of differentiated planetesimals

ASAHARA, Yuki[1*] ; OHTANI, Eiji[1]

[1]Tohoku University

Partitioning behavior of carbon has not been determined well though it is one of the strong candidates for light element in the earth ' s core. We investigated partitioning of carbon with sulfur and oxygen between metallic- and silicate liquids at 6 GPa and 2073 K in carbonaceous chondrite composition (Allende meteorite; CV3). High pressure experiments were conducted with multi-anvil high pressure apparatus. Graphite was used as capsule material. Composition of coexisting metallic- and silicate liquids were measured by electron microprobe with wavelength dispersion type spectrometer except for carbon in silicate liquid. To estimate carbon concentration in silicate liquid, carbon concentration of bulk recovered sample was measured by elemental analyzer. Present result suggests that in oxidized carbonaceous chondrite composition, partitioning coefficient of carbon [$D^{Metallicliquid/Silicateliquid} = C^{Metallicliquid}/C^{Silicateliquid}$; C is concentration of carbon in wt.%] is close to 1, and it increases with increasing the Fe^{metal}/Fe^{oxide} ratio of the bulk carbonaceous chondrite composition.

Experimental study of Group-I kimberlite: evidences for carbonatite primary melt and implication to mantle plumes

LITASOV, Konstantin[1*] ; SHARYGIN, Igor[2] ; SHATSKIY, Anton[2] ; OHTANI, Eiji[3]

[1]Novosibirsk State University, Novosibirsk, Russia, [2]V.S. Sobolev Institute of Geology and Mineralogy SB RAS, Novosibirsk, Russia, [3]Department of Earth and Planetary Materials Science, Tohoku University, Sendai, Japan

The experiments on the origin of Udachnaya-East kimberlite (UEK) have been performed using a Kawai-type multianvil apparatus at 2-6.5 GPa and 900-1500 ^{o}C. The studied composition represented exceptionally fresh Group-I kimberlite containing (wt.%): SiO_2 = 25.9, TiO_2 = 1.8, Al_2O_3 = 2.8, FeO = 9.0, MgO = 30.1, CaO = 12.7, Na_2O = 3.4, K_2O = 1.3, P_2O_5 = 1.0, Cl = 0.9, CO_2 = 9.9, and H_2O = 0.5. Super-solidus assemblage consists of olivine (Ol), Ca-rich garnet (Gt), Al-spinel (Sp), perovskite (Pv), CaCO3 (calcite or aragonite), and apatite at 4-6.5 GPa with an addition of clinopyroxene at 3-4 GPa and Na-Ca carbonate with molar ratio of (Na+K)/Ca $\sim$ 0.44 at 6.5 GPa and 900 ^{o}C. The apparent solidus was established between 900 and 1000 oC at 6.5 GPa. In the studied P-T range, melt has Ca-carbonatite composition (Ca/(Ca+Mg) = 0.6-0.8) with high alkali and Cl contents (2.8-6.7 wt.% K_2O, 7.3-11.6 wt.% Na_2O, 1.2-3.7 wt.% Cl). The K, Na and Cl contents and Ca/(Ca+Mg) value decrease with temperature. It is argued, that the primary kimberlite melt at depth $>$200 km was essentially carbonatitic ($<$5 wt.% SiO_2), however, evolved toward carbonate-silicate composition (with 15-20 wt.% SiO_2) during ascent. The absence of orthopyroxene among the run products indicates that xenogenic orthopyroxene was preferentially dissolved into kimberlite melt. The obtained subliquidus phase assemblage (Ol + Gt + Sp + Pv) at P-T condition of UEK source region differs from lherzolite lithology of this source. Both petrological observations and experiments indicate that kimberlite magma lost substantial amount of CO_2 at shallow depths.

Our study combined with earlier experiments on carbonate-silicate systems at pressures to 30 GPa implies that liquid phase of thermo-chemical plume generated at the core-mantle boundary is represented by alkali-carbonatite melt. This conclusion has broad geodynamic implication providing insight into fluid regime of mantle melting under hotspots along margins of African large low-shear-wave-velocity province. We conclude that the long term activity of rising hot mantle plume and associated carbonatite melt (i.e. proto-kimberlite melt) causes thermo-mechanical erosion of the subcontinental lithosphere mantle (SCLM) roots and creates hot, oxidized, and deformed metasomatic layer at lower parts of initially depleted SCLM, which corresponds to depths constrained from the sheared Gt-lherzolites. The sheared Gt-lherzolites undoubtedly represent the samples from this layer.

Gas geochemistry and soil CO2 flux in active volcanic areas, China

WEN, Hsinyi[1*] ; YANG, Tsanyao frank[1] ; GUO, Zhengfu[2] ; FU, Chingchou[1] ; CHEN, Aiti[1] ; ZHANG, Maoliang[2]

[1]Department of Geosciences, National Taiwan University, [2]Institute of Geology and Geophysics, Chinese Academy of Sciences

Changbaishan intra-plate volcano and Tengchong hydrothermal area are two of the active volcanic areas in China. In order to better understand current status of magma/hydrothermal activities of the Changbaishan intra-plate volcano and Tengchong hydrothermal area, we have conducted the soil gas survey and bubbling gas sampling from hot springs around the Tianchi crater lake and Rehai geothermal area.

In Changbaishan volcano, the results show that CO_2 is the major component gas for most samples. The maximum value of helium isotopic ratio of 5.8 R_A (where R_A = $^3He/^4He$ in air) implies more than 60% of helium is contributed by mantle component, while carbon isotope values fall in the range of -5.8 to -2.0 ‰ (vs. PDB), indicating magmatic source signatures as well. Nitrogen dominated samples, 18Dawgo, have helium isotopic ratio of 0.7 R_A and carbon isotope value of -11.4 ‰, implying the gas source might be associated with regional crustal components beneath 18Dawgo. The first-time systematic soil CO_2 flux measurements indicate the flux is ca. 22.8 g m^{-2} day^{-1} and 6.8 g m^{-2} day^{-1} at the western and southern flank of Changbaishan, which is at the same level as the background value in the Tatun Volcano Group (24.6 g m^{-2} $day^{-1)}$, implying that Changbaishan may not be as active as TVG.

In Tengchong hydrothermal area, the preliminary results show that CO_2 is the major component gas for most samples. The helium and carbon isotopic ratio fall in the range of 0.5 R_A to 3.5 R_A and -4.7 to -1.6 ‰ (vs. PDB), respectively. We also analyzed the hot springs water. The δD and δ^{18}O values fall in the range from -59.8 to 84.6 ‰ and -6.20 to -12.38 ‰ (vs. SMOW), respectively. Rehai has the highest helium isotopic ratio of 3.5 R_A, which implies ca. 40% of helium is mantle-derived. The δD and δ^{18}O results implied the water in this area was affect by primary magmatic water. Nevertheless, samples from Banglazhang and Shihchiang hydrothermal areas show much lower helium isotopic ratio of 0.8 R_A and 0.5 R_A, respectively. It suggests that the local tectonic setting plays an important role for the gas degassing in this area.

The reaction between $MgCO_3$ and SiO_2 at high pressure and temperature and genesis of ultra-deep diamonds

MAEDA, Fumiya[1*] ; OHTANI, Eiji[1] ; KAMADA, Seiji[1] ; SAKAMAKI, Tatsuya[1] ; TAKAHASHI, Suguru[1] ; TAKAHATA, Akihiro[1] ; OHISHI, Yasuo[2] ; HIRAO, Naohisa[2]

[1]Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University, [2]Japan Synchrotron Radiation Research Institute

Carbon, one of the important light elements for the Earth science, is reserved in the deep part of the Earth. The evidence of the deep carbon is found in ultra-deep diamonds or estimations of carbon fluxes between the surface and interior of the Earth. Subducting slabs are considered as an important C-source of the Earth. Following reactions of $MgCO_3$ and SiO2 are potentially important in the slabs descending into the deep mantle:

$MgCO_3$ (magnesite) + SiO_2 → $MgSiO_3$ (perovskite) + CO_2

CO_2 → C (diamond) + O_2

These reactions can play a fundamental role in the deep carbon cycle.

In this work, we investigated the reaction between $MgCO_3$ and SiO_2 up to about 80 GPa and 3000 K using a laser-heated diamond anvil cell combined with in-situ synchrotron X-ray diffraction (XRD) technique and Raman spectroscopy. The starting material is the powered 1:1 (in mole fraction) mixture of natural magnesite (Brazil, Bahia) and reagent α-quartz. 5 wt.% platinum powder was added to the sample mixture in order to absorb laser and estimate the pressure in the sample chamber. NaCl, KCl or SiO_2 glass powder was stuffed into the sample chamber as pressure media. XRD patterns of high P-T samples and recovered samples were acquired at beamline BL10XU of SPring-8. Raman spectroscopy was carried out to high-pressure conditions. Raman spectroscopy was also conducted for the recovered samples.

In the present results made at about 70 GPa, diamond and $MgSiO_3$ perovskite are detected at temperatures greater than 1750 K. The high P-T XRD patterns in the experiments at 50-60 GPa and 2000-3000 K show the appearance of a small amount of $MgSiO_3$ perovskite. Our study demonstrated that formation of diamonds was confirmed in the range of 1300-1500 km depth of the lower mantle in subducting slabs due to the reaction of $MgCO_3$ with SiO_2 and the breakdown of CO_2. This phase relations have a possibility to explain one of the origins of diamonds from the lower mantle.

Microcracks preceding ruptures: insights gained from laboratory acoustic emission study

LEI, Xinglin[1*]

[1]Geological Survey of Japan, AIST, Japan

Earthquakes in the crust are caused by the rapid shear fracture of a fault. Thus, understanding the source processes of earthquakes relies on the understanding of shear fracturing in rocks. Abundant experimental evidence shows that macroscopic shear fracturing within rocks and other brittle materials does not occur by the growth of a single shear crack in its own plane. Rather, it is preceded by a very complex pervasive evolution of some pre-failure damage. Therefore, studies focusing on both fracture dynamics and pre-failure damage are a subject of interest in seismology. Fracturing dynamics and the pre-failure damage can be inferred from AE statistics as the number of AE events is proportional to the number of growing cracks, and the AE amplitudes are proportional to the length of crack growth increments in the rock. Therefore, the AE technique, which monitors the spatiotemporal distribution of AE events, is applied to the analysis of the micro-cracking activity inside the sample space, and it can be performed under an artificially controlled pressure, which is very important for the simulation of underground conditions.

The fracture of intact rocks as well as rocks containing natural structures (joints, faults, foliations) under constant stress rate loading or creep conditions is generally characterized by typical stages with different underlying physics. Through an integrated analysis of several AE statistics obtained from AE data collected with the high-speed AE waveform recording system, a three-phase pre-failure-damage model has been proposed and further enforced with new data. The primary phase reflects the initial rupture of pre-existing microcrack population in the sample or in the fault zone. Sub-critical growth dominates the secondary phase. The third phases termed nucleation phase corresponds to the initiation and accelerated growth of the ultimate fracture. In earthquake seismology, researchers have a special interest with the nucleation phase since faulting nucleation governs the predictability of earthquakes.

Lithology, density and size distribution of pre-existing cracks, meso-scale and macro-scale heterogeneities all have an overall role in AEs. There are some cases in which some phases are not clear. In general, homogeneous (both fine-grained and coarse-grained) rocks with pre-existing cracks likely show all phases. Heterogeneous or weak rocks such S-C cataclasite normally show a lack of the primary phase. Samples with few pre-existing cracks and samples containing optimally oriented weak structures, likely show an unpredictable fracturing behaviour as well as a lack of primary and secondary phases, in addition the nucleation phase has a small number of AEs.

Rules obtained at the laboratory scale are helpful for understanding natural earthquakes on a significantly larger scale. However, we cannot simply bridge laboratory scale to a scale several orders larger. At every step up from a smaller scale to a larger scale, we encountered something different. The difference could be small for each step but, after many steps, we could see something quite different. Studies on all scales are important. Quantitative investigation of rock fracture using AE techniques is still an interesting field for the future. On one hand, it may shed some light on earthquake seismology. On the other hand, it may provide a fundamental technical background promoting applications including: enhanced geothermal systems (EGS), extraction of shale gas and core bed gas, and CO2 geological storage. The latter of which involves fluids being intensively pumped into the deep Earth under high pressure; injection-induced earthquakes would be a problem that must be well-addressed.

Radio wave emission in friction or collision of various materials

TAKANO, Tadashi[1*] ; HANAWA, Rikuya[1] ; SAEGUSA, Saegusa[1]

[1]Nihon University

1. Introduction

In fracture of rock, radio wave emission was found experimentally [1]. This phenomenon could be used to detect a rock fracture during an earthquake or a volcanic activity [2] [3]. The cause of the radio wave is expected to be micro-discharges, which are generated by an inhomogeneous potential distribution around micro-cracks [4]. However, the theory of emission is not completely understood yet.

In order to clarify the cause of radio wave emission, we carried out experiments to detect the emission in the cases of friction or collision of various materials. This paper describes the experimental results, and a brief explanation of physical process.

2. Tested systems and experimental results

We tested the following systems using the manufactured measuring system at 1 MHz, 300 MHz, 2.0 GHz, and 18.8 GHz [5].

(1) A lighter using piezoelectricity

This device makes sparkles by knocking a mineral with piezoelectricity. Due to discharges, strong radio wave is emitted, and detected in our measuring system.

(2) A lighter using friction of OL metal

Formerly, this type of a lighter was widely used for igniting cigarettes. The alloy metal of cerium and iron rubs a revolving drum so that sparkles are made changing the friction power to thermal energy. Despite significant sparkles, radio wave could not be detected in this case.

(3) Igniter using a flint stone

A flint stone is struck against iron pyrites so that small flakes of iron are scattered being made hot. The flint stone is mostly chart In Europe, and quartz, sanukite, or obsidian in Japan. Sparkles cannot be made by striking two bulks of flint each other. Radio wave is not emitted in this case.

(4) Striking a steel lump with a steel hammer

Radio wave is emitted in this case. Probably, the kinetic energy is converted not to thermal energy but to the excitation of electrons or atoms so that inhomogeneous potential distribution is realized.

3. Conclusions

In general, sparks are not the origin of radio wave emission. This emission is esteemed a non-thermal phenomenon. An inhomogeneous potential distribution makes micro-discharges that emit radio waves. In some cases, the cause of an inhomogeneous potential distribution makes the sparks.

Further study is needed to clarify the mechanism of the energy transfer to electron excitation.

Seismoelectric phenomena of electrokientic nature associated with the formation of cracks in porous media

REVIL, Andre[1*]

[1]Colorado School of Mines, department of Geophysics

I will describe the physics of the generation of electromagnetic disturbances associated with the formation of cracks in porous media. The mechanism is electrokinetic in nature (i.e., associated with the flow of the pore water with respect to the solid phase of a porous material). I will describe the occurrence of these electromagnetic signals and how they can be inverted jointly with seismic signals to determine the position of the hydromechanical disturbance and its moment tensor. I will also demonstrate that electrical fields of electrokinetic nature are associated with the formation of crack through a set of laboratory experiments (see figure below showing the fluctuation in the electrical potential on the surface of the block and the amount of recorded acoustic emissions). The associated electrical field fluctuations can be remotely monitored and the resulting signals used to localize their causative source. The technique is similar to what is performed in electroencephalography (in the medical world) in which an electrical field (associated with the opening of ionic channels at the synapses between the neurons) can be measured on the scalp of a patient and inverted to localize and monitor brain activity. A laboratory experiment shows how these electrical fields can be recorded at the surface of a cement block during the fracking of the block. The measurements are performed with a research-grade medical electroencephalograph and inverted using the genetic algorithm to localize the causative source of electrical current and therefore localize the evolution of the crack. Two snapshots of electrical signals are used to show how the breakage evolves over time. A second experiment is performed to see if we could localize a pulse water injection from a shallow well in field conditions and in the case of a heterogeneous subsurface.

Waveform analysis of seismo-magnetic signals in Boso, Japan

HAN, Peng[1*] ; HATTORI, Katsumi[1] ; FEBTY, Febriani[1] ; HIROKI, Yamaguchi[1] ; CHIE, Yoshino[1]

[1]Graduate School of Science, Chiba University

To clarify the seismo-magnetic phenomena, it is essential to establish theoretical models to explain how the phenomena come out. A reliable model should coincide with field observations. Thus, the fundamental part is to find out what are the signals associated with earthquakes. Therefore, in this study we have checked detailed waveform of seismo-magnetic signals observed in Boso, Japan. Our preliminary results indicate that there are mainly two kinds of seismo-magnetic signals: one is noise-like signals; the other is transient/quasi-rectangular signals. The former are mainly detected before the 2005 M6.1 Boso earthquake; the latter is observed mainly during slow slip events.

Quantitative evidence of the coupling between seismic and electromagnetic signals

HUANG, Qinghua[1*]

[1]Peking University

There are some reports of the coupling between seismic and electromagnetic signals from both the natural earthquakes and the active field experiments. Such coupling effect may provide some useful information of earthquake process and/or oil exploration. Although the coupling mechanisms are not well understood at the current stage, there are some candidate mechanisms, such as the electrokinetic effect and piezoelectric effect. We focused this study on seismic and electromagnetic coupling for the data observed during earthquakes or synthesized from our numerical simulation method based on electrokinetic effect and earthquake models. We presented a quantitative analysis method of the correlation between seismic and electromagnetic signals. As an example of the field data, we investigated the data recorded during the Ms5.7 Ningqiang earthquake, China. The results indicated that there is a clear coupling between seismic and electromagnetic signals. As a further example of the synthetic data of seismic and electromagnetic signals, we obtained the synthetic seismic and electromagnetic signals using our numerical simulation method and confirmed the existence of coupling between the seismic and electromagnetic signals in the synthetic data.

This study is supported by the National Natural Science Foundation of China (41025014, 41274075).

The Development of self-potential tomography to estimate the ground water condition

OTSUBO, Hiroshi[1] ; HATTORI, Katsumi[1] ; YMAZAKI, Tomohiro[1*]

[1]Graduate school of science, Chiba University

Landslides are one of the most severe natural disasters in the world and there are two types; rainfall induced landslides and landslides triggered by an earthquake. In this research, basic study on early warning system for landslides will be performed to understand rainfall-induced landslide process by hydrological and electromagnetic changes. The final goal of this research is to develop a simple technology for landslide monitoring/forecasting using self potential method. The advantages of this method are lower cost and easier to set up than the hydrological approaches using pore pressure sensors. The laboratory experiments show that the self-potential variation has relationship with the water and soil displacements. But, we can not estimate the ground water condition by self-potential yet. So, in this study, we developed self-potential tomography to estimate the ground water condition.

Measured self-potential value under the ground and charge distribution to estimate is given by the Coulomb's law. Therefore, this is inverse problem. To solve the inverse problem, we adapt Phillips-Tikhonov regularization with Generalized Cross Validation (GCV). To evaluate the reconstructed charge distribution and investigate the relationship with the ground water condition, computational simulations and applications to practical data by using the sandbox experiment has been examined.

It is found that the developed algorithm is effective through numerical simulations. Results of application to sandbox experiments show good performance but there are some problems to solve.

The details will be given in our presentation.

Induced seismicity due to fluid injection at a deep well in Youngstown, Ohio, USA

KIM, Won-young[1*]

[1]Lamont-Doherty Earth Observatory, Columbia University, [2]Earthquake Research Institute, University of Tokyo

Over 100 small earthquakes (Mw 0.4-3.9) were detected during January 2011- February 2012 in the Youngstown, Ohio, USA area, where there were no known earthquakes in the past. These shocks were apparently close to a deep fluid injection well, and hence, were immediately suspected as induced by the fluid injection. This 14-months seismicity included a half-dozen felt earthquakes and culminated with a Mw 3.9 shock on 31 December 2011, about 24 hours after the fluid injection ceased in the deep well in Youngstown. Among the 109 shocks, 12 events greater than Mw 1.8 were detected by regional network, whereas 97 small earthquakes (0.4 <Mw <1.8) were only detected by using the waveform correlation detector.

Among these shocks, 21 earthquakes were accurately located by using the local portable station data. All of the accurately located earthquakes were distributed along a set of subsurface faults striking N265 (due East-west) and dipping steeply to the north – consistent with the focal mechanism of Mw 3.9 mainshock on 31 December 2011. All of the well-located earthquakes have occurred at depths ranging from 3.5 to 4.0 km in the Precambrian crystalline basement.

We conclude that the recent earthquakes which occurred during 2011 - 2012 in Youngstown, Ohio were indeed induced by the waste fluid injection at a deep injection well due to increased pore pressure along the preexisting East-west trending faults located close to the wellbore in the Precambrian basement. We found that the earthquakes are located along a 1.2 km-long, East-west trending subsurface en echelon fault, and that the seismicity initiated at the eastern end of the subsurface fault – close to the injection point, and migrated toward the west – away from the wellbore, indicating that the expanding high fluid pressure front increased the pore pressure along its East-west trending path and progressively triggered the earthquakes. Further, we observe that the occurrence of these earthquakes is generally correlated to the total daily injection volume and that several sharp peaks in the daily injection volume correlate with the occurrence of earthquakes. We observed that several periods of quiescence of seismicity follow gaps in surface injection volumes and pressure (sudden drops in injection pressure followed by prolonged low pressure), which may indicate that the earthquakes were directly caused by the pressure buildup in the fractured Precambrian basement and stopped when pressure dropped. Geohydrologic properties of the Youngstown, Ohio area behaved as a fractured Precambrian rock similar to the Rocky Mountain Arsenal, Colorado, USA site of induced earthquakes during 1960s.

Characteristics of Microcracks in the Nucleation Stage of Natural Earthquake

FUJINAWA, Yukio[1*] ; NODA, Yoichi[2] ; TAKAHASHI, Kozo[3]

[1]MierukaBosai Inc., [2]Tierra Tecnica Ltd., [3](former) Communication Research Laboratory

At the last JpGU meeting we reported that a deep underground electric field measurement using special antenna could detect micro-cracks appearing in the nucleation stage of the Tohoku Earthquake (Fujinawa et al., 2013). Here we report several results of further analysis on the characteristic pulse-like phenomena.

1) Detection Distance:

Some events of B-type variation have clear first and second phases (Figure 1). The S-P time is 25ms corresponding to about 180m of the epicentral distance. Majority of events have no apparent P phases due to the small strength of the P phase and/or large dissipation. The detection distance of P phase is about 200m. On the other hand the S phase of the frequency of some 100Hz and amplitude of 2mV suggests detection distance of some 10km, much larger than that of the acoustic emission signal of order several hundred meters by elastic observation.

The characteristic electric field variation induced by crack through electro-kinetic mechanism have been discussed by systematic formulations (Pride, 1994; Revil and Leroy, 2004). As to the wave mode, there are four kinds of wave, slow P and fast P wave (ordinary p wave), S-wave (ordinary S wave) and electromagnetic wave (EM). Events containing P phase have occasionally small forerunners at about the origin time possibly corresponding to (see Fig.1).

2) Correspondence to main shock:

The seismological approaches (e.g., Kato et al., 2012) showed that there were two slow seismic slip events from mid-February to the Tohoku Earthquake and microearthquake activities around the foreshocks and mainshocks. Those activities were whole around the epicentral zone, about 300 km northeast from the observation site. The detection distance of the electric field change by the borehole antenna is at most 100 kilometer. Our observational evidence including temporal evolution of the microcrack activity and b value of 0.7 suggest that the micro-cracks of B-type are related to the nucleation process of the main shock, though they occurred at the edge of the giant rupture area. We propose that the nucleation process is not limited at around the asperity, but extends to whole rupture zone. More extensive monitoring of the microcrack of magnitude less than -5 can provide clue to this question.

3) Intermittent Criticality

There appeared undulation of microcrack activity after the most active period around 9th March , 2011. The undulation has been suggested to reflect the intermittent criticality indicating another phase of nucleation (Sornette and Sammis, 1995; Kapiris et al., 2005). As approaching to the main shock there appeared two kinds of events. One kind is a superposition of several smaller events. It is interpreted that small events substantially increased with the result of picking up more smaller events in the time interval of data length of 100ms. The second kind is like a long chain of small events. These feature suggest that microcrack activity has changed at the last stage of nucleation stage.

4) It is well known that the crust of the earth is elastic-porous medium filled with fluid as water. The research on the rupture of such kind of medium had a remarkable development in early 1990 contributing to interpret the mysterious seismo-electric phenomena associated earthquakes enabling systematic treatment and suggesting new method of geophysical prospecting. The formulation of Pride and Revil have been used to interpret the phase of faster propagation of EM signal with velocity much larger than the p-wave speed (Fujinawa et al., 2011), the ULF band anomalies associated the slow-slip (Han, 2013) . And, our electromagnetic method has been suggested to detect micro-cracks preceding natural earthquakes to identify the nucleation stage providing a break-through for the short term prediction method. The converted electromagnetic mode at the material contrast from elastic seismic wave has been proved to be profitable means to survey for oil and gas.

Electromagnetic emissions from fracture of semiconductor pyrite

OZAWA, Mitsuyuki[1*] ; MUTO, Jun[1] ; NAGAHAMA, Hiroyuki[1] ; NAGASE, Toshiro[2]

[1]Department of Geoenviromental Sceinces, Graduate School of Science, Tohoku University, [2]The Tohoku University Museum

Introduction

When elastic waves propagate in orebodies composed of semiconductor minerals, electromagnetic (EM) radiation with radio frequency occurs. Its frequencies were 10-100 times higher than those of the elastic waves. They were observed by geophysical exploration surveys and laboratory experiments. These previous studies suggested that generation of radio waves is closely related to the rectifying property of orebodies which is attributed to semiconductor minerals. Semiconductor minerals are divided into p- or n-type conductivity by its charge carrier. When p- and n-type are joined, the resulting junction (p-n junction) has the rectifying property. Because many p-n junctions of semiconductor minerals exist as which connect in parallel and in series in the orebody, they also show rectifying property. Previous research measured only large scale rectifying property of orebody to understand the generation mechanism of radio wave. However, due to the lack of the measurement of rectifying properties of each micro p-n junction in semiconductor minerals, quantities evaluation was difficult.

Composition of semiconductor minerals is heterogeneous due to the presence of impurities and lattice defects. Because rectifying property depends crucially on the composition, clarifying the composition at each micro region is needed. In this research, we measured the composition and rectifying property of semiconductor pyrite to discuss the possibility of EM emission from the ore bodies.

Methods

Semiconductor pyrite sample was obtained from Waga-Sennin mine, Akita prefecture, Japan. It was cut into slabs with a thickness of about 0.38 cm and an area of 1.4 cm^2.

We obtained composition of the sample surface by electroetching method and SEM-EDS. Thermal probing method allowed us to discriminate between p- and n-type conductivity. By electrical probing, we quantified the rectifying properties.

Results

After the electrolytic etching, heterogeneity of composition in the sample surface was emerged as the difference in solubility. The difference of soulubility caused etching figure and zonal structures. Thermal probe method revealed that the differences of p-n type regions corresponded to the difference in solubility of each region. P-types regions showed a higher solubility than n-type regions. According to the SEM-EDS analysis, about 1.0 wt.% of Pb inclusions were precipitated parallel to crystallographic planes in the p-type regions.

In the electrical probing method, rectifying effects were observed at p-n junctions. We obtained the current and voltage characteristic of p-n junction. The reverse and forward breakdown voltages were estimated to be 1.5 V and 0.3 V, respectively.

Discussion and conclusion

When two types of rocks make contact, electrons move between the surfaces of rocks, producing the potential difference between them. This electrification becomes a possible source of EM radiations during separating rocks. If we regard p- and n-type semiconductor minerals as the two types of rocks, the contact potential is given by the forward breakdown voltage of p-n junction. When the junction is split into two pieces, separated surface can be regarded as capacitance plates. If the surface charge density of plates reaches the Paschen's minimum charge density of breakdown (e.g. air 5.0×10^{-5} C/m^2), corona discharge occurs. We estimated the charge density of separated plates at p-n junction to be 2.7×10^{-4} C/m^2. Given the effect of charge relaxation, we must take into account separation velocity of plates. In this case the critical separation velocity to cause corona discharge is estimated to be 2.0 km/s. Therefore, it is expected that the pyrite fractured by propagation speed higher than 2.0 km/s can cause corona discharge.

In conclusion, the fracturing of pyrite becomes a possible source of EM radiations. Further investigation is needed to clarify the properties (e.g. frequency) of EM radiations from the orebodies.

Pulsed granitic crust formation revealed by comprehensive SHRIMP zircon dating of the SW Japan granitoids

TANI, Kenichiro[1*] ; HORIE, Kenji[2] ; DUNKLEY, Daniel[3] ; ISHIHARA, Shunso[4]

[1]Japan Agency for Marine-Earth Science and Technology, [2]National Institute of Polar Research, [3]Curtin University, [4]Geological Survey of Japan/AIST

The origin of continental crust is a fundamental question in Earth's evolution. Granitoids, its volcanic equivalents, and metamorphic and sedimentary rocks with granitic compositions, are the main components of the upper continental crust. It is therefore important to understand the geodynamic settings in which juvenile granitic magma is generated from mantle-derived sources. Convergent plate margins, such as the Mesozoic circum-Pacific orogenic belts, are regarded as one of the plausible candidates for the post-Archean continental crust formation, as they are associated with abundant calc-alkaline I-type batholiths. However, the fundamental tectonic processes that triggered these voluminous granitic crust formations in the Mesozoic have remained largely unresolved due to the lack of precise temporal constraints on the granitic magmatism. We are currently undertaking a comprehensive geochronological study of the granitic batholith exposed in the Southwest Japan Arc, which is typical of the Mesozoic circum-Pacific orogenic belts utilizing high-precision zircon U/Pb geochronology.

In order to precisely determine the space-time distribution of the granitic magmatism that occurred in the SW Japan Arc during the Mesozoic, we have used the zircon U/Pb method to date a comprehensive suite of granitic rocks from the Chugoku Region in the SW Japan. Contrary to the results previously obtained using conventional geochronological methods, which suggested that the magmatism occurred gradually from ~100 to ~50 Ma, with the plutons forming over long time intervals, the newly obtained zircon ages reveal three clear pulses of granitic crust formation at 85, 60 and 35 Ma separated by 25 million year intervals. The 85 Ma magmatism was the most voluminous and was distributed in a broad zone that extends ~120 km across-strike, whereas the magmatism at 60 and 35 Ma were focused on the northern margin of the SW Japan Arc. Furthermore, the granitic magmatism at 85 Ma involved sediment-incorporated, ilmenite series granitic rocks, while the magmatism at 60 and 35 Ma involved more juvenile, mantle-derived, magnetite series rocks. Thus, not only did the granitic magmatism in SW Japan occur in pulses, there was also a spatial and compositional transition in the magmatism through time. This can be best explained by enhanced subduction zone magmatism during the Mesozoic, rather than the previously proposed model in which it was suggested that the granitic crust was formed by the subduction of a mid-ocean ridge on the Pacific Plate during the Middle Cretaceous.

Petrology and zircon geochronology of the Hikami Granitic Rocks in south Kitakami Mountains,Japan

SASAKI, Jun[1*] ; TSUCHIYA, Nobutaka[1] ; ADACHI, Tatsuro[2] ; NAKANO, Nobuhiko[2] ; OSANAI, Yasuhito[2] ; ADACHI, Yoshiko[3]

[1]IwateUniversity, [2]KyushuUniversity, [3]NiigataUniversity

The Hikami Granites,pre-Cretaceous older granitic complex of the South Kitakami Terrane,has long been controversial on their age of intrusion. Since unconformable relationship between the granites and the Silurian formation was shown by Murata et al.(1974). However CHIME age determinatin for the grainites (Adachi et al.,1994),indicates Silrian to Permian age.We examined the zircon U-Pb ages of 13 samples from the Hikami Granitic Rocks, and solidification age of around 450Ma were obtained.

Bulk rock chemical compositions of the Hikami granites were compared with Paleozoic granitic rocks in Japan. Petrochemical similarity between Hikami Granitic Rocks and the granitic rocks in the Kurosegawa Belt is consistent with the correlation between the South Kitakmi and Kurosegawa Belts.

Sr-Nd-Pb-Hf isotopic variations of Cretaceous to Paleogene granitic rocks from northeast Japan

TSUCHIYA, Nobutaka[1*] ; KAGASHIMA, Shin-ichi[2] ; HIRAHARA, Yuka[3] ; TAKAHASHI, Toshiro[3] ; SENDA, Ryoko[3] ; CHANG, Qing[3] ; KIMURA, Jun-ichi[3]

[1]Iwate University, [2]Yamagata University, [3]JAMSTEC

The Japanese Islands represent a segment of a 500 Ma old subduction related orogen developed along the western Pacific convergent margin, and most tectonic units are composed of late Paleozoic to Cenozoic accretionary complexes and their high P/T metamorphic equivalents (e.g., Maruyama, 1997; Isozaki et al., 2010). Maruyama (1997) described the formation of the Japanese Islands has been taken as the standard model for an accretionary orogeny. He also stated that the most important cause of the orogeny is the subduction of an oceanic ridge, by which the continental mass increases through the transfer of granitic melt from the subducting oceanic crust to the orogenic belt. On the other hand, Jahn (2010) described that the subduction-accretion complexes consisting of granitic and sedimentary rocks in southwest Japan are composed mainly of recycled old continental crust. Kagami et al. (1999) described that the Honshu Arc can be divided into three groups based on their Sr-Nd isotope characteristics: the Kitakami, North (Abukuma belt), and South (Ashio/Mino belts) Zones, in order of increasing Sr isotopic enrichment, with Nd isotopic depletion from NE to SW. We present Sr-Nd-Pb-Hf isotopic ratios for granitic rocks in northeast Japan.

Sr-Nd-Pb-Hf isotopic study are made for granitic rocks from the Kitakami belts (Kitakami Mountains), the Abukuma belts (Shirakami Mountains, Obonai area, Taihei Mountain, Sekiryo Mountains, and Abukuma Mountains), and the Ashio/Mino belts (Okutone area, Tadami area, Okutadami area, Taisyaku Mountains, and Ashio Mountains). Newly isotopic data from these granitic rocks show increasing enrichment of crustal component in order of the Kitakami, Abukuma, and Ashio/Mino belts. Multi-isotope plots of these rocks indicate that the trend in variation could result from the mixing of depleted and enriched components. The depleted component is likely to originate from the magmatic flux related to the Lower Cretaceous ridge subduction. On the other hand, the mixing model of subducted sediments and depleted mantle cannot explain the variation of Nd-Hf isotopic compositions of granitic rocks. The enriched component requires existence of a reservoir with low Hf initial isotope ratio, which is considered to be zircon-rich sediment derived from old continental protolith (Chauvel et al., 2008). In addition, the granitic rocks in Kitakami zone shows rather different trend from the granitic rocks in other districts. It can be explained by the hypothesis that the granitic rocks in the Kitakami zone were derived from the mixing of mantle component with enriched end menber of lower Hf initial isotope ratio. This model is consistent with the fact that the Kitakami zone is characterized by the occurrence of adakitic rocks related to Lower Cretaceous ridge subduction.

Garnet-bearing acidic igneous bodies in Mt. Kenashi-yama area, Fujikawaguchiko-machi, Yamanashi, Japan

NAGAHATA, Hiromi[1*] ; ISHII, Teruaki[2]

[1]Graduate school, Open University of Japan, [2]Fukada Geological Institute

Introduction The gernet-bearing quartz porphyrite body in Mt. Kenashi-yama area Fujikawaguchiko-machi, Yamanashi, Prefecture was described by Katada (1956). On the other hand, there are many reports on garnet-bearing boulders in this area (Togawa et al., 1996; Togawa et al., 1997; Matsubara et al., 2008; Tamura et al., 2010).

On the detailed field works, we recognized three groups of garnet-bearing acidic igneous bodies in this area.

Geology The studied area is in the northern end of Izu-Bonin Arc, and is located east side of Misaka group, middle to late Miocene.

Lithology Three garnet-bearing acidic igneous bodies are recognized, which are named A, B and C groups.

[A group (lava flow(?))] This group exists in 1,100m to 1,200m above sea level, and is located from WSW to ENE over 2km long. The rock consists of quartz (10%-20%, md : maximum diameter = 5mm), feldspar (10%-25%, md = 4mm), garnet (1%, md = 3mm) and groundmass(60%-65%). The rock of A group shows high dense appearance.

[B group (volcanic ash(?))] This group exists at 1,200m, and this group may be exist along above the A group. This group can be assumed as garnet-bearing volcanic ash, because this group contains volcanic glasses (at under microscope) and rock fragments (If B group is not volcanic ash, this group may be the weathered zoon of A group). The B group consists of quartz (10%, md = 5mm), garnet (1%, md = 3mm) and clay matter 80%.

[C group (dike)] This group exists in 1,300m to 1,400m, and is located from WSW to ENE, over 3km long. The rock is little fragile, and consist of quartz (3%-20%, md = 4mm), feldspar (3%-20%, md = 3mm), garnet (0.1%, md = 3mm), hornblende (1%, maximum length = 9mm) and groundmass (65%-85%).

Chemical analysis Representative samples of each groups are analyzed by X-lay fluorescent analysis on 10 major elements. The SiO_2 contents of three groups are 72wt%-76wt%. It mean that these rocks are classified into rhyolite according to alkali-SiO_2 diagram (Le Bas, et al., 1986). There are slightly high in Na_2O, and slightly low P_2O_5 than Tanzawa Hosokawadani rhyolite (Yamashita, 1997).

Discussion and Consideration It can be assumed that three groups of garnet bearing acidic igneous bodies are recognized in Mt. Kenashi-yama area. They are located along WSW-ENE direction 2-3km long. A, B and C groups are possibly lava flow, volcanic ash and intrusive rock, respectively. All of them may be classified into garnet-bearing rhyolite.

Two types of websterite from the Ust'-Belaya ophiolite, Far East Russia: Origins and implications

MACHI, Sumiaki[1*] ; ISHIWATARI, Akira[2] ; MORISHITA, Tomoaki[1] ; HAYASAKA, Yasutaka[3] ; ARAI, Shoji[1] ; TAMURA, Akihiro[1]

[1]Natural Sci & Tec., Kanazawa Univ., [2]NE Asia Center, Tohoku Univ., [3]Earth & Planet. Sys. Sci., Hiroshima Univ.

The Ust'-Belaya ophiolite is located in the Koryak Mountains, Far East Russia. We report two types of websterite in the mantle section of the ophiolite.

The lithology of the mantle peridotites from the ophiolite is variable from very fertile lherzolite to moderately depleted harzburgite. The mineral chemistry of the very fertile lherzolite shows similar signature to those of the subcontinental peridotite. The two types of websterite (type1 and type2) occur in them as dikes/veins. Type1 is composed of brownish colored cpx, opx and Al-spinel. On the other hand, type2 is composed of green colored cpx, opx and Cr-spinel.

Type2 websterite is similar to those reported from many other ophiolites. Websterites, which are characterized by extremely aluminous spinel similar to the type1 websterite, are never found in ophiolitic peridotites but are described in passive margin peridotites (e.g. Zabargad Island in Red Sea and Iberia Abyssal plain peridotites). These websterites are generally interpreted as high-pressure cumulates and the host peridotites are considered as fragments of subcontinental mantle.

The mantle section of the Ust'-Belaya ophiolite represents, at least partly, fragments of subcontinental mantle. The two types of websterite might be related to two different magmatisms in two different tectonic settings; type1 is formed former subcontinental to oceanic environment and then type2 is formed later oceanic to arc environment.

Keywords: Ust'-Belaya ophiolite, websterite, subcontinental mantle

Field geological considerations on the formation mechanism of platy joints in lava flows

SATO, Kei[1*] ; ISHIWATARI, Akira[2]

[1]Grad. School Sci., Tohoku Univ., [2]CNEAS, Tohoku Univ.

Columnar jointing and platy jointing are characteristic types of jointing in volcanic rocks. The origin of columnar joints has been discussed for centuries, and at the present day it is considered that they are the result of cooling and contraction of lava (Aydin and DeGraff, 1988). However, platy joints have far less attracted researchers than columnar joints and their formation mechanism is still controversial. Platy joints can develop in thick (>100 m) and voluminous lava flows which have glassy margins such as ”flood andesite” in Kyushu, Japan (Nagao et al., 1995) and ridge-forming lava flows at Mount Rainier (Lescinsky and Sisson, 1998), probably reflecting stress distribution or physical property within solidifying lava. Previous studies attributed formation of platy joints (sheeting joints) to late stage shear of lava flow and/or microlite orientation (Lescinsky and Fink, 2000), deflation of flow (Spörli and Rowland, 2006) or both flowage and shrinkage of lava (Bonnichsen and Kauffman, 1987). Although absolute evidence for the origin of platy jointing has not been found, restraining of internal lava by solidified flow margin would be an important factor in any case and density (volume ratio of crystals to glass) difference between flow margin and interior would be also important when we consider thermal contraction. It is also a problem when platy joints form, especially in the case that columnar and platy joints intersect without terminating each other. Occasionally platy joints are filled with tridymite and/or mica mineral with or without andesitic to dacitic melt, which might be segregated from the crystallizing lava body, suggesting that platy joints start to form at early stage of cooling of lava.

Oxidation stats of Fe within constituent minerals in spinel-lherzolite xenolith from Tariat Depression, Mongolia: Signif

EJIMA, Terumi[1*] ; OSANAI, Yasuhito[2] ; OHFUJI, Hiroaki[3]

[1]National Institute of Advanced Industrial Science and Technology, [2]Kyushu Univ., [3]Ehime Univ.

The Tariat depression is one of the most famous areas of deep-seated megacrystic xenoliths and mantle-derived xenoliths in the Baikal-Mongolia rift. Spinel-garnet-bearing websterite, garnet lherzolite and spinel lherzolite have been found in this area (Osanai et al. 2010). In this study, oxidation state of Fe in olivine (Ol), orthopyroxene, clinopyroxene and spinel in fresh spinel-lherzolite xenolith, and olivine in host basalt in Tariat depression were investigated using Mossbauer spectroscopy, X-ray FeL?/FeL?-intensity ratio analysis (EPMA method) and transmission electron microscopy (TEM).

Olivine, clinopyroxene, orthopyroxene and spinel have homogeneous chemical compositions. Olivine is forsterite with average composition of Fo90Fa10, Clinopyroxene is Na-bearing diopside [(Na0.17Ca0.71Mg0.81Fe0.09Al0.20)?2.00(Si1.89Al0.11)?2.00O6], and have symplektite consisting of diopside and glass on the rim with the width of ˜50 micro m. The chemical composition of the glass is similar to that of feldspar with compositions of An. Orthopyroxene is [(Mg0.85Fe0.09Al0.04Ca0.02)(Si0.94Al0.06)O3]. Spinel is [(Mg0.81Fe2+0.22)?1.03(Al1.80Cr0.17)?1.97O4].

The Fe2+: Fe3+ ratios of forsterite, orthopyroxene, clinopyroxene and spinel determined by Mossbauer analysis are 97(1):3(1); 85(8):15(1); 74(4):26(3); 66(8):34(5), respectively. Fe3+ in olivine is not attributed to any precipitates nor minute inclusions, which was confirmed by TEM observation, and, thus, exists in olivine structure. Fe of olivine phenocrysts from host basalt lava is only Fe2+ which was proved by EPMA method.

Fe3+-bearing forsterite in spinel-lherzolite xenolith is considered to have been stable under mantle condition.

Al/Si disordered anorthite in anorthite megacryst from Miyake-jima: effect of non-stoichiometry on Al/Si distribution

ECHIGO, Takuya[1*] ; HOSHINO, Mihoko[2] ; KIMATA, Mitsuyoshi[3] ; SHIMIZU, Masahiro[3] ; MATSUI, Tomoaki[4] ; NISHIDA, Norimasa[5]

[1]Faculty of Education, Shiga University, [2]Mineral Resources Research Group, AIST, [3]Earth Evolution Sciences, University of Tsukuba, [4]Faculty of Education, Kagoshiama University, [5]Research Facility Center for Science and Technology, University of Tsukuba

The crystal chemistry of anorthite with the low content of albite (An92.0Ab3.4), part of a rapid cooled, anorthite megacryst occurring in 1940 ejecta from Miyake-jima volcano, Japan, has been investigated using single-crystal X-ray diffractometer and electron microprobe analyzer with wavelength dispersive X-ray spectroscopy (EMPA-WDS). The structure was refined in space group P-1 and cell parameters, a = 8.182(6) Å, b = 12.883(4) Å, c = 7.092(4) Å, α = 93.19(4) ^{o} , β = 115.91 (4) ^{o} , γ = 91.18 (4) ^{o} . The final weighted R-factor is 3.77 % for 1549 reflections. Averaged T-O distances are 1.681 Å for T1(0), 1.674 Å for T1(m), 1.677 Å for T2(0) and 1.680 Å for T2(m), indicating each Al occupancy of 0.501, 0.453, 0.472, and 0.496, respectively. These results suggest that the Al/Si-distribution in the tetrahedral framework is highly disordered (QOD = 0.06), which results in having the c-axis in half along that determined in Al/Si ordered anorthites (c ˜14 Å).

Formation temperature of perlite and its texture by heating experiments of obsidians from Hokkaido

IKEYAUCHI, Ryo[1] ; WADA, Keiji[1*] ; SAITO, Takeaki[1]

[1]Hokkaido University of Education at Asahikawa

The obsidians from Hokkaido were heated in electric furnaces to transform the perlite in a form like pumice in vitreosity, because remained water in obsidians becomes the gas and makes air bubbles by heating.

We examined foaming temperature of the obsidians from 13 samples in 7 Hokkaido sources, and the relations with its foaming temperature and the water content of the obsidians. In addition, we changed a heating temperature and a condition of the heating time and examined the difference in foaming form of the perlite.

Finally, we considered a relations with foaming process of the obsidians and the internal structure of the perlite through the microscopy of the perlite.

Estimation of intracrystalline distribution coefficient of Mg-Fe ions in olivine using Cs-corrected STEM

MIYAKE, Akira[1*] ; TOH, Shoichi[2] ; FUKUNAGA, Keiichi[3] ; KURIBAYASHI, Takahiro[4]

[1]Kyoto Univ., Sci., [2]Fukuoka Univ., Sci., [3]JFCC, [4]Tohoku Univ., Sci.

Intracrystalline distribution coefficient of Mg-Fe ions between the two types of the octahedral sites (M1, M2-site) of olivine, $(Mg,Fe)_2SiO_4$, have been estimated using X-ray or neutron diffraction studies. Recently, the high angle annular dark field (HAADF) method using scanning transmission electron microscopy with the correction of spherical aberration (Cs-corrected STEM) visualizes the element column sites in crystalline samples. In the present study, the intracrystalline distribution coefficient of Mg-Fe ions in olivine were tried to estimate using HAADF-STEM. And furthermore, Crystal Structure Analysis of same sample was carried out using e four-circle X-ray diffractometer. We used the synthetic forsterite and the natural olivine from San Carlos, Sri Lanka and Miyake-jima. HAADF-STEM images parallel to a-axis show the Mg / Fe atom columns and the columns which alternately formed of Si and O atoms. Intracrystalline distribution coefficients estimated from the brightness in M1/M2-sites for synthetic forsterite, the olivines from San Carlos and SriLanka are good agreement with those estimated from X-ray method. On the other hand, that obtained from Miyake-jima is different with that obtained from X-ray method.

Keywords: STEM, olivine, intracrystalline distribution coefficient

A Novel Approach for the Classification of Mineral Ore Particles by A Statistical Raman Spectroscopic Method

SASAKURA, Daisuke[1*] ; HAYAUCHI, Aiko[1]

[1]Malvern Instruments Division of Spectris Japan

[Introduction]

Mineral ores extracted by mining go through a milling process before ore dressing. An important factor in both milling and ore dressing operations is the determination of the particle size distribution of the materials being processed, commonly referred to as particle size analysis. An elemental analysis technique such as X-Ray fluorescence and destructive wet chemical analysis can determine the quantity of mineral species present in the ore, however, these chemical analysis methods do not allow the study of the composition of individual particles of different size and shape. The statistical Raman spectroscopic method is a novel approach which can resolve this problem. Using this method the Raman spectra of several hundred particles is determined after size and shape classification of each individual particle by automated particle image analysis. Raman spectroscopy can be used to acquire the spectra of any inorganic compounds such as metal oxides and nitrides which are Raman active. Many mineral resources are mined as inorganic compounds. Therefore, Raman spectroscopy can be used for the identification of the chemical composition of mineral ores. Using the statistical Raman spectroscopic method described herein, it is possible to calculate the particle size distribution and proportion by mass or volume of each chemical component or mineral species based on Raman spectroscopic information. This study will report and discuss the capability of the statistical Raman spectroscopic method using iron ore as a model material.

[Material and Method]

Iron ore samples were purchased from a vendor. These samples had been through the ore dressing process. Statistical Raman analysis was carried out using a Morphologi G3SE-ID instrument (Malvern Instruments, UK) equipped with a dry powder sample dispersion unit (SDU) and Raman module. The laser wavelength of Raman excitation was 785nm the laser power was less than 5mW and the irradiation time was 5 sec. The particle image measurements were made in diascopic mode with a total magnification 250x. Iron ore dry powder samples were dispersed using the SDU using a short duration pulse of compressed air. Measurements were made automatically using Standard Operating Procedures (SOPs) which define the software and hardware settings used. Measurement sample was dispersed on to glass plate as sample carrier which was minimized environmental exposure by the enclosed sample chamber unit. Particle identification by Raman analysis used the spectrum correlation coefficient approach.

[Results and Discussion]

A Total of 66,436 particles of iron ore were measured by image analysis. The circle equivalent diameter particle size distribution by volume (VCED) exhibited a monomodal distribution with size distribution percentiles as follows: 8.62μm (d10), 21.83μm (d50), 51.29μm (d90). A subset of 700 particles were selected and the Raman spectra were measured. Particles over 20 micron in size were selected randomly from the image analysis data and Raman spectra were acquired. The spectra enabled identification of 4 components (Fig.1). The relative proportion of each component by volume or number of particles is shown in Table 1. Component (A) comprised approximately 90% of the sample. This component exhibited a Raman spectrum typical of α-Fe_2O_3 [1]. It is assumed that components (B) and (C) are polymorphs based on the ratio of the intensities at 221cm^{-1} and 245cm^{-1}. Component (D) exhibited a spectrum typical of α-FeOOH and composed less than 3% of the sample. This result does show that the statistical Raman analysis approach can detect components present at quite low concentrations.

[Summary]

This report illustrated the application and capability of statistical Raman analysis for the characterization of mineral ores using a new approach based on combining chemical and particle size / shape information.

Assessment of Nakhile porphyry Cu mineralization potential using geological, geochemical and statistical studies: a case

BOOMERI, Mohammad[1*] ; NAKASHIMA, Kazuo[2] ; F, Yavari[1]

[1]Univ. of Sistan and Baluchestan, [2]Yamagata Univ.

The Nakhile Cu mineralization is located in 145 km northwest of Zahedan in Sistan and Baluchestan province of Iran. This area is geologically located in boundary part of Lut block and flysch zone of east Iran. Geology of the study area consists of Cretaceous to Eocene andesitic lavas and tuffs that were intruded by a dioritic to quartz-dioritic stock. The intrusive rocks are mainly altered and mineralized. Based on the petrography and XRD studies, main mineral in all types of the igneous rocks is plagioclase and the main texture is porphyry. Other minerals are clinopyroxene, amphibole, biotite, quartz, and secondary minerals that vary in the igneous rocks. A large part of the intrusive rocks is rich in pyrite. The pyrite occurs as veins, veinlets and disseminated in the stock. Cu mineralization occurs as vein and can be divided into hypogene and supergene mineralization. Hypogene mineralization is characterized by chalcopyrite and pyrite while supergene mineralization is characterized by malachite, azurite, jarusite, ghothite, hematite and limonite. The propylitic alteration is dominant feature of the intrusive rocks as a wide outer zone. Potassic, phyllic and argillic alterations are also important in the area. The potassic alteration is probably important in the center part of the stock in depth. phyllic and argillic alterations are mainly formed by supergene processes.

The samples that were collected from the least altered and altered rocks in the study area were analyzed by ICP were processed by convenient software such as EXEL and SPSS to obtain statistic parameters of: skewness, maximum, minimum and standard deviation. Then, the histograms for the amount of Cu, Au and related elements were drawn and their correlation coefficients were calculated. There are remarkable positive correlations between Cu, Au and Ag indicating their similar origin. The highest content of Cu is 7000 ppm in the study samples. The Cu anomalies are mainly observed in central and eastern parts of the area. The highest content of Au is 6000 ppb. The Au anomalies are mainly observed in western parts of the area. The higher contents of Pb, Zn and Ag are observed more away from the intrusive rocks.

The outcrops in the area are mainly similar as propylitic alteration zone of porphyry Cu deposits that is characterized by secondary hydrothermal epidote and chlorite and pyrite. The Cu porphyry mineralization and other alteration zones specially potassic probably occur in depth in the area.

A leucogranite stock rich in high field strength elements, Kanamaru-Oguni area on the Niigata-Yamagata border, NE Japan

KAMEI, Atsushi[1*] ; NAITO, Kazuki[2] ; TAKAMURA, Sayaka[3] ; KAGASHIMA, Shin-ichi[4] ; OKUZAWA, Koichi[5] ; SEKI, Yoji[6] ; WATANABE, Yoshio[2]

[1]Department of Geoscience, Shimane University, [2]Geological Survey of Japan/ AIST, [3]Ricoh Japan Corporation, [4]Department of Earth and Environmental Sciences, Yamagata University, [5]Technical Research Institute, Obayashi Corporation, [6]Faculty of Science and Technology, Tokyo University of Science

A small stock of leucocratic Grt-two mica granite enriched in high field strength elements (HFSEs) has recently been found in the Kanamaru?Oguni district of the Asahi?Iide mountains in the Ashio Belt of the NE Japan arc. The granite has a high-K peraluminous composition, and is categorized as an A-type within-plate granitoid, according to several geochemical discriminants based on HFSEs. However, total Zr+Nb+Ce+Y contents are lower (166-192 ppm) and Rb/Ba ratios are higher (19-48) than those typical of A-type granitoids (Zr+Nb+Ce+Y $>$350, Rb/Ba $<$10). This suggests that this stock is in fact a highly fractionated granite, rather than an A-type intrusive. The stock solidified at shallow depth (about 3 - 6 km) from a silisic granitic magma, under moderately water-rich conditions. Geochemical modeling shows that the petrogenesis of the granite can be explained by partial melting of crustal rocks, leaving abundant plagioclase as a residual phase, with subsequent active fractional crystallization of plagioclase + alkali-feldspar. Many other small stocks composed of Grt-two mica granite occur in the Asahi and Iide mountains. The granitic activity ranges from Late Cretaceous (ca 90 Ma) to Paleogene in age. Although most of these stocks were derived from melting of various crustal rocks, some are highly differentiated, and have HFSE concentrations similar to the Kanamaru-Oguni stock studied here.

HFSE-rich granitoids also occur sporadically within the other Japanese geological units, but they are restricted in the southwestern Japan. The granitoids in the Inner and Outer Zones of SW Japan differ in composition. The HFSE-rich granitoids in the Inner Zone originated from middle to lower crustal materials, and were then strongly differentiated before emplacement. This is similar genesis to the granite in the Kanamaru?Oguni district. In contrast, the solitary HFSE-rich granitoid in the Outer Zone crops out at Cape Ashizuri. This occurrence is the only classic A-type intrusion in Japan, and is considered to have formed by a low degree of partial melting of the upper mantle or mafic lower crust. Although the HFSE-rich granitoids within the SW Japan arc may be similar geochemically to within-plate or ocean-ridge granites, they are in fact volcanic arc granites produced within the subduction zone by specific activities.

Rare earth element compositions of the Kitahata body in the Fukae granite, northern part of Kyushu

KAWANO, Yoshinobu[1*]

[1]Department of Environment Systems, Faculty of Geo-environmental Science, Rissho University

Cretaceous granitic rocks are widely distributed in northern part of Kyushu (Karakida, 1985), and Fukae granite is located in Kitahata district, Karatsu city, Saga Prefecture. The Fukae granite in this area (hereinafter, Kitahata body) consists of granite, aplite and felsic inclusion. The felsic inclusion is an oval figure about 50 cm in diameter, and is gradually changing from the surrounding granite. Main constituent minerals of the Kitahata body are quartz, k-feldspar, plagioclase and biotite, with apatite, zircon, opaque minerals as accessories. K-Ar biotite age of the body is 95.8+/-2.4 Ma (Kitahata village history compilation committee, 2008). Rare earth element compositions are analyzed about ten samples, for comparison with estimated result of Kawano (2013).

In chondrite normalized REE patterns, values of LREE of the Kitahata body are the highest, and, aplite and felsic inclusion are lower than them. Normalized La/Lu ratios of the Kitahata body are also higher than those of the aplite and the felsic inclusion. Although the negative abnormalities of Eu are not observed in the Kitahata body and the felsic inclusion, it is clearly observed in the aplite. That is, Eu/Eu∗ratio of the aplite is low and the Kitahata body and the felsic inclusion show a similar value. SiO_2 contents increase from the Kitahata body to the felsic inclusion and the aplite. The values of LREE and La/Lu ratio of the felsic inclusion and the aplite which are rich in SiO_2 are lower than those of the Kitahata body, and it is suggested that they have the different origin from the Kitahata body. Although aluminum saturation index of the Kitahata body is larger than 1.0, it of the felsic inclusion is less than 0.9 and shows the character of meta-aluminous. The origin of the felsic inclusion not be considered to be a sedimentary rock, but it may originate in different felsic magma.

Petrographic and geochemical studies of granitoids from the Inbi intrusives, Inner Zone of Southwest Japan

SATO, Kei[1*] ; KAMEI, Atsushi[2] ; MINAMI, Masayo[1] ; ASAHARA, Yoshihiro[3] ; KATO, Takenori[1]

[1]Center for Chronological Research, Nagoya University, [2]Department of Geoscience, Shimane University, [3]Department of Earth and Planetary Scicences, Nagoya University

We report a data set of whole rock compositions of seven granitoids from the early Paleogene Inbi intrusives and a granitoid from the mid Paleogene Namariyama intrusives, Inner Zone of Southwest Japan. The Inner Zone where voluminous granitic plutons occur is subdivided from the north to the south into three areas in terms of mineralogical and petrological characteristics of granitoids: the San-in Belt, the San-yo Belt, and the Ryoke Belt. The examined Paleogene intrusives, which belong to the San-in Belt, show volcano-plutonic association on the eastern side of younger Daisen volcano at the southern part of Tottori Prefecture and the northern part of Okayama Prefecture [e.g. 1-5].

Seven early Paleogene granitoids were collected from three plutons of the Inbi intrusives: Tottori granite, Ningyo Toge granite, and Sangenya granite [4]. Minerals in polished thin sections were first described under microscope. All of the granitoids from the Inbi intrusives contain quartz, feldspars, biotite and iron oxide. Most of them except for Tottori granite contain amphibole. Sphene is found as accessory mineral in some thin sections.

Each mixture of lithium tetraborate and powdered rock was put into a platinum crucible, and then ignited in a furnace at 1000 degree-C and cooled for preparing a glass bead. And then, major and trace elements were measured using XRF analyzer. To prepare sample solutions for measuring trace elements including REEs, the powdered rocks were first digested in a PTFE beaker with HF/HClO4 mixture on a hotplate at 120-140 degree-C, and then residue probably including heavy minerals such as zircon was dissolved in sealed high-pressure container with HF/HCl mixture at 180 degree-C. The first step decomposed fraction and residual one were well-mixed, and then this mixture was split into two aliquots: one was separated from other elements using a quartz column filled with cation exchange resin for measuring REEs, and the other aliquot was for analysis of trace elements except for REEs. These solutions were analyzed using ICP-MS.

Chemical analyses for whole rock compositions of seven Inbi granitoids yielded the following results. Molecular Al2O3/(CaO+Na2O+K2O) values are given as I-type with a range from 0.96 to 1.10. Relationship of Na2O+K2O vs. total FeO vs. MgO shows calc-alkaline series on AFM diagram. SiO2 content ranges from 65.7 wt% to 73.4 wt%, and relationship between Si and other major elements gives clear differentiation trend on Harker variation diagrams. Five samples of the granitoids are categorized as high-K series. Many granitoids in this area suffer weathering. The resulting in weathering yields a decrease of CaO (from 2.5 wt% to 1.7 wt%) and Na2O (from 4.1 wt% to 3.6 wt%) for Ningyo Toge granites. Whereas Sangenya and Ningyo Toge granites contain about 200 to 360 ppm Sr, Tottori granite contains only 90 ppm Sr. The values of Ti normalized by the mean MORB composition [6] against seven granitoids yield a trend of depletion in Ti. Those of REEs normalized by the MORB composition are given as enriched LREE pattern, negative Eu anomaly, and relatively flat MREE and HREE patterns. All of these normalized patterns have characteristics as volcanic arc granites [e.g. 7].

Petrology of ultramafic rocks in the Gosaisho series, northeastern Japan: Is the Gosaisho series the SSZ ophiolite?

SATO, Yuki[1*] ; ISHIWATARI, Akira[2]

[1]Dept. Earth Sci., Grad. Sch. Sci., Tohoku Univ., [2]Center for NE Asian Studies, Tohoku Univ.

The Abukuma plateau, which extends ˜180km in N-S and ˜50km in E-W directions, is located along the Pacific coast of northeastern Japan. This plateau is composed mainly of Cretaceous granitic rocks and regional metamorphic rocks. In the Gosaisho-Takanuki district that is located in the central part of the plateau, the Gosaisho metamorphic rock series in the east overthrust onto the Takanuki metamorphic rock series in the west (e.g. Umemura, 1979). The Gosaisho series is mostly composed of mafic and siliceous rocks, and the Takanuki series is mainly composed of pelitic-psammitic rocks. In the Gosaisho series, many small ultramafic bodies are present in the areas adjacent to the Takanuki series. Metamorphic rocks in the Abukuma Plateau have been well studied since the late 19th century, excepting these ultramafic rocks.

The ultramafic rocks in the Gosaisho-Takanuki distinct are affected by contact metamorphism of the Cretaceous granitic rocks in various degrees, but their protoliths are judged as mantle peridotites and ultramafic cumulates based on their bulk rock chemistry. The ultramafic cumulates are sometimes accompanied by metagabbros. In an ultramafic body called Mount Ohtsube, mantle peridotites are distributed at the foot of the mountain and cumulates occupy its top part. It is likely that the ultramafic bodies in this area are the fragments of the lower part of an ophiolite. We also note that cortlandites and associated gabbroic rocks are present in this area. They are always contained in granitic bodies, and it is likely that intrusion of cortlandites coincided with the Cretaceous felsic magmatism.

The bulk rock chemistry of the peridotite is poor in Ca and Al contents (CaO $<$0.6 wt. %, Al_2O_3 $<$1.6 wt. %). This suggests that they are highly depleted mantle peridotite. On the one hand, Cr# of spinel in the peridotite, which supposedly correspond to the degree of mantle depletion, show a wide range (14 - 87) from place to place. The spinel is poor in Ti content (TiO_2 $<$0.2 wt. %). These characteristic features of spinel suggest that the mantle section was of arc origin (Arai et al., 2011). This is consistent with the bulk rock chemistry of the associated metagabbro which is rich in Ca and Al, and poor in Ti contents (CaO = 11.6 - 17.0 wt. %, Al_2O_3 = 13.8 - 18.5 wt. %, TiO_2 = 0.06 - 1.06 wt. %). It is also noteworthy that some ultramafic cumulates are very rich in Fe (up to Fo = 73).

In the Gosaisho series, siliceous rock contain early Jurassic radiolarian fossils (Hiroi et al., 1987). In addition, some low-grade metamorphic rocks show original pillow structure (Nohara and Hiroi, 1989). Hiroi et al. (1998) argued that the Gosaisho Series represents the mid-ocean ridge origin oceanic crust which overthrust onto the terrigenous Takanuki Series. However, in some places, there are calc-alkaline intrusions which have experienced regional metamorphism with the country rocks (Umemura, 1970). This is consistent with our idea that the ultramafic rocks are of arc origin. Therefore, it is suggested that the Gosaisho Series is the arc-related, supra-subduction zone ophiolite which thrust onto the Takanuki Series in the Jurassic period. However, it is also possible that the early Paleozoic Hayachine-Miyamori ophiolite (e.g. Machida and Ishiwatari, 2013). Comprehensive study of mafic and ultramafic rocks in the Gosaisho series is needed to solve this problem.

Experimental petrology of Goseong volcanoes,Korea

FUJINAGA, Nozomi[1*] ; SANO, Takashi[2]

[1]Graduate School of Geo-environmental Science, Rissho University, [2]Department of Geology and Paleontology, National Museum of Nature and Science

Genozoic volcanoes with composition of alkali basalts are widely distributed in Southwest Japan, Korea, and East China.On the basis of geochemical studies, several models to explain magma origin of the alkali basalts were proposed (e.g., upwelling of hot asthenosphere, melting of stagnant slab, and so on).However, little is known about differentiation processes for the alkali basalts based on petrological studies.We therefore performed a series of experimental determinations of melting relation in alkali basalts on Goseong volcanic field, Goseong-do, Korea.Goseong volcanic field consists of seven volcanic plugs, and some of them are accompanied by lava flows.We have carried out petrological studies on alkali basalts from all the seven plugs.The alkali basalts have phenocrysts of olivine and augite and microphenocryst of spinel.Whole rock compositions show that the alkali basalts are relatively primitive (FeO/MgO $<$0 and MgO $>$11 wt %), and mineral chemistry supports this (Forsterite content in olivine $>$87).The most primitive rock was selected for melting experiments at 1110-1220 ℃ and 1 bar under the oxygen fugacity along the fayalite-magnetite-quartz buffer.The experimental results show that mineral assemblage (olivine, spinel, and plagioclase) is different from natural one (olivine, spinel, and augite), indicating that crystallization pressures were probably higher than the melting pressure (1 bar).Thus, we will conduct melting experiments at high pressures in future work.

Metamorphic evolution of garnet-sillimanite gneiss from Ambatofotsy region, Antananarivo domain, east-central Madagascar

ICHIKI, Takashi[1*] ; ISHIKAWA, Masahiro[1]

[1]Yokohama National University

Madagascar is situated within the central part of the Neoproterozoic East African Orogen (EAAO: Jacobs and Thomas, 2004) that marks the join between East and West Gondwana. Therefore, Madagascar is one of the most significant areas to understand the process of Orogen formation. In this study we report the newly found inclusion of kyanite + staurolite + muscovite + rutile in garnet and the mode of occurrence and discuss the metamorphic evolution of the garnet-sillimanite on the basis of estimated results by using various geothermobarometers and phase equilibrium by constructing psuedosection.

The Antananarivo domain is mainly composed of the felsic metamorphic rocks with subordinate amounts of the metasedimentary rocks (Tucker et al., 2012). There exposed magnetite-orthopyroxene-quartz gneiss (metamorphosed banded iron formation), garnet-orthopyroxene rock and garnet-hornblende-biotite gneiss around the garnet-sillimanite gneiss in the eastern part of the domain. The garnet-sillimanite gneiss is mainly composed of garnet, sillimanite, k-feldspar, plagioclase, and quartz with subordinate amounts of biotite, muscovite, monazite, zircon, rutile and graphite. Sillimanite is present in the matrix and as inclusion in garnet. Kyanite is only present as inclusion in garnet. Garnet (X_{Mg}=0.17-0.18) also contains spinel and abundant quartz and monazite inclusions. Spinel shows Mg poor (X_{Mg}=0.21-0.22) and Zn rich (ZnO = 18.4-19.0 wt.%) compositions. We newly found kyanite + staurolite + muscovite + rutile in the garnet. This staurolite shows Mg poor (X_{Mg}=0.12) and Zn rich (ZnO=3.1 wt.%) composition. Garnet is replaced rim of grain by radial aggregate of biotite (X_{Mg}=0.58) + sillimanite.

As a result of the petrographic observation, the metamorphic condition of the garnet-sillimanite gneiss was increased from the stability field from staurolite + quartz to garnet + kyanite (Spear and Cheney, 1989). Garnet + sillimanite + spinel + quartz was stable during the peak metamorphic condition. The estimated peak pressure and temperature condition is ca. 800 ℃ at 0.9 GPa by using garnet-sillimanite-plagioclase-quartz geobarometer (Spear, 1993) and garnet-sillimanite-spinel-quartz geothermobarometer (Nichols et al., 1982) with garnet activities calculated after Berman (1990). Garnet is replaced rim of grain by radial aggregate of biotite (X_{Mg} = 0.58) with sillimanite. This reaction is hydrous reaction from garnet + k-feldspar + H_2O to biotite + sillimanite + quartz with decreasing temperature (Le Breton and Thompson, 1988). This retrograde metamorphic condition is almost consistent with the estimated P-T condition from the garnet-hornblende-biotite gneiss. The estimated pressure and temperature condition is ca. 700 ℃ at 0.6 GPa by using garnet-hornblende geothermometer (Graham and Powell, 1984), hornblende-plagioclase geothermometer (Holland and Blundy, 1994) and garnet-hornblende-plagioclase-quartz geobarometer (Kohn and Spear, 1990). In summary we newly identified the clockwise P-T path from the garnet-sillimanite gneiss exposed in Ambatofoty region, eastern part of the Antananarivo domain.

Petrogenesis of garnet-clinopyroxene rocks from the Gondwana collisional orogeny

TAKAMURA, Yusuke[1*] ; TSUNOGAE, Toshiaki[1] ; IINUMA, Minako[1] ; KOIZUMI, Tatsuya[1] ; SANTOSH, M.[2] ; MALAVIARACHCHI, Sanjeewa[3]

[1]Univ. Tsukuba, [2]China University of Geosciences Beijing, [3]Univ. Peradeniya

Madagascar - Southern India - Sri Lanka - East Antarctica region, which is regarded as a part of the East African - Antarctic Orogenic Belt formed by complex subduction-accretion-continent tectonic events related to the amalgamation of Gondwana Supercontinent during Neoproterozoic, is characterized by the presence of major suture zones (e.g. Palghat-Cauvery Suture Zone in southern India) which correspond to paleo-plate boundaries formed by the closure of Mozambique Ocean at ca. 530-550 Ma. The dominant lithologies of the suture zones are felsic to intermediate orthogneiss, metasediments, and mafic-ultramafic suites. Particularly, the occurrence of mafic-ultramafic suites (ophiolite or layered intrusion) is a unique character of the suture zones compared to surrounding granulite blocks and cratons. Here, we report new petrological and geochemical data of metagabbroic garnet-clinopyroxene rocks from Sri Lanka and discuss its petrological implications. Mineral assemblages of the rocks are garnet + clinopyroxene + orthopyroxene + ilmenite + hornblende + plagioclase (type 1), and garnet + plagioclase + clinopyroxene + orthopyroxene + quartz + ilmenite (type 2). Type 2 rock shows a decompression texture of orthopyroxene + plagioclase symplectite formed by a reaction: garnet + quartz=>orthopyroxene + plagioclase. Similar rocks and textures have been reported from the Palghat-Cauvery Suture Zone in South India (Nishimiya et al., 2008; Sajeev et al., 2009; Saitoh et al., 2011), Highland Complex in Sri Lanka (Osanai et al., 2006), and Lutzow-Holm Complex in East Antarctica (Saitoh et al., 2012). Temperature and pressure conditions inferred for the type-1 Sri Lankan metagabbro based on pseudosection analysis in NCFMASHTO system is 970-1040C and 8-10.5 kbar, which is significantly lower in pressure than the results of Osanai et al. (2006) (>18 kbar, >1000C). Recent petrological and geochemical studies of the Palghat-Cauvery suture zone in southern India suggest that similar metagabbros and related mafic-ultramafic suites occur as various blocks within ortho- and paragneisses as melange. Similar occurrences and P-T evolution of metagabbro bodies in several Gondwana fragments suggest that the Palghat-Cauvery Suture Zone might continue to the Lutzow-Holm Complex (East Antarctica) through Highland Complex (Sri Lanka).

Neoarchean and Middle Neoproterozoic bimodal magmatism in the Gondwana orogeny, South India

KOBAYASHI, Airi[1*] ; TSUNOGAE, Toshiaki[1] ; KOIZUMI, Tatsuya[1]

[1]Univ. Tsukuba

Detailed petrological investigations for bimodal association of basaltic and rhyolitic magmas, which is regarded to have formed at subduction or rift zones, provides important information to investigate magma petrogenesis and tectonic evolution in a convergent or divergent margin settings. Here, we report first preliminary petrological and geochemical data of the Neoarchean charnockite-mafic granulite association in the Madras Block and Middle Neoproterozoic granite-amphibolite association in the Mesoarchean Coorg Block, southern India. Irregular-shaped mafic granulite (basaltic andesite) occurs as blocks of about tens of centimeter within charnockite (dacitic) in the Madras Block, while amphibolite (basaltic trachy-andesite) blocks in the Coorg Block are surrounded by sub-alkaline granite. Although there is no obvious texture of magma mixing in the Madras samples probably due to post-magmatic high-grade metamorphism and complete recrystallization, plagioclase in the contact zone between mafic enclave and host granite from the Coorg Block shows oscillatory and dusty zonings, which might suggest bimodal magmatism in Middle Neoproterozoic divergent margin in southern India.

Infiltration of CO_2-H_2O binary fluid and formation of patchy charnockite from Southern India

ENDO, Takahiro[1*] ; TSUNOGAE, Toshiaki[1] ; M., Santosh[2]

[1]Univ. Tsukuba, [2]China University of Geosciences Beijing

Since the first discovery of patches, veins and ladders of coarse-grained orthopyroxene-bearing felsic granulite (incipient charnockite) within foliated amphibolite-facies gneiss from Kabbal in Karnataka, southern India, by Pichamuthu (1960), the origin and petrogenesis of charnockite and its implications for granulite processes in lower crust have been the focus of many petrologists. According to previous studies, charnockite formation in the SGT is considered to have resulted by the infiltration of CO_2-rich anhydrous fluids along structural pathways within upper amphibolite-facies gneisses, resulting in the lowering of water activity and stabilization of orthopyroxene through breakdown of biotite (e.g. Janardhan et al., 1979; Newton et al., 1980; Hansen et al., 1987; Santosh et al., 1990; Newton, 1992; among others).

This study presents new petrological data of ‘ incipient ’ charnockite developed within garnet-biotite (Grt-Bt) gneiss from Kakkod with the western Trivandrum Granulite Block (TGB), India. In this locality, bulk rock compositions of charnockite and the host Grt-Bt gneiss are almost equivalent. The result of conventional geothermobarometry using Grt-Opx-Pl-Qtz assemblage shows the peak metamorphic condition of 860-960 ℃ and 6.9-8.4 kbar, which is consistent with the results of mineral equilibrium modeling. The metamorphic condition certainly corresponds to granulite-facies event, and it is higher than those reported from other incipient charnockite localities in the TGB and adjacent Nagercoil Block. Furthermore, the estimated metamorphic condition is too high for the stability of the host Grt-Bt gneiss that contains a mineral assemblage formed at amphibolite-facies condition. In addition, althought pseudosecondary fluid inclusions are composed of pure CO_2, secondary fluid inclusions contain CO_2-H_2O binary fluid. Therefore, patchy chanorckite in Kakkod from the TGB is considered to have formed by infiltration of CO_2-H_2O binary fluid during a retrograde stage. The petrogenetic model of incipient charnockite formation proposed in this study is therefore different from reported petrogenesis from other localities.

Relationship of zeolites and host rocks

SHIMIZU, Kouhei[1*] ; YASUI, Mana[2]

[1]Department of Natural Sciences, Faculty of Knowledge Engineering, Tokyo City University, [2]Department of Resources and Environmental Engineering, Waseda University

Natural zeolites occur in various rocks, such as igneous rocks, sedimentary rocks, and metamorphic rocks, at surface and shallow zone of upper crust.

In this research, the relationship between chemical composition of the host rocks and zeolite species are discussed in terms of the basis of chemical analysis of samples from Izu Peninsula and the Chichijima of Ogasawara (Bonin) Islands.

Although origin relations between the microscopic zeolite species and host rock compositions are seen under the conditions of low water/rock ratio, like a burial diagenesis, low degree regional metamorphism, and contact metamorphism, it has reported that macroscopic crystals occur in veins and geodes, not controlled by host rock composition, as they produced under the conditions of high water/rock ratio of hydrothermal alteration, in a previous work. (Utada 1995)

Result and discussion

The identification of the zeolites species are characterized by X-ray diffractometry and bulk rock chemical composition of host rocks are analized by X-ray fluorescence.

To research 10 pointss of Chichijima (Ogasawara islands) and 2 points of Izu Peninsula, eight kinds of zeolite (Heulandite, Analcime, Chabazite, Mordenite, Erionite, Phillipsite, Stilbite and Yugawalite) were able to be identified.

Samples from Chichijima, Stilbite was detected on Miyanohama, Hatsuneura north side, Hatsuneura south side, Suzaki, Buta seashore, and Kin-shi beach.. Stilbite did not occur on the samples from other 4 points

As a resalts Si/Al ratio of the host rocks are clearly different between the points of Stilbite occured and not occured, Si/Al ratio of former rocks were 5.248˜7.672, the latter rocks were 4.230˜4.768. The boundary of Stilbite occurrence S1/Al ratio of host rock seems to be around 5. . In the Chichijima (Ogasawara islands), correlation was found between host rocks and formed zeolites.

Three pyroxene andesite (pigeonite-augite-hypersthen andesite) from Hakone volcano

ISHII, Teruaki[1*]

[1]Fukada Geological Institute

Pigeonite phenocryst bearing volcanic rock is very rare in the world. Pigeonite-augite-hypersthen andesite (= three pyroxene andesite or pigeonite andesite) from Hakone volcano is very famous according to the detailed studies on the pyroxenes using microscope by the late professor Kuno (Kuno 1935, Kuno 1936).On the bases of the detailed EPMA analyses of the pyroxene crystallization sequences as well as estimated magmatic temperatures using pyroxene geothermometer, for the pigeonite andesite, the author suggests the following working hypothesis, i.e. the pigeonite andesit was induced by magma mixing between three pyroxenes andesite magma (about 1070 degree C) originated from the primitive high temperature hydras tholeiite magma within secondary magma reservoir opened for water, and the high temperature magma (about 1110 degree C) in the secondary magma reservoir. The key concept is that cocrystallization of three pyroxene phenocrysts under open system for water in the secondary magma reservoir.

The structural water in hydrothermally synthesized monazite

ABE, Takeyasu[1*] ; NAKAMURA, Michihiko[1]

[1]Department of Earth Sciences, Tohoku University

Introduction: The U-Th-Pb dating of accessary minerals such as zircon and monazite is widely applied for various types of rocks [1,2,3]. There has been proposed another method to obtain geochronological information from these minerals: quantifying the degree of metamictization (destruction of crystal structure by radioactive components). It is reported for zircon that the water content (up to 10 wt%) is in proportion to the degree of metamictization, thus to the concentration of radioactive nuclei and geological age[4]. Monazite on the other hand usually undergoes much less metamictization than zircon due to the higher bond strength of P and O compared to that of Si and O; this results in the lower water content in the metamictized monazite. Determination of the structural water content in monazite without radioactive damage is thus necessary to constrain the ”initial” water content prior to hydration. The water content bears significance also for better understanding the crystal chemistry of monazite. In this study, we synthesized monazite single crystals at hydrothermal condition and determined the content of structural water as a function of pressure.

Experimental method: The hydrothermal synthesis of monazite was conducted at a temperature of 800 degC and pressures of 1.5, 10 and 15 kbar using a cold-seal pressure vessel and a piston cylinder apparatus. The $CePO_4$ reagent was encapsulated with H_2O or H_2O-NaCl solution and run for ca. 100 hours. The FT-IR analyses of the obtained monazite single crystals were conducted to determine the concentration of structural OH on the basis of Lambert-Beer’s Law. The molar absorption coefficient was estimated by linear calibration curve against the OH stretching vibration wavenumber [5].

Results and Discussion:The broad absorption band was observed at 3100-3600 cm^{-1} in the crystals synthesized in all the experimental conditions. The water content of synthesized monazite was estimated approximately to be 20-70 ppm, showing no large pressure dependence. FT-IR analyses of pleochroic absorption are on-going to determine the OH dipole orientation within the crystal structure.

Phase relation in ternary feldspar system at high temperature

KODAMA, Yu[1*] ; MIYAKE, Akira[1] ; HOKADA, Tomokazu[2] ; KAWASAKI, Toshisuke[3]

[1]Kyoto Univ., Sci., [2]National Institute of Polar Research, [3]Ehime Univ., Sci.

During cooling of rocks or by change of chemical composition of feldspar, feldspar transforms to other polymorphs and forms various micro-textures. Observing micro-textures of feldspar is a useful approach to give a constraint to the thermal history of the rock. It has been known that the feldspars in ultrahigh-temperature (UHT) metamorphic rocks have ternary feldspar (Tfs) composition and those have the various and complex microtextures. However, the occurrence and the formation process of micro-textures in Tfs had not been studied in detail and they could not be interpreted by the widely used phase diagram with 2nd-order C2/m-C-1 phase transition at high temperature. And furthermore, although many experimental studies were performed, with respected to the phase relation on the plagioclase feldspar and alkali feldspar systems, the detailed experiments for the phase relations in the An-Ab-Or ternary feldspar system were restricted and its phase relations still remain ambiguous. Due to the high crystallization temperature of ternary feldspar (Tfs), Tfs would preserve the information about thermal history in more detail than those recorded on alkali feldspars and plagioclase feldspars. Previous thermodynamic studies on the C2/m - C-1 phase transition (Kroll et al., 1980; Salje et al.1985, Carpenter, 1988) were carried out using the in situ powder X-ray experiments on pure Ab compositions. Due to the spatial resolution of analytical instruments, they missed the formation of the micro-texture on C2/m - C-1 phase transition. In this study, high temperature and high pressure experiments were carried out to decide the phase relation at high temperature including the phase relation between the C2/m and the C-1 in the An-Ab-Or ternary feldspar system at 1100 - 1300C and 10 kbar. We reveal the formation process of complex micro-textures of Tfs in UHT metamorphic rock by the present phase diagram.

We employed mixture of powdered lamellae-free oligoclase and sanidine crystal as starting materials. Bulk composition of starting materials was prepared by varying ratio of oligoclase and sanidine. We focused whether micro-textures derived from the C2/m - C-1 phase transition were formed or not. Experimental products were observed using field emission scanning electron microscopy (FE-SEM, JEOL JSM-7001F) and annular dark-field scanning transmission electron microscopy (ADF-STEM, JEOL JEM-2100F) to observe micro-textures.

Exsolution lamellae by a compositional gap between the C2/m and the C-1 which has near (010) interface, were observed in the run products synthesized at 1100 - 1200C. This result strongly suggests that the C2/m - C-1 transition is the first order phase transition. Moreover, the glass phase was observed in run products synthesized at 1250 - 1300C. From these experimental results, we propose the phase diagram on the Olg (An25Ab75) -Or pseudo-binary.

Napier Complex in northern Enderby Land, East Antarctica is one of the most famous regional ultrahigh-temperature (UHT) metamorphic terranes in the world. Although Tfs in Napier Complex has the complex microtextures (e.g., Harley 1985; Sheraton et al. 1987; Hokada, 2001), the occurrence and the formation process of micro-textures in Tfs have not been understood in detail. By the phase diagram obtained in the study, the formation process of Tfs in the felsic gneiss and the micro-texture in Tfs were revealed as following process. At first heterogeneous distribution of Olg, Tfs, and myrmekite-like textures were result of melting of the felsic gneiss and following crystallization. And then, the peak metamorphic temperature is estimated to be at least 1200 - 1250C. At the cooling process, the complex exsolution textures of Tfs are composed of (010) coarse lamellae derived from C2/m - C-1 first order phase transition and (-901) fine lamellae derived from spinodal decomposition.

Quantitative Analysis of Rock Samples by ICP-Quadrupole Mass Spectrometer (QMS)

AJIRO, Takuya[1*] ; OOKI, Seigo[2] ; CHAKO TCHAMABE, Boris[3] ; OHBA, Takeshi[2]

[1]Cource of Chemistry, Graduate School of Science, Tokai University, [2]Department of chemistry, School of Science, Tokia University, [3]School of Science and Technology, Tokai University

ICP-Quadrupole Mass Spectrometers (QMS) can analyze multi-element quickly with high sensitivity. One problem is the interference by polyatomic molecules. For example, polyatomic molecules, such as ArO and ArCl, obstruct the analysis of Fe and As, respectively. In order to remove polyatomic molecules, ICP-QMSs using the collision gas was developed. For collision gas, generally inert gas such as He gas has been used. In this study, we try to analyze major and trace elements of standard rocks and volcanic rocks of Cameroon Volcanic Line by a ICP-QMS with He collision cell.

The iCAP-Q (ThermoScientific Inc) was selected for study. The plasma was operated at 1.7 kW and 27 MHz. The flux of Ar was about 16 L/min. The sampling cone can be removed easily without any tools and cleaning procedure is simple. The plasma gas, which is injected to vacuum system, is bended to 90 degree by an ion lens and reach to He Collision Cell. Neutral molecules are removed efficiently by the ion lens. Helium collision cell has a function as small QMS, removing interfering ions lighter than target element. The polyatomic molecules are also removed due to the reduction of their kinetic energy with He collision. The ions passing He collision cell go to the main QMS and their signals are detected by analog or pulse detections.

We used three standard rocks (JA-2, JB-2, and JB-3) and volcanic rocks at Borombi Mbo Volcano, Cameroon. The 50 mg of rock powder was put into 100 mL Teflon digestion vessel with 2.0 mL of 35 wt% HCl, 1.0 mL of 60 wt% $HClO_4$, and 0.5mL of 50 wt% HF. The vessel was set in microwave heating system (Multiwave 3000, Parkin Elmer Inc.). The microwave power was increased to 500 W by 50 W/min and kept over 60 min. After heating, the digestion vessel was cooled down to 50 ℃. In the cooled vessel, 2.5 mL of saturated H3BO3 water and 2.5 mL of pure water were added, and the vessel was heated by microwave heating system again. The micro wave power was increased to 1400W by 280 W/min and kept for 20 min. After cooling, pure water was added to the sample solution and total volume was adjusted to 50 mL.

Yields of major elements in standard rocks, except for Si, were almost more than 70 %. In case most of trace elements, those were also more than 70%. Furthermore, there was no significant difference in the yield of most elements when we analyzed several times for a common sample. It is found that major elements, except Si, and most of trace elements of volcanic rocks can be analyzed by using a single ICP-QMS. In case of volcanic rock samples of Cameroon, type of these samples were identified to be an alkali basalt based on Nb/Y versus Zr/TiO_2 diagram. This result is consistent to the previous study on Cameroon Volcanic Line (A. Marizoli et al., 2000).

Validation of mass attenuation coefficients in quantitative electron probe microanalysis (EPMA)

KATO, Takenori[1*] ; JEEN, Mi-jung[2] ; CHO, Deung-lyong[3] ; SATO, Kei[1]

[1]Center for Chronological Research, Nagoya University, [2]Center for Research Facilities, Pusan National University, [3]Geological Mapping Department, Korea Institute of Geoscience and Mineral Resources

Mass attenuation coefficients (m.a.c.s) are important factors of accuracy in quantitative electron probe microanalysis (EPMA). New m.a.c.s are calculated from the latest version of two datasets[1][2] for Z = 1 - 92. The combination of two datasets solves the problems within them, such as spurious discontinuity and unnatural increase at high-energy sides of absorption edges. New m.a.c.s improve accuracy including geological applications.

SEM-EDS Automated Particle Analysis of Mineral Compositions of Rocks

MUTOU, Hitomi[1*] ; SHIMADA, Aiko[2] ; ONODERA, Hiroshi[3]

[1]JEOL Ltd.SM APPLICATION DEPARTMENT SM BUSINESS UNIT, [2]JEOL RESONANCE Inc. SM APPLICATION DEPARTMENT, [3]JEOL Ltd.SA APPLICATION DEPARTMENT SA BUSINESS UNIT

Rocks consist of various kinds of minerals depending on their localities and formation processes. Mineral compositions of rocks are very important to study their sources and formation processes. X-ray fluorescence analysis (XRF) is commonly needed for mineral composition analysis. The XRF analysis provides the average composition of elements in a rock. Analysis of mineral particles in a rock is sometimes more important to find features of a rock. However, the analysis of a large number of mineral particles in a rock one by one requires a great deal of time. In recent years, the automated particle analysis combined with a scanning electron microscope (SEM) on energy dispersive X-ray spectrometer (EDS), which is called SEM-EDS automated particle analysis has rapidly been advancing. This method enables fast analysis of a large number of particles one by one directly.

In this report, analysis of the mineral compositions of two rocks -the Koujaku granite and the Hakkoda second-stage pyroclastic flow deposition (Ht2) - was carried out with SEM (JSM-IT300LA, JEOL)-EDS (JED2300, JEOL) automated particle analysis. The samples for this analysis were prepared as follows: rocks were crushed separately and each crushed rock embedded in resin was polished. More than a few thousand particles of the rocks were analyzed. In the Koujaku granite, quartz was a dominant constituent. K-feldspar and alkali feldspar were contained in a higher concentration than plagioclase. In addition, some colored minerals were contained. In the Ht2, pumice was a dominant constituent. In addition, quartz, feldspar and some colored minerals were contained. Additionally, many particles in the Ht2 consisted of multiple minerals unlike in the Koujaku granite. In the presentation, we will give more detailed descriptions of minerals and their components of the rocks.

Dependence of water concentration distribution of columnar joints formation in analogue experiments

HAMADA, Ai[1*] ; TORAMARU, Atsushi[2]

[1]Earth and Planet. Sci., Kyushu Univ., [2]Earth and Planet. Sci., Kyushu Univ.

Columnar joints of igneous rocks and ignimbrites have various morphological patterns. As their unit structure, column structure can be classified in terms of straight or curved. Columnar joint is formed by volume contraction due to cooling and tensile stress accumulated inner the volume is released as sequentially cracks according to the temperature gradient during cooling. Basic research to explain how curved columns are formed has not been conducted. In this study, we report the results of reproducing curved structure in analogue experiments by drying starch and water mixture. We put the mixture into a cylindrical container and light a lamp (60W) 1.5cm above the surface of mixture. We take images with X-ray CT of the specimen before drying perfectly and observe the spatial distribution of water concentration of the mixture on the way to form columnar joints. As a result, we recognize that water concentration distribution at a depth in mixture increases with the horizontal distance from just below the lamp. The direction of crack developing from the surface of the mixture to inner is almost perpendicular to the contour of water concentration. We confirm that the effect of heat from the lamp on the surface of the mixture differs with the distance from the lamp and it suggests inhomogeneous water concentration in mixture is caused by the difference of drying rate depending on the distance from the lamp. We also report the relationship between the direction of crack advance and the change of water concentration distribution with time.

Slab-fluids contain chlorine

KAWAMOTO, Tatsuhiko[1*]

[1]Institute for Geothermal Sciences, Kyoto University

We found that the fluid inclusions of sub-arc mantle peridotites have 5.1 wt. % NaCl beneath the Pinatubo, a frontal volcano (Kawamoto et al., 2013 PNAS) and 3.7 wt. % NaCl beneath the Ichino-megata, a rear-arc volcano (Kumagai et al., under review). Based on these observations, we suggest that the slab-derived fluids are saline fluids.

In order to understand the effects of salinity on the arc-magma chemsitry, two series of elemental partitioning experiments between silicate melts and aqueous fluids have been carrying out with and without Cl in synchrotron facilities. The experiments show that highly saline fluids can transfer Pb, Rb, and Cs more effectively than Sr and Ba from subducting oceanic lithosphere to the mantle wedge. As suggested by Keppler (1996, Nature), saline fluids can be an important agent to transfer large ion lithophile elements. Geochemical studies have suggested that three chemical components are involved in the formation of arc-basalts: the depleted mantle, aqueous fluid, and melt components (Pearce et al., 2005 G-cube). If supercritical fluids contain Cl and then subsequently separate into aqueous fluids and melts (Kawamoto et al., 2012, PNAS), then it follows that such aqueous fluids will inherit much of the Cl and also some of the large ion lithophile elements to explain qualitatively the geochemical features of Mariana arc basalts. In contrast, Cl-free aqueous fluids may not be able to transfer Pb to the magma source. Our partitioning experiments were conducted using highly saline fluids (12-25 wt % (Na, K)Cl). Based on the geochemical features, slab-fluids are likely to contain Cl, although their amount remains to be quantified.

Numerical modeling of water-rock reaction with a focus on the earth's surface environment

YOKOYAMA, Tadashi[1*]

[1]Osaka University, Graduate School of Science, Department of Earth and Space Science

Water-rock interaction proceeds by the interplay between dissolution/precipitation, diffusion of ions, and water flow in rock pores. The reaction-transport process in rock is quantitatively described by:

$\phi(\partial c/\partial t) = D_e(\partial^2 c/\partial x^2) - v\phi(\partial c/\partial x) + Ar_0 f(c)$

This equation is an example of the one-dimensional reaction-transport equation, and c is the solute concentration (mol/cm^3), t is the time (s), x is the distance (cm), ϕ is the porosity (dimensionless), D_e is the effective diffusion coefficient (cm^2/s), v is the flow rate in pores (cm/s), A is the surface area per unit volume of rock (cm^2/cm^3), r_0 is the rate constant (mol/cm^2/s). $f(c)$ is the function that expresses the concentration dependence of the dissolution rate (mol/cm^2/s), and for quartz, $f(c)=(1-c/c_{eq})$ (c/c_{eq} is the equilibrium Si concentration) (Scott et al., 2009). By solving the reaction-transport equation, we can know how the distributions of the solute concentration and dissolution rate and the amounts of primary and secondary minerals change with time. Such analysis is called the reactive transport modeling and has been applied to the studies of various processes including soil formation (Maher et al., 2009) and the reactions associated with geologic storage of CO_2 (Xu et al., 2010).

The parameters used in the reaction-transport equation can be estimated by direct measurement in the field, laboratory experiment, and fitting in the modeling. To reproduce natural process accurately, we need to estimate each parameter as precisely as possible. However, it is difficult to evaluate what value is most proper. For example, the reactive surface area A is often determined by measuring the volume of gas adsorbed on the mineral or by approximating the geometry of the mineral. However, the proportion at which the reactive surface area determined by these processes contributes to actual reaction is often unclear. In addition, there are cases where various $f(c)$ have been proposed for a specific mineral and the dissolution rate varies with time (White and Brantely, 2003). In such case it is unclear what equation should be used. Therefore, the way of setting appropriate parameter is one of the main subjects of research.

In water-rock reaction on the earth's surface environment, evaluation of the effect of water saturation is important because water saturation changes dynamically as a result of the occurrence of intermittent drying and infiltration. It has been reported that both the hydraulic conductivity and effective diffusion coefficient in rock decrease with decreasing water saturation and this significantly affects the result of the reactive transport modeling (Yokoyama, 2013). In addition, how water saturation affects the reactive surface area has been revealed recently (Nishiyama and Yokoyama, 2013).

Kinetics of overall silica precipitation within the Earth's crust

SAISHU, Hanae[1*] ; OKAMOTO, Atsushi[2] ; TSUCHIYA, Noriyoshi[2]

[1]AIST, [2]Tohoku University

The kinetics of dissolution and precipitation of silica minerals is important to reveal the geochemical reaction and to estimate how long silica deposits forms in the Earth's crust. The present kinetic equation for silica-water reactions was determined at 0-300 C and in the low Si saturated solution, where quartz growth on quartz surfaces occurs than that of nucleation of silica polymorphs [1]. However, the precipitation experiments of the high Si supersaturated solution showed that the co-precipitation of silica polymorphs via nucleation could occur [2], and the euhedral quartz crystals precipitates without precursor of silica polymorphs from the solution with minor components (Al and Na) [3].

In this study, the overall precipitation rate of silica minerals, which includes surface reaction of quartz (first term) and nucleation of silica polymorphs (second term), is derived empirically to estimate the total amount of silica precipitation within the Earth's crust. The previous kinetic equation of surface reaction [1] is applied as the first term. Based on the precipitation experiments of flow rate, the nucleation-controlled precipitation of silica minerals is expressed in a first order rate equation in the second term. The applicability of the nucleation term determined as the nucleation parameter is only in the conditions that precipitation occurs: in the solution supersaturated with respect to quartz, and in the supercritical conditions of water. The rate constant of nucleation is derived as a function of Al concentration in the solution based on the experiments of silica precipitation [3].

By using the new kinetic equation, silica-water interaction was simulated at the wel WD-1a of the Kakkonda geothermal field, Japan, which penetrated the boundary of the hydrothermal convection and heat conduction zones [4]. Amount of dissolution and precipitation of silica minerals increases with decreasing of the fracture permeability. The largest amount of silica precipitation occurs in the downflow fluid at the permeable-impermeable boundary regardless of the fracture permeability.

The equilibrium consideration [5] and the kinetic results indicate that, if open fractures forms at the depth of the permeable-impermeable boundary, the impermeable zone could be reproduced by precipitation of silica minerals, which cause the sustainable division between the permeable zone and the impermeable zone in the Earth's crust.

Sedimentary pore-fluid origin of H_2O-rich fluid in mantle wedge revealed by halogens and noble gases

KOBAYASHI, Masahiro[1*] ; SUMINO, Hirochika[1] ; NAGAO, Keisuke[1] ; ISHIMARU, Satoko[2] ; ARAI, Shoji[3] ; YOSHIKAWA, Masako[4] ; KAWAMOTO, Tatsuhiko[4] ; KUMAGAI, Yoshitaka[4] ; KOBAYASHI, Tetsuo[5]

[1]GCRC, Univ. Tokyo, [2]Dept. Earth Environ. Sci., Kumamoto Univ., [3]Dept. Earth Sci., Kanazawa Univ., [4]Inst. Geothermal Sci., Kyoto Univ., [5]Dept. Earth Environ. Sci., Kagoshima Univ.

H_2O plays an important role in mantle processes in subduction zones. Yet its subducting processes to the mantle remain unknown because of scarcity of direct observations of H_2O in mantle-derived materials. Since halogen and noble gas are strongly partitioned into ?uids and they show distinct elemental and/or isotopic ratios depending on their origins, their compositions in mantle rocks can provide complementary constraints on the behavior and origin of H_2O in the mantle. Although only few researches have been conducted, the subduction of halogens and noble gases derived from sedimentary pore fluids (seawater trapped in pores of deep-sea sediments) has been suggested. Pore fluid?like halogens and noble gases were found in mantle wedge peridotites which captured H_2O-rich fluids just above a subducting slab [1]. H_2O-rich fluid inclusions whose salinity is similar to that of pore fluids (salinity of pore fluids is the same level as that of seawater [2]) are found in a mantle xenolith from a subduction zone [3]. We investigated halogen and noble gas compositions of mantle wedge peridotites from subduction zones to better constrain how far the in?uence of subducted sedimentary pore fluids extends into the mantle.

The samples studied are harzburgitic xenoliths from the Avacha volcano in Kamchatka and the Pinatubo volcano in the Philippines, and alpine-type peridotite from the Horoman massif in Japan. H_2O-rich ?uid inclusions have been found in olivine of those mantle peridotites [3,4,5].

We applied the noble gas method, in which halogens (Cl, Br, and I) are converted to corresponding isotopes of Ar, Kr, and Xe by neutron irradiation in a nuclear reactor and then the concentrations of noble gas isotopes are determined by noble gas mass spectrometry. Halogen detection limits of this method are from two to ?ve orders of magnitude lower than conventional method, which enable to determine the low halogen abundances in mantle-derived materials. By crushing samples under ultra-high vacuum, noble gases are selectively extracted from H_2O-rich fluid inclusions. Unirradiated peridotites were also analyzed to obtain precise noble gas isotope compositions.

The halogens of all peridotites are heavily enriched in I, although the halogen ratios are distinctive in each locality. These high I/Cl ratios show a strong contribution of sedimentary pore fluids [2]. The noble gases except for He have the elemental and isotopic ratios similar to elementally fractionated atmospheric noble gases dissolved in seawater, which is probably equivalent to those dissolved in sedimentary pore fluids. The $^3He/^4He$ ratios are similar to that of the mantle and distinctly higher than the atmospheric ratio. This indicates that the fluids derived from subducting slabs acquired He from the ambient mantle, where He is much more enriched than in seawater.

These pore fluid?like halogen and noble gas signatures are strong evidence that the H_2O-rich fluids in the studied peridotites are derived from sedimentary pore fluids and transported to the mantle.

Relations among temperature, dehydration of the PHS plate, and a large earthquake, a SSE, and LFEs in the Tokai district

SUENAGA, Nobuaki[1*] ; YOSHIOKA, Shoichi[2] ; MATSUMOTO, Takumi[3]

[1]Graduate School of Science, Kobe Univ., [2]RCUSS, Graduate School of Science, Kobe Univ., [3]NIED

In this study, we performed numerical simulations of temperature distribution at the plate boundary and estimated the dehydration process of hydrous mid ocean ridge basalt (MORB) in the oceanic crust in the Tokai district, central Japan. We discuss the relationships among temperature, dehydration, and a future megathrust earthquake, deep low-frequency earthquakes (LFEs), and a slow slip event (SSE). Our results identified a strongly coupled region for an expected megathrust Tokai earthquake based on temperature conditions at the plate boundary. The depth range of the plate boundary where the megathrust earthquake may occur is 9∼21 km, narrowing toward the east. An SSE is estimated to have occurred in the transition zone between unstable and stable sliding. Hypocentral depths of LFEs deviating from the isodepth contours of the Philippine Sea plate toward the east may be explained by differences in the dehydration process associated with phase transformations in hydrous MORB.

The regional and single-vein scale distribution of the CO2 fluids in the Shimanto accretionary complex, Muroto area, SW

MUSHA, Michimasa[1*] ; TSUCHIYA, Noriyoshi[1] ; OKAMOTO, Atsushi[1]

[1]Enviromnetal Studies of Tohoku University

Carbon dioxide and methane are major carbonic components of the fluids in the crust. The crustal fluids generally have composition of C-H-O system, mainly composed of H_2O, CO_2, and CH_4, and they may be carried down into Earth's interior at subduction zones. Many studies have examined fluid components in various accretionary prisms under low-grade metamorphic conditions, and CH_4 is showed as the only carbonic species. Therefore, there is little information on the variation of the components of C-H-O fluids in subduction zones.

The Tertiary (Paleogene and Neogene system) Shimanto belt, southwest in Japan, is one of the best-studied ancient accretionary complexes. The Muroto Peninsula belongs to the Tertiary Shimanto belt, and it is mainly composed of sandstones, mudstones and conglomerates with small amount of basalt. Mineral veins were mainly composed of quartz, with small amount of calcite near the vein walls, while many studies have showed CH4 is the only carbonic component in the Shimanto belt, therefore it is unclear why calcite precipitated in the veins in absence of CO_2. Lewis (2000) reported the fluid inclusions of CH_4 and CO_2 mixture at one area in the Muroto Peninsula, but the extensive distribution of CO_2 fluids in the whole peninsula is not clear. In this study, we examined the distribution of C-H-O fluids from the Murotohanto Peninsula, as fluid inclusions in the mineral veins, using microthemometry and Laser Raman spectroscopy, in regional scale and single vein scale.

Fluid inclusions from quartz in the veins are composed of one-phase carbonic inclusions (only CH_4) and two-phase aqueous inclusions (carbonic vapor and H_2O liquid). Carbonic components of the vapor phase in the two-phase inclusions are gradually transited from CH4-dominant in the north area of the belt to a CO_2?CH_4 mixture in the south; the $CO_2/(CO_2 + CH_4)$ ratio in mole fraction (X_{CO2}) vary from 0 ˜0.3 in the north area to 0 ˜0.9 in the south.

In single vein scale, we examined single CO_2-bearing vein from the south area of the Peninsula, where X_{CO2} is 0 ˜0.8. The CO_2 ratio in the carbonic species is decreased from the vein wall (X_{CO2} = 0.5?0.8) to the vein center, in which carbonic species in the fluids is only CH_4 (X_{CO2} = 0). The existence of CO_2 only near the vein walls is in good agreement of the precipitation of calcite near the vein walls. The homogenization temperature increases from ˜180 ℃ to 240?250 ℃, indicating the transition of the carbonic species from CO_2?CH_4 to CH_4 during vein formation.

The dominant species of carbonic species in most accretionary prisms is CH_4 under low-grade metamorphic conditions, and thermodynamic calculation about equilibrium in the C-H-O fluids also shows that CH4 is dominant carbonic species in the equilibrium with graphite under the P?T conditions of formation of the CO_2-bearing veins (235?245 ℃, 165?200 MPa). The CO_2-fluids are preferentially distributed close to an out-of-sequence thrust that brings the Murotohanto sub-belt into contact with the late Oligocene?early Miocene Nabae sub-belt with its many volcanic lavas and intrusive rocks. Therefore, the CO_2-fluids were considered to be magmatic-origin, and that the fluids were injected and mixed with the CH_4pore-fluids of the sediments in the accretionary prism in the timing of formation of CO_2-bearing veins.

Visualization of deep-seated fluid flow in Tokusa Basin, Yamaguchi Prefecture

NISHIYAMA, Nariaki[1*] ; TANAKA, Kazuhiro[2] ; SUZUKI, Koichi[3]

[1]Yamaguchi University, [2]Yamaguchi University, [3]Central Research Institute of Electric Power Industry

It is known that highly saline fluids spout out in spite of inland area in Japan (Sakai et al. 1978). These fluids spout out not only at the surface of the ground surface but also at the flowing borehole. However, the erupted region of ascending fluid from flowing borehole and its relationship to the geological structure is not identified. Electromagnetic surveys applying Controlled Source Audio-frequency Magneto-Telluric Method was carried out in the Tokusa basin, Yamaguchi Prefecture to obtain the two dimensional distribution of resistivity to clarify the geological structure and the distribution of deep-seated fluid.

The study area is consisted of the Late Cretaceous welded tuff, rhyolitic lava, and the Holocene sediments. Low resistivity zone continuously is distributed along the Tokusa-Jifuku fault (Sagawa et al, 2008) in bedrock more than 2.5km long and is distributed in north side of the fault in sediments like a tongue shape. Resistivity of erupted highly saline water corresponds to that obtained by CSAMT. Groundwater of the shallow wells drilled in the sediments shows the NaCl type. Therefore, low resistivity zone in the sediments corresponds to the highly saline water diluted by surface groundwater. As a result, deep-seated fluid in the Tokusa basin rises along the Tokusa-Jifuku fault in the basement rock and then flows to river subjected to the dilution by surface groundwater.

Can clay minerals account for the non-asperity on the subducting plate interface?

KATAYAMA, Ikuo[1*] ; KUBO, Tatsuro[1] ; SAKUMA, Hiroshi[2] ; KAWAI, Kenji[3]

[1]Department of Earth and Planetary Systems Science, Hiroshima University, [2]National Institute for Materials Science, [3]Department of Earth and Planetary Sciences, Tokyo Institute of Technology

Seismicity along the subducting plate interface shows a regional variation, in which large earthquakes occur repeatedly at the strongly coupled patches that are surrounded by weakly coupled regions. This model suggests that the subduction plate interface is heterogeneous in terms of frictional properties; however, mechanism making the difference in strong and weak coupling is still not well understood. We consider this difference to relate to the alternation of plate interface due to aqueous fluids that result in the spatial distribution of clay minerals. In this study, we measured the frictional healing of clay minerals and discuss whether the frictional properties of clays can account for the weakly coupled non-asperity regions in the subducting plate interface.

We carried out a series of slide-hold-slide frictional experiments to examine the time-dependent frictional restrengthening of the simulated fault gouge. In the experiments, the axial loading was interrupted for periods ranging 10 to 3000 s after steady-state friction, and we measured the difference between the steady-state friction and the peak friction after each holding period. Mechanical data were recorded continuously with a sampling rate of 10 Hz and the frictional coefficient was calculated from the shear force divided by the normal force assuming zero cohesion.

The preliminary results show that the frictional strength of clay minerals (smectite and chlorite) slightly increases with holding time; however, the healing rate is significantly smaller than that of dry silicates such as quartz. Similar weak healing rate has been reported in the serpentinized simulated faults (Katayama et al., 2013). These experimental results suggest that the recovery of fault strength is different in materials, in which clay minerals show weak and slow recovery whereas dry materials show relatively quick and thereby strong coupling on the fault surface. Aqueous fluids that are released from the descending plate may change the mineralogy on the plate interface where clay minerals become dominant at the channel of fluid flow surrounding the unaltered dry patches that potentially act as a seismic asperity. Thus, the heterogeneous fluid pathway and spatial distribution of clay minerals may play a key role for the formation of asperity and non-asperity on the subducting plate interface.

Oxidation state of arc primary magma-inferred from sulfur speciation of melt inclusions

SHIMIZU, Kenji[1*] ; KASHIWABARA, Teruhiko[1] ; TAMENORI, Yusuke[2]

[1]JAMSTEC, [2]JASRI, SPring-8

Oxidation state of arc magmas highly influences the chemical behaviors of redox sensitive elements such as chalcophile and some siderophile elements in subduction zone. Therefore, Oxidation state of arc magmas is essential to understand arc magma geneses and evolutions of ore deposits. It has been suggested that sub-arc mantle is oxidized by subducted materials such as fluid, sediments and oceanic crust. However, recent studies contradicted that the oxidation state of primary arc magma (sub-arc mantle) is similar to the average upper mantle and oxidation is caused by differentiation associated with crystallization and interaction within preexisting crust (e.g. Lee et al., 2012, Science, v336, p64).

In order to constrain oxidation state of primary arc magmas at an immature subduction zone, we have analyzed S6+/ΣS of boninitic and tholeiitic melt inclusions within Cr-spinel from Bonin Islands and Guam by soft X-ray microbeam at SPring-8/BL27SU. Boninite in Bonin Islands uniquely formed at the early stage of subduction formation (~50 Ma) by melting of highly depleted hydrous mantle and 0-7 myrs later, related arc tholetiites erupted in southern Bonin Islands and Guam by melting of depleted mantle (Ishizuka et al., 2011, EPSL, v306, p229). Compositions of melt inclusions fully cover compositional ranges of whole-rocks and some boninitic melt inclusions have MgO higher than 20 wt%, showing that they are very primitive magmas. S6+/ΣS of boninitic and tholeiitic melt inclusions are 0.57 to 0.78 and 0.47 to 1, respectively; S6+/ΣS of all high-MgO (7 to 12 wt%) tholeiitic melt inclusions are >0.9. Oxygen fugacities of primary boninite and tholeiite are estimated to be ΔFMQ >+1 and >+1.5, respectively by experimental results of Jugo et al. (2010, GCA, v74 p5926), indicating that sub-arc mantle is oxidized even at an early stage of subduction zone. Between the period of eruption of boninite and tholeiite, not only mantle sources but also the subducting component in term of oxidation state of sub-arc mantle may have changed.

Evaluating slab-fluid contribution into inhomogeneous mantle source: geochemical variation of Central and East Java arc

HANDINI, Esti[1*] ; HASENAKA, Toshiaki[1] ; WIBOWO, Haryo edi[2] ; SHIBATA, Tomoyuki[3] ; MORI, Yasushi[4] ; HARIJOKO, Agung[2]

[1]Graduate School of Science and Technology, Kumamoto University, [2]Geological Engineering, Gadjah Mada University, [3]Institute for Geothermal Sciences, Kyoto University, [4]Kitakyushu Museum of Natural History and Human History

The spatial distribution of the volcanoes in Central and East sections of Java arc denotes the widest and the narrowest of Java Island. Central Java section corresponds to the largest range and depth of Wadati-Benioff Zone along the island (180-360 km), whereas East Java section shows the narrowest range (190-220 km). However, both sections equally show wide geochemical variation with the function of slab-depth. Both also mark the appearance of the rear-arc alkaline suites in a different slab depth (360 km for Central Java, and 220 km for East Java). Geochemical datasets of basalt to basaltic andesite (further screened on Zr/Nb basis) from these sections were compiled to evaluate the contributions of slab-derived fluid to the mantle sources, and to assess the possible mantle sources of these magmas.

We group the lavas of the Central and East Java into two series: (1) the volcanic front series (VF), calc-alkaline suites of frontal- and middle-arc region volcanoes of Central and East Java, and (2) the rear-arc series (RA) consists of alkaline suites from Central and East Java (Muria, and Ringgit-Beser and Lurus, respectively). The VF series consistently shows typical island arc geochemistry, with strong LILE enrichment (Sr, Ba, Pb, and Rb) relative to HFSE. The RA series, mainly Muria, indicate stronger enrichment of LILE than other volcanoes closer to the trench. Ringgit-Beser and Lurus, the rear-arc lavas of East Java, behave differently in LILE enrichment. Ringgit-Beser lavas shows stronger LILE enrichment than that of lavas from Lurus, within the same enrichment range of Muria lavas. In the other hand, Lurus lavas are showing obvious HFSE depletion compared to OIB. The decreasing trend of LILE/HFSE and LILE/LREE (e.g. Ba/Nb, Ba/La, Pb/Ce, Pb/Nb) is observed across both Central and East Java sections. These ratios become lower toward the rear-arc of both sections, and the lowest in the rear-arc of Central Java. In various normalized plots (such as Nb vs. Ba/Nb), the VF series are plotted within the range of typical island arc basalts (IAB). Muria lavas, the rear-arc alkaline suite of the Central Java, resemble OIB and other non-arc type alkaline rock characteristics, but with positive indications of being island arc, such as negative Nb and Ti anomalies. Ringgit-Beser and Lurus alkaline lavas of East Java, however, are associated with other arc-type alkaline rock characteristics, with stronger signature of island arc than Muria.

Our analyzed samples show that lavas from East Java are closer in compositions to primitive magmas compared to Central Java's. The thicker overriding crust beneath Central Java than East Java possibly acts as the magma retainer that allows extensive fractionation. Across-arc variation of slab-derived fluid in both sections are observed as shown by decreasing LILE/HFSE and LILE/LREE toward rear-arc, suggesting the decreasing amount of slab-fluid added to the great slab-depth. The slab-fluid added to the volcanic front of East Java is slightly higher than that of Central Java, which may be controlled by the narrow range of slab dehydration area in the former that allows more fluid to concentrate. The low ratio of these trace elements in the rear-arc of both sections suggests that these parts have also been affected by dehydration of subducted slab. The stronger slab-fluid contributions in the rear-arc alkaline lavas of East Java than that of Central Java may reflect the role of shallower slab depth. Different mantle characteristics between the rear-arc of Central and East Java may reflect several possibilities: (1) the inhomogeneous mantle plume (E-type/EMI) beneath both sections, or (2) stronger EMI-type mantle contribution to Central Java than to East Java, or (3) the combination of both.

Reaction progress and porosity change in hydrothermal alternation at Olivine/Quartz boundary

OYANAGI, Ryosuke[1*] ; OKAMOTO, Atsushi[1] ; TSUCHIYA, Noriyoshi[1]

[1]Graduate School of Environmental Studies, Tohoku University

Serpentinization in oceanic lithosphere is a fundamental process to bring water into deep earth ' s interior. It is known that silica activity controls the reaction paths during the hydrothermal alternation of peridotites [e.g. 1,2], however the detailed reaction mechanism induced by silica transport is poorly understood. In this study, we conducted hydrothermal experiments in olivine (Ol)-quartz (Qtz)-H2O system for investigating the mechanism of silica metasomatism at crust/mantle boundary.

Composite powders, which was composed of Qtz zone and Ol zone was set in inner tubes, with diameters of 1.7 mm and heights of 50 mm, and then loaded into autoclave with alkaline solution (NaOH,aq, pH = 13.8 at 25 ℃). Temperature and pressure are 250 ℃ and vapor-saturated pressure (= 3.98 MPa), respectively. After the experiments, the inner tube was cut into ten segments to evaluate the reaction progress as a function of the distance from Ol/Qtz boundary (hereafter denoted X), by Thermogravimetry and XRD. In order to evaluate the spatial variation of the reactions, the area of each minerals (olivine and reaction products) and pore was measured from the back-scattered electron (BSE) images of the thin section.

After 46 days, the H2O content near the Ol/Qtz boundary is lower (3.9 wt.% H2O) than that in (12 wt.%) at the margin of the reaction tube. The reaction products after olivine changed systematically as away from Ol/Qtz boundary from smectite+serpentine zone to the serpentine+brucite zones. In the smectite+ serpentine zone, the (Mg+Fe)/Si ratio of the products increases from 0.5 to 1.5, indicating that proportion of serpentine with respect to smectite increased away from the boundary. With increasing time, the smectite+ serpentine zone was enlarged, where as the serpentine+brucite zones was retreated.

Based on the combined analyzes of BSE images, TG and SEM-EDS, we obtained the reaction progresses of individual elementary reactions between 25 and 46 days as follows:

(1) In the smectite+ serpentine zone, smectite was formed via hydration of olivine and dehydration of serpentine by supply of silica. As the result, overall reaction has a variation in the smectite+ serpentine zone; △mH2O is negative (hydration) at X=0-4 mm, it is positive (dehydration) at X=4-10 mm. Volume expansion factor (V/V0) is much higher (=1.4) at Ol/Qtz boundary than other zones (=˜1.1), mainly due to Si-metasomatic reaction.

(2) Far from the Ol/Qtz boundary(X = 20-40 mm), there is no influence of silica supply, indicating that silica was completely consumed in the smectite+ serpentine zone. In these area, serpentinization proceeds as the typical olivine hydration reaction to produce brucite and serpentine with constant Srp/Brc ratio.

(3) In the transient zone, serpentine was formed by two ways: hydration of olivine and dehydration of brucite by supply of silica. These two serpentine forming reaction resulted in a large amount of serpentine in this area, and high volume expansion factor (=˜1.4).

Due to these two volume expansion reactions, low porosity (˜5%) area developed locally, never-theless porosity of other area is 30%. The amount of silica (△mSiO2,aq), which consumed from 25 to 46days, is largest at Ol/Qtz boundary, and monotonically decreases with increasing distance. If excess silica are available, the zones affected by silica will increase gradually with increasing time during hydrothermal alteration around mantle/crust boundary. In contrast, the porosity has a minimum around X = 15 mm in the transition zone, because Ol-hydration and Brc-dehydration reaction proceed with large volume expansion. Such volume expansion reaction and mineral changes causes the mechanical strength of boundary.

Distribution and transportation of melt in subduction zones

ISHII, Kazuhiko[1*]

[1]Graduate School of Sciences, Osaka Prefecture University

Volcanic and seismic activities in subduction zones are the result of complex interaction of geophysical and geochemical processes. I have investigated the hydration and dehydration and the generation and transportation of melt in subducting slab and adjacent mantle wedge using a numerical model. The model includes hydration and dehydration of the slab and mantle wedge, melting and solidification of mantle peridotites, permeable flow of melt and aqueous fluids, and solid flow of mantle peridotites with water- and melt-induced weakening. The model shows the melt distribution in the mantle wedge beneath the volcanic front and extending sub-parallel with the subducting slab. The detailed geometry of the melt distribution is strongly dependent on the parameters including water solubility of peridtites and permeable flow velocities of melt and aqueous fluids. I will discuss the effect of these parameters on the melt distribution and the interdependence among the geodynamic processes in the subduction system.

Effects of mineral grain size variation on fluid migration in the mantle wedge

WADA, Ikuko[1*] ; BEHN, Mark D.[2]

[1]IRIDeS, Tohoku University, [2]Woods Hole Oceanographic Institution, USA

In this study, we investigate the effect of mineral grain size on the migration paths of aqueous fluids in the mantle wedge. Grain size is an important parameter that controls the grain-scale permeability of the mantle; in general, the smaller the grain size, the less permeable the mantle is, provided that the pores between grains are connected. The migration paths of aqueous fluids are therefore dependent on the grain size distribution, influencing the location and the degree of hydrous melting in the mantle wedge and the location of arc volcanism. We develop a 2-D fluid migration model with generic subduction zone geometry. In the model, we adopt grain size distributions calculated by coupling a subduction zone thermal model with a laboratory-derived grain size evolution model for a range of subduction parameters (Wada et al., 2011). The fluid migration model also includes the effects of mantle flow velocities and mantle-flow-induced pressure gradients, both of which are also calculated from the thermal model. The calculated grain size immediately above the slab is on the order of 10?100 micrometers beneath the forearc region, depending on the slab thermal structure, and it increases down-dip to a few cm beneath the arc region. Our preliminary modeling results with a simplified fluid influx pattern indicate that the aqueous fluids tend to become trapped in the down-going mantle due to low permeability and dragged down-dip until permeability becomes high enough for the fluids to migrate upward. Grain size above a colder slab tends to be smaller than that above a warmer slab, and therefore fluids become dragged down-dip further in a cold-slab subduction zone than in a warm slab subduction zone. A colder slab also tends to release fluids at deeper depths than a warmer slab, influencing the pattern of fluid influx into the mantle wedge. In this study, we calculate the fluid influx along the base of the mantle wedge, using the thermal modeling results and thermodynamic calculations based on Perple_X, and quantify fluid migration in the mantle wedge with the grain size and fluid influx distributions that are consistent with a given slab thermal structure.

Keywords: subduction zone, mantle wedge, aqueous fluid migration, grain size, slab dehydration, arc volcanism

Temperature dependence of seismic velocities in a antigorite serpentinite at 1 GPa

SHIRAI, Ryo[1*] ; WATANABE, Tohru[1] ; YONEDA, Akira[2] ; MICHIBAYASHI, Katsuyoshi[3]

[1]Deaprtment of Earth Sciences, Faculty of Science, University of Toyama, [2]Institute for Study of Earth's Interior, Okayama University, [3]Institute of Geosciences, Shizuoka University

Serpentines play key roles in subduction zone processes including water transport, seismogenesis, exhumation of high-pressure rocks, etc. Geophysical mapping of serpentinized regions in the mantle wedge leads to further understanding of these processes. Seismic properties of serpentinized peridotites are critical to interpretation of seismological observations. Antigorite is a major form of serpentine, which is stable to higher temperatures. The single-crystal elastic properties were recently revealed via Brillouin scattering technique (Bezacier et al., 2010; 2013). However, the temperature dependence of elastic properties is still poorly understood. We have measured elastic wave velocities in a antigorite serpentinite at high temperature and pressure conditions.

A black massive antigorite serpentinite was collected from the Nagasaki metamorphic rocks, western Japan. It is composed of antigorite (98.0 vol.%), diopside (1.5 vol.%) and magnetite (0.5 vol.%). Microstructural observation reveals an interpenetrating texture characterized by randomly oriented antigorite blades. Antigorite CPO data shows weak concentration of antigorite axes. Elastic wave velocities measured at 180 MPa shows very weak anisotropy in elasticity. Cylindrical samples (D=L=6mm) were made with ultrasonic machining.

Measurements were made at the pressure of 1 GPa and the temperature of up to 550 C, by using a piston-cylinder type high pressure apparatus at ISEI, Okayama University. The pulse reflection technique was employed for velocity measurement. One LiNbO3 transducer with the resonant frequency of 5 MHz was used to transmit and receive ultrasonic signals. The length of the sample at high pressure and temperature conditions was estimated from the length of the recovered sample.

Both compressional and shear wave velocities linearly decrease with increasing temperature. The temperature derivatives are -3.6$\times 10^{-4}$ (km/s/K) and -2.7$\times 10^{-4}$ (km/s/K) for compressional and shear wave velocities, respectively. The temperature derivative of compressional wave velocity is close to that observed in the direction subparallel to antigorite *c*-axis (Yano et al., in prep.). The temperature dependence of c33 might dominate that of the effective elastic constants of a randomly oriented polycrystalline aggregate. Applications to seismological observations will also be discussed in this presentation.

Detection of structured water on quartz interface by Raman-FTIR spectroscopy and its evaluation by molecular dynamics

ISHIKAWA, Satoru[1*] ; SAKUMA, Hiroshi[2] ; TSUCHIYA, Noriyoshi[1]

[1]Graduate School of Environmental Studies, Tohoku University, [2]National Institute for Materials Science

Molecular structure of water in thin film shows different characteristics compared with that of free water. Thin film water was observed at mineral grain boundaries, and its structure might be influence by mineral surface.

High temperature-pressure cell for micro-Raman and Fourier-transform infrared (FT-IR) spectroscopy have been developed to investigate molecular structure of thin film water at high temperature and pressure conditions. As a result of micro-Raman and FT-IR spectroscopic measurements of water, the broad peak around 3400 cm^{-1}, attributed to OH stretching vibration mode of water molecular, was observed at ambient temperature and pressure. The broad peak shifted to higher wavenumber with increasing temperature on metal reflector. Compared with the result of IR properties of water on metal reflector, IR properties of water on artificial quartz surface exhibit different trend: the broad peak contained the peak component of the lower wavenumber (around 3200 cm^{-1}), even at high temperature.

In addition, molecular dynamics simulations were performed under the conditions of the experiment using MXDORTO. In the simulation, the water of a few nanometers of quartz near the surface was structured. The distribution of water density was different from the free water. These properties are discussed in the hydrogen bond between water molecular and silanol (Si-OH) of quartz.

Generation process of brecciated marble at Hiraodai karst, Kyushu, Japan

ISHIYAMA, Saya[1*] ; ANDO, Jun-ichi[1] ; NAKAI, Shun'ichi[2] ; OTA, Yasuhiro[3] ; DAS, Kaushik[1]

[1]Department of Earth and Planetary Systems Science, Hiroshima University, [2]Earthquake Research Institute, the University of Tokyo, [3]Kitakyushu Museum of Natural history & Human history

Geofluid is believed to be closely related to the seismic and volcanic activities. However, the detail relationship of geofluids with seismicity and volcanic activity is not studied properly through geological observations. We have found recently the brecciated marble widely distributed at Hiraodai karst plateau, Fukuoka Pref. This brecciated marble offers unique opportunity to study the relationship between geofluid and seismicity. Here, we shall explore the generation process of this brecciated marble through geological, microstructural and geochemical methods using polarization microscope, SEM, TEM, EPMA, microthermometric and MC-ICP-MS techniques.

The marble in Hiraodai karst plateau was thermally metamorphosed due to Cretaceous Hirao granodiorite intrusion. The brecciated marble occupies about 0.7 km x 1km of area in the central part of the karst. The main results of the present study are as follows.

1) The brecciated marble is composed of the rock fragments with variety of sizes ranging from millimeter to meter scale, and having angular to rounded shapes.
2) Numerous fluid inclusions are observed in the thin section of the brecciated marble.
3) TEM observation shows that the dense tangled dislocations are formed in calcite grains of the brecciated marble.
4) The homogenization and freezing temperatures of the fluid inclusions are about 240 deg C and 0 deg C, respectively.
5) The whole-rock and mineral separates (biotite and plagioclase) of Hirao granodiorite yields Rb-Sr isochron age of 129.4 +/- 2.4 Ma. Interestingly, Rb-Sr data of the fluid inclusions also lie on the Rb-Sr isochron of Hirao granodiorite.

The above-mentioned results of 1) and 2) suggest that the brecciation occurred by fluid infiltration and that the fragments were moved and rotated at very high speed. The result 3) demonstrates that the calcite grains of the brecciated marble experienced high stress. These three results together indicate that the brecciation process might generate seismic wave. On the other hand, the results of 4) and 5) suggest that the possible origin of the fluid inclusion is the released fluid from the Hirao granodiorite magma. Therefore, the brecciation of marble distributed at Hiraodai karst plateau was probably generated by magmatic fluid from Hirao granodiorite under high stress condition at 129.4 +/- 2.4 Ma ago.

Equation of state of topaz-OH in the subducted sediment under high pressure and high temperature

NIIZATO, Mizuki[1*] ; INOUE, Toru[2] ; CAI, Nao[2] ; SUENAMI, Hideki[2] ; KAKIZAWA, Sho[2]

[1]Department of Earth Sciences, Ehime University, [2]Geodynamics Research Center, Ehime Univercity

Dehydration reactions of hydrous minerals in the subducted sediment produce a H_2O-rich fluid which causes generations of magma, decreases of melting temperature of sediment, and variations of magma compositions. Topaz-OH [$Al_2SiO_4(OH)_2$], which is one of hydrous minerals, is considered to be existed in the sediment of the subducting slab. Topaz-OH is the end-member of natural topaz [$Al_2SiO_4(OH,F)_2$]. The stability field of topaz-OH extends to 1500 degree C at 5-10 GPa (Wunder *et al*., 1993; Ono. 1998; Schmidt *et al*., 1998). The equation of state (EoS) for the natural topaz has been also estimated (Komatsu *et al*., 2003; Gatta *et al*., 2003). However, the EoS of the end-member topaz-OH has not been performed yet. In this study, we performed *in situ* X-ray diffraction (XRD) experiments under high pressure and high temperature for determining the thermal elastic properties of topaz-OH.

The starting material of topaz-OH was synthesized at 10 GPa and ˜1000 degree C from the quench experiment using multi-anvil apparatus. The high pressure (3-8 GPa) and high temperature (up to 800 degree C) *in situ* XRD experiments were carried out using MAX80 installed at beam-line NE5C at PF-AR, KEK, Japan. These XRD patterns were collected by the energy dispersive method. Thermal elastic properties were calculated from EoS fit v5.2 software (Angel, 2000) using 3rd order Birch-Murnaghan EoS.

From *in situ* XRD experiments, we successfully determined thermal elastic properties using all-data for fixed K'=4 as below: V_0=354.7(1) Å ^{3}, K_0=169.8(22)GPa, $(dK_T/dT)_P$=-0.013(7) GPaK^{-1}, a_0=1.61(23)$\times10^{-5}K^{-1}$, b_0=1.36(41)$\times10^{-8}K^{-2}$. From the detailed analysis of compression data, we found the change of the compression properties near 7 GPa. This change was also seen in a- and b-axis. Therefore we re-calculated the thermal elastic properties using two data sets: (I) below 7 GPa (II) above 7 GPa at room temperature. These calculation results from low pressure data show V_0=355.2(1) Å ^{3}, K_0=160.1(2)GPa, however those from the high pressure data show V_0=356.5(9) Å ^{3}, K_0=153.1(89) GPa (K'=4 fixed). Compared to the natural topaz, topaz-OH shows relatively large volume and bulk modulus. This shows that the volume and bulk modulus increase with increasing OH content. Compared bulk modulus with density, topaz-OH locates near the line for Birch's law and indicates large bulk modulus and density as same as Phase D [$Mg_2SiO_4(OH)_2$]. We suggest that high density topaz-OH enhances the slab subduction and transports water to deeper earth's interior.

Water content in arc basaltic magma in northeast Japan and Izu-Mariana arc estimated from melt inclusions in olivine and

USHIODA, Masashi[1*] ; IKEGUCHI, Naoki[1] ; TAKAHASHI, Eiichi[1]

[1]Dept. Earth and Planetary Sciences, Tokyo Institute of Technology

Primitive arc basalt magma is generated by partial melting of sub-arc mantle with adding aqueous fluid which was derived from dehydration of subducting slab. Aqueous fluid has profound effects on melting temperature of the mantle, crystallization pathways of generated magmas, and explosivity of magmas. Precise estimation of H_2O content in arc basalt magma is important to evaluate the effect of water on generation, differentiation, and eruption of magmas in subduction zones. We estimated variation of water content of arc basaltic magmas in the northeast Japan arc and the Izu-Mariana arc using a simple plagaioclase phenocryst hygrometer and melt inclusion analysis of olivine phenocrysts.

A simple plagaioclase phenocryst hygrometer was constructed by high-pressure and high temperature experiments using internally heated pressure vessels: SMC-2000 and SMC-5000 installed at the Magma Factory, Tokyo Tech (Ushioda et al., 2013, VSJ fall meeting). High-pressure and high-temperature experiments were conducted for relatively primitive basalt from Miyakejima volcano under hydrous conditions. OFS (Ofunato scoria: Tsukui et al., 2001; Niihori et al., 2003) is one of the most primitive basalt in the last 10,000 years. All experiments were conducted near the liquidus of plagioclase ($\pm$magnetite) and therefore the composition of melt is essentially the same as the starting material. H_2O content of melt was calculated by weight ratio of melt using mass balance calculation of all phases assuming that water was concentrated only in melt. Partition coefficient ${K_D}^{pl-melt}{}_{Ca-Na}$ is proportional to H_2O content in melt. In the experimental conditions, both pressure and temperature effects are negligible.

We then chose geochemical data sets of relatively primitive basaltic rocks (with no evidence of magma mixing) and most frequent Ca-rich plagioclase phenocrysts from 15 arc basaltic volcanoes, which includes both frontal arc volcanoes and rear-arc volcanoes from literature. In 15 volcanoes, plagioclase phenocrysts of high anorthite content (An$>$90) are commonly observed, whereas plagioclase phenocrysts in rear arc volcanoes usually have lower anorthite content (90$>$An$>$80). Estimated H_2O content of basaltic magma is 3 wt.% H_2O or higher.

We also analyzed H_2O content of melt inclusions in olivine phenocrysts using FTIR micro reflectance measurement (Yasuda, 2011) and FTIR micro transmission measurement (absorption coefficient: Yamashita et al., 1996) in order to compare H_2O content between melt inclusion analysis and this simple plagioclase phenocryst hygrometer. For example, melt inclusions of olivine phenocrysts in scoria from Ko-Fuji volcano had up to 3.7 wt.% H_2O which was consistent with estimate from our simple plagioclase phenocrysts hygrometer. In Miyakejima volcano, melt inclusions of olivine phenocrysts from OFS contained up to 3.3wt.% H_2O although H_2O content was 5.2 wt.% estimated from this hygrometer. In either case, basaltic magmas in volcanic front have 3 wt.% H_2O or higher.

DEM simulation on fracturing induced by hydration and dehydration reactions

OKAMOTO, Atsushi[1*] ; SHIMIZU, Hiroyuki[2]

[1]Graduate School of environmental Studies, Tohoku University, [2]Institute of Fluid Science, Tohoku University

Dehydration and hydration reactions play significant roles on the global water circulation in the solid Earth, and cause drastic change in the mechanical properties of the subduction zone interface. Progress of both reactions requires an effective transport of water (release or supply) between the reaction sites and outer system, and are commonly characterized by large changes in solid volume, porosity, and fluid pressure. Reaction textures with fracturing are commonly observed both in hydration and dehydration hydration reactions. However, the dynamic relationship among reactions, fluid transport and deformation (fracturing, plastic deformation) is too complicated to be understood solely by observations of natural occurrences.

In the present study, we carried out numerical simulations on fracturing induced by hydration or dehydration reactions by using distinct element method (DEM). At first, we consider a dehydration reaction like a dehydration of serpentine. In the model, the following factors are introduced: (1) pressure dependence of reaction rate, (2) grain boundary as weak and water-saturated region, and that (3) mineral grains become permeable after fracturing or reacted. In this model, reaction rate drastically decreases with progress of dehydration reaction, when fluid cannot escape from the system.

We examined two rock systems; one is composed of reactive minerals (uniform-reactive system) and the other one is composed of reactive minerals embedded in unreative matrix minerals (reactive minerals in matrix system). In both systems, one is drain-boundary, whereas all the others are undrain-boundary. The spatial variation in fractures and progress of reactions are contrasting between the two systems. In the uniform-reactive system, fracturing does not occur and reactions uniformly occur from the drain-boundary, because fluid effectively escapes through newly-produced pore-network. In contrast, the reactive-mineral-in-matrix-system, the fracture network is produced among the reactive grains, and heterogeneous distributions of reaction progress was produced in the rocks. We will further discuss the key parameters to controls the fracture patterns and difference between hydration and dehydration reactions.

Investigation on the temporal change in attenuation within ruptured fault zone of the 1999 Chi-Chi, Taiwan earthquake

MA, Kuo-fong[1*] ; WANG, Yu-ju[1]

[1]Department of Earth Sciences, National Central University

Attenuation, noted as 1/Q, had been considered as a geophysical parameter related to the fluid content, temperature and fracture of the medium. The attenuation parameter related to S-wave named as Qs has more significant indication to the factors indicated above. The damage zone of a large earthquake was often considered as a fracture zone, especially the hanging wall of a thrust faulting earthquake, which suggests a zone with possible high attenuation (decrease in Q). Earlier Qp and Qs tomography studies revealed the feature with high attenuation on the hanging wall of the ruptured Chelungpu fault of the 1999 Chi-Chi earthquake. To examine the attenuation character in the rupture fault, we further investigate the temporal variation of the attenuation, specifically in Qs, within the hanging wall before, following and after the earthquake. We observed a decreasing in Qs within the fault rupture zone two years following the 1999 Chi-Chi earthquake by Qs tomography images and an analysis of single-path Qs near the Chelungpu fault. The synthetic and sensitivity tests of the Qs determination were carried out accordingly to justify the temporal variation. A Qs value within the hanging wall above the hypocenter was determined to be 157 two years following the Chi-Chi earthquake, which is significantly lower than the values of 238 and 289 prior to and two years after the main shock, respectively, from the Qs tomography. Similar values using a signal-path Qs analysis, from events within the ruptured fault zone to stations along the fault were obtained. The corresponding Qs values were 247 prior to the Chi-Chi earthquake. After the earthquake, we obtained the Qs values of 158 and 318 for the time, two years following and two years after the earthquake, respectively. Considering the two independent methods in determination of Qs, the reduction in Qs of 89 two years following the Chi-Chi earthquake in both method is significant. Along with 1% Vs reduction revealed by the analysis of repeating earthquakes, our studies suggested possible reduction both in Vs and Qs within the fault zone after the Chi-Chi earthquake. The observation of temporal changes in Qs after the Chi-Chi earthquake implies variations of pore fluid saturation in the ruptured fault zone. The reduction in Qs two years following the Chi-Chi earthquake might indicates high pore-fluid saturation within fractured fault zone rocks due to post-seismic redistribution of the fluid.

Chemical characteristics of hot springs in Southwestern part of Taiwan

SUGAI, Shuto[1*] ; TANAKA, Hidemi[1] ; TERUSAWA, Shuji[1] ; TSUNOMORI, Fumiaki[2] ; MURAKAMI, Masaki[3] ; KAWABATA, Kuniyo[2]

[1]School of Science, The University of Tokyo, [2]Geochemical Research Center, Graduate School of Science, The University of Tokyo, [3]OYO Corporation

Taiwan is located at the junction of the Ryukyu Trough and the Manila Trench which are the boundaries of the Philippine Sea Plate and the Eurasian plate. While the Philippine Sea plate is subducting beneath the Eurasian plate at the offshore of eastern Taiwan, the Eurasian plate is subducting beneath the Philippine Sea plate at Manila Trench at the south offshore of western Taiwan. The plate boundary is riding on the Taiwan Island in the vicinity of Kaohsiung, southern Taiwan, and the plate boundary appears as active faults to the north. Many faults striking NE - SW have been developed, and there are some hot springs and mud volcanoes (Hamada et al., 2009) along those faults.

We focused on the hot springs around Chiayi and Tainan, southwestern Taiwan in this study. These hot springs show temperature around 34 - 70 ℃ which are distributed about 20 km apart from the active faults to the east, arranging from north to south. We have conducted chemical analyses for the hot spring water taken from these springs and report the results of these analyses in this presentation.

Estimate of isotopic composition and flux of Arima type fluid

TANAKA, Hidemi[1*] ; TERUSAWA, Shuji[1] ; SUGAI, Shuto[1] ; TSUNOMORI, Fumiaki[2] ; MURAKAMI, Masaki[3] ; KAWABATA, Kuniyo[2]

[1]School of Science, University of Tokyo, [2]Geochemical Research Center, Graduate School of Science, University of Tokyo, [3]OYO Corpoartion

It has been well known that change in chemical compositions of ground water is associated with crustal activities including large earthquakes. Research for change in chemical compositions of fluids associated with earthquakes is still continuing all over the world. However, reasons to choose the location of wells to measure the chemical and isotopic compositions of the fluids, and to choose particular chemical and isotopic compositions for measurements have not been unambiguous so far.

Because no deterministic theory has been established to predict large earthquake from anomalous chemical precursor signals so far, and fluid-monitoring research to explore earthquake precursor is significantly declined in the community, it would be less meaning to collect more chemical precursors of the earthquakes by repeating procedure in future.

Instead, there are some meaning if observed chemical change can be explained by physical and chemical process in the crust associated with crustal activities. At present, following three subjects are especially important. First, establishing the reliable basis to choose proper fluids and wells, second, designing and constructing the mass-spectrometer which has sufficient performance for fluid continuous monitoring at on-site close to the fault zone, and finally, establishing and improvement of diagnostic theory of fault zone fluid.

Based on the idea mentioned above, the results of examination of fluid of hot springs at Arima area are presented. There are several hot spring sources which are flown out continuously to the surface. After hot spring drillings at the 1940 to 1950's constant amounts and quality of these hot springs are maintained by branch of coal government office of Kobe City. Many researches have been done for the hot springs so far, including surface geology, shallow underground structure, source of fluids and fluids paths. Fluid paths are inferred to be fracture zones of particular fault zones by results of geological survey and resistivity analysis. It is important to recognize these kinds of fluids as "fault zone fluids", since identification whether monitored fluids flow through fault zone or not is important issue to examine the crustal activities from the chemical and isotopic compositions of the fluids. It is also well known that fluids from Arima hot springs show specific isotopic compositions which is inferred to be very deep origin. In this presentation, we discuss about quantity of flux of deep source fluids of Arima hot spring which is important issue to answer the question why we need to observe the fluids for crustal activities and where? and compare the results between this and previous studies.

Basic experiments for continuous monitoring of CH3 in the field by Mass spectrometer

KAWABATA, Kuniyo[1*] ; TSUNOMORI, Fumiaki[1] ; MURAKAMI, Masaki[3] ; TANAKA, Hidemi[2]

[1]Geochemical Research Center, Graduate School of Science, The University of Tokyo, [2]Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, [3]OYO Corporation

Continuous gas monitoring in the field is important issue for various purposes such as for heat trapping gas monitoring, poisonous gas monitoring and scientific objective. In order to analyze the gas in the field, small-sized gas analyzer using mass spectrometer have been developed in our group. In the field, identifying the location of the emitted gas is needed. To detect gas-emission in distant places from the analyzer, we made basic laboratory experiments using methane gas. In this presentation, we introduce the results of the experiment.

Geophysical Research of Tachikwa Fault Zone by Rn-222 and Cl- Concentration in Groundwater

SHIMODATE, Tomoya[1*] ; TSUNOMORI, Fumiaki[2] ; YASUHARA, Masaya[3] ; HAYASHI, Takeshi[4]

[1]International Christian University, [2]The University of Tokyo, [3]AIST, [4]Akita University

The 2011 off the Pacific coast of Tohoku Earthquake enhanced the probability of earthquake in Tachikawa Fault Zone. To evaluate the physical condition of Tachikawa fault zone, we researched Rn-222 concentration in groundwater, which is known as a precursory anomaly of earthquake. Additionally, we focused on the connection between the concentration of chloride ion in groundwater and fault damage zone and measured chloride ion in groundwater as well. Our purpose in this paper is to detect suitable groundwater for continuous measurement: (1) The depth of aquifer is deep enough to reach the bedrock. (2) Water contains much enough radon to monitor. (3)Water contains chloride ion whose concentration is controlled by the condition of fault damage zone.

Radon concentration in confined aquifer is supplied by alpha decay of radium in the surface of the grain. If the specific surface area of the grain changes according to physical condition of fault, radon concentration in the groundwater would change. The upper edge of bedrocks, main source of radon, has a depth of under 2,000 m around Tachikawa Fault Zone and it deepen in the west.

We focus on the distribution of chloride ion around Ayasegawa Fault is similar to one around Tachikawa Fault Zone. Low concentration of chloride ion in groundwater around Ayasegawa Fault is affected by fault damage zone, and we expect that groundwater around Tachikawa Fault Zone also shows low concentration of chloride ion due to fault damage zone. We use RTM1688(SARAD) for radon measurement, and ion chromatography for chloride ion measurement.

As a result, samples around the fault show high concentration of radon and low chloride ion. This suggests that the well around fault reach the bedrock and contain low concentration of chloride ion due to fault damage zone. These samples would show concentration change according to earthquake.

Precursory Change of Radon Concentration in Groundwater before 2011 Tohoku Earthquake

TSUNOMORI, Fumiaki[1*]

[1]Graduate School of Science, University of Tokyo

We will report characteristics of radon concentration changes in groundwater at the Nakaizu observatory around the Tohoku earthqauke, 2011.

Radon concentration in groundwater sometimes responds to crustal deformation before the earthquakes. The phenomenon was well known in 1980, and many scientists tried to detect such anomalous signals in order to find a chemical indicator of earthquakes. However few researches have studied a mechanism of the phenomenon. Nonetheless a lot of anomalies of the radon concentration relating to earthquakes are reported every year, thus it is important to clarify the fundamental process of radon concentration change in an aquifer. We would like to report the characteristics of radon concentration change around the 2011 Tohoku earthquake, and to discuss a fundamental model of the radon concentration change in an aquifer.

An anomalous increase in radon concentration was measured at the Nakaizu observatory on the Izu Peninsula prior to the 2011 Tohoku earthquake using a custom-made radon counter. Since the increase was more than three times the standard deviation of radon concentration variations over 35 years of recorded data, it is considered likely that it is a precursor to the earthquake. Following the earthquake, the radon concentration decreased exponentially to the background level. The anomalous increase is explained using a modified volatilization model containing three important aquifer parameters: the groundwater saturation ratio, the fracture surface area per unit volume, and the porosity. The modified model can also explain the radon concentration behavior prior to the 1978 Izu-Oshima-Kinkai earthquake.

Cooling history of a fracture zone in the Kojyaku granite, Tsuruga area: Constraints from multi-system thermochronology

SUEOKA, Shigeru[1*] ; YASUE, Ken-ichi[1] ; NIWA, Masakazu[1] ; SHIMADA, Koji[1] ; ISHIMARU, Tsuneari[1] ; UMEDA, Koji[1] ; YAMADA, Ryuji[2] ; DANHARA, Tohru[3] ; IWANO, Hideki[3] ; GOUZU, Chitaro[4]

[1]Japan Atomic Energy Agency, [2]National Research Institute for Earth Science and Disaster Prevention, [3]Kyoto Fission-Track Co., Ltd., [4]Hiruzen Institute for Geology and Chronology Co., Ltd.

Ages of faulting are generally estimated from ages of displaced geomorphic markers, e.g., terrace surfaces, alluvial deposits, or artificial structures. However, these markers are not always available, such as for faults in basement rocks. Such faults have been attempted to date by detecting chronological anomalies (e.g., Ikeya et al., 1982; Murakami and Tagami, 2004; Yamada et al., 2013; Gansawa et al., 2013) or dating hydrothermal veins or clay minerals formed after faulting (e.g., Zwingmann et al., 2004; Watanabe et al., 2008; Siebel et al., 2009; Yamasaki et al., 2013). However, definitive procedures to determine faulting ages based on such geochronological methods have not been established because thermogenesis and mass transport along fault zones are not simple. More basic and case studies are desirable to improve these methods.

We introduce an attempt to date a fracture zone observed in the northwestern part of the Tsuruga peninsula, southwest Japan, by constraining its cooling history from fission-track (FT), K-Ar, and U-Pb thermochronometries. In the northern part of the Kinki Triange, including the Kohoku and Tsuruga bay areas, NE-SW or NW-SE strike-slip faults such as the Kohokusanchi and Nosaka-Shufukuji fault zones, are dominant (e.g., The Headquarters for Earthquake Research Promotion, 2003a, b). Strike-slip faults in mountainous areas are generally difficult to date by using geomorphic markers. The fault we study is a strike-slip fault formed in the Tsuruga body of the Kojyaku granite (Kurimoto et al., 1999), along which no gromorphic marker is available. We dated 1) the fault gauge, 2) uncrushed host granitic rock, and 3) dolerite intruding within a few meters from the fault. The dispersions between zircon U-Pb ages and zircon fission-track ages of 1) and 2) are not significant at 2 sigma level and both of the zircon fission-track lengths are not shortened, implying 1) and 2) shared the cooling histories between closure temperatures of zircon U-Pb (>900 deg. C) and zircon fission-track methods (210-350 deg. C). On the other hand, apatite fission-track ages of 50.8 +/- 18.5 Ma for 2) and 28.4 +/- 13.6 Ma for 1) may be interpreted to be reflections of different cooling histories below 90-120 deg. C, closure temperature of apatite fission track method. Although the younger age of a) is attributable to the faulting during the Neogene/Quaternary or intrusion of the dolerite at 19.1-18.8 Ma inferred from plagioclase and whole-rock K-Ar ages, definitive conclusions are difficult to be drawn because of the wide error bars of the apatite FT ages and luck of apatite fission-track length data. In this presentation, we are going to give more precise discussions based on apatite fission-track length analyses.

Keywords: dating of a fault, fission-track thermochronology, K-Ar dating method, U-Pb dating method, Kojyaku granite

Chemical and isotopic examinations of Arima-type high saline hotspring water in south-west Japan

TANAKA, Hidemi[1*] ; TERUSAWA, Shuji[1] ; SUGAI, Shuto[1] ; TSUNOMORI, Fumiaki[2] ; MURAKAMI, Masaki[3] ; KAWABATA, Kuniyo[2]

[1]School of Science, University of Tokyo, [2]Geochemical Research Center, Graduate School of Science, University of Tokyo, [3]OYO Corpoartion

Many researches have been conducted to explore component source, heat source and water source of hot spring in Japan. Matshubaya et al.,(1974) classified hot springs into four types by isotopic ratio of hydrogen and oxygen in water and geology (1) volcanic type, (2) Arima type, (3) coastal type, (4)Green tough type. Of these, Arima type is said to have deep origin source because hydrogen and oxygen isotope ratios suggests that the origin is mixture of meteoric water and magmatic water, and dissolving gas have abnormally high He isotopic ratio.

Sugimoto (2012) selected 180 hot springs that seem to be classified as Arima type from 6058 hot springs in Japan, using Li/Cl and Br/Cl values. Li/Cl is used as index of temperature of water was experienced (You et al., 1996). Br/Cl expresses influence from sea water and biological effect (Hurwitz et al., 2005: Uemura et al., 1988). He selected hot springs which have more Li/Cl and less Br/Cl as Arima type. But, his discussion was only about dissolving ion and not discussed hydrogen and oxygen isotope ratios used in the definition of Arima type.

So, we reselected 185 hot springs that seems to Arima type by Sugimoto (2012) method from 9887 hot springs in Japan and sampled 67 hot springs for isotopic analysis and ion analysis. As a result, the hot spring with the isotope shift in the same way as Arima hot spring is found along Median Tectonic Line (MTL) at Kinki, Western Shikoku and Central Japan (Kashio) districts. All mixing lines are converged to one point. Thus, we refer the fluid with this isotopic composition as origin water of Arima type. Since they converge to one point in the relationship of the hydrogen isotope ratio of the chloride ion concentration, the composition of the original water is as δD = -35 ‰, δ18O = 5 ‰, Cl- = 42g/l. The method to determine the isotopic composition and the resultant value of δD and δ18O is more convincing than those from previous results. Because shift lines from several regions are coincided at one point.

Keywords: Arima hot spring, Oxygen Isotope, Hydrogen Isotope, Brine fluids, original composition

Spatial and temporal evolution of slip and seismicity during the 2013-2014 Boso slow slip event

FUKUDA, Jun'ichi[1*] ; KATO, Aitaro[1] ; OBARA, Kazushige[1] ; MIURA, Satoshi[2]

[1]Earthquake Research Institute, University of Tokyo, [2]Graduate School of Science, Tohoku University

GPS time series data show that transient crustal deformation has been occurring in the Boso peninsula, central Japan, since December 2013. Observed spatial and temporal patterns of surface displacements suggest the occurrence of transient aseismic slip on the subducting Philippine Sea plate. In addition, an increased rate of seismicity was observed from 31 December 2013 to 9 January 2014 off the east coast of the Boso peninsula. The location of the increased seismicity partly overlaps with the areas of seismic activity during the past Boso slow slip events.

To estimate spatial and temporal evolution of aseismic slip, we use GPS data from 71 stations of the GEONET in the Kanto region and data from 6 stations located along the east coast of the Boso peninsula, which are operated by Earthquake Research Institute of University of Tokyo and Tohoku University. The data are analyzed with GIPSY-OASIS II software to obtain daily coordinate time series at the 77 stations. Secular velocities, seasonal variations, and postseismic deformation following the 2011 Tohoku-oki earthquake are removed from the time series. We use a modified version of the Network Inversion Filter to estimate spatial and temporal evolution of daily cumulative slip and slip rate on the Philippine Sea plate. Slip slowly started around 20 December 2013 off the east coast of the Boso peninsula and then slip rapidly accelerated around 28 December and propagated to the west. Slip continued to accelerate until 3 January and then rapidly decelerated until 9 January.

To investigate spatial and temporal correlation of slip and seismicity, we use a matched-filter technique to detect earthquakes in the area of increased seismic activity. The detected earthquakes are located along the northern edge of the large aseismic slip and migrated from east to west during the period of rapid aseismic slip (31 December to 9 January). This migration pattern is consistent with the propagation of rapid aseismic slip, suggesting that the earthquakes are triggered by stress loading due to the propagation of aseismic slip. We do not identify significant seismic activity before 28 December, indicating that the slow slip event started well before the initiation of the seismic activity.

A slow slip event near the Boso Peninsula immediately triggered by the 2011 Tohoku-Oki earthquake

KATO, Aitaro[1*] ; IGARASHI, Toshihiro[1] ; OBARA, Kazushige[1]

[1]ERI University of Tokyo

It has been recognized that a series of slow slip events, accompanying with ordinary earthquakes, take place with recurrence intervals from 5 to 7 years near the Boso Peninsula along the plate interface of the subducting Philippine Sea plate [e.g., Hirose et al., 2012]. Immediately after the 2011 Tohoku-oki earthquake, intensive afterslip have been detected to start along the plate interface of the Pacific plate from off Tohoku region to southward Kanto region [e.g., Munekane et al., 2012; Fukuda et al., 2013]. It is well known that both the Pacific and the Philippine Sea plates are subducting beneath the Kanto region, and interacting with each other. Therefore, it is expected that the Philippine Sea plate might be dragged by the speeding Pacific plate during the intensive afterslip. We hypothesize that the dragging of the Philippine Sea plate by the Pacific plate leads to triggering of a slow slip event near the Boso Peninsula immediately after the Tohoku-Oki earthquake.

In order to verify the above hypothesis, we analyzed the seismicity including small repeating earthquakes, applying the matched filter technique to continuous waveforms. We used all available earthquakes associated with three sequences of slow slip events in 2007, 2011, and 2014 as template events. Then, we searched for events those have similar waveforms to ones of each template event from continuous waveforms. Based on the new earthquake catalog, we found out an abrupt increase in the swarm-like seismicity at the slow slip source area from March 12 to 14, 2011. In addition, some repeating earthquakes were extracted in the swarm, indicating aseismic slip transient. We, thus, interpret that the seismic swarm were linked to a newly detected slow slip event, which has not been previously recognized. However, based on the amount of aseismic slip deduced from the repeating earthquakes, moment released by the slow slip event is estimated to be smaller that by previously recognized slow slip events. We thus conclude that a small slow slip event might be triggered through the dragging of the Philippine Sea plate by the Pacific plate immediately after the Tohoku-Oki earthquake.

Tidal correlations of earthquake swarms associated with slow slip events off Boso Peninsula

TANAKA, Sachiko[1*]

[1]NIED

We investigated statistical correlations between Earth tides and earthquakes in the four swarms associated with slow slip events (SSEs) off Boso Peninsula in 2002, 2007, 2011, and 2014. Following Hirose et al. (2012), we selected the SSE-related events from the Hi-net earthquake catalog. For each event, we assigned the tidal phase angle at the origin time by theoretically calculating tidal Coulomb failure stresses with a frictional coefficient of 0.2. For the fault plane, we assumed a landward-dipping reverse fault from the F-net moment tensor solution of the largest earthquake (Mw 4.9) in the 2014 swarm. Based on the distribution of tidal phase angles, we statistically tested whether they concentrate near some particular angle or not by using the Schuster test. In this test, the result is evaluated by p-value, which represents the significance level to reject the null hypothesis that the earthquakes occur randomly irrespective of the tidal phase angle. The result of analysis shows the 2014 swarm was strongly correlated with tidally-induced stresses (p = 0.01%). The distribution of tidal phase angles exhibited a peak near the angle 0, which corresponds to the time of the maximum tidal stress promoting fault slip. We suggest that tidal stress fluctuations can trigger earthquakes when superimposed on stress buildup caused by nearby slow slip. On the other hand, the other three swarms show insignificant correlations with tides. The resultant p-values are 87%, 16%, and 14% for the 2002, 2007, and 2011 activities, respectively. Geodetic observations indicate larger slow slip in these three episodes than in 2014 (Hirose et al., 2013; Kimura, 2014). It is highly likely that the swarm earthquakes in those activities were fully triggered by stress perturbations imparted by large slow slip. Tides appear to have exerted little or no influence on triggering in that case.

Interplate coupling and SSE in the Tokai region after 1981 using leveling data

OCHI, Tadafumi[1*]

[1]AIST

The long-term SSE in the Tokai region, central Japan, from mid-2000 to mid-2005 [Suito and Ozawa (2009)], had continued five years, which was much longer than other SSEs around the world [e.g. Schwartz and Rokosky (2007)]. After the termination of the SSE in 2005, no obvious long-term SSE has been detected and that makes difficult to discuss a recurrence interval of the events. In order to reveal whether the event repeats or not, and if it repeats, in order to clarify the interval and a temporal and spatial change of the interplate coupling and the slow slip, I analyzed a leveling data before the era of GEONET.

Various types of geodetic observations have been conducted in the Tokai region and there are some previous works about the temporal change of the crustal deformation using the data of these observations. For example, Kimata and Yamauchi (1998) analyzed EDM data and Kobayashi and Yoshida (2004) analyzed tidal data to detect irregular feature in the crustal deformation. In this study, I analyzed leveling data in the Tokai region from 1981 to 1999 and reveal spatially the temporal change of the vertical deformation velocity. Leveling observations have been conducted four times a year along the route from Kakegawa City to the Omaezaki Cape and once a year along the others around the Omaezaki Cape. I used all the data from these observations and inferred two-year-averaged vertical deformation rate using the time-dependent network adjustment [Fujii (1991)]. The estimated error of the rate is about 2 mm/yr, which is twice as much as the error of GNSS vertical data in this region [Ochi and Kato (2013)]. Comparing with the other geodetic data, the biggest advantage of the leveling data is that it can produce a spatial view of the crustal deformation with small error.

From the results of the analysis, two patterns of the crustal deformation that may correspond to existence and non-existence of the SSE appear alternately. The pattern that resembles that of in the 2000-05 was detected around 1982-83, 1988-90 and 1997. The duration of the event in 1982-83 is shorter than that of 1988-90, which is again shorter than that of 2000. Summing up these results, it is clear that there are various durations in the SSEs. In addition, if the small event in 1997 is taken into account, small and large events occur alternately and the intervals after the large event may tend to get longer. However, as the 1997 event is temporally close to the large long-term SSE after 2000, the SSE would affect the analysis of 1997 data and it should be considered further.

I also inferred the temporal change of the interplate coupling and slow slip using the results. In order to overcome the lack of temporal resolution, I fixed the distribution center of the slow slip to the same place by the results by Ochi and Kato (2013), the northwestern part of the Lake Hamana with the depth around 30-40 km. According to the forward modeling, the pattern of the crustal deformation in the 1982-83 and 1988-90 require somewhat smaller amount of SSE. On the other hand, the interplate coupling beneath the Omaezaki Cape constantly continues whether the SSE occurs or not.

A shallow slow-slip-event in northern Hokkaido in 2012-2013: An event triggered by seismic waves.

IKEDA, Shohei[1*] ; HEKI, Kosuke[2]

[1]Graduate School of Science, Hokkaido University, [2]Department of Natural History Sciences, Faculty of Science, Hokkaido University

GNSS (Global Navigation Satellite System), as represented by GPS (Global Positioning System), enabled us to study SSE (Slow Slip Event), slow displacement of fault without exciting seismic waves. In this study, we report that baseline length between the Horonobe and the Nakatombetsu GNSS stations (part of the GEONET, GNSS Earth Observation Network) in Northern Hokkaido, shortened by ˜2 cm over 4-5 months period from 2012 summer to the early 2013. We assumed that an SSE is responsible for this change, and inferred fault parameters of this unique SSE. There have been lots of reports on repeating SSE at plate boundaries, e.g. off the Boso Peninsula, the Nankai Trough, and the Ryukyu Trench. In the Northern Hokkaido, a block boundary is considered to run north-south (Loveless and Meade, 2010) with the convergence rate of about 1 cm/year. This shallow SSE we report here is considered to have occurred at this boundary.

At first, we analyzed time series of the distance change between Horonobe and Nakatombetsu, together with a few additional GNSS stations nearby and estimated the fault parameters of this SSE by grid searches. The estimated slip was about 10 cm (Mw was ˜5.9), which suggests that a similar SSE recurs every decade. However, these GNSS stations started in 2002, and we do not have information on the previous SSE. We modeled the time series using lines with two breaks, and we constrained the onset time and the ending time of the SSE by minimizing the root-mean-square of the post-fit residuals. The optimal onset and termination was 2012.64 and 2013.08, respectively. Around the onset time, there was a deep earthquake beneath Sakhalin (M7.7) on August 14, 2012, and there were four M4 class earthquakes close to the Horonobe station in July, 2012. Seismic waves generated by these earthquakes may have triggered this SSE. At the termination time, there was an M4.8 earthquake on 3 Jan. 2013 at the depth of 24 km on the westward extension of the SSE fault. From mechanical point of view, it is difficult to consider that this earthquake encouraged the termination of SSE.

Seismicity and pressure changes observed around DONET at the same time

SUZUKI, Kensuke[1*] ; TAKAHASHI, Narumi[1] ; HORI, Takane[1] ; KAMIYA, Shin'ichiro[1] ; NAKANO, Masaru[1] ; KANEDA, Yoshiyuki[1]

[1]JAMSTEC

The Philippine Sea plate is subducting to northwest below the Eurasian plate along the Nankai trough in southwestern Japan at a convergence rate of about 65 mm/year. In this region mega-thrust earthquakes have repeatedly occurred along the Nankai trough and caused serious and widespread damages in central and western Japan. The Japan Agency for Marine-Earth Science and Technology (JAMSTEC) installed permanent ocean bottom observation stations named as Dense Oceanfloor Network System for Earthquakes and Tsunamis (DONET) off the Kii Peninsula to monitor earthquakes and tsunamis and to decrease damage due to those. Because several kinds of continuous data have sent to JAMSTEC in real time, we can discuss continuous seismicity and other seismic/geodetic information. It is important for considering occurrence of large earthquakes to judge seismicity of small earthquake and to monitor crustal deformation.

Suzuki et al. (2013) has reported that quiescence of seismicity and ocean bottom pressure changes around DONET have occurred almost at same time from Feb. 2013 to Sep. 2013. In this study we extended observational period until Jan. 2014. As a result of investigation by using similar method with Suzuki et al. (2013), these changes seem to have continued after Sep. 2013. Quiescence of seismicity has not finished yet; seismicity is lower than one predicted from ETAS model (Ogata, 1989) represented by five parameters fitted by using data between 2012. Although pressure changes have been observed at only three stations (KMB05, KMB06 and KMB07) on Sep. 2013, pressure change at KMB08 was also observed on extended time series in addition to the three stations. We will try to estimate fault slip model that can cause these pressure changes and investigate how that fault slip influence to seismicity.

Detection of short-term slow slip events along the Nankai Trough by observations of groundwater level or pressure

KITAGAWA, Yuichi[1] ; KOIZUMI, Naoji[1*]

[1]Geological Survey of Japan, AIST

Non-volcanic deep low-frequency (DLF) tremors are detected on plate boundaries along many subduction zones around the world [Obara,2002; Ide, 2012]. Short-term slow slip events (S-SSEs), which cause small crustal deformation with no usual seismic waves, are also detected in subduction zones [Rogers and Dragert, 2003; Schwartz and Rokosky, 2007; Sekine et al., 2010]. There is a close spatial and temporal correlation between DLF tremors and S-SSEs. However, S-SSEs do not always occur in areas where DLF tremors occur and vice versa. Therefore, it is important to clarify the detailed spatial and temporal correlations in order to know what occurs on the plate boundaries along subduction zones. In general, detecting S-SSEs via crustal deformation is more difficult than with DLF tremors when using a seismograph. One major reason for this is that the decay of crustal deformation by distance is much larger than that of seismic waves. Therefore, it is necessary to develop new tools or techniques to detect S-SSEs. For this purpose, we attempted to detect S-SSEs in the Nankai Trough, Japan by conducting groundwater pressure observations at ANO station in Mie Prefecture, Japan. The ANO is a groundwater observation station operated by the Geological Survey of Japan, AIST, for earthquake prediction research. The groundwater pressures changed due to six S-SSEs that occurred near ANO from June 2011 to April in 2013. The fault models of these S-SSEs, which were estimated mainly by observing the crustal strains and tilts, explained the changes in the groundwater pressures. We also considered the conditions for detecting S-SSEs via groundwater observations. The volumetric strain changes caused by the S-SSEs along the Nankai Trough were 10-20 nstrain/day at most [Kobayashi et al., 2006], where nstrain means 10^{-9} strain. Therefore, the strain-converted noise level should be 5 nstrain/day or smaller to detect the S-SSEs. Taking the actual conditions of groundwater observation into consideration, it is necessary that the noise level should be smaller than 50 mm/day and that the strain sensitivity of the groundwater pressure or level should be larger than 1 mm/nstrain for the required strain-converted noise level.

Time evolution of non-volcanic tremor episode

OBARA, Kazushige[1*] ; MATSUZAWA, Takanori[2] ; TANAKA, Sachiko[2] ; MAEDA, Takuto[1]

[1]Earthquake Research Institute, Univ. of Tokyo, [2]NIED

Non-volcanic tremor in subduction zones like as Nankai is one of slow earthquake phenomena in the transition zone between the seismogenic zone and the stable sliding zone on the subducting plate interface (Obara, 2002). Major tremor episodes with duration longer than several days are always accompanied by short-term slow slip events (SSEs). The space-time correlation of tremor and SSE suggests that the time evolution of tremor episode reflects the rupture process of SSE. Based on the similarity, studying the mechanism of slow earthquakes is important to understand the activity style of megathrust earthquake. Therefore, we investigate the time evolution of tremor episode based on the clustering catalog (Maeda and Obara, 2009, Obara et al., 2010) because the tremor is well-detected compared to other slow earthquakes.

Tremor belt-like zone is divided into some segments based on their spatial extent and recurrence interval (Obara, 2010). Each segment includes some sub-segment as units of tremor activity (Obara et al., 2013). Tremor episode usually initiates from the deeper part of the tremor belt-like zone. If the episode reaches to the updip part of the tremor zone, it becomes a major episode associated with detectable SSE (Obara et al., 2011). We sometimes observe major episodes initiated from the shallower part. The time evolution of tremor energy at the beginning stage of the tremor episode depends on the location of initiation point. If the episode starts from the deeper part, the evolution velocity is small for a while then increases rapidly after the tremor migration front reaches to the updip edge. On the other hand, the evolution velocity is high if the episode starts from the shallower part. This suggests that the tremor patches radiating high energy concentrate at the updip side. The time evolution of tremor energy at the beginning stage of each episode is not related to the final size of the episode. The size of episode may be controlled by the strain energy accumulation at each portion on the way of migration. This is the same for along-strike evolution of tremor episode. The propagation of tremor episode depends on the slip deficit in each sub-segment ahead of the rupturing sub-segment. We observed temporal deceleration of migration speed in front of the small gap as the sub-segment boundary. On the other hand, we detect acceleration of the migration speed at a common spot during passage of the major tremor episode several times. This spot is considered as a sweet spot where tiny tremor activity continuously occurs in the shallower part of the tremor zone. This spot frequently generates tremor episodes and is considered to be strongly inhomogeneous. Such variation on the plate interface may control the rupture process of SSE.

Fundamental properties of non-volcanic low frequency tremor catalogues

TAKEDA, Naoto[1*] ; KOIZUMI, Naoji[1] ; MATSUZAWA, Takanori[2] ; TANAKA, Sachiko[2] ; OBARA, Kazushige[3] ; MAEDA, Takuto[3]

[1]GSJ, AIST, [2]NIED, [3]ERI, Univ. of Tokyo

Since a discovery of non-volcanic low frequency tremor (NVT) in the subduction zone of southwest Japan (Obara, Science, 2002), the NVT has been found in various subduction zones or bottom of faults all over the world, and has been studied by many researchers. In these studies, an envelope cross-correlation technique for NVT detection and making a catalogue of NVT is important to discuss spatial and temporal activity of NVTs (e.g.; Maeda & Obara, JGR, 2009; Ide, Nature, 2010; Nakata et al., Nature Geoscience, 2008; Imanishi et al., GRL, 2011). There are some differences in NVT catalogues in the same region, since each study developed an original program for NVT catalogue. Furthermore, in some cases, even if they use a same program, parameters to detect NVT in the program were changed depending on a scope of the study. Consequently, there are some different features of NVT activity between the catalogues. In this report, we compare three catalogues, made by Japan Meteorological Agency (JMA), National Research Institute for Earth Science and Disaster Prevention (NIED) and Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST), regarding a resolution of location and a NVT scale-sensitivity property as fundamental properties of the NVT catalogue.

Based on the method to estimate the resolution of location from a standard deviation of relative location (Ide, Nature, 2010), we calculated the resolution of location in each catalogue using several standard deviations of relative location. The estimated epicentral resolutions in three catalogues are almost 2-3km.

The NVT scale-sensitivity was estimated by a ratio of NVT counts in catalogues. For example, the sensitivity of the NIED catalogue for magnitude (M) based on the JMA catalogue was defined as $N_{nied-jma}(M)/N_{jma}(M)$. Here, $N_{jma}(M)$ is total counts of low frequency earthquakes (LFEs) with M listed in the JMA catalogue, and $N_{nied-jma}(M)$ is total counts of NVT in the NIED catalogue which is also listed in the JMA catalogue. To examine the relationship between the scale and the sensitivity in the catalogues, we used magnitude and NVT energy as the scale in the JMA and the other catalogues, respectively. By comparison of the NVT scale-sensitivity properties, it is found that these catalogues have characteristic scales in the sensitivity. Furthermore, the sensitivities of all catalogues decrease for large scale NVT. This is attributed to the increase of lost counts due to complex waveforms of highly active NVT. In our presentation, we show some examples of different features of NVT activities arising from different scale-sensitivity properties.

We conclude that these fundamental properties are useful not only for a comparison of catalogues, but also for an optimization of parameters in the programs of NVT detection.

Acknowledgments: We use the earthquake catalogue reported by JMA, and seismic waveform data provided by NIED (Hi-net), AIST, JMA, University of Tokyo, Kyoto University, Kyushu University, Kochi University, and Nagoya University.

Determination of focal mechanisms of non-volcanic tremors using S-wave polarization: Correction for shear wave splitting

IMANISHI, Kazutoshi[1*] ; UCHIDE, Takahiko[1] ; TAKEDA, Naoto[1]

[1]Geological Survey of Japan, AIST

Non-volcanic tremors (NVTs) have been found at various plate boundaries during the last decade. Focal mechanisms of NVTs are important for better understanding physical mechanisms of tremor generation. Stacking of many similar event waveforms greatly enhances the signal to noise ratio of tremor signals, which enables us to use conventional focal mechanism determination methods based on P-wave first motion polarities and/or waveforms (Ide et al., 2007; Bostok et al., 2013). However, the stacking approach cannot resolve spatio-temporal variations of focal mechanisms, so a new method is needed.

Imanishi and Takeda (2010) conducted a polarization analysis to continuous seismic data and showed that the scatter in the particle motion directions becomes small in accordance with a period of NVT activity. The same conclusion was reported for Cascadia tremors by Bostock and Christensen (2012). Because NVTs are primarily composed of shear waves (e.g., Obara, 2002), our observed particle motions contain information regarding focal mechanisms. However, the shear wave particle motion should be treated in caution, since shear-wave splitting may distort the particle motion excited by a seismic source (e.g., Zhang and Schwartz, 1994).

In this study, we first explored the existence of seismic anisotropy using tremor signals. A standard shear-wave splitting analysis (Silver and Chan, 1991) was used to determine the fast polarization direction (LSPD) and the lag time between fast and slow shear waves (DT). The analysis detected clear split arrivals separated by about 0.1 s, indicating the need of the correction for splitting effects to recover radiation pattern of S-wave. The LSPD shows two major directions which are normal or subparallel to the strike of the plate margin. These results are consistent with previous studies using regular earthquakes (e.g., Saiga et al., 2011), demonstrating that tremor signals are also available to investigate seismic anisotropy.

We then determined focal mechanisms of NVTs by correcting for splitting effects on particle motions. The actual procedure is as follows:

(1) We rotate two horizontal seismograms to the fast and slow directions, advance the slow wave by the lag time, and rotate back to NS and EW directions.

(2) A polarization analysis is subject to 1 minute windows to determine S-wave polarization angles.

(3) Average and standard deviation of polarization angles are calculated at each hour.

(4) A grid search approach is performed at each hour to determine the best double-couple solution using polarization angles of multiple stations. Here the epicenter is determined by an average of locations using our ECM catalogue. The depth is assumed to be 35 km.

(5)Uncertainty is estimated based on a bootstrap approach.

We applied the above method to a tremor sequence at northern Mie prefecture that occurred at the beginning of April 2013. Most solutions show NW-dipping low-angle planes or SE-dipping high-angle planes. Because of 180 degrees ambiguity in polarization angles, the present study alone cannot distinguish compressional quadrant from dilatational one. Together with the observation of very long frequency earthquakes near the present study area (Ito et al., 2007), however, it is reasonable to consider that they represent shear slip on low-angle thrust faults. It is also noted that some of focal mechanism solutions contain large strike-slip component. We will present the spatial and temporal characteristics of focal mechanism solutions based on the analysis of more tremor sequences.

Improved estimation of seismic energy radiation from deep low-frequency tremor

ANNOURA, Satoshi[1*] ; OBARA, Kazushige[1] ; MAEDA, Takuto[1]

[1]Earthquake Research Institute, the University of Tokyo

Deep low-frequency tremor occurs associated with slow slip event on the subducting plate interface at the downdip part of the megathrust seismogenic zone. Studying these phenomena is considered to play an important role to understand the mechanism of the megathrust earthquake. Until now, spatio-temporal distribution of tremor has been well investigated to get a whole picture of tremor activity. In this paper, we proposed a method for assessing energy radiation of tremor more quantitatively.

The Hybrid Method (HM) [Maeda and Obara, 2009] is a technique which determines epicenter and seismic energy of tremor simultaneously by using relative arrival time and amplitude distribution of the tremor envelope. To avoid false event detection, the " HM selected catalog " constructed with a threshold of a high Variance Reduction (VR>90) has been used for tremor study. However, when tremor activity is very high, envelope correlation between stations is relatively poor because of complicated waveforms. Then the VR generally becomes low and some parts of tremor during the active stage are not included in the HM selected catalog [Takeda et al., 2014]. Therefore, in order to investigate the energy release of tremor activity precisely, we have to re-evaluate it by using the waveform data.

Here, we developed a method for estimation of tremor energy by using measurement of tremor duration time from envelope waveform and the HM catalog. We started to search the duration around an origin time of tremor in the HM selected catalog. Then we determined the tremor duration when the amplitude is higher than noise level at each station simultaneously. At each tremor duration, we determined epicenter using centroid location of hypocenters of HM selected catalog within corresponding time and determined energy radiation by summing up of energy of tremor epicenters with VR of larger than 60.

As a result, we found characteristic spatial distribution of energy. It has been already known that there are two peaks of the number of tremors in the dip direction [Obara et al., 2010]. In this study, we found that high-energy region is distributed in the shallower part of the source area of tremor along the strike of the subducting Philippine Sea plate. This biased distribution of high-energy radiation suggests that the shallower part is more brittle in the brittle-ductile transition zone where tremor occurs. This brittle part may radiate higher seismic energy when shear slip occurs. This research will lead to quantitative assessment of the role of tremor in the stress relaxation process in the subduction zone.

The role of tectonic tremor in slow earthquake

YABE, Suguru[1*] ; IDE, Satoshi[1]

[1]Dept. EPS, The University of Tokyo

Since the discovery of the slow earthquake, tectonic tremors, very low frequency earthquakes (VLFs), and slow slip events (SSEs) are thought to have close relation. Although the tremor activity is often regarded as a proxy of SSEs, the degree of proximity is yet unclear due to the lack of detailed quantitative comparison between them, especially for tectonic tremors. Here, we develop a method to estimate the seismic energy of tremors and apply it to tremors in four subduction zones (Nankai, Japan; Cascadia, USA-Canada; Jalisco, Mexico; South Chile). This method estimates the seismic energy of tremors, after evaluating the regionally averaged seismic attenuation and the site amplification factors, which has not been considered enough in previous studies estimating the seismic energy of tectonic tremors. Then the catalog of the energy rate, which is the seismic energy divided by the tremor duration, is compared with some characteristics of tremors, VLFs, and SSEs.

We have observed three types of spatial distributions in terms of energy rate; heterogeneous, homogeneous, and isolated. In regions where the energy rate is heterogeneously distributed on the plate interface, such as Nankai and northern Cascadia, tremor activities almost always initiate from where the energy rate is low. Sometimes the initial tremors trigger more energetic tremors nearby, which are further followed by a long-distance tremor migration along the strike of the subducting plate. These energetic tremors tend to have longer recurrence intervals, and seem to control the onset of a large-scale tremor migration, which probably corresponds to a SSE. In Nankai, the energy rate of tremors estimated between 2-8 Hz is large where VLFs have been detected in the frequency range of 0.02-0.05 Hz. These observations suggest that the characteristics of tremors are regionally various, but similar in different frequency ranges. In the region where tremor activities are isolated, such as East Shikoku, Jalisco and South Chile, each tremor activity has occurred independently, and the relations between the energy rate and the recurrence intervals cannot be seen. In the region where the energy rate is homogeneously distributed on the plate interface, such as a part of southern Cascadia, tremor activities have occurred spontaneously in the entire tremor zone.

Our observation suggests a possibility that the spatial distribution of the energy rate of tectonic tremors might control the behavior of slow earthquakes in the region. When the energy rate is distributed heterogeneously, some energetic tremors seem to control the activity of SSEs, as a switch that ignites a large-scale migration. When tremor patches are isolated, they are passively controlled by the tectonic loading. When it is homogeneously distributed, minor tremor activities, which rupture the only part of the tremor zone, cannot occur.

Effect of long-term SSE and megathrust earthquake on tremor activity

IDO, Miki[1*] ; SUDA, Naoki[1]

[1]Graduate school of Science, Hiroshima University

Tremor activity migrates with a velocity of ∼10 km/day along the strike of subducting plate boundary. Recently it has been shown that migration front draws a parabolic pattern in spatio-temporal distribution of tremors, indicating that tremor migration is diffusional process [Ide 2010]. We analyzed activities from 2001 to 2013 in western Shikoku, and obtained diffusion coefficients on the order of 10^4 m^2/s for all the activities. Relatively large values ($>1.5\times10^4$ m^2/s) were obtained for the activities during long-term slow slip events (SSEs) in the Bungo Channel region or just after the 2011 Tohoku earthquake (SSJ2013). In this study we investigate the relation between these activiteis and external stress perturbations.

To evaluate perturbations due to these events, we calculated Coulomb stress changes (ΔCFF) using Coulomb 3.3 [Toda et al. 2011]. The long-term SSEs in 2003 and 2010 produced ΔCFF of 28.7 and 5.4 kPa, respectively. These values are large enough to affect tremor occurrences because they are on the same order of magnitude as the tidal effect, which modulates tremor occurrences. The Tohoku earthquake produced ΔCFF of 0.4 kPa. Although it is smaller than the tidal effect by an order, a long-time stress change due to possible viscoelastic response would give some effect on tremor occurrences. Since such a stress perturbation is widespread on the plate interface, it could accelerate tremor migration observed as high diffusion coefficient. We also compare tremor activities with the seismicity calculated with a rate- and state-dependent friction law.

Improvement of tectonic tremor detecting and locating methods: Case study in Shikoku and Kanto

CHAO, Kevin[1*] ; OBARA, Kazushige[1]

[1]ERI, the University of Tokyo

Obtaining accurate tremor sources in time and space is important because it provides essential information that reveals the mechanism of tremor activity. Recent findings of triggered tectonic tremor in recently discovered regions in Hokkaido (Obara, GRL, 2012), Kyushu, and Kanto (Chao and Obara, AGU Meeting, 2012) provide an ideal dataset with which we can test the clock-advanced model, which predicts the occurrence of triggered tremor in regions where ambient tremor occurs. In this study, we improve upon two existing tremor detecting and locating methods: 1) the WECC (Waveform Envelope Correlation and Clustering) auto-detecting algorithm (Wech and Creager, GRL, 2008), which auto-detects tremor episodes, and 2) the improved conventional envelope cross-correlation technique (Obara, Science, 2002; Chao et al., BSSA, 2013), which accurately pinpoints the locations of short duration tremor sources in space. Using WECC, we detected tremor episodes in western Shikoku and compared the results with existing NIED tremor catalogs (Maeda and Obara, JGR 2009; Obara et al., GRL, 2010). Our preliminary results indicate that during testing period (i.e., tremor episodes between 2012/05/25 and 2012/06/02), the WECC was able to successfully auto-detect the same ambient tremor episodes listed in the NIED tremor catalogs. The tremor detections by WECC show similar tremor migrations pattern as the features from the NIED tremor catalog. In addition, the WECC is able to capture more small tremor episodes that are not included in the NIED catalog. Our next step will be to apply the WECC to the entire dataset to determine whether it can successfully detect all tremor episodes while minimizing noise. Using the modified envelope cross-correlation technique, we plan to conduct a 3D grid search to locate accurate triggered tremor sources in Kanto following several teleseismic earthquakes. This modified technique has been used to locate micro-earthquakes (M<=0.5) in western Shikoku, and a comparison of the hypocenter of these micro-earthquakes with those from the JMA earthquake catalog showed that they were located within 5km of one another.

Volcanic Deep Low-Frequency Earthquakes and Cooling Magma

ASO, Naofumi[1*] ; TSAI, Victor[2] ; IDE, Satoshi[1]

[1]Graduate School of Science, The University of Tokyo, [2]Seismological Laboratory, California Institute of Technology

Deep low-frequency earthquakes (LFEs) are deep earthquakes that radiate low-frequency seismic waves. While tectonic LFEs on plate boundaries are thought to be slip events, the physical mechanism of volcanic LFEs around the Moho beneath volcanoes is not well understood. For initial brittle failure to be produced at these temperature-pressure conditions, high strain rates should exist there.

Since an ascending magma diapir tends to stagnate near the Moho, where there is a density discontinuity, we suspect its thermal contraction acts as a driving force of volcanic LFEs. In the present study, we estimated thermal strain rates caused by a cooling magma near the Moho beneath volcanoes.

We calculated thermal evolution after an initial perturbation of 400K uniformly within planar and cylindrical magma intrusions. Then, we estimated thermal strain rates within the region of δT $<$200K, where the medium can be treated as a Poissonian elastic body. We assume a thermal diffusivity of 6×10^{-7}m^2/s and a thermal expansion coefficient of 2×10^{-5}/K, taking into account latent heat release and the density change caused by a phase change of partially molten material.

As a result, strain rates larger than the effect of tectonic loading ($>5\times10^{-14}$/s) is observed for planar magmas of width of $<$200m and cylindrical magmas of radius of $<$160m. Even if the initial crack were not observed because of small amplitude and high attenuation, an exited larger-scale deformation such as a resonance would be observed as an LFE.

The orientation of produced strain rates differs between planar intrusions and cylindrical intrusions. Assuming that magma shape and strain rate correspond to source distribution and source mechanism, respectively, we expect a correlation between source distribution and source mechanism for volcanic LFEs. Although a part of this relationship has been recognized for the LFEs in eastern Shimane in western Japan [Aso and Ide, 2014], more mechanism analyses are needed to verify our model.

Spatiotemporal Distribution of Shallow Very Low Frequency Earthquakes along the Nankai Trough and the Ryukyu Trench

ASANO, Youichi[1*] ; MATSUZAWA, Takanori[1] ; OBARA, Kazushige[2]

[1]National Research Institute for Earth Science and Disaster Prevention, [2]Earthquake Research Institute, The University of Tokyo

We have investigated spatiotemporal distribution of shallow very low frequency earthquakes (sVLFEs) along the Nankai trough and the Ryukyu trench. Three component seismograms recorded at 40 broadband stations of the NIED F-net were analyzed by using waveform-correlation and back-projection techniques after processing a band-pass filter (0.02 to 0.05 Hz). Here we used known 6 sVLFEs and 17 regular interplate earthquakes near the trench axis as template events. Time series of cross-correlation function (CC) at each station was calculated from continuous waveform data and triggered seismograms of template events. Assuming surface wave propagation, CCs are back-propagated onto possible origin times and horizontal locations. We obtained sVLFE epicenters by performing a grid search in time and space domains to maximize the averaged CCs from all stations under the condition of high signal to noise ratios that was defined as amplitude ratios between two time windows before and after the surface wave arrivals from the epicenters. As the result of this analysis for the last decade, we detected infrequent activity of sVLFE episodes at a few clusters adjacent to the locked zone related to the megathrust earthquakes along Nankai trough: in 2004 and 2009 of Kii peninsula, in 2003 and 2009 off cape Muroto, and in 2003 and 2010 off cape Ashizuri. On the other hand, sVLFE episodes in Hyuga-nada and areas along the Ryukyu trench are frequent. Such a variation of seismicity of sVLFEs revealed from this study based on the same detection capability may suggest the difference of the plate coupling in the seismogenic zone.

Relationship between very low frequency earthquakes and repeating slow slip events in the south Ryukyu Trench

NAKAMURA, Mamoru[1*] ; SUNAGAWA, Naoya[1]

[1]Faculty of Science, Univ. Ryukyus

The repeating slow slip events (SSEs) occur on the upper interface of subducted Philippine Sea plate at the depth from 30 to 50 km in the south Ryukyu Trench region (Heki & Kataoka, 2008). The afterslip of the March 2002 earthquake (Mw=7.2) is distributed at the west of the fault of the repeating SSEs. This afterslip continued from March 2002 to 2005 (Nakamura, 2009).

Recently, very low frequency earthquakes, which occurred continuously along the Ryukyu Trench, were detected (Ando et al., 2012). The occurrences of SSEs, afterslip, and very low frequency earthquakes reflect the state of slip in the plate interface.

Then we investigated the relation between the SSEs with very low frequency earthquakes.

We employed the broad-band seismometer network of NIED (F-NET) and IRIS. We used the station of Ryukyu Islands, Kyusyu, SSE (Shanghai), and TATO (Taipei). The used the waveforms of vertical component for the analysis. The period we used are from January 1, 2002 to September 30, 2013. We filtered the band-pass range of 0.02-0.05 Hz to the waveforms, and detected the low-frequency events and picked the arrival times of surface waves manually. The local and teleseismic earthquakes were eliminated using the earthquake catalogue. The local events were also eliminated with checking the high-pass filtered record. Then we determined the location of low frequency events assuming that the observed waves were Raleigh waves.

We determined the 6299 low frequency events for 12 years. Almost events are distributed along the Ryukyu Trench axis. The low frequency events are clustering at the south Iriomote Island, south of Okinawa Island, and near Amami Island. The events are also distributed near the Okinawa Trough. However, the events in the Okinawa Trough would be the apparent distribution by miss-location of hypocenter determination which is caused by the linear distribution of seismic stations along the Ryukyu Arc.

Next we investigated the cumulative number of low frequency earthquakes in the clusters. The activity of the low frequency events at the cluster of the south of Iriomote Island decreased from 2005 to 2010, and increased since late of 2011. The activation of very low frequency events occurred after the occurrence of repeating SSEs. The 24 SSEs had occurred since 2002, and the 14 activation of the low frequency events occurred after the SSEs. The occurrence rates of the VLFEs during the SSEs increased about 2-3 times than the averaged ones. However, the activation of usual earthquakes during the SSEs occurred only two times. These suggest that the SSEs would trigger the VLFEs.

Activity characteristics of deep very low frequency earthquake and asperity structure

NIZATO, Taro[1] ; SUDA, Naoki[1*] ; MATSUZAWA, Takanori[2]

[1]Hiroshima Univ., [2]NIED

Deep very low frequency earthquake (VLF) and deep nonvolcanic tremor (NVT) concurrently occur with short-time slow slip event (SSE) in the Nankai subduction zone. Among them VLF is least known since seismic records are usually noisy at dominant periods of VLF signals (20-50 sec). We have developed a new grid-based method for monitoring VLF activity in the Nankai subduction zone. In this method we assume that VLF occurs at equally-spaced grids on model plate boundary, and that VLF at each grid has a fixed source mechanism predetermined from plate boundary model and observed plate convergence direction. Previous studies have used the grid moment-tensor method in which depth and source mechanism are freely determined. These parameters are predetermined in the present method, so that it is expected that small VLFs can be detected even from low S/N records.

As a preliminary study we analyzed Hi-net accelerometer records for two activities in western Shikoku in September 2006 and March 2007. We detected a large number of VLFs compared with previous studies, and observed the following characteristics: (1) Some VLF occurrences were rapidly activated than NVT occurrences, and VLF activity highs were sometimes delayed relative to NVT activity high, (2) There was an NVT cluster with or without VLF depending on activity, (3) Rapid tremor reversals are associated with VLFs, (4) Clusters with maximum moment release were different between VLF and NVT, (5) The cluster of maximum VLF moment release was located in the updip portion next to the region of maximum SSE moment release. Some of these characteristics can be explained by a nested or fractal asperity model, in which small NVT asperities are contained in a VLF asperity.

Preseismic behaviors involving slow slip in rate-state earthquake sequence models with a hierarchical asperity concept

NODA, Hiroyuki[1*] ; NAKATANI, Masao[2] ; HORI, Takane[1]

[1]JAMSTEC, IFREE, [2]The University of Tokyo, ERI

Understanding preseismic phenomena before large earthquakes is of critical importance in assessing possibility of disaster mitigation by detecting and recognizing them. The 2011 Tohoku-Oki earthquake has long recorded geophysical data for tens of years prior to it. Since the earthquake, multiple studies have reported potentially important phenomena involving slow slip which may be particular to ripe asperities. It is our mission for modelers to see if they are consistent with, or appear naturally without fine tuning of numerical models of earthquake sequences accounting for interseismic processes, as well as earthquake ruptures.

The off-Miyagi to off-Fukushima region was locked at least from Apr. 1995 to Mar. 2002 [Nishimura et al. 2004], with the shallower region not being able to be constrained by on-land GPS stations [Loveless and Mead, 2011]. The region started creeping from 2005 [Ozawa et al., 2012]. Recently, Katsumata [2013, JpGU] pointed out that seismic quiescence [Katsumata, 2011] correlates with the locked period, and inferred that this region may have been creeping at least from 1980 to 1988. In the shallower region near the hypocenter of the Tohoku-Oki earthquake, a couple of slow slip events were reported by Ito et al. [2013], one in Nov. 2008 and the other in Feb. 2011. This interval is much shorter than that for the larger scale events inferred by Katsumata [2013].

Suito et al. [2011] reported that M7-class earthquakes along the Japan Trench after 2005, including the Mw 7.3 preshock 2 days before the Tohoku-Oki earthquake, had unusually large amount of afterslips. The postseismic moment releases are comparable to or even larger than the coseismic ones, with the centroid being located close to the epicenters, not deeper than them.

In the present talk, we present that qualitatively similar behaviors to those observations are recognized in numerical models reported by Noda et al. [2013, JGR]. They presented rate-state earthquake sequence simulations accounting for a hierarchical asperity concept [Ide and Aochi, 2005]; a large tough patch has a small fragile patch in it. Importantly, those simulations were not meant to mimic the Tohoku-Oki earthquake through fine tuning of the model, and are representing general behaviors characteristic to the rate-state (aging law) earthquake sequence with a certain kind of heterogeneity in the parameter distribution.

In those simulations, interseismic penetration of a creep front into a locked velocity-weakening patch often becomes non-steady and accompanied by aseismic transients before nucleation. This is because the critical length scale for impossibility of coherent steady-state slip [Rice et al., 2001] can be smaller than the nucleation size [Rubin and Ampuero, 2005]. In the simulation, the transients take place both in the large tough patch and in the small fragile patch when a creep front penetrates inwards to a certain extent. A transient does not necessarily, but may lead to nucleation. In addition, such an elevated aseismic slip rate in the large patch seems to be a necessary condition for cascade-up rupture growth from the small patch if it is smaller than the nucleation size of the large patch.

A small event which only ruptures the small patch is sometimes followed by a large event before the afterslip smearing out. Such small events are classified as precursory events, since clear causality is recognized between them and the following large ones; the large ones are initiated either by delayed cascade-up or by large nucleation hosted by the afterslip. The precursory small events tend to have larger afterslip than non-precursory ones.

In the rate- and state-dependent friction law, logarithmic slip rate is, by definition, proportional to stress minus strength which correlates with fracture energy. Therefore temporal changes in the aseismic slip rate in a so-called asperity, if detectable, could be used to infer the ripeness of it.

Numerical simulation of slow slip events before the 2011 Tohoku-Oki Earthquake

NAKATA, Ryoko[1*] ; ARIYOSHI, Keisuke[1] ; HYODO, Mamoru[1] ; HORI, Takane[1]

[1]JAMSTEC

In the Japan Trench, the M9.0 great interplate earthquake occurred on 11 March 2011, off the coast of Tohoku, Japan. Before this earthquake, two slow slip events (SSEs) were observed on 2008 and 2011. The second SSE occurred on February 2011 at the downdip end of the huge-coseismic-slip region, and it continued at least until the occurrence of the M7.3 largest foreshock on March 9 [Ito et al., 2013]. In addition, following the largest foreshock, postseismic slip propagated to the location of the mainshock hypocenter and triggered the dynamic rupture there [Ando & Imanishi, 2011].

In this study, we numerically simulated cycles for occurrences of seismic and aseismic events along the Japan Trench with the 3D geometry of the Pacific plate. We model the M9 2011 Tohoku-Oki Earthquake, the largest foreshock of the M9 earthquake, and the SSE before the foreshock using the slowness law, which is a type of rate- and state-dependent friction law. We set frictional properties at source area of earthquakes and SSEs to satisfy a condition of unstable slip and slow slip, respectively. We evaluated simulation results achieved using different values of frictional parameters with respect to characteristics such as the slip history leading to the 2011 Tohoku-Oki earthquake and crustal deformation before and after the Tohoku-Oki earthquake.

As a result, we quantitatively reproduced the observed scenario. Temporal characteristics of the resultant scenario were sensitive to both sizes and locations of the circular fault patches. Now, we are improving our model to reproduce various characteristics qualitatively. Based on some of the reasonable results achieved, we will discuss frictional conditions for the pre-seismic process of the 2011 Tohoku-Oki earthquake.

Deep Triggered Non-Volcanic Tremor in the Slow Earthquake Active Regions in South Chile and Ecuador

CHAO, Kevin[1*] ; OBARA, Kazushige[1]

[1]ERI, the University of Tokyo

Deep non-volcanic tremor has been observed at many major plate-boundary faults and intraplate faulting systems. Recent studies have shown that the tremor triggered by surface waves of teleseismic earthquake occurs on the same fault patches as the spontaneously occurring ambient tremor. The observations suggest that the triggered tremor can be used as a proxy to estimate the background tremor activity. Here we search for tremor triggered by teleseismic earthquakes in south Chile and Ecuador where the ambient tremor and slow slip event have been observed respectively. In south Chile, we analyzed a temporal array data between 2004 and 2006 and observed clear triggered tremor following the 2004 Mw9.0 Sumatra, 2005 Mw8.6 Nias, and 2006 Tonga earthquakes. Triggered tremor sources are located at the central of the ambient tremor zone. The results indicate both Love and Rayleigh waves promote the tremor triggering potential. The tremor triggering threshold is around 2 kPa, similar to which in Parkfield. In Ecuador, we can only use single station to infer the existence of triggered tremor due to lack of seismic stations in this region. During the period between 2004 and 2012, we observed triggered tremor following the 2010 Mw8.8 Chile and 2007 Mw8.0 Peru earthquakes. Since there is no other station within 500 km near that station, we roughly estimate that the triggered tremor sources are located within 50 km from the station based on the attenuation of tremor from previous studies and the estimation of the time difference between P- and S-waves of triggered tremor. We infer that the triggered tremor source might be located at the region where the slow slip event has been observed. The apparent tremor triggering threshold in Ecuador is about 40 kPa. The high threshold infer a low background tremor rate or simply due to the network capability.

Shallow low-frequency tremor activity in the Hyuga-nada, revealed by ocean bottom seismographic observation

YAMASHITA, Yusuke[1*] ; YAKIWARA, Hiroshi[2] ; UCHIDA, Kazunari[1] ; SHIMIZU, Hiroshi[1] ; HIRANO, Shuichiro[2] ; MIYAMACHI, Hiroki[2] ; UMAKOSHI, Kodo[3] ; YAMADA, Tomoaki[4] ; NAKAMOTO, Manami[1] ; FUKUI, Miyo[1] ; KAMIZONO, Megumi[1]

[1]Institute of Seismology and Volcanology, Kyushu Univ., [2]Nansei-Toko Observatory for Earthquakes and Volcanoes, Kagoshima Univ., [3]Graduate School of Fisheries Science and Environmental Studies, Nagasaki Univ., [4]Earthquake Research Institute, Univ. of Tokyo

In order to reveal the detail of microseismicity from the shallower part of the plate boundary to seismogenic zone in the Hyuga-nada region, we have conducted Ocean Bottom Seismographic observation from May 19 until July 6, 2013. We used 12 Ocean Bottom Seismometers (OBSs) with a three-component short-period seismometer. During this observation, we observed many low-frequency tremors (SLFT) which mainly occurred from end of May to end of July 2013 [*Yamashita et al*., 2013 AGU fall meeting]. We report the detail of SLFT activity in the Hyuga-nada region based on the semi-automatically analysis using envelope correlation method (ECM)[*Obara*, 2002].

The differential arrival times between OBS stations using ECM were obtained from the lag times with maximum cross-correlation coefficient between the pair of the root mean square (RMS) envelopes which were converted from composite horizontal components waveform with applying a 2-8 Hz bandpass filter. RMS envelopes were smoothed by using 5 s window and performed down-sampling with a 20Hz. The length of RMS envelops for calculating of cross-correlation coefficients was set for 150 s. If the maximum cross-correlation coefficient for a pair was larger than 0.85, and more than or equal to 6 pairs, we searched minimum RMS residual position by a grid search algorism. These processing were performed automatically for the continuous RMS envelope records every 75 s (i.e., overlapping two moving window for 75 s). After the calculation, we carefully examined the candidate tremor events to distinguish ”regular” earthquakes, T-phase signals, or background noise.

Based on the result of SLFT location by ECM, we identify two migration episode of the SLFT: 1st episode started in east off Tanegashima Island from end of May, 2013, migrated northward along strike of subducting plate, veered away to the north-west in the around S08 station, then reached under the S06 station on July 12 - 14. 2nd episode started in the south of S08 station on July 17, migrated northward and veered away to the north-west in the around S08 station, reached around the S07 station, veered away to the east, reached around the S09 station.

These migration episodes suggest that undetected short-term slow-slip event may have occurred at the same time in the shallow part of the Hyuga-nada region. Around the focal area of SLFT, the Kyushu-Palau ridge is subcudting: the SLFT activity was only found on the south side (i.e., Ryukyu arc side). In particular, the depth of plate boundary around the S08 station is southwestward deepening down to 10 km depth [*Park et al*., 2009]. Therefore, the episodic slow-slip extended to northward with SLFT activity, and shifted to northwest-ward caused by the Kyushu-Palau ridge which act a segment boundary to controle the interplate slip phenomena.

The Slow Slip Event off the Boso Peninsula on January 2014 and the associated earthquake swarm

KIMURA, Hisanori[1*]

[1]National Research Institute for Earth Science and Disaster Prevention (NIED)

Introduction

Off the Boso Peninsula, at the southeastern Kanto, central Japan, slow slip events (SSE) accompanied with earthquake swarms recurs with time interval of 4-7 years. SSEs have occurred in 1983, 1990, 1996, 2002, 2007, and 2011 and the latest SSE recurred from Dec. 2013 to Jan. 2014 with interval of 2 years and 2 months. In this study, detailed activity of the earthquake swarm and a fault model of the Boso SSE were determined.

Data and Methods

High precision hypocenter distribution was determined for earthquakes shallower than 30 km off the Boso Peninsula, from Jan. 1, 2005 by Double Difference method incorporating waveform correlation analysis. Hypocentral parameters determined by NIED Hi-net (automated hypocenters were partly included) were used as initial hypocenters.

A rectangular fault model with uniform slip was determined using genetic algorithm inversion for fault location and geometry and the weighted least squares method for slip amounts, following a method of Obara *et al*. (2004) based on tilt data recorded by high sensitivity accelerometer co-installed in NIED Hi-net station. In this analysis, slip direction was fixed to the direction of relative plate motion.

Results

Most earthquakes occurred around the northern edge of the seismic region where seismic swarms associated with the previous Boso SSEs occurred. Seismic swarms first occurred at the eastern offshore area and then migrated to the western onshore area. Migration from offshore to onshore regions is common feature among the previous Boso SSEs. Distribution of earthquake swarms is similar to that of the 2007 SSE, although spatial distribution and number of events are slightly smaller than the 2007 SSE.

The maximum crustal tilting of about 0.4 μ radian with northwestward direction was observed at KT2H station and the fault model was determined to be located off the Boso Peninsula with size of M_W6.1. Location of SSE slip overlaps with locations of the 2007 (Sekine *et al*., 2007) and initial stage of the 2011 (Hirose *et al*., 2012) SSEs. Tilting direction is similar to tilting direction of the 2007 SSE, however, its amount is about a half of the 2007 SSE (M_W6.4) and the SSE size is also smaller. Smaller number of earthquakes is likely to reflect smaller size of the SSE. In the 2011 SSE, west-northwestward tilting of about 0.3 μ radian was observed for the first two and a half days and size for this period was estimated as M_W6.2. Its direction and amount are similar to those of the 2014 SSE and the SSE size is also close.

Discussion

Recurrence interval of the 2014 SSE was shortest for the last about 30 years. The size of the 2011 SSE was estimated to be comparable to previous SSEs and a possibility that the 2011 SSE was hastened by the stress increase caused by the 2011 Off Tohoku Earthquake and its afterslip has been proposed (Hirose *et al*., 2012). On the contrary, size of the 2014 SSE is likely to be smaller than previous SSEs. This result infers that the SSE slip is smaller supposing the same source area and the SSE recurred with shorter interval with smaller stress accumulation. Further analysis is necessary to reveal the detailed source process of the Boso SSE for monitoring of the stress accumulation.

A long-term slow slip event in central Shikoku in 2013

KOBAYASHI, Akio[1*]

[1]Meteorological Research Institute

A long-term slow slip event in central Shikoku is investigated using the GEONET GNSS data. We estimated the steady deformation rate at each GNSS station from the daily coordinates for the period from January to December 2012. Then the steady deformation rates were subtracted from all the coordinate data. The artificial offsets of the coordinate were corrected using data set shown on the web site of the Geospatial Information Authority of Japan. We can see south-eastern displacements less than 1 cm at GNSS stations in central Shikoku for one year from October 2012. These unsteady displacements are also seen in the time series of the baseline lengths between central Shikoku and Chugoku district.

We estimated slip distribution on the plate boundary, assuming the unsteady displacements were caused by a slip on the plate boundary. The estimated slip is distributed in central Shikoku. Center of the slip is located slightly southeast of the belt of deep low-frequency earthquakes. The size of the slip is equivalent to Mw 6.2, which is smaller than other long-term SSEs along the Nankai Trough.

Rate and state simulation of Yaeyama slow slip events in the southwestern part of the Ryukyu Arc, Japan

OKUDA, Ryosuke[1*] ; HIRAHARA, Kazuro[1] ; MIYAZAKI, Shinichi[1] ; KANO, Masayuki[1] ; OHTANI, Makiko[1]

[1]Graduate School of Science, Kyoto Univercity

Slow slip events (SSEs) are recurring on the plate interface beneath the source regions of the interplate large earthquakes. It has been proposed that the activity of SSE possibly changes before the occurrence of large interplate earthquakes. Hence, it is essential to know the frictional properties for producing SSEs to predict the occurrence of large earthquakes. Our final goal is to optimize frictional parameters on the fault related to SSE through a data assimilation method which combines the observational data and the forecast ones derived from a simulation model, and then to give information on the occurrence of large interplate earthquakes. In this paper, as a first step of such a data assimilation, we construct a simulation model reproducing the observed spatio-temporal slip evolution of SSE.

In this paper, we consider the Yaeyama SSEs. Around the Yaeyama islands in the southwestern part of the Ryukyu Arc, Japan, GPS observations have caught the frequent recurrence of SSE activity. Around there have occurred almost no large earthquakes that affect the SSE activities during the observational period, which leads to a relatively simple simulation model of SSE. Those are the reasons that we select SSE on this area.

Heki and Kataoka(2008) reported the following features of Yaeyama SSEs; 1) SSEs recur on a plate interface at depths of 20-40km, 2) the average recurrence interval is 6.3 months, 3) its standard deviation is 1.2 months, 4) the slip rate released by SSEs is 11.0 cm/yr, in spite of the estimated convergence rate of 12.5 cm/yr.

We construct a simulation model which reproduces the above mentioned features of SSE. We set a dipping fault embedded in a homogeneous elastic half space. The friction on the fault is assumed to obey a rate-and state-dependent friction law, and the slowness law of state evolution (Dietrich, 1979). To simulate SSE, following Kato(2003), we set an asperity at depths of 20-40 km on a stable sliding plate interface, whose frictional properties are characterized by frictional parameters A, B and L. The asperity has the rate weakening frictional property of $A-B<0$ and its radius is nearly equal to or less than the nucleation radius determined by frictional parameters. We also consider the possible presence of a locked zone, namely an asperity, at the shallow portion of the plate boundary close to the Ryukyu Trench, which might cause the 1771 Meiwa tsunami (Nakamura, 2009). Dating of tsunami stones suggests a possible recurrence of 150-400 years of large tsunami (Araoka et al., 2013), and the large tsunami events close to the Ryukyu Trench might have recurred in several hundred years.

It is found that the interval of SSE can be adjustable by changing the friction parameters. For example, if a single asperity with the size of 80 km has frictional parameters of A=50 kPa, B=56kPa, and L=2.2 mm, the interval is about 6 months. Further, if we add another asperity with 40 % slip deficit rate of the convergent rate of 12.5 cm/yr just above the SSE asperity zone, the slip rate released by SSEs reduces to the observed rate of 11.0 cm/yr. The released slip rate depends on the location, size and assigned slip deficit rate of the shallow asperity. The locking state at the shallow portion is important to give information on the occurrence of possible tsunami earthquake, and we need the further investigation. For reproducing the observed fluctuation of recurrence intervals of SSE, we need to consider the interaction among multiple asperities or the hierarchical asperity model where a large asperity has small asperities with different properties inside itself.

Array observation of short span strainmeter in the Kii peninsula

KANO, Yasuyuki[1*] ; HOSO, Yoshinobu[1] ; ONOUE, Kensuke[1]

[1]DPRI, Kyoto Univ.

Crustal deformations have been observed associated with deep low-frequency tremors occurring below the Kii peninsula and Shikoku. Strain measurements by an extensometer at Kishu operated by DPRI, for example, show that the sources with epicentral distance of 30 - 40 km causes strain changes of $10^{?9}$ to $10^{?8}$ occurring within several days. Although the traditional extensometer observations can detect these strain changes, it is difficult to make detailed analyses because of the limited number of stations. We designed a short-span extensometer with 1.5 m-long standard measure. Strong coupling of the instrument to the ground is important for stable observations, so three anchor bolts fixed to the base of the instrument are cemented into a 50-cm-deep hole. We observed crustal deformation associated with deep low-frequency tremors by the short-span extensometer installed at Nakaheji. We detected strain change associated with low frequency events occurred on March 2013. We are preparing another sites for installation of the strainmeter around the western Kii Peninsla to constract array of strainemters. The array observation contributes to improve the detection capability of crustal deformation by eliminating noise caused by weather disturbance and to have better understanding of slow slip events such as slip distribution.

Reconstraction of paleostress states in the Walanae fault zone in South Sulawesi using the multiple inverse method with

NISHIKAWA, Osamu[1*]

[1]Akita University

Paleostress analysis using the multiple inverse method with calcite twin data was performed in the East Walanae fault (EWF) zone in South Sulawesi, Indonesia. The geomorphic trace of the EWF can be recognised as a distinct line between the Bone Mountains and the Walanae Depression, around which an intensive deformation zone characterised by various scales of faults and folds are developed. Carbonate rocks with numerous calcite twins and mesoscale faults are ubiquitous around the EWF trace. Therefore EWF zone is a useful location for testing the inclusion of calcite twin data in the multiple inverse technique to determine paleostress states. One to three poles of differently oriented twin lamellae and c-axis orientation were measured for each grain from three mutually perpendicular thin sections for 11 samples using a U-Stage optical microscope. The data set for multiple inverse method consists of the attitude of the e-plane, gliding direction and sense of shear of e-twinning. We prepared data files not only for twinned e-planes but also for the remaining untwinned e-planes in a grain with one or two twin sets. We incorporated the untwinned e-plane data for determining stress states with the multiple inverse method using calcite twins. In the analysis, the identified stress states by twinned e-plane data were tested calculating misfit angle β, the angle on the untwinned e-plane between the calculated maximum shear stress direction for every identified stress state and the observed potential gliding direction. It is possible to say that the sampled rocks had never experienced stress states to activate any of the untwinned e-planes. Therefore, if most untwinned e-plane data (95% or more in this study) are incompatible(β >30 degree) with the stress state identified from twinned plane data, then the stress state is viable for both the twinned and untwinned e-planes.

The analysis using calcite twin yielded reliable paleostress states similar and consistent with those from fault-slip data throughout the study area. Dominant and common stress states are characterized by NE-SW-to-E-W-trending σ1 and vertically to moderately-south-plunging σ3 with generally small values of stress ratio ϕ. These stress states were most likely caused by collision of eastern Sulawesi with the Australian fragments since the Pliocene, and they could have activated the EWF as a reverse fault with a dextral shear component, accounting for the contraction deformation structures and landforms along the trace of the fault. Calcite twin and mesoscale faults were activated predominantly during the fold tightening stage and subordinately before folding.

Capability of calcite twin for estimating stress magnitudes and orientations

YAMAJI, Atsushi[1*]

[1]Kyoto University

Calcite has three e-twin planes, each of which has a critical resolved shear stress at ˜10 MPa along the twin gliding direction; and the planes and direction have certain crystallographic orientations (e.g., Lacombe, 2010). We quantified the tightness of the constraints from twin and untwin data on stress conditions. It is shown that twin and untwin data place tight constraints if differential stress is low and large, respectively. Their tightness converges to the same value with increasing differential stress. The constraint from a calcite grain becomes tighter with increasing number of twin sets in the grain. It is also shown to be important to cope with sampling bias to utilize untwin data: The number of twin data compared to the total of twin and untwin ones tend to be underestimated by ˜25%. It is found that calcite e-twin loses resolution in determining stress magnitudes and orientations if differential stress is greater than ˜200 MPa.

Enhanced detectability of stress tensor inversion from heterogeneous fault-slip data with preferred orientations

SATO, Katsushi[1*]

[1]Div. Earth Planet. Sci., Kyoto Univ.

Fault planes occasionally have preferred orientations according to the slip tendency (e.g., Lisle and Srivastava, 2004), which is defined as the ratio between normal and shear stresses (Morris et al., 1996). In contrast, most stress tensor inversion methods calculate crustal stress states from fault-slip data on the assumption that faults slip along the resolved shear stress vectors on their surfaces. This assumption called Wallace-Bott (W-B) hypothesis allows low values of slip tendency on ”misoriented” faults so as to consider faulting along pre-existing weak surfaces in rock masses. However, the weak assumption causes the loose constraint on stress. For example, when a set of conjugate faults is observed, one usually determines principal stress axes as bisectors of fault planes. On the contrary, W-B hypothesis permits only to constrain the axes within the angle between fault planes. Such a disadvantage severely lowers the detectability of multiple stress conditions from heterogeneous fault-slip data. To avoid this problem, this study proposes a new method of stress tensor inversion by combining the W-B hypothesis and the slip tendency.

This study employed a stress tensor inversion method called HIM (Yamaji et al., 2006; Sato 2006) which maximize the fitness between observed slip directions and shear stress vectors. The fitness value is modified to be the product of the conventional fitness and the slip tendency. Artificial fault-slip data are analyzed to examine the performance of the new method. The data set includes 200 faults compatible with N-S compressional stress and 50 faults compatible with E-W tensional stress. The former has random orientations of fault planes and the latter has a preferred orientation so that they have large values of slip tendency. As the result, the conventional HIM could not detect the latter stress, while the new method could detect both stresses.

The new method is applied to fault-slip data from Late Miocene Awa Group in eastern Boso Peninsula. Mesoscale faults in this area have at least two different origins; reverse-faulting stress and normal-faulting one (e.g., Angelier and Huchon, 1987). The new method successfully detected both stresses without a priori classification of faults into subsets.

Reconstruction of absolute stress based on a condition of aftershock occurrence

IMANISHI, Kazutoshi[1*] ; UCHIDE, Takahiko[1]

[1]Geological Survey of Japan, AIST

Absolute crustal stress is essential to understand the earthquake generation process. If focal mechanisms both before and after an earthquake together with the fault slip model of the earthquake are available, the magnitude of absolute stress can be constrained (e.g., Hardebeck and Hauksson, 2001; Wesson and Boyd, 2007; Yang et al., 2013). However the application of those methods is inherently limited, because background seismicity is generally low. In this study, we propose a method to reconstruct an absolute stress field incorporating a condition of aftershock occurrence, which is applicable to areas without enough pre-mainshock focal mechanisms.

We suppose that there are pre-existing weak planes represented by aftershock focal mechanisms. Because these planes were locked before the mainshock but afterwards activated, it is reasonable to expect that the slip-tendency, defined by the ratio of shear to normal stress acting on a given plane (Morris et al., 1996), increases after the occurrence of the mainshock. On the basis of this consideration, we search the best absolute stress field as follows.

(1) We assume a pre-mainshock homogeneous absolute stress field (**B**) in the study area. We then compute a post-mainshock stress field (**A**) at each aftershock location by combining the stress change due to the mainshock and the aforementioned pre-shock stress field.

(2) For the fault plane of each aftershock, we compute a pre- and a post-mainshock slip-tendency ($T_s{}^b$ and $T_s{}^a$, respectively) based on the pre- and post-mainshock stress fields, **B** and **A**, respectively. Regarding the computation of $T_s{}^a$, we adopt the component of stress acting in the slip direction on a fault instead of the shear stress itself. Therefore, $T_s{}^a$can have a negative value.

(3) We compute the summation of $T_s{}^a$ of aftershocks that satisfy the condition of $T_s{}^a > T_s{}^b$. If both nodal planes satisfy the condition, the larger $T_s{}^a$ is used for the summation.

(4) We repeat the procedure (1) to (3) by changing the initial stress field **B**, and search a stress field that has the largest sum of $T_s{}^a$.

Numerical tests of this method work well. It is noted that multiple candidates of stress fields were inferred, if we did not incorporate the condition of $T_s{}^a > T_s{}^b$, suggesting that the condition is important in the situation without pre-mainshock focal mechanisms. We then applied the method to the 2013 M6.3 Awaji Island earthquake. Focal mechanisms of 115 aftershocks were determined from P-wave polarity data as well as body wave amplitude. A finite fault slip model of the mainshock was derived from slip inversion analysis (see Uchide and Ide, 2007) of KiK-net strong-motion data. A preliminary analysis shows that the pre-mainshock stress field is characterized by a reverse-faulting regime with a WSW-ENE oriented maximum compression and the differential stress of 200-300 MPa.

Acknowledgements: Seismograph stations used in this study include permanent stations operated by NIED (Hi-net, KiK-net), JMA, ERI, and DPRI. We modified a program coded by Satoshi Ide to estimate the focal mechanism solutions. We thank Yoshimitsu Okada for the use of his code in our stress change computation.

Motions after rainfall in borehole tiltmeters and the azimuth of crustal stress before and after 2011 Tohoku Earthquake

SHIMADA, Seiichi[1*] ; KIMURA, Takeshi[1]

[1]NIED

Shimada (1987) has revealed that in borehole telemeter generally the tilt motions after rainfall are tilting to a certain azimuth which is named 'rainfall component', and the perpendicular azimuth is named 'rainfall-free (RFF) component'. In the time series of the RFF component, very little motions are seen after rainfall. From the observations of tiltmeters in NIED Kanto-Tokai network, Shimada (1987, 1989) has found that the azimuths of the RFF component are generally coincided with the azimuth of the crustal maximum compressive stress obtained from the experiments of hydrofracturing and the mechanisms of middle or large scale earthquakes. This is interpreted that the azimuth of the strike of the nearby open crack of the borehole is generally coincided with the azimuth of the crustal maximum compressive stress.

In this study, we examine the azimuth of tilt motions after rainfall for Hi-net borehole high-sensitivity accelerometer (tiltmeter) in the periods from April to December in 2010, 2011, and 2012 before and after the 2011 Great Tohoku Earthquake in the region of the border of Ibaraki and Fukushima prefectures, and the time variations of the azimuth of the maximum principal crustal stress.

The left figure shows the azimuth of the RFF component of the seven borehole tiltmeters in this area obtained from the time series from April to December 2010. In IWEH site, the azimuth of the RFF component is almost N-S direction, suggesting in the nearby area of this site the maximum compressive stress was not E-W direction even before the 2011 Great Tohoku Earthquake. Among the sites south of IWEH site, in the sites near IWEH site and coastal sites the RFF components are generally almost NE-SW direction, suggesting in the area the maximum compressive stress does not coincide with E-W direction which is seen widely in NE Japan before the 2011 Great Tohoku Earthquake.

The right figure shows the azimuth of the RFF component of the same seven borehole tiltmeters obtained from the time series from April to December 2011 or 2012. In this period, there occurs many offsets and large drifts after those offsets arose by the induced earthquakes and aftershocks of the 2011 Great Tohoku Earthquake, and it is not so easy to detect the detections of the motions after rainfall and the azimuth of the RFF components comparing with the period in 2010. In HTAH and YBKH sites, there seems very little time variations in the azimuth of the RFF component. Also in IWEH site, the time variation of the azimuth of the RFF component is only 10 degree. In IWWH site, the azimuth of the RFF component changes significantly, and almost N-S direction. In DGOH site also the azimuth of the RFF component changes from the NE-SW direction before the earthquake to the NNE-SSW direction. In THGH sites, there are very large noises in N-S component in 2012, which is probably mechanical faults, and there seems very little time variations in the azimuth in 2011 compared with that in 2010. In JUOH site, very little tile motions are seen after rainfall, suggesting the closing of the crack opened in 2010 because of the time variations of the azimuth of crustal stress.

Estimating from the tilt motions after rainfall before and after the 2011 Great Tohoku Earthquake in the Hi-net sites in the area of the border of Ibaraki and Fukushima prefectures, it is suggesting that the area with the N-S direction maximum compressive stress is exist near the IWEH site even before the earthquake, and that mainly in the area west of IWEH site the maximum compress stress shifts near N-S direction after the earthquake.

Evaluation of faults in the site of power plants and stress analyses

SHIGEMATSU, Norio[1*]

[1]Active Fault and Earthquake Research Center, AIST

The expert meeting on the investigation of fracture zones in the site of the Ohi power station of NRA (Nuclear Regulation Autority) concluded that the F-6 fault in the site is not an active fault. Stress tensor inversion was a key technique to make the conclusion during the discussion. In this talk, I will explain how stress tensor inversion was used to evaluate the faults.

It is difficult to evaluate faults based on paleoseismological techniques in the site of many of the power plants, due to the lack of young sediments and tectonic landforms. For the evaluation of the safty of the power plants, it is important to evaluate if the faults in the site are active. Degree of the activity of the faults is not always important. Stress tensor inversion based on the fault slip data is useful because the phenomenon is relatively clear.

There are two concepts to evaluate if the faults are active or not using stress analyses. One is to compare the structures in the fault with the present stress such as slip tendency. The other is that stress tensor inversion is used as a tool to construct the tectonic histories. The former concept may have a problem concerning the stability of stress, especially after large earthquakes. The later concept used stress tensor inversion to determine the sequence of tectonic stages. Tectonic stage is the period during which faults had repeated to move due to the control of similar stress condition. Once the structures in faults at different places were identified to be controlled by the same stress condition, those structures were formed during the same tectonic stage. The comparison of the result of this analysis with the result of fault trenching enables us to evaluate if the faults are active or not.

Stress rate dependency and effect of volatile element on seismicity of volcano-tectonic earthquakes

MORITA, Yuichi[1*]

[1]ERI, Univ. of Tokyo

Even in a quiescent period, magma is charged and discharged intermittently beneath volcanoes, and volcano-tectonic earthquakes often occur with ground inflation that is caused by upward migration of magma. Moreover, an increasing volatile element sometimes leads an increasing seismicity. Therefore, it is well known that the seismicity around a volcano is one of the well-established indicators of volcanic activities. Many evidences show that increasing seismicity is followed by volcanic eruptions or magma intrusions because magma migration makes large stress change. On the other hand, the increasing seismicity does not always result in volcanic eruptions. We need to evaluate seismicity quantitatively and discriminate some kinds of effects that generate earthquakes. At present, research in this field has not been established well. It is partly because we cannot propose the model that express temporal variation of seismicity quantitatively, and we do not have enough observation data except some volcanoes where dense observation networks are installed multi-disciplinary.

We proposed to apply the Rate and State Friction (RSF) law to the seismicity occurring at Izu Oshima volcano where dense GPS network as well as seismic one are installed. At the volcano, stress rate changes are observed every 1 to 2 years because of the intermittent magma charging and discharging processes. We presented in last fall meeting of volcanological and seismological society that a simple RSF law model cannot reproduce the observed seismicity fully. We try to revise the model and get remarkable improvement. Aim of this presentation is to reveal the effect of stress rate as well as the other effect, such as volatile element emitted from magma that affect the seismicity around volcanoes, and demonstrate that the seismicity has large potential to monitor the condition not only in the stress rate but also in the volatile density beneath volcanoes.

In Izu-Oshima volcano, seismicity is well correlated with stress rate caused by magma accumulation except the period after the long-term inflation is weaken in 2011. In several volcanoes, increasing volatile component causes decreasing normal stress at fault plane in seismogenic zone and earthquakes are generated intensely (e.g. Northern Volcanic Rift zone in Iceland, La Fossa volcano in Italy). The weakened inflation means that fresh magma is less supplied and emission of volatile decreases in Izu-Oshima volcano. Therefore, we added the effect of the increasing and decreasing volatile element in the previously proposed RSF law, and revised the model. Finally, we can complete successfully the revised model that realize the observed seismicity for all analyzed period.

In conclusion, temporal variation in seismic activity around volcano is mainly due to changes in stress field generated by the magma accumulation and partly caused by effect of volatile element that affects the confining pressure of the fault surface at seismogenic zone. The effect of the stress field is well modeled by ordinary RSF law, and its parameters can be estimated from the data in quiescent period. If observed seismicity exceeds the level that estimated from the model, the volatile element much emitted from magma and it may be precursor to the volcanic eruptions. Therefore, the difference between observed seismicity and the calculated one based on the RSF law is one of the powerful indicator to forecast volcanic eruptions. We propose that there are two kinds of earthquake generating mechanisms around the volcano. Further study at other volcanoes will be helpful to understand the volcano-tectonic earthquake systematically. In future, we should examine the model from direct observation of volcanic gas at volcanoes.

Investigation into stress field and strength at hypocenters at South African gold mines

OGASAWARA, Hiroshi[1*] ; KATO, Harumi[2] ; HOFMANN, Gerhard[3] ; ROBERTS, Dave[3] ; CLEMENTS, Trevor[4] ; PIPER, Phil[4] ; YABE, Yasuo[5] ; NAKATANI, Masao[6] ; NAOI, Makoto[6]

[1]Ritsumeikan University, [2]3DGeoscience Inc., [3]Anglogold Ashanti ltd., [4]Groundwork ltd., [5]Tohoku University, [6]The university of Tokyo

We report on in-situ stress measurements at seven sites at South African gold mines. The depth ranged from 1.0 to 3.4 km (deepest level in the world where mining is in progress). The measured maximum stress ranged from to 146MPa. In the ranges of stress above 100 MPa have not been able to be measured before we introduced a downsized Compact Conical-ended Borehole Overcoring technique (CCBO; ISRM suggested) in South African gold mines, which has several advantages over the methods widely used in South Africa.

The in situ measurements were carried out at the sites with minimal disturbance by mining or geological features at depths of 3.3 and 3.4 km at Tau Tona and Mponeng mines, respectively, both allowing confirmation that the virgin stress assumptions in the mine were acceptable with slight modification. With the modified virgin stress assumptions, the loading conditions for seven seismic events (ML >2.9) over a 9-year period at Tau Tona mine were back-analyzed with an elastic boundary element method that allows non-linear ride and closure on displacement discontinuity elements (Map3D Fault-SlipR), successfully constraining the stress or the strength on the source faults. At the Pink and Green dykes at 116L at Mponeng mine, the rupture plane of a ML2.1 event was finely delineated by the Japanese-German acoustic emission (AE) network with eight AE sensors deployed within several tens of meters from the rupture plane. It was confirmed that, with the virgin stress assumption and the strength, Map3D was able to reproduce an area of ride consistent with the rupture plane delineated by the AE network. A hole of about 90m length was drilled to intersect the ML2.1 rupture plane to constrain stress by analyzing borehole breakout and core discing. The stress thus constrained was consistent with those estimated with Map3D although the former is a little bit larger than the latter. In situ stress measurements were carried out near seismic damage caused by a ML1.5 event, which took place in the area that a Map3D model with simplest geology structure could not predict high stress. The measured stress state was comparable to that evaluated at the above-mentioned seismic sources.

Seismicity is high at a shaft pillar at 1.0 km depth at Ezulwini mine, where BX CCBO stress measurement was carried out. The measured maximum principal stress was significantly higher than the stress at sites at 3.4km depth with no mining activities.

Compared with continuous in-situ strain monitoring in other mines, we discussed the time evolution of stress in rock mass at a depth of 3.3km for a ˜1.5-year period 90m beneath a dip pillar at Mponeng mine. The pillar contained a 30m-thick dyke which a ML2.1 seismic event obliquely bisected. We analyzed the recordings of two multi-component Ishii borehole strainmeters which had been already installed nine months prior to the ML2.1 event. One of the strainmeters was installed in the dyke (gabbros) and the other in the host rock (quartzite) near the dyke contact, both being within a few tens of meters from the ML2.1 rupture plane.

The magnitudes and directions of the principal strain changes were similar for both strainmeters in the period prior to the ML2.1 event. This suggested that the increase in stress in the dyke was significantly larger because the dyke was significantly stiffer than the host rock.

After the ML2.1 event, associated with the start of mining on the eastern side of the strainmeters, the pattern of deformation changed between the two strainmeters.

The above-mentioned characteristics of deformation were compared with numerically modelled deformation by an elastic boundary element method using Map3D Fault-Slip. The magnitude of the Map3D strain changes were, however, several times smaller than the observed strain changes both prior to and after the ML2.1 event. The rock mass just around a stope in deep tabular mining is fractured and behaves time-dependently and non-linearly. Whatever the inelastic deformation, the stress field in an elastic area can be reproduced within reason provided that the boundary condition (deformation, force or stress) is appropriately specified on the elastic-inelastic boundary. Because it is well known that time-dependent inelastic stope closure is much larger than instantaneous elastic stope closure, as a trial, we analyzed a response to an additional forced stope closure using Map3Di (Seismic Integrator version). It was then found that the forced additional stope closure better accounted for both the magnitude and the deformation pattern observed by in situ strain monitoring. We concluded that the effect of inelastic deformation around the stope was significantly larger than the elastic effect induced by the advance of mining faces, and the direct effect of the very close ML2.1 event was not so significant.

A great amount of better maintained data sets of strain are now being accumulated in four gold mines, which will allow us to discuss in further depth.

Distribution of fault plane solutions of smaller events associated with the motion of Kuril forearc sliver

HIRATSUKA, Shinya[1*] ; SATO, Tamao[2] ; SUGAWARA, Sou[3] ; IMANISHI, Kazutoshi[4]

[1]ISV, Faculty of Science, Hokkaido Univ., [2]Sci. and Tech., Hirosaki Univ., [3]JGI, Inc., [4]AIST

In order to find the direct evidence of motion of fore-arc sliver along the Kuril trench, we investigated the distribution of fault plane solutions along the estimated boundary of Kuril fore-arc sliver in Hokkaido. Using the P-wave polarity data as well as P- and SH-wave amplitudes, we determined the fault plane solutions of smaller events ($2.0<M<3.5$) with the number of P-wave polarity data are 10 or greater. The result is summarized as follows. Along the volcanic front in eastern Hokkaido, strike-slip fault type of events with WNW-ESE trending P-axes are distributed, which is consistent with the motion of Kuril fore-arc sliver along the volcanic front. In the western side of Hidaka Mountains, reverse fault type of events with P-axes sub-parallel to the trench are widely distributed, which is consistent with ongoing process of collision of Kuril fore-arc sliver with northeastern Japan arc. In more detail, we found that reverse fault type of events with NE-SW trending P-axes, which rotates counterclockwise from trench parallel direction are concentrated near the epicenter of 1982 Urakawa-oki earthquake (M7.1). The P-wave velocity perturbation derived from tomography study for the lower portion of the overriding plate show a good correlation with the distribution of events with NE-SW trending P-axes. The seismic tomography study suggests that the lower half of the delaminated lower crust extends to the source region of the 1982 Urakawa-oki earthquake, which may cause counterclockwise rotation of P-axes near the epicenter of 1982 Urakawa-oki earthquake (M7.1).

Permeable fractures detected by geophysical loggings and their relation to in-situ stress

KIGUCHI, Tsutomu[1*] ; KUWAHARA, Yasuto[1] ; SATOH, Takashi[1] ; KOIZUMI, Naoji[1]

[1]GSJ, AIST

We examine a relation between the orientation of permeable fractures and the state of in-situ stress by using several logging data measured in 16 boreholes at hard rock sites. Geological Survey of Japan, AIST has constructed 16 integrated borehole observation stations in and around the Kii Peninsula and the Shikoku Island since 2006. Three boreholes with different depths of about 600, 200, 30 m were drilled at each site and various kinds of geophysical loggings were conducted. We obtained the values of strike and dip angle of all fractures including the permeable ones from the borehole wall images of borehole televiewer/camera. Permeable fractures intersecting the borehole were detected by analyzing the logging data of fluid electric conductivity, sonic and temperature. The magnitude and orientation of horizontal principal stress were estimated from hydraulic fracturing stress measurements at 6 sites and the orientation of maximum horizontal stress (SHmax) were evaluated at 11 sites from the images of borehole breakout and/or induced tensile fracture.

The preliminary results from the 6 hydraulic fracturing sites are as follows: The total numbers of all fractures and the permeable ones at each site are in ranges from about 2,000 to 5,000 and from about 20 to 30, respectively. The distribution of the orientation of all fractures at each site shows various values of strike and dip angle. We classify the fractures in three types: tensile fracture (Mode I fracture), shear one and others among the distribution by considering the in-situ state of stress at each site. The tensile type has orientations parallel to SHmax and relatively high dip angles. The shear fracture is optimally oriented for shear failure in the current stress field. It is difficult at any sites to say that characteristics of the distribution of the orientation of all fractures are described only with tensile or shear failure types. Next, an examination of the permeable fracture orientation shows that large number of the permeable ones at the Niihama site have strike orientations almost parallel to SHmax and high dip angles. This feature is different from that for all types of fractures at this site. This suggests that the current stress field controls the existence of the permeable fractures at Niihama site. On the other hand, the distributions of the orientations of permeable fractures at other 5 sites have different characters from the Niihama case: The orientations of permeable fractures have the same tendency with all fractures including non-permeable fractures.

Change in paleostress in offscraped accretionary complex, Kayo formation, the Shimanto Belt, Okinawa island

HASHIMOTO, Yoshitaka[1*] ; MOTOMIYA, Yuhei[1] ; UJIIE, Kohtaro[2]

[1]Kochi University, [2]Tsukuba University

It is important to understand a stress state of subduction zone because it is strongly related to development of accretionary complex, strength of fault, geometry of subduction zone and earthquake process. The purpose of this study is to examine paleo-stress in a off-scraped accretionary complex in Shimanto Belt, Okinawa island.

The study area is Kayo formation in the northeastern coast of Okinawa island. The Kayo formation consists mainly of coherent turbidites, and it was highly deformed by folds and thrusts. Those geological structures of the formation represent characteristics of fold-thrust belt in forearc area[Ujiie,1998].

Flexural slip associated with folding is commonly observed. In addition, many micro-faults cutting bedding are also observed. On the slip surfaces both of flexural slip surfaces and micro-faults, slicken lines and slicken steps are identified. From the structures, slip data (strike and dip of fault plane, slip direction and slip sense) was obtained.

The number of slip data for micro-fault is 153 in ˜2 km wide of study area. Using the slip data, we conducted micro-fault inversion analysis to examine the stress orientation and stress ratio. The stress ratio is defined as ϕ=(σ2-σ3)/(σ1-σ3). We used software MIM (Yamaji,2000) for stress analysis and K-means clustering (Ostubo et al, 2007) for automated picking of center of cluster. After the stress analysis, we combined the stress data with stress polygon to examine stress magnitude semi-quantitatively. The stress polygon is based on Anderson ' s theory. We assumed the vertical stress is always gravity force, which is converted from assumed depth.

As a result of analysis, 4 stress solution (KY1-KY4) were obtained. KY1) NE-SW horizontal compression with high stress ratio, (ϕ=0.88), KY2) KY3) NW-SE high angle compression with low to intermediate stress ratio (ϕ=0.22,0.45), and KY4) NW-SE horizontal compression with intermediate stress ratio (ϕ=0.65).

We picked up the micro-fault with misfit angle less than 40? for each stress. Misfit angle is the angle between calculated slip direction and observed slip direction on the micro-fault surface. Reverse faults are dominant in KY1 and KY4 and normal faults are dominant in KY2 and KY3.

The stresses are projected to horizontal surface and to Shmax (perpendicular to fold axis), Shmin (parallel to fold axis), and Sv. Using stress ratio and stress projection above, linear functions in Shmax and Shmin space are obtained. We can examine the semi-quantitative Shmax and Shmin value for the stresses in overwrapping area between the linear functions and stress polygon.

Magnitudes of shear stresses for KY2, KY3, KY1 and KY4 on the horizontal decollement were also estimated as τ2=39.2˜54.7[MPa], τ3=52.1˜64.2[MPa] and τ1=79.0˜212.3[MPa], τ4=48.0˜137.7[MPa]. The shear stress for reverse fault (KY1, KY4) is bigger than the shear stress for normal fault (KY2, KY3). If the differences in stress represent the stress change in seismic cycle, the differences in shear stress indicate stress drop as -16.2˜173.1[MPa]. Stress drop in general earthquake ranges 0.03˜30[MPa]. The obtained stress drop in this study includes the range of general stress drop.

Development of heterogeneous rheological model of the Tohoku Island arc-trench system

MUTO, Jun[1*] ; SHIBAZAKI, Bunichiro[2]

[1]Dept. Earth Sci., Tohoku Univ., [2]Building Res. Inst.

Subduction zone earthquake cycles can be characterized by various deformation processes taking place around the plate boundary and surrounding area. For example, after slip, viscoelastic relaxation and locking of the plate boundary are three primary processes among them. In order to illuminate the recovery of plate coupling after the Mw 9.0 Tohoku-Oki earthquake and strain budgets of island arc during cycles, the detailed viscoelastic structure of the Tohoku region is developed using seismologically determined subsurface structures and densely measured geothermal gradient data. The model is oriented perpendicular to the Japan Trench and also transects an area of large coseismic slip of the 2011 Tohoku Oki earthquake. Petrological model proposed by the laboratory measurement of seismic velocity of various rocks [Nishimoto et al., 2005] was utilized to infer rheologically major minerals from seismic velocity structures. We used geothermal gradient data from the inland Hi-net borehole [Matsumoto, 2007], as well as geothermal gradient data compiled from around Japan [Tanaka et al., 2004]. The strain-rate-dependent, steady state effective viscosity was calculated using constitutive laws of various rocks under the assumption of homogeneous geologic shortening rate [Sato, 1989]. The calculated viscosity structures show lateral viscosity gradients both parallel and normal to the trench axis. Moreover, the minimum viscosities are predicted to be 10^{19} Pa s in the mantle wedge and 10^{20} Pa s in the oceanic mantle. The values are consistent with previous estimates obtained by postseismic deformation analysis of subduction zone earthquakes with similar magnitudes (Mw ˜9). However those minimum values only appear in depths of 30-100 km in the upper mantle and the viscosity increases further with depths because of the pressure hardening effect. Taking the high values of viscosities in shallower part of the lithosphere, the thickness of high viscous layers found to have lateral variations implying the heterogeneous elastic layer thickness. Model viscosity structures of the Tohoku region utilizing realistic temperature and rheological properties of rocks can be used to evaluate the effect of rheological heterogeneity in the postseismic deformation field of the Tohoku-Oki earthquake observed by dense network of geodetic observations. In the presentation, we will mention the detailed information on the choice of the flaw law parameters, and physical and ambient conditions for NE Japan to calculate the viscosity structures. We also show how these heterogeneities affect the crustal deformation of the NE Japan during subduction zone earthquake cycles.

Detailed seismic attenuation structures beneath the Hokkaido corner, northern Japan (3)

KITA, Saeko[1*] ; NAKAJIMA, Junichi[2] ; HASEGAWA, Akira[2] ; UCHIDA, Naoki[2] ; OKADA, Tomomi[2] ; KATSUMATA, Kei[3] ; ASANO, Youichi[1] ; KIMURA, Takeshi[1]

[1]NIED, [2]RCPEV, Graduate School of Science, Tohoku University, [3]ISV, Hokkaido University

1. Introduction

In the Hokkaido corner, the Kuril fore-arc sliver collides with the northeastern Japan arc. Using travel-time data compiled from the nationwide Kiban seismic network and a dense temporary seismic network [Katsumata et al, 2002], Kita et al. [2012] determined high-resolution 3D seismic velocity structure beneath this area for deeper understanding of the collision process of the two fore-arcs. In this study, we merged waveform data from the Kiban-network and from the temporary network, and estimated the seismic attenuation structure to understand seismotectonics and collision process beneath Hokkaido.

2. Data and method

We estimated corner frequency for each earthquake by the spectral ratio method of coda waves [e.g. Mayeda et al., 2007]. Then, we simultaneously determined values of t∗and the amplitude level at low frequencies from the observed spectra after correcting for the source spectrum. Seismic attenuation (Q-1 value) structure was obtained, inverting t∗values and employing the 3-D ray-tracing technique of Zhao et al. [1992]. The study region covers an area of 41-45N, 140.5-146E, and a depth range of 0-300 km. We obtained 154,293 t∗at 316 stations from 6,196 events (Mj>2.0) that occurred during the period from Aug. 1999 to Dec. 2012. Horizontal and vertical grid nodes were set with spacing of 0.1-0.3 degrees and 10-30 km, respectively.

3. Results

The calculated stress drops are distributed from 0.1 to 100 MPa. Stress drops of intraslab earthquakes increase with focal depth. The values of stress drops of events in the slab mantle tend to be larger than those in the slab crust at depths of 80 to 170 km, which might contribute to understanding of the physical nature of intraslab earthquakes.

Seismic attenuation structure is imaged for the region above the subducting Pacific slab at depths down to ˜80 km. For the forearc side of the eastern and western parts of Hokkaido, high-Qp zones are generally imaged at depths of 10 to 80 km in both the crust and mantle wedge above the Pacific slab. In contrast, low-Qp zones are clearly imaged in the mantle wedge of the backarcside.They are distributed in deeper parts and reach the Moho beneath the volcanic front. Locations of these low-Qp zones correspond to the low-Vp and low-Vs zones imaged by Zhao et al. [2012]. These suggest that the upper head of the mantle-wedge upwelling flow is detected beneath Hokkaido also by our seismic attenuation imaging.

In the Hokkaido corner, to the west of the Hidaka main thrust a broad low-Qp zone is imaged at depths of 0?60 km. Location of this broad low-Qp zone almost corresponds to that of the low-V zone in the collision zone found by Kita et al. [2012]. Fault planes of the 1970 M6.7 and 1982 M7.1 earthquakes are located at the edges of a broad low-Qp zone, being in contact with a high-Qp zone at 10 to 35 km. These results suggest that the occurrence of these anomalously deep and large inland earthquakes is related to the presence of hydrous minerals or fluids.

The subducting oceanic crust beneath the Hidaka region is imaged as a low-Q zone whose location corresponds to the low-Vp and low-Vs zone of Kita et al. [2012], suggesting the existence of hydrated materials at the top of the slab. Just above the slab surface, moderately low-Q zones are imaged at depths of 90 to 100 km beneath eastern and southern Hokkaido and at depths of 110 to 130 km beneath the corner, which are located at depths deeper than the upper plane seismic belt. These observations suggest the existence of the hydrated mantle wedge by the aqueous fluids supplied from the oceanic crust right below.

Crustal deformation in the Mid-Niigata area and its implication for strain concentration

SAGIYA, Takeshi[1*] ; MENESES, Angela[1]

[1]Nagoya University

The Mid-Niigata area is located within the concentrated strain belt along the eastern margin of the Japan Sea. This area suffered from two large earthquakes, the 2004 Chuetsu and the 2007 Chuetsu-oki earthquakes. Based on GPS velocity data calculated from daily coordinate time series of GEONET, we identified significant time dependence of the interseismic crustal deformation patterns before, between, and after these two earthquakes. Modeling results of the deformation pattern changes are summarized as follows. 1) Contraction before 2004 occurred between the source regions of the two earthquakes and it was attributed to aseismic faulting across almost the whole elastic layer, implying that the observed strain was largely inelastic. This interpretation is also supported from a fact that the historical seismic energy release in this area is much smaller than that expected from geodetic strain accumulation. 2) After two earthquakes, aseismic faulting seems to have continued without explicit time decay. The aseismic faulting is estimated close the source fault of the main shocks, implying that postseismic strength recovery did not occur on the main shock fault or a nearby parallel fault was activated to accommodate regional contraction. This is consistent with an idea that the upper crust in this area is segmented to smaller blocks and the mechanical behavior is very sensitive to external stress changes.

Tectonic stress fields in subduction zones governed by frictional strength of plate interfaces

MATSU'URA, Mitsuhiro[1*] ; NODA, Akemi[2] ; TERAKAWA, Toshiko[3] ; FUKAHATA, Yukitoshi[4]

[1]Institute of Statistical Mathematics, [2]Kozo Keikaku Engineering Inc., [3]Nagoya University, [4]Kyoto University

Tectonic crustal motion in plate convergence zones varies from mountain building (e.g., Himalaya) to back-arc spreading (e.g., Mariana) [1, 2, 3]. Such difference in tectonic crustal motion reflects the diversity of tectonic stress fields. So our question is what causes the diversity of tectonic stress fields in plate convergence zones. Recently, from a theoretical study [4], we revealed that the tectonic stress field consists of basically two different sorts of stress fields; one of which is a horizontally compressional stress field due to frictional resistance at plate interfaces, and another is a horizontally tensile stress field due to steady plate subduction. On a geological timescale, the former can be regarded as constant in time, but the latter increases with time. So, if the earth's crust were infinitely strong, tectonic stress fields in plate convergence zones would become tensile in time everywhere. Actually, the earth's crust includes a number of defects with low strength, over which inelastic deformation (brittle fracture and/or plastic flow) occurs so as to release the tectonic stress caused by mechanical interaction at plate interfaces. From these considerations, we may conclude as follows. When the plate interface is very weak in comparison with the earth's crust, a horizontally tensile stress field becomes dominant, which causes back-arc spreading as in the case of Mariana. When the plate interface is very strong, a horizontal compressional stress field becomes dominant, which causes mountain building as in the case of Himalaya. Tectonic stress fields in most subduction zones, where the strength of plate interfaces are comparable to that of the earth's crust, are between these two extreme cases.

Sequential inversion of GPS time series data to estimate spatiotemporal change in interplate coupling

NODA, Akemi[1*] ; MATSU'URA, Mitsuhiro[2]

[1]Kozo Keikaku Engineering Inc., [2]Institute of Statistical Mathematics

To estimate steady increase rates of slip deficits at plate interfaces, first, we obtain linear trends of the time series of GPS daily coordinate data by removing seasonal variations and coseismic and postseismic changes due to episodic events. Then, we invert the linear trends (surface displacement rates at GPS stations) into steady slip-deficit rate distribution on a plate interface with completely relaxed slip-response functions for an elastic-viscoelastic layered half-space model under gravity (Noda et al., 2013, GJI). Noda et al. (SSJ 2012 Annual Meeting) demonstrated that this method is applicable to GPS time series data in northeast Japan for the interseismic period (March 1997-February 2008) before the 2008 Ibaraki-oki (Mw6.8) and Fukushima-oki (Mw6.9) earthquakes. After these events, the trends of GPS time series data gradually change with time (Suito et al., 2011, EPS), indicating spatiotemporal change in interplate coupling preceding the 2011 Tohoku-oki mega-thrust earthquake.

The change in slip-deficit rate distribution disturbs a steady stress state in the asthenosphere, and so we need to use the viscoelastic transient slip-response functions for the analysis of GPS time series data after the 2008 events (Noda et al., 2013, GJI). An exact treatment of the viscoelastic inverse problem to estimate cyclic slip processes at a plate interface has been given by Fukahata et al. (2004, GJI), but it is not applicable to the present problem because the change in slip-deficit rate distribution is not a cyclic but transient process. So, we propose a simple inversion technique, called sequential inversion of GPS time series data, to estimate spatiotemporal changes in slip-deficit rates at plate interfaces. A similar sequential inversion technique has been used by Lubis et al. (2013, GJI) for the analysis of afterslip distribution following the 2007 southern Sumatra earthquake (Mw8.5) on the assumption that the asthenosphere has been in a steady stress state until the 2007 event.

In the present study, we estimate the spatiotemporal change in interplate coupling by applying the sequential inversion technique to GPS time series data for March 2008-February 2011, and reveal the slip history at the North American-Pacific plate interface off Tohoku during the 14 years before the 2011 Tohoku-oki mega-thrust earthquake.

Middle Miocene swift migration of the TTT triple junction and rapid crustal growth in SW Japan

KIMURA, Gaku[1*] ; HASHIMOTO, Yoshitaka[2] ; KITAMURA, Yujin[3] ; YAMAGUCHI, Asuka[4] ; KOGE, Hiroaki[1]

[1]Dept. Earth and Planetary Science, The University of Tokyo, [2]Kochi University, [3]Kagoshima University, [4]Atmosphere and Ocean Research Institute, The University of Tokyo

We review recent progress in geological and geophysical investigation in SW Japan, the Nankai Trough and the Philippine Sea Plate (PSP), and propose a comprehensive hypothesis for the Miocene tectonics of the Nankai Trough. New interpretations are as follows: Near-trench magmatism in the outer zone of SW Japan might have various reasons. The possibility of an arc-arc collision in particular should be examined, in addition to the previous model of an oceanic ridge and hot PSP subduction. The indentation structure at Capes Ashizuri, Muroto in Shikoku, and Shiono on the Kii Peninsula may be explained by the collision of the active arc or topographic peaks such as seamounts, contrary to the previous ”kink-folding” model due to recent E-W compression. This inference is drawn from comparison between the many modern examples of seamount collision and sandbox analogue experiments. Crustal components of SW Japan might consist mainly of igneous plutonic rocks, in contrast to the previous inference of Cretaceous to Tertiary accretionary complexes. This is especially the case in the outer zone to the north of Capes Ashizuri, Muroto and Shiono. This is inferred from geophysical observation of gravity anomalies, velocity and resistivity, together with geological estimations of caldera age and the size of its root pluton. Episodic crustal growth due to intrusion of igneous rock and subduction of the PSP may have stopped after ˜11 Ma and restarted at ˜7-8 Ma. New accretionary prism was again developed after ˜6 Ma. This inference is suggested by recently conducted ocean drilling program.

Spatial relationship between the volcanic chain and high gravity anomalies in subduction zones

FUKAHATA, Yukitoshi[1*]

[1]DPRI, Kyoto University

The most conspicuous features of arc-trench systems are active seismicity, characteristic topography and gravity anomalies, and volcanism. The topography and gravity anomalies are low in the trench and high in the arc, which can be theoretically explained by mechanical interaction between the subducting oceanic plate and the overriding plate (Sato & Matsu'ura, 1993, GJI; Hashimoto et al, 2004, PAGEOPH). Because the topography is more complicated to be understood, free-air gravity anomaly is more suitable to be compared to the theoretical model. Free-air gravity anomalies with long wave length basically represent the effect of tectonic force, which disturbs gravity equilibrium.

Volcanoes align along the volcanic front in most arcs. Since both of the high free-air gravity anomalies and volcanic front have a subparellel strike to the trench, it should be possible to classify arc-trench systems according to the spatial relationship between them. Based on such an idea, Fukahata (2008, JPGU meeing) classified arc-trench systems, but there was a problem that the recognition of the location of high gravity anomalies was quite subjective. So, in this study, I improved this process.; the location of high gravity anomalies were more quantitatively recognized. As a result, the location of high gravity anomalies relative to the volcanic front did not change for most arcs, but I found that it was difficult to define its location in some arcs (mostly tensile). Using the result, I discuss the spatial relationship between the volcanic chain and high gravity anomalies in subduction zones and consider causes of topographic evolution of island arcs.

Uplift and denudation history of the Yoro-Suzuka-Nunobiki Mountains: Constraints from apatite FT thermochronology

SUEOKA, Shigeru[1*] ; TSUTSUMI, Hiroyuki[2] ; TAGAMI, Takahiro[2] ; HASEBE, Noriko[3] ; TAMURA, Akihiro[3] ; ARAI, Shoji[3] ; SHIBATA, Kenji[1]

[1]Japan Atomic Energy Agency, [2]Kyoto University, [3]Kanazawa University

The Yoro-Suzuka-Nunobiki Mountains are fault block mountains distributed along the Isewan-Tsurugawan Tectonic Line, a tectonic boundary between the Kinki and Chubu districts. The Kinki district on the west of the mountains is characterized by predominance of reverse faults and alternation of N-S trending mountain ranges and basins (Kinki Triangle; Huzita, 1962), whereas the Chubu district on the east of the mountains has predominance of strike-slip faults and westerly tilting landforms (Chubu tilting block; Kuwahara, 1968). Miyoshi & Ishibashi (2008) mentioned that the Philippine Sea Plate slab beneath the region around the Yoro-Suzuka-Nunobiki Mountains has shallow subduction angle and form a convex shape (Isewan-Kohoku slab) and proposed this shallow slab resulted in the tectonic boundary between the Kinki and Chubu districts in the region. On the eastern and western sides of the Yoro-Suzuka-Nunobiki Mountains, two major subsidence areas have formed and moved northward since the end of the Miocene as recorded by deposition of the Tokai group and Kobiwako group (e.g., Yokoyama, 1995; Yoshida, 1990). On the other hand, there is some debate over the formation process and mechanism of the Yoro-Suzuka-Nunobiki Mountains; Okada (2004) speculated the mountains have uplifted from south to north generally corresponding to the northward moving of the subsidence areas, whereas Ohta and Takemura (2004) proposed the formation of the mountains were still later and independent from the formation of the subsidence areas.

We are attempting revealing uplift and denudation history of the Yoro-Suzuka-Nunobiki Mountains in the past few million years by using apatite fission-track (AFT) thermochronology. We have obtained AFT ages and length distribution data in one site for the Yoro Mountains, eight sites for the Suzuka Range, and one site for the Nunobiki Mountains. Highlights of the results are as below: 1) the AFT ages range 47-30 Ma, 2) the ages were youngest in the middle to south parts of the Suzuka Range and get older to the north and south, 3) thermal histories calculated from the AFT ages and length distributions indicate rapid cooling events in the past few million years in the middle to south parts of Suzuka Range, but not in the Yoro and Nunobiki Mountains and the north part of the Suzuka Range, 4) the rapid cooling events in the past few million years are attributable to the the uplift of the Suzuka Range since ~1.3 Ma (Yokoyama, 1995). We are conducting additional AFT analyses in seven sites of the Nunobiki Mountains to expand our results to the south. In this presentation, we are planning to provide progressed discussions containing the results of the additional data.

Self-affinities for Amplitude and Wavelength of Folds

KIKUCHI, Kazuhei[1*] ; NAGAHAMA, Hiroyuki[1]

[1]Department of Earth Science, Graduate School of Science, Tohoku University

In general, many folds are apparently curved or jagged on a wide range of scales, so that their geometries appear to be similar when viewed at different magnifications. By Matsushita and Ouchi (1989a, b)'s method, we also analyzed the self-affinities of folds in the North Honshu Arc, Japan (Kikuchi et al., 2013). Based on this analysis, geometries were found to be self-affine and can be differently scaled in different directions. We recognize the self-affinities for the amplitude and the wavelength of folds and a crossover from local to global altitude (vertical) variation of the geometries of folds in the Northeast Honshu Arc.

Buckingham's Pi-theorem is sufficient to the first problems of fold systems (Shimamoto, 1974). However, the complete similarity cannot give us the self-affinities of folds. A general renormalization-group argument is proposed to the applicability of the incomplete self-similarity theory (Barenblatt, 1979). Based on the general renormalization-group argument, we derive the self-affinities for the wavelength (L) and the amplitude (a) of folds:

$$L^{(1-d)} \propto a.$$

The relationship between Hurst exponents H of fold (Kikuchi et al., 2013) and d are equation:

$$1\text{-}d=H,$$

where H is index of the continuity of a given fold curve and obtained by the ratio between horizontal scaling exponent and vertical scaling exponent. d is an exponent of a given incomplete self-similarity theorem.

In $d \neq 0$ case, the Hurst exponent $H \neq 1$ indicates self-affinities for the given fold curve. In this case, scale invariance of the fold might be affected by a variety of tectonic processes under the anisotropic stress field. In $d = 0$ particular case, the Hurst exponent $H = 1$ indicates self-similarity for the given fold curve. In this case, scale invariance of the fold might not be affected by a variety of tectonic processes under the anisotropic stress field. These results imply that anisotropic stress fields by gravitation and tectonic stresses might cause self-affinities of folds. Self-similarity and self-affinities of the fold might be affected and by a variety of tectonic processes under the isotropy or anisotropic stress field.

Reason for strange appearance of Mt. Hakone, and Reason why the Boso Triple Junction has moved to the west most

MASE, Hirofumi[1]*

[1]none

(Refer to the chart)

Mt. Fuji penetrates through the north end of the Philippine Sea Plate(PHSP), and is the front of land side plate incision, and is the starting point of Suruga and Sagami Trough(1). Mt. Hakone and Mt. Mihara have decided the position of Sagami Trough.

”Tokai Slab” seems to stop beneath the north side of Mt. Fuji. On the other hand, ”Sagami Slab” seems to sink and reach the interior of Kanto.(3) It is unnatural as one board. Though the crustal deformation that GPS caught shows that the Izu Peninsula moves to the west, tendencies of Izu islands and Southern part of Kanto to move to the north are strong(4). In 135-140∗east, it has been understood that the section of especially 140∗meets the requirement of the temperature structure that the power to make the Pacific Ocean’s side go north is generated. In a word, I think that only the side of ”Sagami Slab” sank greatly in PHSP in the past and the current situation was caused.

Then, where is the crack (lateral fault) that becomes a boundary? There is the earthquake-prone zone that symbolizes subducting of Slab on the north side of the Mt. Hakone(5). If the edge of west side within the range of that distribution is traced, the Mt. Hakone and Mt. Mihara can be connected in a smooth line(red broken line). The line of blank for south-north, that divides the earthquake-prone zone to the east and the west, passes the Mt. Hakone(blue broken line). Because there was no fault in the south from Mt. Mihara, I think the slipping fault shifted to the fault shown in blue broken line though there was an age that the fault shown in red broken line slipped. The Mt. Hakone has the meaning of the west edge of PHSP in the Izu-islands-east and of the starting point of subducting.

On the other hand, why has the trench axis around the Boso Triple Junction moved to the west most? Pacific Plate that goes west compresses land side Plate and PHSP that get on on it into the direction of east-west. And, pulls them for south-north. The Part where land side Plate and PHSP overlap shifts mutually and the overlap becomes shallow. The upper plates expand for south-north to Pacific Plate. As a result, the trench axis becomes easy to go west by the east-west compression. Land side Plate and PHSP and Pacific Plate become tight in the direction of east-west. And, fold and collapse occur in them. As a result, the trench axis becomes easy to go west further. Because usual stresses are absorbed to the fold and collapsing, the trench axis is not easy to returns east even if a massive earthquake occurs. This is the cause that the trench axis moves to the west.

The Ocean Floor was Expanded by Increasing Seawater

MADO, Shinichiro[1*]

[1]MAROSA

Introduction

I wrote this paper in order to present the negation of a hypothesis which supports the plate tectonics. The hypothesis is 'Spreading Oceanic Floor Hypothesis'. This negation is based upon a new fact that has been revealed recently. I concluded the negation by such facts and my original reasoning. I already presented another fact negating the hypothesis of 'Spreading Oceanic Floor'. The abstract titled 'it was not switching global geo-magnetic fields that created the alternating anomalies over oceanic ridges' was presented at the Japan Geoscience Union Meeting 2013. Therefore, one of reasons that support the hypothesis of spreading oceanic floor was already denied. In this paper I will deny another reason of the hypothesis, which says that the plates of the oceanic floors are spreading.

What is the question

The Hypothesis of Plate tectonics was evolved from Wegener's 'Continental Drift Hypothesis' and based upon 'The Hypothesis of Spreading Oceanic Floor'. However, the hypothesis of spreading oceanic floor is denied as far as it means the spreading plate of oceanic floor. It is denied by the fact that the oceanic floors spread not because the oceanic plates themselves spread but merely because the seawater increased. Therefore, the hypothesis of plate tectonics lost one of its evidences.

The Expanding Oceanic Floor

The hypothesis of plate tectonics is supported by the hypothesis of spreading oceanic floor. The rapidity of the movement of the plate was estimated by the switching pattern of geo-magnetic anomaly near the ridges. The farer and farer it comes from the ridges, the older and older the dates of the basalts and fossils become. The estimated dates fit well the dates estimated from the pattern of geo-magnetic anomalies. It was proved that the rapidity was estimated 2cm par one year for the Pacific Ocean[1],[2].

Rising Sea Level Caused by Increasing Seawater

However, the hypothesis of spreading oceanic floor neglected the fact that the sea level increased greatly. The sea level increased more than 6000m after the creation of oceanic plates. That fact was revealed by the remaining river valleys on the oceanic floors. For instance the Kushiro River reaches more than 6000m in depth$^{[Fig1-B]}$. The Itoi River reaches about 3500m in depth$^{[Fig1-A]}$.

These facts revealed that the seawater increased greatly after the creation of the oceanic plates. It takes very long time to raise sea level to recent level. Gradually the amount of seawater is increasing even now.

Provably the increase of seawater is caused by crustal movements squeezing water from the rocks of the crust. The squeezed water becomes hot springs.

The date of the fossils near the ridges are newer because those places are higher and newly became under the sea level.

Conclusion

The oceanic floors spread not because the oceanic plates spread but because the seawater increased largely after the creation of the oceanic floor plates.

Therefore, it has no relation between the dates of the oceanic plates and the date of fossils contained in upper layers. Therefore, one of evidences of plate tectonics was lost.

Noble gas evidence of deep plume origin of the Louisville hotspot

HANYU, Takeshi[1*]

[1]Japan Agency for Marine-Earth Science and Technology

Louisville seamount chain has been considered to be one of the long-lived hotspot tracks on the Pacific plate, but its magmatic source has not been well understood. I report noble gas compositions of the drill cores from four of the five seamounts drilled during IODP Expedition 330. Because the samples are aged (50-74 Ma), a stepwise crushing test for noble gas extraction from olivine phenocrysts and submarine glasses was made to assess contamination of post-eruption radiogenic nuclides. This test confirmed extraction of magmatic noble gases with minimal release of post-eruption radiogenic nuclides from the olivine samples; however, this was not always the case for the glass samples. The 3He/4He ratios in the olivine phenocrysts range from a value similar to those of mid-ocean ridge basalts (MORB) to slightly elevated ratios up to 10.6 Ra. Although these ratios are not as high as those observed in other ocean island basalts, two Louisville seamount basalts exhibit a primordial Ne isotopic signature that can be clearly discriminated from MORB Ne. The He and Ne isotopic compositions of the Louisville seamount basalts can be explained by the mixing of less degassed mantle and depleted upper mantle with different He/Ne ratios. The presence of the less degassed mantle component in the source of the Louisville seamounts documents the deep origin of the mantle plume.

One of the major objectives of the IODP Expedition 330 was to test the geodynamic model that predicts lateral advection of mantle plumes in the convecting mantle [Koppers et al., G-cubed, 2004; Steinberger and Antretter, G-cubed, 2006]. This model assumes a primary mantle plume that is rooted deep in the mantle, and the trajectory of a plume conduit is influenced by the overall mantle flow, which can be monitored by the hotspot drift on the Earth's surface [Tarduno et al., Science, 2009]. The paleomagnetic and dating results from IODP Expedition 330 verified the geodynamic modeling predictions for the Louisville seamount chain together with the Hawaiian-Emperor seamount chain [Koppers et al., Nat. Geosci., 2012]. The present noble gas data gives a guarantee for the deep-rooted Louisville plume assumed in the geodynamic model.

Preliminary result of the oceanic mantle structure revealed by ”Normal Oceanic Mantle Project”

ISSE, Takehi[1*] ; SHIOBARA, Hajime[1] ; SUGIOKA, Hiroko[2] ; ITO, Aki[2] ; TAKEO, Akiko[1] ; UTADA, Hisashi[1] ; KAWAKATSU, Hitoshi[1] ; TONEGAWA, Takashi[2] ; TANAKA, Satoru[2]

[1]ERI, Univ. of Tokyo, [2]Institute for Research on Earth Evolution, Japan Agency for Marine-Earth Science and Technology

The oceanic mantle is an important region to understand the Earth system, because more than 2/3 of the surface is covered by oceanic area. Since 1990s, we have operated several seafloor observations by using newly developed long-term broadband ocean bottom seismometers (BBOBSs) in the northwest and central part of the Pacific Ocean. These observations have revealed the structures in and around the subduction zone in the Pacific Ocean and in the Pacific superswells, respectively. However, we have no observation and result in the normal oceanic regions. To reveal the normal oceanic mantle structure from observational approach, we conduct a long-term observation called “ Normal Oceanic Mantle Project ” (NOMan project) from 2010, deploying ocean bottom geophysical (seismic and electromagnetic) instruments in the northwestern Pacific Ocean. We conduct two arrays in that region. One is northwest side of the Shatsky Rise (Area A) and the other is southeast side of the Shatsky Rise (Area B). Sea floor age of Area A is 125 - 135 Ma, that of Area B is 135 - 145 Ma, so that the shear wave structures of those area should be similar.

By using seismograms of the NOMan project, other BBOBS observations, and permanent broadband seismic stations on land, we have determined the three-dimensional shear wave velocity structure of the upper mantle in the northwestern Pacific Ocean to reveal this area to be really normal. We used a surface wave tomography technique in which multimode phase speed of the surface wave are measured and inverted for a 3-D shear wave velocity structure by incorporating the effects of finite frequency and ray bending.

Our obtained model shows that lateral heterogeneity of each area is not strong and that average structures are different in two areas. Area A is consistent with previous models, whereas Area B is faster than previous models. We think for the present that Area A seems to be normal oceanic mantle, though Area B is not. We will recover all BBOBSs in this year. These BBOBS’s data enable us to obtain more reliable mantle structures.

Seismic anisotropy in the oceanic lithosphere/asthenosphere system estimated by the broadband ocean bottom seismology

TAKEO, Akiko[1*] ; ISSE, Takehi[1] ; NISHIDA, Kiwamu[1] ; KAWAKATSU, Hitoshi[1] ; SHIOBARA, Hajime[1] ; SUGIOKA, Hiroko[2] ; ITO, Aki[2] ; UTADA, Hisashi[1]

[1]Earthquake Research Institute, University of Tokyo, [2]IFREE, JAMSTEC

The uppermost mantle structure beneath the oceanic basins is essential to discuss the oceanic lithosphere/asthenosphere system, the most simple and representative system of the theory of plate tectonics. Seismic anisotropy within the oceanic lithosphere and asthenosphere is especially important, as it reflects the flow and deformation in the uppermost mantle. Previous structural studies have been, however, limited in terms of the depth range: the top of lithosphere at depths of ˜10-20 km by refraction surveys, and the structure deeper than ˜30 km by surface-wave tomography studies. There has been no discussion from the top of the lithosphere continuously to the asthenosphere, which needs the broadband analysis of surface waves at periods of 3-100 s. In addition, there has been limited discussion about the intensity of seismic anisotropy because of the difficulty of estimating the absolute value of seismic anisotropy by surface-wave tomography studies.

We have developed a new multi-band method to analyze surface waves in broadband array records of ocean bottom seismometers for determining seismic anisotropy structure at depths of ˜10-100 km quantitatively (Takeo et al 2013 JGR, submitted to GJI). The method uses the ambient noise cross-correlation method for analyzing surface waves at periods of 3-30 s and to determine structure at depths shallower than ˜50 km, as well as the array analysis method of teleseismic waveforms at longer periods for determining deeper structures.

In previous studies, we have applied the multi-band method to records obtained in three oceanic regions: the Shikoku Basin region (Takeo et al. 2013 JGR), the southwestern region of the Shatsky Rise (Takeo et al. submitted to GJI) and the French Polynesia region (Takeo et al. 2012 SSJ Fall Meeting). In this study, we applied the same method to the records of broadband ocean bottom seismometers obtained by the normal oceanic mantle (NOMan) project at two oceanic regions (northwestern and southeastern regions of the Shatsky Rise) from 2010 to 2013. By combining the results for five oceanic regions with different seafloor ages between 20 and 155 Ma, we can discuss the seismic structure and its anisotropy in the oceanic lithosphere and asthenosphere, and the deformation of mantle related to plate motions.

The results for five oceanic regions can be summarized into five points: (i) the high-velocity lid and the low velocity zone corresponds to the oceanic lithosphere and asthenosphere, (ii) the transition from the lithosphere to the asthenosphere occurs at depths of 40-90 km, (iii) the average intensity of S-wave radial anisotropy is 3-6 % at depths of 10-150 km with the velocity of horizontally propagating and vertically polarized S-wave slower than the horizontally polarized S-wave, (iv) the intensity of S-wave azimuthal anisotropy at depths of 10-100 km is weaker than that of S-wave radial anisotropy and weakens with depths, and (v) the azimuth of maximum S-wave velocity is not perpendicular to ancient spreading axis in general. These results indicate complex deformation system in the present and ancient oceanic asthenosphere related to the presence of partial melting, the unusual fabric of olivine and so on. We will summarize these results and discussions, and will also present the potential of the broadband ocean bottom seismology to elucidate structure and deformation in the oceanic lithosphere/asthenosphere system and in other oceanic systems such as hotspots, mid-ocean ridges and subduction zones.

Locality and cause of the characteristics of high-frequency Po/So wave propagating in heterogeneous oceanic lithosphere

FURUMURA, Takashi[1*] ; KENNETT, Brian[2]

[1]Earthquake Research Institute, The University of Tokyo, [2]Research Schoole of Earth Sciences, The Australian National University

In our previous study (Kennett & Furumura 2013; Geophys. J. Int.) we described the characteristics of the propagation of the high-frequency mantle phases Po and So. These oceanic Pn and Sn phases can be observed after propagation over many thousands of kilometres from the source, retaining high frequencies but acquiring a long and complex coda. This study concentrated on the way in which these characteristics can be sustained by fine-scale heterogeneity in the oceanic lithosphere that reinforces the influence of multiple P reverberations in the ocean and sediments as recognized by Sereno & Orcutt (1985; 1987). A form of quasi-laminar heterogeneity with horizontal correlation lengths around 10 km and vertical correlation lengths of about 0.5 km provides a good representation of the Po and So wavefield as also noted by Shito et al. (2013). This class of heterogeneity creates a strong scattering environment within the lithosphere that helps to sustain the Po and So phases over long distances. Propagation of So is most effective in thick old lithosphere, e.g., in the northwest Pacific Plate. Amplitudes of So are reduced significantly by propagation through thinner lithosphere in the Philippine Plate.

In this study we look at the entire Pacific basin and map out the propagation patterns for Po and So, which have the general characteristic of much more efficient propagation in the western sector than in the east that is much less well sampled. There are stronger changes in the nature of So than Po. For the same frequency S waves have a shorter wavelength than P waves, and so the So phase is more sensitive to the effects of both lateral variations in lithospheric structure and seismic attenuation.

We explore the relation of the nature of the observations of Po and So and the age of the lithosphere, based on 2-D FDM simulation seismic wave propagation for examining the influence of changes in lithospheric structure across fracture zones and similar features. The strong diffuse scattering field created in the oceanic lithosphere is hard to destroy and it is quite difficult to explain situations where So is very much weaker than Po, except by introducing enhanced seismic attenuation for younger lithosphere and the warmer asthenosphere in the neighborhood of spreading centers.

Distribution of petit-spot volcanoes in relation to deformation and structures on a subducting plate

HIRANO, Naoto[1*] ; NAKANISHI, Masao[2]

[1]Center for Northeast Asian Studies, Tohoku University, [2]Graduate School of Science and Technology, Chiba University

Tiny submarine volcanoes, known as petit-spots, occur in regions of plate flexure prior to subduction and seamount-loading (Hirano *et al.*, 2006, 2013). The surface morphology and distribution of petit-spot monogenetic volcanoes are influenced by the stress field in the lithosphere. The magmas produced by the accumulation of melt originating from asthenosphere just below the site of plate-flexure, are able to rapidly ascend to the surface from the base of the lithosphere (Hirano *et al.*, 2006; 2011; Valentine & Hirano, 2011). As monogenetic petit-spot volcanoes are too small to be detected by satellite altimetry, their study requires a research vessel equipped for shipboard acoustic multibeam surveys. Although previously surveyed areas are limited to the regions off the Japan Trench, the eruption ages of petit-spot volcanoes in this region represent monogenetic eruptions over a period of >9 Myr over a large area, and the eruptions are related to the outer rise bathymetry. Such tiny volcanoes are ubiquitous in regions of plate flexure worldwide, and have been recently reported from the Tonga Trench (Hirano *et al.*, 2008), the Basin and Range province (Valentine & Hirano, 2010), south of Greenland (Uenzelmann-Neben *et al.*, 2012), the Chile Trench (Hirano *et al.*, 2013), an accretionary complex in Costa Rica (Buchs *et al.*, 2013), and submarine French Polynesia (Hirano *et al.*, submitted).

The spatial distribution of submarine petit-spot volcanoes remains poorly constrained because shipboard bathymetry has not covered the entire northwestern Pacific Plate. If petit-spot volcanoes occur only in regions of plate flexure, then tiny submarine volcanoes should appear homogeneously on the submarine surface of outer rises. However, areas devoid of volcanoes and lava have been found surrounding areas of petit-spot volcanoes (i.e., sites A?C in Hirano *et al.*, 2006), indicating that the local characteristics of the lithosphere, in addition to plate flexure, control the occurrence of petit-spot volcanoes. Here we report that the distribution of petit-spot volcanoes is controlled by the tectonic structure of the seafloor. We conducted submersible dives along the linearly distributed petit-spot knolls by JAMSTEC *Shinkai6500* in April 2014. Areas with tectonic fabrics appear on the subducting Pacific Plate off the Japan Trench, including a ridge-perpendicular fabric zone (RPPFZ), ridge-parallel abyssal hills (RPRAH), and subducting 'horst and graven' structures (HAGS) (Nakanishi *et al.*, 2011). At Site C, which is a trench-oceanward slope offshore from Soma City, Fukushima Prefecture, the trend of the Japan Trench changes from N?S in the north to NE?SW in the south, where two areas of trench-parallel HAGSs are intersecting in a complex manner (Nakanishi *et al.*, 2011). The distribution of young volcanic cones of more than 80 petit-spots, reported from Site C by Hirano *et al.* (2008), seems to be controlled by the fabrics of RPPFZ and RPRAH, the trends of which are continuous with the HAGS to the north and south along the trench-oceanward slope, respectively. Although the RPPFZ is not recognized as a fracture zone, its trend is sub-parallel to that of the neighboring Nosappu and Kashima fracture zones (Nakanishi, 1993). As the RPPFZ and RPRAH that control the petit-spot distribution are clearly original structures of the lithosphere (in contrast to HAGS), the occurrence of petit-spot eruptions is possibly related to lithospheric structures.

Magnetic Anomalies in the Southern Indian Ocean Revisited

NOGI, Yoshifumi[1*] ; SATO, Taichi[2] ; HANYU, Tomoko[3]

[1]National Institute of Polar Research, [2]National Institute of Advanced Industrial Science and Technology, [3]Graduate University for Advanced Studies

Magnetic anomalies in the Southern Indian Ocean are vital to understanding initial breakup process of Gondwana. However, seafloor age estimated from magnetic anomalies still remain less well-defined because of the sparse observations in this area. To understand the seafloor spreading history related to the initial breakup process of Gondwana, vector magnetic anomaly data as well as total intensity magnetic anomaly data obtained in the Enderby Basin, Southern Indian Ocean, are used. The strikes of magnetic structures are deduced from the vector magnetic anomalies.

Magnetic anomaly signals, most likely indicating Mesozoic magnetic anomaly sequence, are obtained almost parallel to WNW-ESE trending lineaments just to the south of Conrad Rise inferred from satellite gravity anomalies. Most of the strikes of magnetic structures indicate NNE-SSW trends, and are almost perpendicular to the WNW-ESE trending lineaments. Mesozoic sequence magnetic anomalies with mostly WNW-ESE strikes are also observed along the NNE-SSW trending lineaments between the south of the Conrad Rise and Gunnerus Ridge. Magnetic anomalies originated from Cretaceous normal polarity superchron are found in these profiles, although magnetic anomaly C34 has been identified just to the north of the Conrad Rise. However, Mesozoic sequence magnetic anomalies are only observed in the west side of theWNW-ESE trending lineaments just to the south of Conrad Rise and not detected to the east of Cretaceous normal superchron signals. These results show that counter part of Mesozoic sequence magnetic anomalies in the south of Conrad Rise would be found in the East Enderby Basin, off East Antarctica. NNE-SSW trending magnetic structures, which are similar to those obtained just to the south of Conrad Rise, are found off East Antarctica in the East Enderby Basin. However, some of the strikes show almost E-W orientations.

Moreover, the thickness of the crust increase just to the north of the Conrad Rise and clear magnetic anomaly signals considered to be magnetic anomaly C34 in this region may indicate continental-ocean boundaries while taking dredged continental origin rock samples at the Ob seamount into account. Therefore, magnetic anomaly C34 identified in the Indian Ocean must be reconsidered. These suggest complicated ridge reorganization occurred during initial breakup of Gondwana in the Indian Ocean.

Origin of the Palau Basin and a revised spreading model of the West Philippine Basin deduced from three-component magnet

SASAKI, Tomohiro[1] ; YAMAZAKI, Toshitsugu[2*] ; ISHIZUKA, Osamu[3]

[1]University of Tsukuba, [2]AORI, University of Tokyo, [3]GSJ, AIST

The western part of the Philippine Sea (PHS) plate was occupied by the West Philippine Basin (WPB) in the north and the Palau Basin (PB) in the south. The WPB is generally considered to have opened from about 50 to 30 Ma, but the details are still unclear; in particular the origin and age of the PB was unknown. Studying the history of the WPB is important for understanding better the initiation and evolution of the IBM Arc. Here we discuss the spreading history of the WPB using new data on three-component magnetic anomaly and swath bathymetry acquired in the PB as well as those obtained previously by JAMSTEC fleets in the southern WPB. NS-trending magnetic boundaries and seafloor fabrics occur in the PB, indicating the formation by EW seafloor spreading. With a constraint from a 40Ar/39Ar age of 40.4 Ma obtained from the northernmost part of the PB, we interpret that the observed magnetic anomalies correspond to polarity reversals from C16n1r to C18n/C18r (35.6 to 38/39 Ma). Previous models of WPB spreading incorporated a spreading-rate decrease around 40 Ma from about 4.4 to 1.8 cm/year. Our study in the southern WPB, however, suggests that the decrease is unnecessary for correlating observed three-component anomalies to the GPTS. A typical profile along 130E corresponds to C16r to C21 (36.3 to 45.3 Ma). The cessation age of the spreading in our interpretation, about 35 to 37 Ma, is older than the previous estimation (about 30 to 33 Ma). It was difficult to constrain rotation of the PHS plate from the magnetic anomaly skewness.

The composition of back-arc basin basalts in the West Philippine Basin and association with mantle dynamics

HARAGUCHI, Satoru[1] ; ISHII, Teruaki[2*]

[1](Faculty of Engineering, University of Tokyo, [2]Fukada Geological Institute

The Philippine Sea Plate was expanded by multiple extensions of backarc basins. Ishizuka et al. (2011) and Haraguchi et al. (2012) pointed out that the enriched mantle was flowed from backarc side during the spreading of the Shikoku Basin from 25 to 15 Ma (Okino et al., 1994, 1999). Haraguchi et al. (Meeting of the Volcanological Society of Japan, 2013) considered that the process of flowing of the enriched mantle estimated by the composition of the backarc basin basalts (BABB) recovered by the drilling of the Deep Sea Drilling Project (DSDP), Ocean Drilling Program (ODP) and Integrated Ocean Drilling Program (IODP). In this study, we attend the BABB of the West Philippine Basin, precede backarc spreading of the Shikoku Basin, and consider mantle dynamics by geochemical characteristics of BABB.

The first drillings in the West Philippine Basin by the Deep Sea Drilling Project are the Leg 31 same as the Shikoku Basin, and following operations are Leg 59 and the Ocean Drilling Program (ODP) Leg 195. And the diving of the R/V *Shinkai 6500* during the Y9611 cruise by R/V *Yokosuka* and dredges during the KR9801 cruise by R/V *Kairei* at the spreading axis (e.g. Fujioka et al., 1999). In this study, we discuss the new analyzed data of the basements of DSDP Leg 58 Site 446 and ODP Leg 195 Site 1201, and compare the data of the former studies.

Site 1201 is located in the west of the West Philippine basin, about 500km north from the Central Basin fault, axis of the spreading center. The main purpose of this site is the set up of the borehole site WP-1. Thickness of covered sediments at this site is more than 500m. The chemical characteristics of basements at this site are the typical BABB, not find the island arc characteristics. SiO_2 and MgO contents of these basalts are 49-53 and 5-8 wt%, respectively, and are similar to the basalts from the DSDP Leg 58 Site 442˜444 in the Shikoku Basin. The TiO_2 contents of these basalts are 0.9˜1.0 wt%, lower than those of the Shikoku Basin. The alkali elements are 1.5-2.8 wt% of Na_2O and 0.1-1.6 wt% of K_2O, similar K_2O and lower Na_2O contents to Shikoku Basin BABB. The trace elements are 320-420 ppm of Cr, higher than Shikoku Basin BABB, and lower Sr, Y and Zr. The Zr/Y and Nb/Zr ratio are also lower than Shikoku Basin BABB. We consider that these characteristics are the existence of the depleted parent mantle before the spreading of the Shikoku Basin pointed by Ishizuka et al. (2011) and Haraguchi et al. (2012).

Site 446 ate located in the Minami Daito Basin between the Daito and the Oki Daito Ridges. Thickness of covered sediments is about 350m. These volcanic rocks are considered to the intrusion in the sediment layer, different from the basement. The chemical characteristics of this volcanics are classified into alkali basalts, and prominent enrichment of TiO_2, more than 4 to 5 wt%. This extremely enrichment of TiO_2 is not found from other inner plate volcanism in the Philippine Sea Plate. Therefore, we assume that the different inner plate volcanism from the mantle plume in the West Philippine Basin about 40 Ma (Deschamps and Lallemand 2002) were more active in the other Philippine Sea region.

We discuss these analyzed data and former data of the basements in the Philippine Sea Region, and consider parental material composition and magma dynamics before 30 Ma.

Long-distance magma transport from oceanic island arc volcanoes

ISHIZUKA, Osamu[1*] ; GESHI, Nobuo[1] ; KAWANABE, Yoshihisa[1] ; OGITSU, Itaru[1] ; TUZINO, Taqumi[1] ; SAKAMOTO, Izumi[2] ; TAYLOR, Rex[3] ; ARAI, Kohsaku[1] ; NAKANO, Shun[1]

[1]Geological Survey of Japan/AIST, [2]Tokai University, [3]University of Southampton

Long-distance lateral magma transport away from volcanic centers is emerging as a common phenomenon where the regional stress regime is favorable. It should also be recognized as an important factor in the construction and growth of island arcs, and a potential trigger for devastating eruptions. In this contribution, we report on recent investigations into the magma dynamics of Izu-Oshima volcano: an active basaltic volcano with an extensive fissure system.

Geophysical observations in the Izu-Bonin intra-oceanic island arc indicate that magma periodically is moved away from the main basaltic composite volcanoes. When Miyakejima erupted in 2000, seismic activity migrated about 30km northwestward from the volcanic centre (Geshi et al., 2002). This event is interpreted to reflect magma injection and dike propagation at a depth range between 12 and 20km (Kodaira et al., 2002). Long-distance lateral magma transport has also been identified at the Nishiyama volcano on Hachijojima Island using petrological, geochemical and structural studies of satellite vents (Ishizuka et al., 2008). Nishiyama has provided evidence for two types of magma transport: Primitive magma moving laterally for $>$20km in the middle to lower crust (10-20km deep) and short distance transport ($<$5km) from shallow, differentiated magma reservoirs. Of these the long-distance transport seems to be controlled by a regional extensional stress regime, while short distance transport may be controlled by the local stress regime resulting from the load of the main volcanic edifice.

Izu-Oshima is flanked by numerous, subparallel NW-SE trending submarine ridges extending up to 22 km to the NW and SE from the center of the volcano. During a recent diving survey we have identified that these ridges are fissures which erupted basaltic spatter and lava flows. Furthermore, lavas are petrographically similar along each ridge, while there are noticeable differences between ridges. The subparallel ridges are observed to transect a series of knolls, the Izu-Tobu monogenetic volcanoes (ITMV), which are dispersed across this area of the rear-arc. However, there is a consistent petrographic difference between these seamounts and the ridges.

We have found similar, and in some cases a matching, geochemistry between the submarine ridges and subaerial ridges of eruptions found ascending the flanks of Izu-Oshima. This implies that the subaerial ridges and submarine ridges together represent the track of a magma transport episode away from the storage system beneath the central volcano.

ITMV and the transecting ridges are found to have quite distinct geochemical characteristics, indicative of different magma sources. Yet, they are essentially found interspersed in outcrop. The most appropriate scenario for their development is one where ITMV are fed by an ”in-situ” underlying source, while the NW-SE ridges are fed by lateral magma transport from Izu-Oshima. Unlike Nishiyama volcano, Izu-Oshima does not show a compositional variation along the length of the ridges, and has no evidence of primitive magmas. Hence, the magma transport is likely to be derived from a crustal chamber where crystal fractionation and plagioclase accumulation has taken place.

Seafloor geodetic observation along the Nankai Trough - Progress report after the 2011 Tohoku-oki earthquake -

SATO, Mariko[1*] ; WATANABE, Shun-ichi[1] ; YOKOTA, Yusuke[1] ; UJIHARA, Naoto[1] ; ISHIKAWA, Tadashi[2] ; MOCHIZUKI, Masashi[3] ; ASADA, Akira[3]

[1]Hydrogr. and Oceanogr. Dept. of Japan, [2]Japan Coast Guard Academy, [3]IIS, Univ. of Tokyo

We have been carrying out GPS/acoustic seafloor geodetic observation on the landward slope of the major trenches around Japan, such as the Japan Trench and the Nankai Trough. From the past observations, we detected intraplate deformation caused by the subduction of oceanic plates and coseismic displacements associated with large earthquakes.

Along the Nankai Trough, we deployed six seafloor reference points in the sea area from off-Omae-zaki through off-Muroto in 2002-2004 and had been carrying out campaign observations. From the observations conducted before the 2011 Tohoku-oki earthquake, we obtained the intraplate velocities of 2-5 cm/year toward WNW, which were generally consistent with those detected by on-land GPS measurements. A closer look gives us the differences of the velocities by sea areas.

Furthermore, to monitor seafloor movement spatially in the whole expected focal regions along the Nankai Trough, we deployed nine new seafloor reference points mainly off Shikoku in January 2012. If we obtain crustal velocities at all the site, it is expected that a spatial variation of interplate coupling will be revealed in the sea area along the Nankai Trough. It has been two years after the expansion of seafloor reference points and seafloor movements westward and northward are being observed at most of the sites.

In this report, we present a progress report on seafloor geodetic observation along the Nankai Trough after the 2011 Tohoku-oki earthquake.

Postseismic seafloor movements following the 2011 Tohoku-oki earthquake detected by GPS/acoustic positioning

WATANABE, Shun-ichi[1*] ; SATO, Mariko[1] ; YOKOTA, Yusuke[1] ; UJIHARA, Naoto[1] ; ISHIKAWA, Tadashi[2] ; MOCHIZUKI, Masashi[3] ; ASADA, Akira[3]

[1]Hydrographic and Oceanographic Department, Japan Coast Guard, [2]Japan Coast Guard Academy, [3]Institute of Industrial Science, University of Tokyo

The Hydrographic and Oceanographic Department, Japan Coast Guard, have been developing precise seafloor positioning systems using the GPS/acoustic combination technique and carrying out campaign observations along the major trenches in the Pacific Ocean, such as the Japan Trench and the Nankai Trough. For example, after the 2011 Tohoku-oki earthquake (Mw = 9.0), we detected a huge coseismic displacement of 24 m toward ESE at MYGI which is located above the epicenter. We have been continued the geodetic observations along the Japan Trench in order to detect postseismic deformation.

The results of the observations show that the displacements vary with the sites even in the directions. MYGI and KAMS had moved toward west-northwest at constant rate. MYGW had moved toward south-southeast. KAMN had moved toward northwest. FUKU and CHOS had moved toward east-southeast. In addition, the displacements at FUKU and CHOS decay with time. For vertical component, significant subsidence was detected at all sites except CHOS where no vertical displacement was detected within the accuracy range.

In this presentation, we will report and discuss the latest results of the seafloor geodetic observation along the Japan Trench.

A summary of the achievement in the project for advanced GPS/acoustic survey

KIDO, Motoyuki[1*] ; FUJIMOTO, Hiromi[1] ; HINO, Ryota[1] ; OHTA, Yusaku[2] ; OSADA, Yukihito[1] ; IINUMA, Takeshi[1] ; AZUMA, Ryosuke[1] ; WADA, Ikuko[1] ; SUZUKI, Syuichi[2] ; TOMITA, Fumiaki[3] ; IMANO, Misae[3]

[1]IRIDeS, Tohoku Univ., [2]RCPEV, Tohoku Univ., [3]Sci., Tohoku Univ.

GPS/acoustic survey is known as a most probable way to measure the crustal deformation of seafloor far from the coasts, where dense GPS network is not available. We, Tohoku University, together with Nagoya University and Japan Coast Guard dedicated in GPS/acoustic survey for more than decade. MEXT has been strongly promotes our activities though financially support as governmental project. We summarize individual topics in the project.

For the moored buoy, collaborating with JAMSTEC and JAXA, we have started long-term continuous and realtime seafloor geodetic survey at Kumano-nada. At the early stage of the project, we employed a small buoy, which can be also used as towing survey, at off-Miyagi site. Because the size of battery is limited, sea-trials was lasting only for two days. However, using this platform, we developed an automatic ranging system and simple on-demand operation technique via UHF communication. In 2012, we have started developing a automatic ranging system in a realistic working condition using a time-proven platform, m-TRITON buoy, operated by JAMSTEC. Together with JAMSTEC and JAXA, satellite communication part and GPS positioning part have been shared for multi-purpose. Tohoku University group concentrate acoustic ranging part and onsite data processing to compute precise traveltimes. Using a limited onsite resource in the buoy, we have eliminated unnecessary and redundant procedure and data as possible. The first sea-trial took place in 2013 for four months and the ongoing second trial has started in 2014 for six months. In the second trial, acoustic ranging data has been successfully transmitted to onshore station every week and we can monitor it from our laboratory.

For the Autonomous Surface Vehicle (ASV) system, we aimed to develop an automatic survey system, which can also be used simultaneous measurements from other platform, such as a research vessel, for improve the ranging accuracy with multi-acoustic-paths. In our system, vehicle is like an unmanned boat (2.4m long and 400kg in weight), whose propulsion system is driven by electric power from onboard diesel generator lasting for a week. As the ASV system demonstrates sufficient performance for our use in GPS/acoustic survey, it can be a candidate of multi surface platform for simultaneous ranging to achieve high accuracy GPS/acoustic measurement taking the spatial sound speed variation into account.

After the Tohoku-Oki earthquake in 2011, the project has an extra mission that significantly enhance the survey framework, especially in deep seafloor ($>$5000m) near the trench axis. In this extra mission, we have developed a new type of seafloor transponder that works at over 5000m depth and its acoustic communication range is greater than 15km. We made 86 transponders in total and constructed 20 new GPS/acoustic station along the Japan Trench in 2012. In addition, we chartered a research ship for about 50 days per year to construct and observe the new stations. At present we have carried out four times of campaign surveys during 2012-2013. At these new stations, we conducted both moving and stationary surveys, the former generally took several hours and the latter 12 hours for each station. We found a problem in acoustic property in the new transponders, which can be corrected with post-processing shown in Azuma et al. (2014, JpGU). Campaign surveys ranges only about one year, but we have observed post-seismic movement at selected stations. These results are reported in Tomita et al. (2014, JpGU). The new transponders are hybrid type so that Japan Coast Guard has started to make measurements with their own system at several stations above.

This work has been supported by MEXT project for advanced GPS/acoustic survey. Stuffs in RCPEV and IRIDeS, Tohoku University gave dedicated support and collaborative operation in the onboard and GPS surveys. The construction and surveys in the new stations were collaboration with Nagoya University.

Detection of post-seismic movement after Tohoku-oki Earthquake using GPS/Acoustic technique

TOMITA, Fumiaki[1*] ; KIDO, Motoyuki[2] ; OSADA, Yukihito[2] ; AZUMA, Ryosuke[2] ; FUJIMOTO, Hiromi[2] ; HINO, Ryota[2] ; IINUMA, Takeshi[2] ; OHTA, Yusaku[1] ; WADA, Ikuko[2]

[1]Graduate School of Science, Tohoku University, [2]International Research Institute of Disaster Science, Tohoku University

Using GPS/Acoustic seafloor geodetic observation (GPS/A observation), we can directly measure seafloor movements, which cannot be obtained from on-land geodetic observation. For example, Kido et al. (2011) and Sato et al. (2011) detected huge co-seismic displacements associated with 2011 off Pacific coast of Tohoku Earthquake near the Japan Trench, 150km distant from the coast.

After the occurrence of the Tohoku-oki Earthquake, we deployed new seafloor benchmarks at 20 sites along the Japan Trench from Ibaraki-oki to Sanriku-oki. Including three sites installed before 2011, we totally have 23 sites to monitor the post-seismic movement for the Tohoku-oki Earthquake. We have conducted four GPS/Acoustic surveys at present (09/2012, 11/2012, 07/2013, 10/2013) at these sites.

The surveys consists of two types of observations; they are moving survey to locate the position of individual seafloor transponders that make up each geodetic site and point survey to determine the precise location of the center of the transponder array. The displacement at each site is estimated from the temporal change of the array center position. However, we identified two dominant factors that influence the precision of the array center positioning in our observation.

The first factor is the instability in the waveforms of acoustic signals. In GPS/A analysis, we calculate cross-correlation waveform between received and transmitted signals, and determine the timing of maximum peak as round trip travel time. However, multiple peaks separated by 0.3-0.5ms each other are found in a cross correlation waveform, whose relative amplitudes are influenced by the relative position between the hydrophone on the research ship and the seafloor transponder. We have developed an algorithm that can automatically picks up the first peak from the multiples and reduces the error in determining round trip travel time. The detail of this problem and the algorithm will be reported by Azuma et al. (2014, JpGU).

The second factor is uncertainty in the position of the hydrophone equipped on the research ship with respect to three GPS antennas at the top of the ship for attitude determination. In our observations, it is difficult to directly measure the relative position of the three GPS antennas and the hydrophone attached at the end of the pole mounted on the ship's side; the provisional position based on the drawing has about 1m offset. The horizontal component of the offset causes systematic deviation in the apparent position of the transponders depend on ship's heading. Taking this behavior into account, we can correct for the horizontal offset with about 5cm in accuracy. The vertical offset is thought to have less influence on the estimation of the array center position because the sound speed correction intrinsically includes the vertical offset. However, accuracy of offset estimation is still insufficient, hence the estimation technique must be refined further.

After these correction, we have succeeded to obtain preliminary movements at 10 sites using the data in two of the four surveys (09/2012 and 07/2013) at present. These preliminary results generally indicate eastward seafloor movements at the northern Sanriku-oki sites and westward movements at off-Miyagi sites. In this talk, we introduce outline of the analysis and up-to-date results of evaluation of the post-seismic movement incorporating the data in 11/2012 and 10/2013.

Understanding recoupling process using a seafloor geodesy in megathrust earthquake zone

OSADA, Yukihito[1*] ; ITO, Yoshihiro[2] ; KIDO, Motoyuki[1] ; HINO, Ryota[1] ; IINUMA, Takeshi[1]

[1]IRiDes, Tohoku University, [2]DPRI, Kyoto Uniersity

The 11 March 2011 Tohoku-Oki earthquake ruptured the interplate boundary off the eastern shore Honshu, generated a devastating tsunami that swept the coastal area along the northeastern Japan. The seafloor geodesy brought important results that showthat the large slip was near the Japan Trench and suggested the heterogeneity of the coseismic slip distribution in the plate interface. The maximum displacement region for interplate earthquake is mainly located offshore region. Therefore it is important to monitor the postseismic displacement and the stress accumulation process using seafloor geodesy. And if we can observe the postseismic displacement near the Japan Trench, we contribute to understand the coupling condition of plate boundary. There is a seafloor acoustic ranging system for direct observation of horizontal displacement on seafloor. We improve this system that adapted for the axis of Japan Trench. The system is designed to measure distances of up to 3 km and to adapt the pressure vesselof 9000m water-depth. We deployed the seafloor acoustic ranging system between 2013 May and 2013 Sep. We observed across the Tranch baseline (about 7km), baseline between the bottom of Tranch to the seaward side of Japan Trench (about 3.6km). We get data both baseline results for 4 month. We report this results on this presentation.

[1]Japan Agency for for Marine-Earth Science and Technology, [2]Tohoku University, [3]Japan Aerospace Exploration Agency

Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Tohoku University and Japan Aerospace Exploration Agency (JAXA) have developed real-time observation system for tsunami and crustal movement using a buoy since 2011. Although observation interval of crustal movement is generally sparse, because the timing depends on availability of observation ship, we aim to construct to observe tsunami in real-time and crustal movement when it is necessary. Because Japan is surrounded by seismogenic zones with large earthquakes and such large event brought huge damages on coastal region people, early detection is needed to reduce the severe damage. Although online cable system is best for it, the cost for the construction and implementation is huge. Therefore, we point use of the buoy as the removable temporal early detection system. The system is composed of a pressure seafloor unit with pressure sensor and acoustic transmission unit, six seafloor transponders and buoy station incorporating some loggers, transducers to communicate with seafloor systems and data transmission system to land. The seismogenic zones, however, are under the environment of high speed sea current like the Kuroshio. Therefore, we use the slack mooring on our system, but the some technical development is needed for adoption of the mooring. For example, low consumption electricity due to high power acoustic signals for the data transmission and We tried sea trial for three months in last year, and confirmed to fully resistance for high speed sea current over 5.3 knots. On the other hand, the issued to be resolved are clarified, which are on acoustic transmission between the pressure seafloor unit and the buoy, the resistance for the fishery activities and so on. We took measures for above issues and deploy the revised system at off the Kumano Basin. The observation period of the second sea trial is six months. In addition to the measures, we implement tsunami mode. In normal case, we obtain tsunami data with an interval of 15 minutes, but, it is switched to be 15 seconds in tsunami mode. The tsunami mode is triggered when a ratio of average for short period of time (STA) and that of long one (LTA) exceed the threshold level. And, we move the timing of the STA and LTA and try to detect the first arrivals of tsunami. Now, we obtain real-time tsunami and crustal movement data via iridium transmission and introduce it in this presentation.

Study for improving efficiency in seafloor geodetic observation by means of multi acoustic ranging

YOKOTA, Yusuke[1*] ; SATO, Mariko[1] ; WATANABE, Shun-ichi[1] ; ISHIKAWA, Tadashi[2]

[1]Hydrographic and Oceanographic Department, Japan Coast Guard, [2]Japan Coast Guard Academy

Japan Hydrographic and Oceanographic Department (JHOD) and the Institute of Industrial Science, University of Tokyo, have been developing a system for precise seafloor geodetic observation with the GPS/Acoustic combination technique. In this observation, the movements of the seafloor reference points are measured with 2 - 3 centimeters precision. JHOD has been carrying out seafloor geodetic observations 2 - 4 times a year for each station and reported the inter-seismic deformation before and after the 2005 Miyagi-oki earthquake and the co- and post-seismic deformations of the 2005 Miyagi-oki earthquake and the 2011 Tohoku-oki earthquake and so on.

After the 2011 Tohoku-oki earthquake, this observation is expected to be broadened and densely-arranged with the objective of large-scale earthquake disaster prevention. In order to expand further seafloor geodetic observation, shortening of observation time, which is about one day for one campaign, is required. Therefore, we are considering a new acoustic ranging method. In this new method, we conduct the acoustic ranging for multi seafloor transponders not individually but sequentially. We report the details of this new multi acoustic ranging method and discuss how much efficiency will be improved by the introduction of the new method.

Hydrothermal heat mining due to the aquifer thickening toward the trench axis: A model for the Japan Trench

KAWADA, Yoshifumi[1*] ; YAMANO, Makoto[1] ; SEAMA, Nobukazu[2]

[1]ERI, Univ of Tokyo, [2]Kobe University

Observation: At the Japan Trench, a 135-Myr-old Pacific plate is subducting beneath the Japan Island. Heat flow on such an old oceanic plate is expected to be 50m W/m^2 by a thermal model of the oceanic plate. However, observed heat flow values range from 50 to 120 mW/m^2 and the averaged value is 70 mW/m^2 (Yamano et al., 2008, Int. J. Earth Sci.). In the area of high heat-flow anomalies, a high V_p/V_s layer (highly porous, and probably highly permeable) is observed within the uppermost part of the oceanic plate (Fujie et al., 2013, JpGU Meeting). The layer thickness is observed to increase toward the trench axis.

Hypothesis: Permeability within the uppermost several hundred meters of oceanic plate is measured to be high for fluid to convect; this layer is called an aquifer. We assume that thickening of the observed high V_p/V_s layer is a consequence of thickening of this highly permeable layer. Accordingly, we construct a numerical model including hydrothermal circulation within an aquifer being thickened with time, and calculate the resulted heat flow anomalies.

Results: Calculations show that heat flow is increased as the aquifer thickness begins to increase. With typical parameter values for the Japan Trench, the result accounts for the observed high heat-flow anomaly of 20 mW/m^2. This high heat-flow arises due to the mining of heat from the base of the thickening aquifer. Downward thickening of the aquifer invades the high-temperature region, and incorporates the heat into convection. As a result, this heat is transported upwards through sediments above the aquifer, and heat flow is increased.

Seismic structure and seismicity surevey at the Kairei hydrothermal vent field in the Indian Ocean

SATO, Toshinori[1*] ; TAKATA, Hiroyoshi[1] ; IMAI, Yuki[2] ; NOGUCHI, Yui[1] ; KOUNO, Akihiro[1] ; YAMADA, Tomoaki[3] ; SHINOHARA, Masanao[3]

[1]Graduate School of Science, Chiba Univ., [2]Dep. Science, Chiba Univ., [3]ERI, Univ. Tokyo

1. Introduction

In the first segment of the central Indian Ridge from the Rodriguez triple junction, the Kairei hydrothermal vent field exists and extrudes hydrothermal fluid with richer hydrogen content compared to other hydrothermal vents in the world. Around the Kairei hydrothermal field, serpentinized peridotite and troctolites, and gabbroic rocks were discovered. These deep-seated rocks exposed around the Kairei field may cause the enrichment of H2 in the Kairei fluids. At the Kairei field, a hydrogen-based subsurface microbial ecosystem and various hydrothermal vent macrofauna were found. In the TAIGA Project (Trans-crustal Advection and In situ reaction of Global sub-seafloor Aquifer), this area is a representative field of TAIGA of hydrogen. To investigate how the deep-seated rocks (originally situated at several kilometers below seafloor) are uplifted and exposed onto seafloor, and the hydrothermal fluids circurate in subsureface, we conducted a seismic refraction/reflection survay and seismicity observation with ocean bottom seismometers (OBSs).

2. Observation

We conducted a seismic survey around the Kairei hydrothermal field from January 27 to March 19 in 2013 using S/V Yokosuka of Jamstec. We used 21 OBSs, an air gun (GI gun) and a single channel streamer cable. Deployed intervals of OBSs are about 7.5 km, and 2 km near the Kairei field. Survey lines are 5 lines NNW-SSE direction parallel to the ridge axis, 5 lines E-W direction, and 5 lines NNE-SSW direction. Line lengths are from 7 km to 30 km. In addition, we conducted other 5 lines pass around the point just above the Kairei hydrothermal field and the Yokoniwa Rise. The air gun was a GI gun with 355 cu. in. (5.5 l), and the shot interval was 40 s (about 100 m).

3. Results

From seismicity observation, we found many micro earthquakes in this area. A swarm of micro earthquakes exists at a location about 1 km northwest of the Kairei field. The swarm has a NNW-SSE strike, parallel to the ridge axis. The depth of the swarm is very shallow (˜4 km from seafloor). This swarm may be relateted to the hydrothermal activities of the Kairei field. At the first segment of the central Indian Ridge, many micro earthquakes occurred. The depth of these events is deeper than that of the swarm near the Kairei field.

Origin of boron in Okinawa Trough hydrothermal fluids using B isotope as a tracer

TOKI, Tomohiro[1*] ; EBINA, Naoya[1] ; SHINJO, Ryuichi[1] ; ISHIBASHI, Jun-ichiro[2]

[1]University of the Ryukyus, [2]Kyushu University

The Okinawa Trough is a back-arc basin located around the Ryukyu Arc, where several hydrothermal systems have been discovered. The Okinawa Trough has a very thick sedimentary cover, and the chemistry of the hydrothermal fluids appeared to be influenced by interaction with the sediment. However, the temperature environments below the seafloor have not been clarified yet in detail. In this study, we investigated B isotope ratios (δ^{11}B) in hydrothermal fluids from Okinawa Trough, and discussed the origin of the boron and the reaction temperature.

The hydrothermal fluid samples were collected by WHATS with Hyper Dolphin and *Shinkai 6500* from Iheya North Knoll, Izena Caldron, Hatoma Knoll, and Yonaguni Knoll IV. The sample was filtered and acidified by HNO_3. B was isolated by microsublimation, and δ^{11}B measurement was carried out using a MC-ICP-MS (Neptune plus). The precision was within 0.3%. All values reported in this study are presented in delta notation relative to NBS SRM 951.

The concentrations of B in the hydrothermal fluids from Okinawa Trough were higher than those from sediment-starved MOR, and the δ^{11}B showed ^{10}B enrichments. A difference of δ^{11}B among Okinawa Trough hydrothermal fields was found; Yonaguni IV ‹ Izena Caldron ‹ Iheya North ‹ Hatoma Knoll. The δ^{11}B in the hydrothermal fluids showed the strong correlation with the carbon isotopic ratios of methane (δ^{13}C-CH_4) in the hydrothermal fluids, suggesting the factor controlling the variation of δ^{11}B in the hydrothermal fluids is identical with the one controlling the variation of δ^{13}C-CH_4 in the hydrothermal fluids. The controlling factor for the variation of δ^{13}C-CH_4 in the hydrothermal fluids is a mixing ratio between thermogenic methane and microbial methane, implying the controlling factor for the variation of δ^{11}B would be a mixing ratio between B derived from sediment at higher temperature and lower temperature.

We calculated the reaction temperature based on the correlated equation of reaction temperature with δ^{11}B fractionation between solid phase and aqueous phase. For δ^{11}B of the solid phase, reported δ^{11}B of surface sediment from Okinawa Trough (– 5.4 and – 2.2 ‰) was used. However, all observed δ^{11}B in the hydrothermal fluids could not be explained. Instead, δ^{11}B of solid phase was estimated between 50 and 400 ℃; the lowest temperature of leaching B from sediment is 50 ℃ and the highest temperature of sub-critical water is 400 ℃. δ^{11}B of sediment involved in B leaching was estimated to be from – 20 to – 10 ‰, which are lower than the δ^{11}B in surface sediment from Okinawa Trough. Hydrothermal alteration lowered δ^{11}B in sediment, suggesting the origin of the B in Okinawa Trough hydrothermal fluids would be altered sediment. For the reaction temperature, the lowest value among Okinawa Trough hydrothermal fluids was obtained in Hatoma hydrothermal fluids, following Iheya North, Izena, and Yonaguni IV, suggesting a large amount of sediment is distributed in recharge zone in Hatoma Knoll, and the B would be derived from the sediment at relatively low temperature. On the other hand, sediment is distributed in reaction zone beneath Yonaguni IV, and the B would be derived from the sediment at relatively high temperature.

The structure of iron- and silica-rich mounds at hydrothermal environment in shallow marine, Satsuma Iwo-Jima

KURATOMI, Takashi[1*] ; KIYOKAWA, Shoichi[1] ; IKEHARA, Minoru[2] ; GOTO, Shusaku[3] ; HOSHINO, Tatsuhiko[4] ; IKEGAMI, Fumihiko[1] ; MINOWA, Yuto[1]

[1]Kyushu University, [2]Center for Advanced Marine Core Research, Kochi University, [3]Geological Survey of Japan, AIST, [4]Japan Agency for Marine-Earth Science and Technology

Satsuma Iwo-Jima Island, located 38km south of Kyusyu, Japan, is a volcanic island in the northwestern rim of Kikai caldera. Iron- and silica-rich mounds develop with hydrothermal activity (pH=5.5, 50-60 degree Celsius) in Nagahama bay located southwestern part of the island. The brownish seawater at the bay is due to mixing of the hot spring water with seawater (Shikaura and Tazaki, 2001). Very high deposition rate (33 cm per year) of iron-rich sediments was observed in the bay (Kiyokawa et al., 2012). In this study, we analyzed samples (20-30 cm long) recovered from mounds at the seafloor of Nagahama bay by the observation with X-ray CT scan, FE-SEM, and the thin-sectioned sample, and the chemical analysis with EDS, XRF, XRD and DNA, and found that the structure of mounds has unique information.

Visual observation indicated that the samples were made from two layer: black high-density hard layer and brownish low-density soft layer. X-ray CT scan observation shows that the inside of samples is constructed from the aggregation of convex structure (3-4 cm). Soft layer is covered by a hard layer as a rim. The soft layer has many pipe-like structures (typical radius: 1 mm). Petrographic observations indicate that soft and hard layers have filament-like forms, and the form in soft layer is perpendicular to that in the hard layer. The number of small particles (about 20 μm) observed on filament-like forms in soft layer increases toward hard layer. FE-SEM observation shows that filament-like form in hard layer consists of aggregation of bacillus-like form as the chain of particle (about 2 μm). At soft layer, on the other hand, bacteria-like form with smaller particles ($<$0.5 μm) is observed. Bacteria-like form could be classified into 3 types (helix, ribbon-like, twisted). Furthermore, the result of XRD and XRF show that hard layer consists of ferrihydrite and opal-A (Si: 26.8%, Fe: 56.0%) and soft one is composed by ferrihydrite, opal-A, quartz, cristobalite and tridimite (Si: 36.5%, Fe: 43.5%). DNA analysis indicated predominance of *Mariprofundus ferrooxydans* that is known as iron-oxidizing bacteria belonging to Zeta-proteobacteria.

The forming process of the mounds at Nagahama bay is that firstly chemical and biological reaction made soft layer. During occurrence of the reaction, volcanic ash originating from Iwo-dake was contained as silica in the soft layer. Bacteria-like form in soft layer is considered to be the stalk made by iron-oxidizing bacteria according to the result of DNA analysis. Such neutrophilic iron-oxidizing bacteria prefers an environment of redox interface between hydrothermal water and seawater (Chan et al., 2011), and their activity made hard rim at outer soft layer. Inside of hard rim, the keeping of both reaction resulted in relative iron-rich layer and layering at hard rim. Because such process occurred repeatedly, the mounds at Nagahama bay had the aggregation of convex structure with many pipes as the hydrothermal vent. The high depositional rate of iron hydroxides is likely to be influenced by the activity of bacteria.

GPS/acoustic measurement using a multi-purpose moored buoy system

IMANO, Misae[1*] ; KIDO, Motoyuki[2] ; OHTA, Yusaku[1] ; FUKUDA, Tatsuya[3] ; OCHI, Hiroshi[3] ; TAKAHASHI, Narumi[3]

[1]Graduate School of Science, Tohoku University, [2]IRIDeS, Tohoku University, [3]Japan Agency for Marine-Earth Science and Technology

For monitoring crustal deformation and tsunami occurrence in the source region of the upcoming Nankai and Tonankai earthquake, JAMSTEC, JAXA, and Tohoku University have jointly developed a realtime continuous observation system using a moored buoy, called m-TRITON, and have started its sea-trial. The system consists of a seafloor pressure sensor for monitoring tsunamis and vertical crustal deformation, a GPS system for monitoring sea-level and position/attitude of the buoy, and a GPS/acoustic system for monitoring horizontal crustal deformation. Measuresd data are transmited to onshore station via satellite communication so that they can be monitored in realtime. The first sea-trial was carried out in Kumano-nada in 2013, and the second trial has been started in 2014 after improvement of the system. In this presentation, we focus on the issues particular to acoustic ranging of GPS/acoustic measurement for the purpose to remedy the system based on the data acquired in 2013, and report new data being acquired in the ongoing second trial in 2014.

The GPS/acoustic system measures horizontal movement of a seafloor banchmark, which consists of six transponders by combining GPS analysis of the buoy and acoustic ranging between the buoy and seafloor transponders. Considering bit-rate of the satellite communication, it is not realistic to send full acoustic waveform. So, it is required to send only the result processed on the buoy. In order to proceed acoustic wave with a low-powered device on the buoy, it is necessary (1) to cut out recorded waveform to the minimum requirement and (2) to send the processed data containing minimum but sufficient information. As for (1), in the current system recorded acoustic waveform is cut out by a window of $\pm$ 20 ms centered at synthetic traveltime calculated from provisional position of the buoy and each seafloor transponder. After that, cross-correlation waveform between the transmitted signal and the received signal is calculated to obtain an accurate observed traveltime. Then (2) send the correlogram only a 1 ms window centered at the maximum correlation peak, which is sufficient to include the sidelobe. Since correlation wave is represented in 8 bit and the sampling rate is in 100 kHz, the size-per-signle wave to be transmitted can be reduced only to 101 byte.

As a result of considering the fluctuating range for the uncertainty of provisional position obtained by the NMEA output of the GPS (˜10 m at most) and the average sound speed variation (˜2 m/s) that affect the synthetic traveltime, the window width of $\pm$ 20ms employed in (1) is a minimum requirement. In order to certainly cut out maximum correlation peak for all acoustic ranging, it is desirable to set the width to $\pm$ 30 ms. As for correlogram to be sent to onshore station, since the envelope of the correlation peak is within the 1 ms, current width is reasonable. However, apparent maximum correlation peak often known to appears due to multiples at sea surface. In that case, it is not possible to achieve proper adjustment only by the width. Therefore the development of an algorithm to detect the true correlation peak is required. We verified based on actual data about the condition that the multiple occurs, and found that it is explained by the incident angle of the sound wave and the directivity of transducer. We are developping an algorithm that automatically detects the true correlation peak based on this hypothesis.

Inversion analysis for slip deficit rate along the Nankai Trough using on- and offshore crustal velocities

WATANABE, Tsuyoshi[1*] ; TADOKORO, Keiichi[1] ; YASUDA, Kenji[1] ; FUJII, Cosumo[1] ; IKUTA, Ryoya[2] ; OKUDA, Takashi[1] ; KUNO, Masahiro[3]

Along the Nankai Trough, megathrust earthquakes occur every 100-150 years. A nationwide continuous GPS observation network in Japan has measured precise crustal deformation in this area for the past decade. However, the sources of these earthquakes are located offshore where slip resolution is generally poor. Since the early 2000s, seafloor geodetic observations using GPS/Acoustic techniques have been conducted against such a background in Japan. Today, seafloor geodetic observations are recognized as an effective and essential procedure for understanding the source process of earthquakes that occur in offshore areas. In this study, we show the result of seafloor geodetic observations using GPS/Acoustic techniques from 2004 to 2012 and estimate slip deficit rates along the Nankai Trough using both onshore GPS velocities and offshore crustal velocities derived from seafloor geodetic observations. We conducted inversion analysis with a priori information, and then, a high slip deficit rate of more than 50 mm/yr was detected off the Shikoku district. This decreases to approximately 30-50 mm/yr off the Kii Peninsula, and then it falls to approximately 10-30 mm/yr around the Suruga Trough relative to the Amurian plate, except for slip deficit rate of nearly 40 mm/yr which was detected at a fault segment beside the seafloor benchmark at the Suruga Bay. In addition, we investigated slip resolution by adding new established seafloor benchmarks off Shikoku district. As a result, we found that slip resolution was still poorer in offshore areas such as off the Ashizuri Cape, the Muroto Cape, and the Kii Peninsula near the trench axis than in onshore areas. Thus, it is important to conduct seafloor geodetic observations in areas with poor slip resolution.

Development and examination of new methods for traveltime detection in GPS/A geodetic data to high-precise and automatic

AZUMA, Ryosuke[1*] ; TOMITA, Fumiaki[2] ; IINUMA, Takeshi[1] ; HINO, Ryota[1] ; KIDO, Motoyuki[1] ; FUJIMOTO, Hiromi[1] ; OSADA, Yukihito[1] ; OHTA, Yusaku[3] ; WADA, Ikuko[1]

[1]IRIDeS, Tohoku Univ., [2]Graduate School of Science, Tohoku Univ., [3]RCPEVE, Tohoku Univ.

The development of a technique for GPS-acoustic (GPS/A) geodetic observations has enabled us to understand the slip distribution of the 2011 Tohoku-oki earthquake. However, there remains an issue with the precision of GPS/A measurement is still lower by two orders of magnitude than that of on-land GPS measurement due to problems in observations and data processing methods. In this study, we focus on the problem for determination of traveltimes of acoustic signals obtained from GPS/A measurement.

The conventional approach for determining the two-way traveltime of observed acoustic signals is to determine the maximum peak of the cross-correlation waveforms between the transmitted and returned signals. However, the maximum peak often differs from the true peak due to the distortion in the correlation waveform which depends on the relative spatial geometry of the ship and station. These misread traveltimes have been re-read manually so far. Such procedure is no longer applicable for processing vast array of data obtained at newly installed over 20 GPS/A stations after the 2011 Tohoku-oki earthquake. The aim of this study is to develop fully automated algorithms for analyzing GPS/A data with high precision. We introduce here two algorithms.

1) We read the maximum peak in the observed correlogram and then deconvolve it by the synthetic correlogram. Then, we apply the same operation to the deconvolved waveform. This procedure is iterated until the correlation coefficient decreases lower than a pre-defined threshold. A true traveltime is defined as the fastest traveltime during the iterations.

2) We classify the observed correlograms into several groups based on their similarity through cluster analyses and choose a master waveform in each group. Then evaluate the traveltime residual between the maximum peak and the true peak in the observed correlogram. Thus obtained residual is applied as the correction value of each clustered group.

We also use a seismic data analysis tool to visually inspect whether above algorithms work properly. We confirmed that the both new methods properly correct for misreadings in the current method, which sometimes amount to several hundred micro seconds. This corresponds roughly to a 0.3-m difference in the slant range. Therefore, with the new algorithms, significant improvement in the estimation of the station location is expected. However, both methods have to be assigned an arbitrary value as a threshold. Further analyses are needed to determine arbitrary threshold values and to construct fully automated algorithms.

A NaI spectrometer for long-term radon measurement at the sea floor

NINAGAWA, Kiyotaka[1*] ; TOYODA, Shin[1] ; FUJIWARA, Taisei[1] ; NAKAGAWA, Masuo[1] ; YAMAMOTO, Isao[1] ; KUMAGAI, Hidenori[2] ; KINOSHITA, Masataka[2] ; KUBO, Shin[3]

[1]Okayama University of Science, [2]Japan Agency for Marine-Earth Science and Technology, [3]CLEAR-PULSE

In the Japanese Islands, the Tokai, Tonankai and Nankai earthquakes are expected within a few decades. It is a very important scientific issue to understand the physicochemical process occurring in the earthquake occurrence belt and the mechanism of earthquakes near the oceanic trench for damage mitigation of human lives and social basis. Increases of the radon concentration in atmosphere and in groundwater before earthquake are reported in the Southern Hyogo Prefecture Earthquake in 1995. In this research, gamma rays from radon daughter radionuclides at the sea floor will be continuously measured on the Kumanonada offing, where is the epicentral area of the expected Tonankai earthquake. The correlation between micro earthquakes and radon concentrations is also investigated to contribute the fundamental research on the response of the fluid in the crust corresponding to change of the crust.

Investigation on the gamma ray at the sea floor has been made only in a certain limited duration up to several hours while the submersible stays at the site for measurement. This time, a time variation of the gamma ray for several months is planned in order to investigate correlation between earthquakes and radon concentration. A battery drive type NaI spectrometer, which will be set on sea floor and can automatically record gamma ray, was designed. In this January it is almost constructed. A preliminary measurement is scheduled in February. After improvements of software and hardware, it will be set on spring water area of the Kumanonada offing from April to September, and will measure for more than about 4.6 months.

Specification of the NaI spectrometer for long-term radon measurement at the sea floor is as follows;
Name: Low consumed power type gamma-ray spectrometer for deep sea
PMT High-voltage : programmable (+1000V max)
Amplifier: Charge sensitive Memory Capacity: 1Gbit (NOR Flash)
Connection: RS-232C 921,600 bps Current: 110mA (on), 10mA (off)
Operation:
1. After initial setting with PC, measurement starts automatically, and records gamma-ray spectra.
2. It has the intermittent mode for electric power saving.
3. Battery Power Supply 30 AA alkaline batteries, 6 series, 9V
4. When the battery power supply voltage falls to 6V or spectral data is over memory capacity, measurement is suspended automatically and the battery power supply is disconnected.
5. It can connect with PC after measurement, and transfer the recorded spectra to PC.

Time stamp experiment of MEMS-gyro for the observation of seafloor crustal deformation using multi-buoy system

MUKAIYAMA, Haruka[1*] ; IKUTA, Ryoya[1] ; TADOKORO, Keiichi[2] ; NAGAI, Satoru[2] ; WATANABE, Tsuyoshi[2]

[1]Graduate school of science , Shizuoka University, [2]Earthquake research center, Graduate school of environmental study, Nagoya University

We are developing a new method for the observation of seafloor crustal deformation using multi-buoy system. The system measures seafloor crustal deformation by determining position of benchmarks on the seafloor using multi-buoy which link-up GPS and acoustic signals. Acoustic ranging is used to measure distance between the buoys and seafloor benchmarks. And kinematic GPS is used to locate the multi-buoy every 0.2 seconds. Now we have deployed 4 seafloor benchmark units at Suruga Bay and 4 units at Kumano Basin. At each survey site, three seafloor transponders are settled to define a benchmark unit. In November 2012, first observation of seafloor crustal deformation using the buoys was held in Suruga Bay. Analyzing observed data, errors of traveltime ' s residual were about 0.2ms(Mukaiyama et al 2012JPGU). These errors were too large. From approximate calculation, it is predicted that these errors of 0.16ms at maximum can be removed by introduction of a gyro compass. So, we introduced MEMS-gyro to multi-buoy observation to monitor the attitude of the buoys at Suruga Bay at November 2013. The MEMS-gyro was NAV440CA by Crossbow Co.. For the attitude monitoring of the observation of seafloor crustal deformation, time stamp is important. Although the gyro introduces time stamp provided by its GPS processor, its accuracy was not evaluated. In this study, we conducted rotation experiments to evaluate the accuracy of its time stamp. In the experiment, we used another GPS antenna system as a time reference. The GPS antenna and the gyro were deployed on a rotation table to synchronize their motions and the time stamp of the rotated gyro was checked with reference to the GPS time. Timing between their motions was evaluated by cross correlation between GPS circular trajectory and the rotation angle of the gyro. Specifically, we rotated the table for 3 min every 1 hour. This subset was repeated 3 times. As a result, delay times in first two sets were about -38ms. But third set was -58ms. The delay became lager. Offset of the average angle between GPS and gyro was also deferent from first two sets to third set. This deference might be caused by that of rotation speed between three subsets. We tried additional experiment with different parameter settings of MEMS-gyro under controlled rotation speed. We will also report the result of this additional experiment.

Three year observations of ocean infragravity waves by broadband seismometers and pressure gauges of Japanese seafloor n

TONO, Yoko[1*] ; NISHIDA, Kiwamu[2] ; FUKAO, Yoshio[1] ; TO, Akiko[1] ; TAKAHASHI, Narumi[1]

[1]JAMSTEC, [2]ERI

Ocean infragravity (IG) waves are sea-surface gravity waves with periods of several minutes and wavelengths up to tens of kilometers. We used a slant-stack technique to detect IG waves from the three-year period records (2011-2013) of the vertical component broadband seismograms and pressure gauges of the seafloor network deployed in the Nankai Trough region (DONET). IG signals show good match in waveform between the seafloor displacement and pressure with propagation speeds consistent with the seafloor depths of 2000 m. The signal intensities are strongly azimuth-dependent. Except for the days with extreme weather, waves incoming from the SE direction (from the deep ocean to the coast across the Nankai Trough) are by far dominant. The incoming direction sharply splits into two, SSE and ESE. Waves from the deeper ocean in the SSE direction are more dominated in longer-period components than those from the shallower ocean in the ESE direction. Amplitudes of these waves clearly show a seasonal variation, high in winter and low in summer. The effect of typhoon is to generate IG waves incoming from the source direction and those incoming from the NE-ENE direction through the corridor between the coast and the Nankai trough. The latter is often stronger than the former.

Evaluation of resolution and estimation error of vessel-based seafloor displacement observation using AUV bathymetry

FUJIWARA, Toshiya[1*] ; MASAKI, Yuka[1] ; YAMAMOTO, Fujio[1]

[1]JAMSTEC

Bathymetry is basic information for any kind of seafloor observation, and therefore vessel-based multi-narrow beam bathymetric surveys are conducted quite often. In recent years, previous bathymetric data exist in most scientifically-important areas. A repeated bathymetric survey reveals seafloor displacement related to geodynamics [e.g. Fujiwara et al., Science 2011]. However, the spatial resolution and estimation error of the seafloor displacement observation from the vessel-based bathymetric survey are not exactly known. Because the observation compares a pair of limited-resolution bathymetric data. Water depth (distance from the vessel's echo sounder to the seafloor) degrades the spatial resolution and precision of depth measurement from the vessel-based survey. While on the other hand, a near-seafloor Autonomous Underwater Vehicle (AUV)-based survey enables us to obtain high-resolution bathymetric data. In this paper, we evaluated the spatial resolution and estimation error of the seafloor displacement observation from vessel-based bathymetric survey. In this evaluation, bathymetric data from vessel-based and AUV-based surveys in the Iheya-North knoll of the Okinawa Trough were used.

AUV Urashima bathymetric survey was conducted in YK07-07 cruise aboard the R/V Yokosuka in May 2007 [Yamamoto et al., 21st Mtg, Japan Society for Marine Surveys and Technology 2009]. The applied multi-narrow beam echo sounder was a SEABAT 7125. R/V Yokosuka bathymetric survey was performed using a SeaBeam 2112 echo sounder in YK06-09 cruise from 18 to 24 July 2006 [Masaki et al., JAMSTEC R&D 2011]. The vessel passed over the survey area six times with each constant speeds and obtained bathymetric data. One survey track was treated as one's independent survey in this evaluation. The beam angle (angle formed by the vertical line and a narrow sounding beam) was within 40^o in the survey area.

AUV bathymetry shows hills (the shallowest depth ∼870 m) in the western side and basins (the deepest ∼1070 m) in the eastern side. The average/median depth is 1010 m. Hydrothermal chimney mounds ∼30 m in diameter and ∼10-20 m in height were found on the hillside in the high-resolution bathymetry. Vessel-based bathymetry is spatially-smoothed as a function of the footprint (area of the narrow sounding beam projected onto the seafloor) size. The footprint size of the Yokosuka survey at a depth of 1000 m is ∼35×35 m-43×55 m (∼5% of water depth). In the vessel bathymetry, geographical features smaller than the footprint size, such as the hydrothermal chimney mounds, cannot be recognized. And seafloor morphology is slightly different from each other track surveys due to distribution of sounding points and measuring error. Standard deviations of depth differences between the AUV- and the vessel-based data were 2.67-3.08 m. The AUV bathymetry are assumed to be the "true" bathymetry, and therefore the precision of the vessel-based depth measurement (standard deviation of measuring error) is considered to be ∼0.2-0.3 % of water depth.

Simulated vessel-based bathymetric data "before and after" the seafloor displacement were made using AUV-based bathymetric data. The displacement was verified by comparing these simulated data using the analysis conditions that neither depth accuracy variation within the area nor locational errors of beam sounding points are allowed. We used the method of Fujiwara et al. [2011] to estimate horizontal displacement. As a result, we found that estimation error of the seafloor horizontal displacement depends on the precision of the depth measurement and is ∼0.2-0.3 % of water depth. As for the seafloor vertical displacement, the smallest displacement that can be detected occurs when the horizontal extent of the deformation is larger than several times the size of the footprint, and in the situation that the amplitude of the depth difference is greater than the precision of depth measurement.

Bathymetric survey and discovery of hydrothermal plume in the Daiichi-Amami Knoll using autonomous underwater vehicle

MINAMI, Hiroki[1*] ; OHARA, Yasuhiko[2]

[1]Hydrographic Surveys Division, Hydrographic and Oceanographic Department, Japan Coast Guard, [2]Ocean Research Office, Hydrographic and Oceanographic Department, Japan Coast Guard

Many submarine volcanoes exist along the volcanic front in the Ryuku Arc. The Daiichi-Amami Knoll, which is located about 70 km off Amami Oshima Island, is one of those submarine volcanoes. Detailed bathymetric survey of this knoll has not been done before, therefore its shape and size have not been known. Japan Coast Guard conducted a high resolution bathymetric mapping of the knoll using survey vessel and autonomous underwater vehicle (AUV) and discovered hydrothermal plumes which are rising from the seafloor, indicating that the presence of hydrothermal activities in the Daiichi-Amami Knoll.

1. Method

The survey was conducted in August and September, 2013 using survey vessel Takuyo and AUV Gondo. The knoll was surveyed with multibeam echo sounder (MBES) installed on S/V Takuyo. Then the detailed survey was done with MBES on AUV Gondo.

2. Bathymetry

The bathymetry of the Daiichi-Amami Knoll indicates that the knoll is a volcanic high. The knoll has flat areas, a caldera with a diameter of 1.6 km and some volcanic cones at its summit. The knoll also has two small depressions near to the volcanic cones and they are deeper about 40 m than the surrounding areas. The relative high of the knoll is about 500 to 700 m and the shallowest depth of the knoll is 245 m.

3. Hydrothermal plume

Water column data acquired by MBES on S/V Takuyo detected the clear hydrothermal plumes in the two depressions. The plumes were especially clear at the rim of the depression. Some plumes were observed to rise from the seafloor of 350 m depth to near sea surface (although no discolored water was visually observed on the sea surface). Plumes were also detected at the slope areas of the volcanic cones. AUV Gondo dived to the depressions at the altitude 40-50 m above seafloor and conducted a detailed survey. The high resolution bathymetric map shows a presence of a numerous small depressions near the plume points. The side scan image by AUV Gondo also shows the plumes acoustically at its nadir.

4. Water temperature

AUV Gondo observed the water temperature at the altitude 40-50 m in the depresions, but distinguished temperature increases were not observed. Temperature profile observation, which was conducted using expendable bathythermograph launched from S/V Takuyo, showed over 2 degrees temperature increase near the seafloor in the depression. This observation along with the presence of plumes indicate the presence of hydrothermal activity in the Daiichi-Amami Knoll.

5. Importance of this survey result

The detailed bathymetry and the presence of plumes in the Daiichi-Amami Knoll were revealed by the survey using survey vessel and AUV. The discovery of plumes suggests the presence of hydrothermal deposits and chemosyhthetic community, therefore being important in terms of seafloor resources. The high resolution bathymetric map acquired by AUV is fundamental information which is useful for scientific research and mineral exploration. This result is a first step for further survey to understand the geological history of the knoll and to secure new seafloor resources.

Topography, geology, tectonics and ore deposit of the Bayonnaise knoll caldera, Izu-Ogasawara arc

HONSHO, Chie[1*] ; URA, Tamaki[1] ; ASADA, Akira[3] ; KIM, Kangsoo[3] ; NAGAHASHI, Kenji[3]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, [2]Center for Socio-Robotic Synthesis, Kyushu Institute of Technology, [3]Underwater Technology Research Center, Institute of Industrial Science, The University of Tokyo

Several hydrothermal sites have been discovered in the volcanic front of the Izu-Ogasawara arc: Myojin knoll caldera, Myojinsho caldera, Smith caldera, Suiyo seamount, and Kaikata seamount. The Hakurei hydrothermal site in the Bayonnaise knoll caldera is the only hydrothermal site discovered in the rift zone of the arc. We analyzed deep-sea multibeam and side scan sonar data obtained using autonomous underwater vehicle Urashima in the caldera and discussed the topography, geology, tectonics, and ore deposit of the caldera.

The survey area ∼3 km x ∼2 km wide covers the southern half circle of the caldera. Major geomorphic elements are, from the outside to the inside, the knoll slope, the steep caldera wall, the flat caldera floor, the central cone with three peaks, and the central depression surrounded by the peaks. The high-resolution bathymetric map shows that large slope failures occurred in the southeastern caldera wall and that the Hakurei deposit is distributed over the failure area. Slope failure is also going on in the southwestern wall and a large collapse may shortly occur. The eastern hill, the main part of the central cone, seems to be a lava dome: it has a small flat surface on the top, convex slopes in the upper part, and rectilinear to concave slopes near the base. The northeastern slope of the dome is relatively flat from top to bottom, indicating that a slope failure occurred there. A series of depressions lying in a NW-SE direction in the western caldera floor would be a crater row, seeing that the terrain gently slopes down from the rim of the depressions. The direction of the crater row suggests that the caldera is under the extension stress in a NE-SW direction.

Morphological and textural characteristics of the Hakurei site were determined by three kinds of analyses. The gray-level co-occurrence matrix was used to describe the texture of the side scan sonar image and to classify the seafloor using cluster analysis. The Hakurei area was distinctly classified to a group that was characterized by high entropy and low homogeneity, and a broad area from the top to the northeast slope of the eastern lava dome was also classified to the group. Some areas belonging to the group were distributed around the top of the southern central cone, in the eastern caldera wall northeast of the Hakurei site, in the southwestern caldera wall, and around the crater row. A band-pass filtered topography was used to determine areas where short-wavelength topographic features like chimneys and mounds observed in the Hakurei site dominate. The band-pass filtering was also performed on the multibeam backscattering intensity data to detect similar patterns to numerous spots of strong backscattering from chimneys observed in the Hakurei area. These results commonly show that areas of similar characteristics to the Hakurei site are distributed in a zone crossing the caldera in a NW-SE direction, from the Hakurei site to the crater row through the central cone.

The Izu-Ogasawara rift zone is separated to many segments ranging in a N-S direction. The Bayonnaise knoll caldera is located on the northeastern margin of an oval depression called the North Myojin rift, which has a longer N-S axis of ∼20 km. It appears that the direction of the crater row, the distributions of hydrothermal or volcanic features, and the distribution of slope failures are along the rim of the North Myojin rift going through the caldera. The North Myojin rift is surrounded by seven knolls including the Bayonnaise knoll. Although hydrothermal activity has been discovered only in the Bayonnaise knoll so far, the geological settings that volcanoes of acidic rocks lying along a circular fault of a depression host ore deposits closely resembles that of the Hokuroku Kuroko region in northern Akita. It is suggested that the Hakurei site is the present field of the Kuroko ore formation.

Electrical resistivity structure of the Snail site at the Southern Mariana Trough spreading center

MATSUNO, Tetsuo[1*] ; KIMURA, Maho[2] ; SEAMA, Nobukazu[2]

[1]National Institute of Polar Research, [2]Kobe University

The electrical resistivity of the oceanic crust is sensitive to the porosity of the crust and the fluid temperature within crustal fractures and pores. The spatial variation of the crustal porosity and the fluid temperature that is related to a hydrothermal circulation can be deduced by revealing an electrical resistivity structure of the oceanic crust involving a hydrothermal site. We carried out a magnetometric resistivity experiment using an active source to reveal an electrical resistivity structure of the oceanic crust at the Snail site on the ridge crest of the Southern Mariana Trough. Active source electric currents were transmitted along and across the ridge axis in a 4000 m^2 area including the Snail site. Five ocean bottom magnetometers were deployed around the Snail site as receivers to measure the magnetic field induced by the transmission of the active source electric currents. The amplitude of the induced magnetic field was calculated by maximizing data density and the signal to error ratio in the data, and locations of the transmissions were determined using several types of calibration data. An optimal 1-D resistivity structure of the oceanic crust, averaged over the experimental area, was deduced by least squares from the data of the amplitude of the magnetic field and the location of the transmission. After calculating magnetic field anomalies, which are deviations of the observed amplitude from the prediction of the optimal 1-D resistivity model, an optimal 3-D resistivity structure was deduced from the magnetic field anomalies through trial and error 3-D forward modeling. The optimal 1-D resistivity structure is a two-layer model, which consists of a 5.6 Ω-m upper layer having a 1500 m thickness and a 0.1 Ω-m underlying half-space. Using Archie's law and porosity profiles of the oceanic crust, the resistivity of 5.6 Ω-m at depths ranging from 800 to 1500 m suggests the presence of high-temperature fluid related to the hydrothermal circulation. The resistivity of 0.1 Ω-m below 1500 m depth may represent a magma mush that is a heat source for the hydrothermal circulation. The optimal 3-D resistivity structure includes a conductive anomaly (0.56 Ω-m in approximately 300 m^2 area down to 400 m depth) just below the Snail site, two resistive anomalies (56 Ω-m with slightly larger volumes than the conductive anomaly) adjacent to the conductive anomaly on the across-ridge side, and three conductive anomalies away from the Snail site. The conductive anomaly just below the Snail site suggests hydrothermal fluid, and the adjacent resistive anomalies suggest areas of low porosity. The size and distribution of the conductive and resistive anomalies near the Snail site constrains the size and style of the hydrothermal circulation.

Crustal Imaging of initial structure in Izu-Ogasawara forearc region obtained by seismic reflection survey

YAMASHITA, Mikiya[1*] ; NO, Tetsuo[1] ; SATO, Takeshi[1] ; KODAIRA, Shuichi[1] ; TAKAHASHI, Narumi[1] ; MIURA, Seiichi[1] ; ISHIZUKA, Osamu[1]

[1]JAMSTEC

The Izu-Bonin (Ogasawara)-Mariana (IBM) arc is known to the typical oceanic island arc, and it is the most suitable area to understand the growth process of island arc. The existence of two paleo arc which consists of Oligocene and Eocene paleo age is known in IBM forearc region by geological and geophysical studies. The Ogasawara ridge is also known to locate the initial structure of arc evolution from geologic sampling of research submersible. In this region, IODP drilling site: IBM-2 is proposed in order to understand the temporal and spatial change in arc crust composition from 50 to 40Ma magmatism. Site IBM-2 consists of two offset drilling holes (BON-1, BON-2). BON-1 designed to first encounter forearc basalt and will reach the sheeted dykes. BON-2 will start in boninites and finish in fore arc basalts. The purpose of these drilling is sampling the full volcanic stratigraphy from gabbro to boninite. This drilling project is already scheduled in 2014. The survey lines along the proposed sites, however, there are no crossing seismic data around BON-1 and BON-2. Therefore, it is need to conduct the MCS survey until 2013 for the evaluation of proposed site.

Japan Agency for Marine-Earth Science and Technology (JAMSTEC) newly carried out multi-channel seismic reflection (MCS) survey using 7,800 cu.in. air gun, 5 km streamer with 444 ch hydrophones in April, 2013. We obtained two seismic reflection profiles of lines IBr11n and IBr11 across from Shikoku Basin and current volcanic front to the paleo arc. The preliminary results show the distribution of volcanic sediments and basement.We also identified the block type structure associated with the uplift in northern side of Kinyo seamout. We will discuss about the characteristics between backarc and forearc from north to south.

Across-arc geochemical variation of Quaternary Basalts dredged from central part of Izu-arc

YOSHIDA, Takanori[1*] ; OKAMURA, Satoshi[1] ; SAKAMOTO, Izumi[2] ; ADACHI, Yoshiko[3] ; IKEDA, Yasuo[4] ; SHINJO, Ryuichi[5] ; SUGAWARA, Makoto[6]

[1]Hokkaido University of Education Sapporo, [2]Tokai University, [3]Niigata University, [4]Hokkaido University of Education Kushiro, [5]Ryukyu University, [6]Mitsubishi Materials Techno Corporation

The Izu-Bonin arc located western margin of the Philippine sea plate extend to ca. 1200 km south from central Honshu of Japan with ca. 400 km width. The Izu-Bonin arc is a match for NE Honshu arc (Nishimura and Yuasa, 1991). Although volcano lying on the volcanic front (VF) of northern part of this arc expose above the sea level (e.g. Izu Oshima, Miyakejima), almost this arc sink down to sea surface. Active rifts (AR) exist just behind VF with 20-30 km width. These are parallel to the VF and Izu-Bonin Trench and enclosed with escarpment. Ishizuka et al. (2003b) reported Ar-Ar age of igneous rocks dredged from central part of Izu-Bonin arc. According to these age data, recent volcanism (<1Ma) occurred only VF and AR. In this study, we report geochemical data of basalt dredged from Myojin volcano, Myojin rift and Aogashima rift. Basalts exhibit evident across-arc variations. Ba/La ratio, Sr, Nd and Hf isotopic ratios decrease correspondingly distance from Izu-Bonin trench toward rear-arc. Whereas (La/Sm)N increase correspondingly distance from Izu-Bonin trench. Based on ratios of trace elements and each isotopic feature, we conclude that VF basalts generated from flux melting of mantle due to adding aqueous fluid to wedge mantle from subducting slab. On the other hand, genesis of AR basalt is to supply supercritical melt (e.g. Kessel et al. 2005) of slab to wedge mantle. Chromian spinel composition, Cr# of inferred chromian spine equilibrated with mantle is 0.75, held in olivine of VF basalt suggest that residual mantle equilibrated with VF primary magma is dunite. Degree of partial melt of AR basalt decrease correspondingly distance from Izu-Bonin trench toward rear-arc. Tollstrup et al. (2010) interpreted magma genesis of basalt after cessation of Shikoku back-arc basin. They proposed that basalts of western seamount chain (WS) and back-arc knolls (BAK) derived from partial melting of mantle due to adding supercritical melt to mantle wedge from subducting slab, whereas aqueous fluid contributed to partial melting of mantle beneath AR and VF. In their discussion, activity age and activity region are not considered. According to their conclusions, supercritical melt related to genesis of basalts from WS and BAK is not contribute to partial melting of mantle wedge recent volcanism (<1Ma). Bryant et al. (2003) revealed that VF basalt volcanism has continued since 15Ma. Moreover, Ishizuka et al. (2003b) reported volcanism has traveled eastward with time in the central Izu-Bonin arc. It means Izu-Bonin arc volcanism has become narrow range with time. Distinct slab flux between VF and AR in this study suggest that occurrence of supercritical melt is traveling with time toward VF side due to change subducting angle of slab into more steep angle since 15Ma to 3Ma (Honda et al., 2007). Therefore supercritical melt related to genesis of basalt from WS and BAK at predate volcanism contribute to AR recent volcanism.

The variety of silisic rocks around the Myojin volcano, central Izu-Bonin arc

YOSHIDA, Takanori[1*] ; OKAMURA, Satoshi[1] ; SAKAMOTO, Izumi[2] ; ADACHI, Yoshiko[3] ; IKEDA, Yasuo[4] ; SHINJO, Ryuichi[5] ; SUGAWARA, Makoto[6]

[1]Hokkaido University of Education Sapporo, [2]Toukai University, [3]Niigata University, [4]Hokkaido University of Education Kushiro, [5]Ryukyu University, [6]Mitsubishi Materials Techno Corporation

The Izu-Bonin arc located western margin of the Philippine sea plate (PSP) extend to ca. 1200 km south from central Honshu of Japan with ca. 400 km width. The Izu-Bonin arc is a match for NE Honshu arc (Nishimura and Yuasa, 1991). Active rifts (AR) exist just behind volcanic front (VF) with 20-30 km width. These are parallel to the VF and Izu-Bonin Trench and enclosed with escarpment. Generally primitive basalts possibly erupted at oceanic arc volcano without any process in the oceanic crust due to be thinner than continental crust. Although it is well known that Izu-Oshima and Miyakejima, located on VF, erupted basalts, Kouzushima, Niijima and Myojin reef are represented volcanoes which provide mostly felsic products exist on the Izu-Bonin arc VF (Tamura et al., 2009). Nowadays extensive seismic experiments in the Izu-Bonin arc have documented the occurrence of middle crust with P-wave velocity of 6.0-7.0km/s (e.g. Suyehiro et al., 1996). Because of the rock, with P-wave velocity of 6.0-7.0km/s, correspond to tonalite exposed Tanzawa complex Izu collision zone and tonalitic xenoliths in the volcanic rocks sampled VF, inferred middle crust of Izu-Bonin arc composed of tonalitic igneous rocks (Suyehiro et al., 1996). In this study, our aim is to understand mechanism of felsic volcanism contribute to making continental crust. Therefore we consider about felsic rocks dredged from Myojin volcano, Myojin rift and Aogashima rift.

Felsic rocks in this study are divided into three suites (type 1, type 2, type 3) on the basis of Zr/Y versus Zr diagram. Type 1 is lowest Zr/Y ratio trend, type 3 exhibit highest Zr/Y ratio and type 2 have intermediate Zr/Y ratio. Type 1 occur mainly VF, and small amount of type 1 appear AR. Type 2 collected overall from VF to AR. Type 3 occurs only AR.

Although Sr and Nd isotopic compositions of type 1 is similer to the basalt from the VF, Hf isotopic compositions of type 1 differ from VF basalt, and Hf isotopic compositions of type 1 is same as mafic xenoliths in VF lava rather than VF basalt. Isotopic features of type 2 are distinguished from lavas erupted normal-arc magmatism after cessation of Shikoku basin. And Isotopic features of type 2 dredged from more AR-side have higher Nd, Hf isotope ratios. Although Sr and Nd isotopic compositions of type 3 is similer to the basalt from the AR, Hf isotopic compositions of type 3 differ from AR basalt, and isotopic compositions of type 3 is different from lavas erupted normal-arc magmatism after cessation of Shikoku basin and tephra data from ODP boring (Straub et al., 2010).

On the basis of Na2O vs ASI diagram, three type felsic rocks in this study agree with compositions of experimental liquids which derived from basaltic source materials (e.g. Sission et al., 2005). There is possibility that felsic rocks derived from associated basalt. But because of Hf isotope ratio, all felsic rocks are not derived from associated basalt. Therefore all felsic rocks, provided by recent volcanism, are rejuvenated products of old arc crust.

Because of isotopic compositions of type 1 are similer to mafic xenoliths in VF lava, type 1 derived from remelting of arc crust which have postdate VF basalt composition (Bryant et al., 2003). Altough There is possibility that type 2 derived from remelting of Oligocene mafic arc crust, type 2 dredged from more AR-side have higher Nd, Hf isotope ratios. It suggests that AR-side type 2 is possibly affected by PSP. Geochemical data which is similer to type 3 have been found out in previous ODP boring data, and it is possible exist crustal material which is peculiar to AR. We long for IODP projects which start at this year to accumulate new AR crustal material data to consider source of type 3. We propose heterogeneous crust model. It have made by underplating or intrusion of mafic magma derived from mantle into PSP for 50Ma.

General remarks of velocity structures of the Ogasawara Plateau, revealed by the Contineltal Shelf Survey of Japan

KANEDA, Kentaro[1] ; NISHIZAWA, Azusa[1*] ; OIKAWA, Mitsuhiro[1] ; MORISHITA, Taisei[1]

[1]JHOD

Japan Coast Guard conducted seismic refraction surveys with OBSs and multi-channel seismic surveys over more than 10 survey lines on the Ogasawara Plateau which is located on the Pacific Plate, close to a plate boundary to the Philippine Sea Plate. Analysis of these seismic data in 2006-2007 revealed that 1)the Ogasawara Plateau collide and partly accreted with the Philippine Sea Plate, 2)crustal thickness of the Ogasawara Plateau is approximately 25 km, close to that of the Izu-Ogasawara Arc, and 3)low velocity structure in lower crust extends below flat seafloor to the south-east to the plateau.

Recently, re-analyzing of the data by utilizing various later phases and MCS profiles revealed more detailed velocity structure of 1')plate boundary between the Pacific Plate and the Philippine Sea Plate, 2')under plating below the Ogasawara Plateau and 3')low velocity structure distributing around the plateau.

Keywords: velocity structure, Ogasawara Plateau, seismic experiment

Acoustic characterization of abyssal plain, northwestern Pacific region

OKINO, Kyoko[1*] ; HONSHO, Chie[1] ; MACHIDA, Shiki[2] ; OIKAWA, Mitsuhiro[3] ; NAKAMURA, Kentaro[4]

[1]AORI, The University of Tokyo, [2]School of Creative Science and Engineering, Waseda University, [3]Hydrographic and Oceanographic Department, Japan Coast Guard, [4]School of Engineering, The University of Tokyo

The old seafloor covered by pelagic sediment has not attracted large scientific attention and remained untouched for many years, however, the recent studies on intra-plate volcanism as well as the increasing interest in deep-sea natural resources focus spotlight on the abyssal plains. We analyzed the multi-beam bathymetry, beam intensity, and side-scan images of abyssal plain in the northwestern Pacific, around the Minami-Torishima (Marcus) Island. The data were collected by Japan Coast Guard as part of Japanese EEZ survey and by R/V Yokosuka for decades. The beam intensity data from multi-beam echo sounder were processed to create a backscatter mosaic without geometric distortion. The mosaic shows a large variation of acoustic characteristics in whole study area. The high backscattering areas at the foot of large seamounts likely reflect the distribution of volcaniclastic sediments and debris. We can also recognize another type of high backscattering areas in flat seafloor, where neither remarkable seamounts nor knolls exist. The latter type partly corresponds to the area where the high concentration of rare-earth elements were reported and may suggest a thin cover of uppermost soft sediment layer. We try to integrate the backscattering mosaics and the statistic analysis of bathymetry and to establish a new method of acoustic characterization of abyssal plain. We also plan to compare our results with piston core samples as ground references and to discuss the sedimentation process and the relationship with intra-plate volcanism on old seafloor.

Spreading stability at the mid-ocean ridges derived from 3D magnetic survey

MATSUMOTO, Takeshi[1*] ; SATOH, Yukitaka[1] ; NOGI, Yoshifumi[2]

[1]University of the Ryukyus, [2]National Institute of Polar Research

The Shipboard Three Component Magnetometer (STCM) has provided vector data of the geomagnetic filed provided detailed information more than total magnetic force measurement. Previous study shows the results about relationship with ocean floor topography and standard deviation of magnetic boundary strike (MBS) calculated from Intensity of the Differential Vectors (ISDV) in Southeast Indian Ridge (SEIR) classified intermediate spreading rate. In this study, the standard deviation of MBS and half spreading rate were analyzed from STCM data in East Pacific Rise (EPR) of fast spreading ridge, Explorer Ridge (ER) and Southeast Indian Ridge (SEIR) classified intermediate spreading ridge and Mid Atlantic Ridge (MAR) categorized as slow spreading ridge. In EPR existing axial high, the results shows that standard deviation and half spreading rate are stable in west of EPR whereas standard deviation and half spreading rate are variability in east of EPR. However standard deviation is low and spreading rate is stable on both sides in MAR developed axial valley. Thus there is no relationship with topographic features and spreading of stability. Additionally, standard deviation of MBS is the low although half spreading rate has variability in ER. The results show differential MBS at the same position in SEIR. As a result, dispersion of MBS is caused by inaccurate measurements of magnetic anomaly. In addition, there is no clear relationship though the simulation was run about plate reconstruction. Therefore spreading stability is controlled by the balance among plate reconstruction, slab pull and magma provided from mantle.

Detailed bathymetry and magnetic anomaly in Central Ryukyu: Implications on westward shift of volcanic front after 2.1Ma

SATO, Taichi[1*] ; ODA, Hirokuni[1] ; ISHIZUKA, Osamu[1] ; ARAI, Kohsaku[1]

[1]Institute of Geology and Geoinformation, Geological Survey of Japan, AIST

Detailed bathymetry and magnetic anomaly were obtained by GH12 cruise in 2012 using R/V Hakurei, in the southern part of Central Ryukyu. Volcanic structures such as caldera were observed on the southwestward extension of the present-day volcanic front, implying recent volcanic front of the Ryukyu arc. Furthermore, bathymetric highs which are sub-parallel to the recent volcanic front were observed and is located ~20 km east. These are accompanied by spotted magnetic anomalies, which continue to Kume-jima via Aguni-jima Islands to the south, suggesting an existence of an ancient volcanic front. The ages of volcanic rocks from these Islands suggest that the magmatic activity along the ancient volcanic front had been active at least until ~2.1 Ma. The magmatic anomalies connecting two volcanic fronts suggest that a volcanic front have moved gradually westward. This shift would be explained by the termination of asthenospheric upwelling and/or rapid retreat of Ryukyu Trench.

Evolution of depositional basin accompanied by recurring caldera collapses in Kikai caldera, southern-off Kyushu, Japan

IKEGAMI, Fumihiko[1*] ; MINOWA, Yuto[1] ; KURATOMI, Takashi[1] ; KIYOKAWA, Shoichi[2] ; OIWANE, Hisashi[3] ; NAKAMURA, Yasuyuki[4] ; KAMEO, Katsura[5]

[1]Department of Earth and Planetary Sciences, Kyushu University, [2]Faculty of Sciences, Kyushu University, [3]Mishima-mura, [4]JAMSTEC, [5]Atmosphere and Ocean Research Institute, Tokyo University

Kikai caldera (Matsumoto, 1943) is a mostly submerged highly active caldera volcano located in 40 km off Kyushu Island. The caldera is recognized as the product of 7300 cal. BP super-colossal eruption with Akahoya tephra (Machida and Arai, 1978; Fukuzawa, 1995) which is widely distributed along the western part of Japan. Previous studies for near-vent onshore geology strongly suggests such a large eruption was not occurred only once, but multiple times in the Kikai caldera (Ono et al., 1982).

In Kikai caldera, 24 lines of multi-channeled seismic reflection surveys were held in two survey cruises (KT-10-18 and KT-11-11) in 2010 and 2011 using R/V Tansei-maru of JAMSTEC (Japan Agency for Marine-Earth Science and Technology). The acquired seismic data for subseafloor structures spotted thick sedimentary basin at the eastern margin of the caldera. The basin covers 70 square km of the 20 km-wide caldera and is next to caldera rim fault. The infill of the basin is characterized by the group of onlapping stratified deposits named B which maximum thickness is more than 600 m. The B-sequence has two major depositional discontinuities in the middle and the top. The lower one is paraconformity and the upper one is disconformity though, the both of them are associated with similar deformation of the basin itself. The deformation is characterized by 1. Dragged-up reflectors along the caldera rim fault, and 2. Slight outward rotation of the deposits. Both characteristics intensify along the depth, which means lower deposits were experienced much more deformation.

The both two types of the deformation suggest the basin was experienced at least two major subsidence event. The former dragged-up structure is interpreted as the incomplete slip of the caldera rim fault for the relief of the subsidence, while the latter rotation shows the slippages were slightly listric. The displacements of the subsidence events could be estimated from the top and bottom of the dragged-up structures, as more than 100 m in the lower-older event and more than 50 m in the upper-newer event. The subsidence would be an abrupt event, as the paraconformity was formed in the lower-older event. The most likely candidate for such a significant subsidence is caldera collapse. As therefore, the basin might be the one of the pre-caldera structure, and it has been experienced multiple caldera collapse events in the past.

Estimates on fluid migration and material recycling via offshore mud volcanoes

KIOKA, Arata[1*] ; ASHI, Juichiro[1]

[1]Atmos. Ocean Res. Inst., U. Tokyo

About 300-400 offshore mud volcanoes are currently confirmed and the double is inferred. Mud volcanism can be viewed as a tectonic window to understand geological frameworks at much greater depth, since mud volcanoes bring up deep substances and fluids to seafloor and are consequently good tools to explore their migration mechanism. Herein we present a global catalog of offshore mud volcanoes and estimate their contributions to subsurface fluid migration and material recycling.

Keywords: Submarine mud volcanoes, fluid migration, material recycling, overpressure

New Marine Sediment Core Database ”COEDO”

NAKANO, Yukihiko[1*] ; ICHIYAMA, Yuji[1] ; HORIKAWA, Hiroki[1] ; TOMIYAMA, Takayuki[1] ; SATO, Yusuke[2] ; KANESHI, Toko[2] ; OGIDO, Eriko[2] ; TAKAESU, Yuki[2] ; NAGAYAMA, Anri[2] ; OSHIRO, Satoshi[2]

[1]Japan Agency for Marine-Earth Science and Technology, [2]Marine Works Japan Ltd.

Japan Agency for Marine-Earth Science and Technology (JAMSTEC) established basic policies on the handling of data and samples (http://www.jamstec.go.jp/e/database/data_policy.html). On the basis of the policies, JAMSTEC provides data and samples in an easily accessible manner. Data and sample information of geological sediment core has been published at ”JAMSTEC Core Data Site” since 2008. In order to improve quality and usability, we reconstructed and released new database in January 2014.

Details of the new database are shown below:

<Name>

COre Electronic Database of Ocean floor (COEDO)

<URL>

http://www.godac.jamstec.go.jp/coedo/e/

<Search Method>

Multiple-filter search using interactive map and basic information filters (Cruise ID, date, location etc.)

In the previous version of the database, users have to take longer steps to reach sample information, because only one of two methods (map search for general users and Cruise ID list menu for science parties) were available. In COEDO, all users can search samples by multiple filters in a single step on a single window.

<On-line accessible data>

Basic information of sediment core (Cruise ID, date of collect, chief scientist, ship name, position, depth), core photo, scanned image, visual core description, X-ray photo, X-ray scanned image, physical property data, literature, link for geochemical data.

We are planning further updates to improve the usability, as follows:

1. Acquiring information of sedimentary ages of core, and making them easily accessible on the database as numerically searchable information.
2. Integration with sample inventory information of JAMSTEC core sample collection, which is currently available at the Kochi Institute for Core Sample Research.
3. Publishing other data, which have not been incorporated into the database yet.

We aim not only improving services to current users, but also making effort to propagate the user community. JpGU and Yokohama city government have a special geological training course for junior/senior high school students at Keio University High School in Yokohama city on April 13. JAMSTEC cooperates with the training course, and provides lecture and practices using actual database and real core samples. In the training course, trainers give lectures on how to obtain marine sediment core onboard and how to study core sample data in COEDO, then trainees observe the actual core samples for which they have just pick up the associated data on the database. The course stimulates trainees’ interest and curiosity on the geological study, and we can nurture the new generation. As a result of this cooperation, we can hopefully increase educational users of JAMSTEC core samples.

Geological Annotation for the Deep-Sea Images

IREI, Kazuhiro[1*] ; OGIDO, Moritaka[1] ; KAYO, Makino[1] ; NAKAMURA, Makoto[1] ; TANAKA, Katsuhiko[2] ; KITAYAMA, Tomoaki[2] ; SAITO, Hideaki[2] ; HANAFUSA, Yasunori[2]

[1]Marine Works Japan LTD., [2]JAMSTEC

The Global Oceanographic Data Center (GODAC) of the Japan Agency for Marine-Earth Science and Technology (JAMSTEC) has been collecting, archiving and disseminating videos and photos acquired by deep-sea research programs using submersibles and remotely operated vehicles owned by JAMSTEC. We register those videos and photos to our database with annotations (keywords), which are names of geological features or organisms, and enable users to search for images of their interest. Those videos and photos with annotations are distributed from the data site called, ″ JAMSTEC E-library of Deep-sea Images (J-EDI)∗1 ″ on the Internet.

Researchers of deep-sea can use the videos and photos distributed by J-EDI as materials for their research or lecture, and also for planning of research cruises or dives, etc. Through the database for marine biodiversity, ″ Biological Information System for Marine Life (BISMaL)∗2 ″ , biological annotations are used to visualize the distribution of organisms or to accumulate the observation record of them, since those videos and photos of deep-sea organisms are not only valuable data, but also indicate the proof of existence of organisms at those points.

We put annotations which can be recognized from the images itself by clicking icons from the prefixed palette or selecting classification name from hierarchical tree. The videos and photos with annotations concerning to the ocean floor geoscience are 41,000 with 95 different kinds of terms out of approximately total 120,000 videos.

To promote the use of deep-sea videos and photos especially in the solid earth science we tried to register more detailed annotations by using scientific papers, reports or documents about research dives and we found that registration of precise annotations takes considerable time. In order to progress the annotating work efficiently we think it necessary to select contents of annotations that lead to an efficient expansion of its use.

In this presentation, we introduce the current status of annotating work for the geological features of the deep-sea and we also show our approach to expand its use.

Vp/Vs ratio in the southernmost Japan Basin and its transition area, Japan Sea deduced from the seismic survey

SATO, Takeshi[1*] ; NO, Tetsuo[1] ; KODAIRA, Shuichi[1] ; TAKAHASHI, Narumi[1] ; KANEDA, Yoshiyuki[1]

[1]JAMSTEC

The Japan Sea is one of very well studied back-arc basins in the northwestern Pacific. To clarify the formation process of the back-arc basin in the Japan Sea, many seismic surveys using ocean bottom seismographs (OBSs) and control sources have been conducted in the sea. The Japan Basin, which located in the northern to eastern Japan Sea, has an oceanic crust formed by seafloor spreading (Hirata et al., 1992; No et al., submitted). On the other hand, the ocean-continent transition area between the Japan Basin and the continental shelf in the eastern margin of this sea may have a thick oceanic crust (No et al., submitted). However, it is unknown the origin and the nature of this thick oceanic crust, due to the lack of the information about lithology in the transition area. To understand the origin and the nature of this thick oceanic crust, it is necessary to obtain the information lithology in the crust of the transition and the basin areas. For this study, we will present the Vp/Vs ratio of the crust from the southernmost Japan Basin to its transition area.

From the southernmost Japan Basin to the continental shelf off the west of Aomori and the northern Oga Peninsula, seismic surveys using OBSs and an air-gun array were undertaken. In vertical record sections of several OBSs, not only the first arrived phases but also later phases reflected from interfaces in the crust and uppermost mantle are visible. Moreover, in horizontal record sections of several OBSs, converted phases from P- to S-waves are apparent. In this study, we have obtained the S-wave velocity structure using travel times of these converted phases. Then, we have obtained the Vp/Vs ratio in the crust from the southernmost Japan Basin to its transition area using the obtained P- and S-wave velocity structures.

In the southernmost Japan Basin off west of Aomori, the Vp/Vs ratio in the sedimentary layer of shows 4 to 8 and has a lateral variation. The Vp/Vs ratios in the crustal upper and lower parts show around 1.85 and 1.8, respectively. On the other hand, in the transition area, the Vp/Vs ratio in the crustal upper part is similar to that in the southernmost Japan basin. This Vp/Vs ratio may show that the nature of the whole crust in the basin area and of the crustal upper part in the marginal area has an oceanic origin. Therefore, the crusts in southernmost Japan Basin and in its transition area are suggested as an oceanic crust and a thick oceanic crust, respectively. The oceanic crust formed by the opening of the Japan Sea may extend to the transition area of the southernmost Japan Basin.

Crustal structure study of the Sea of Japan: Recent results and future perspectives

NO, Tetsuo[1*] ; SATO, Takeshi[1] ; KODAIRA, Shuichi[1] ; ISHIYAMA, Tatsuya[2] ; SATO, Hiroshi[2] ; TAKAHASHI, Narumi[1] ; OIKAWA, Nobutaka[1] ; KANEDA, Yoshiyuki[1]

[1]JAMSTEC, [2]ERI, Univ. of Tokyo

In recent years, crustal structure study of the Sea of Japan has advanced. Various new seismic data have been obtained in the Sea of Japan; for example, the two ship seismic surveys study (Sato et al. 2007) and onshore-offshore seismic survey (Earthquake Research Institute, 2013) conducted by the University of Tokyo, and 2D/3D seismic reflection survey conducted by R/V SHIGEN (JOGMEC, 2013).

From 2007 to 2012, we conducted marine seismic surveys using the multichannel seismic reflection system and ocean bottom seismometers; the surveys covered the area between the Japanese coast of the Sea of Japan and the Yamato and Japan Basins. Based on the results, the crustal structure of the eastern margin of the Sea of Japan was classified into three types: island arc crust, thick oceanic crust, and oceanic crust (Sato et al. 2014; No et al. submitted). In addition, our studies found that the contractive deformation zones of the eastern margin of the Sea of Japan are associated with the crustal structure distribution. Further, seismic data suggests that the crustal structure in the south (off Yamagata to Niigata) differs from that of the north (off Akita to Nishi-tsugaru). These differences are critical in understanding the relation between the spatial distributions of the seismogenic and contractive deformation zones (JAMSTEC, 2013). These results can contribute to the review of long-term evaluations of earthquake occurrence potentials and the discussion of the seismogenic study in the eastern margin of the Sea of Japan.

In 2013, new projects have been observing and studying earthquakes and tsunamis in the Sea of Japan. *Integrated Research Project on Sei* scheduled in 2014 in order to conduct a seismic survey in the blind areas of the existing observations, which are in the southwest region of the Sea of Japan and off western Hokkaido. The addition of new observation data will advance the study of crustal structure in the Sea of Japan. In this study, we aim to improve the accuracy of the position and size of the source faults in the Sea of Japan. In addition, we investigate the relation among tectonic history, crustal structure, and factors that form source faults in the Sea of Japan. In the future, we aim to clarify the seismogenic zone of the Sea of Japan using new seismic data.

Results of 2013 Off-Joetsu and Hokuriku survey for the integrated research project on seismic and tsunami hazards around

SATO, Hiroshi[1*] ; ISHIYAMA, Tatsuya[1] ; SHIRAISHI, Kazuya[2] ; ABE, Susumu[2] ; KATO, Naoko[1] ; KURASHIMO, Eiji[1] ; TAKEDA, Tetsuya[3]

[1]Earthquake Research Institute, Univ. Tokyo, [2]JGI. Inc., [3]NIED

An obvious convergent plate boundary cannot be recognized in the Sea of Japan, and convergence accommodates in defused wide area of the back arc. To estimates Tsunami and seismic hazards along the coastal area of Sea of Japan, more detailed survey to identify source faults are needed. A new research project funded by MEXT named ”the integrated research project on seismic and tsunami hazards around the Sea of Japan” began in FY 2013. To obtain the information of source faults, we performed deep seismic reflection profiling off-Joetsu and Hokuriku area in the central part of Honshu, Japan. We used two vessels; a gun-ship with 3020 cu. inch air-gun and a cable-ship with a 2-km-long, streamer cable with 156 channels and 480 cu. inch air-gun. Common-mid point reflection data were acquired along 9 seismic lines with total 715 km in length. The seismic profiles portray the structure of failed rift basins, such as Toyama trough and Sado strait, bounded by rift axis reverse faults with rift axis vergence, which represents reactivation of boundary faults between mafic intrusion and pre-rift basement. Noto Peninsula is marked by syn-rift normal faults and their reactivation by shortening deformation. The back arc side of the SW-Japan arc experienced NS trending shortening deformation in the latest Miocene. From the Noto peninsula, undeformed Pliocene sediments covers folded Miocene. Some normal faults reactivated as active strike-slip and reverse faults. The survey results contributed to construct source faults models of Tsunami and seismic hazards estimation.

Lithospheric Structure of the Hidaka Collision Zone, Hokkaido, from Reanalysis of 1998-2000 Hokkaido Transect Data IV

IWASAKI, Takaya[1*] ; TSUMURA, Noriko[2] ; ITO, Tanio[3] ; SATO, Hiroshi[1] ; KURASHIMO, Eiji[1] ; HIRATA, Naoshi[1] ; ARITA, Kazunori[4] ; NODA, Katsuya[5] ; FUJIWARA, Akira[5] ; ABE, Susumu[5] ; KIKUCHI, Shinsuke[6] ; SUZUKI, Kazuko[7]

[1]Earthquake Research Institute, the Univsesity of Tokyo, [2]Chiba University, [3]Teikyo Heisei University, [4]Hokkaido University, [5]JGI. Inc., [6]JAPEX, [7]Schlumberger Ltd.

The Hidaka region in the central part of Hokkaido Island, Japan, is known as an arc-arc collision zone ongoing from the middle Miocene. In 2012, we started reinterpretation for a series of seismic reflection/refraction surveys from 1994 to 2000 in this collision zone. In this analysis, we used integrated and sophisticated processing and analysis techniques. including CRS/MDRS method for seismic reflection data and refraction tomography both very dense arrival time data from both the reflection and refraction/wide-angle reflection data. The most important finding so far obtained is a clear image of the NE Japan Arc subducting eastward under the northern part of the collision zone. However, the following problems are remained unsolved.

(1) Shallow structure beneath the Hidaka Collision zone is still unsolved. Particularly, the structure just east of the Hidaka Main Thrust is not sufficiently evaluated from our seismic data.
(2) Delamination of the Hidaka crust as in the southern part of this collision zone is not unclear. Our CRS/MDRS processing for the reflection data provided no positive evidence for the delamination.
(3) Deeper collision structure of the NE Japan Arc and the Kuril Arc is still not constrained. It is necessary to elucidate the subducting structure of the NE Japan Arc from amplitude data as well as travel time data.

In this paper, we focus the items (1) and (3) from seismic refraction/wide-angle reflection approach. Previous refraction tomography elucidated a thick (4-5 km) undulated sediments in the hinterland, the outcrop of crystalline crust beneath the Hidaka Metamorphic Belt with higher Vp and Vp/Vs and an enormously thick (>8-10 km) sedimentary package beneath the foreland. In order to obtain the more reliable structure model, we intensively revised the travel time data obtained both from seismic reflection/wide-angle reflection line and reflection lines. The seismic tomography using these revised data sets indicate a clearer high velocity (>6.1 km/s) anomaly just east of the HMT. We also recognized some wide-angle reflections around 5-10 km deprth beneath the HMT, from which we expect to determine the finer structure at the collision front. Our present analysis indicates the wide-angle reflection data sample a part of the lower crust of the subducting NE Japan Arc beneath the fold-and-thrust belt. According to the preliminary result, its velocity is ranging from 6.5-7.0 km/s. By combining the amplitude analysis, we expect to estimate the more reliable Moho depth of the NE Japan Arc than in the previous analyses.

Seismic crustal structure beneath the southeastern part of northeast Japan by dense seismic array observation

KURASHIMO, Eiji[1*] ; SATO, Hiroshi[1] ; ISHIYAMA, Tatsuya[1] ; HIGASHINAKA, Motonori[2] ; ABE, Susumu[2] ; IWASAKI, Takaya[1]

[1]ERI, Univ. Tokyo, [2]JGI, Inc.

The 2011 Tohoku-Oki Earthquake (Mw9.0), that occurred on the Japan Trench off the eastern shore of northern Honshu, Japan, generated enormous crustal deformations. Seismic activity in northeastern Japan increased significantly after the 2011 Tohoku-Oki Earthquake. Detailed crustal structure and deep geometry of the active fault is important to constrain the process of earthquake occurrence. Active and passive seismic experiments were conducted to obtain a structural image beneath the southeastern part of NE Japan (Sato et al., 2013). The geometry of the active faults have been revealed by seismic reflection profiling (Sato et al., 2013). Natural earthquake data set is useful to obtain a deep structural image. Forty portable seismographs were deployed along a 70-km-long line between Souma and Takahata during the period from August 16, 2012 to December 24, 2012. Each seismograph consisted of a 1-Hz 3-component seismometer and off-line data recorder (Shinohara et al., 1997). Waveforms were continuously recorded at a sampling rate of 200 Hz. In the area of the present study, deep seismic reflection profiling was conducted using vibrators (Sato et al., 2013). The off-line recorders observed the controlled seismic signals as well as natural earthquakes. During the seismic array observation, the JMA located 2956 earthquakes in a latitude range of 37.2-38.5 N and a longitude range of 139.6-141.3 E. We selected 200 earthquakes, all of which occurred near the survey line. In order to obtain a high-resolution velocity model, a well-controlled hypocenter is essential. Due to this, we combined the seismic array data with permanent seismic station data. The arrival times for the first P- and S waves obtained from local earthquakes and Vibrator shots were used in a joint inversion for earthquake locations and three-dimensional Vp and Vp/Vs structures, using the iterative damped least-squares algorithm, simul2000 (Thurber and Eberhart-Phillips, 1999). Permanent seismic stations observed the controlled seismic signals as well as natural earthquakes. We added the arrival time data of these controlled sources into the dataset to improve the shallow velocity structure. The depth section of Vp structure along the survey line shows that lateral variation of the Vp value at a shallow depth. This lateral variation correlates with the surface geology along the profile.

Shallow geologic structure around the northern part of the Futaba Fault, northeast Japan, based on gravity survey

KOSHIYA, Shin[1*] ; TERUI, Kyoko[2] ; YONEZAWA, Kenta[1] ; SATO, Hiroshi[3] ; KATO, Naoko[3] ; ABE, Susumu[4] ; HIGASHINAKA, Motonori[4]

[1]Faculty of Engineering, Iwate Univ., [2]Graduate School of Engineering, Iwate Univ., [3]ERI, Univ. of Tokyo, [4]JGI, Inc.

The Futaba Fault, bounding the eastern margin of the Abukuma Mountains, is known as a left lateral fault in the Cretaceous and Paleogene period with a remarkable fracture zone of a few hundreds meter win width. It trends NNW-SSE and divides into two branches between which the Wareyama horst develops. During early to middle Miocene, E-W extensional stress field caused large normal displacement along the western fault to form a half graben filled with sediments including breccia. In late Miocene, it had been a right lateral fault. In present, the eastern fault is active, along which left lateral offsets with western upheaval ingredient are geo-morphologically observed. Thus the Futaba Fault has experienced the complicated history of development. In this study, we modeled two dimensional shallow geological structure across the faults mainly based on gravity survey. The gravity survey was conducted across the faults with a G-type gravity meter (G827; LaCoste and Romberg Inc.) along two E-W survey lines, one of which is ca. 12 km long, (line 1), and the other of which is ca. 13km long (line 2). Each interval of observation sites is about 200 m. The elevation of observation sites was surveyed with a electric level and a RTK-GPS. Acquired gravity data was processed to obtain Bouguer anomaly mostly according to the methodology of Geological Survey of Japan, AIST (2004). We assumed that the density for Bouguer and terrain corrections were 2.2 g/cm^3. In each survey line, Bouguer anomalies after trend correction show the highest value around the Wareyama horst consisting of pre-Paleogene basement rocks and a few maxima in the western side of the horst. We assume four layers in our model, which have densities of 2.00 g/cm^3 (layer 1), 2.2 g/cm^3 (layer 2), 2.55 g/cm^3 (layer 3), and 2.67 g/cm^3 (layer 4) , respectively. The interpretation of the model is as follows. Layer 1 is correlated to the surface covers and Pliocene sedimentary rocks, layer 2 lower to middle Miocene sedimentary rocks, layer 3 Miocene breccia and layer 4 basement rocks. We will discuss the shallow structure across the faults in detail.

Keywords: Futaba fault, gravity anomaly, active fault

We discuss in this study about characters of crustal architectures around the Toyama trough revealed by new seismic reflection and refraction profiles and seismic tomography, and active structures based on Neogene geology and tectonic geomorphology. As revealed by onshore offshore deep seismic reflection profiling across the Toyama trough funded by MEXT named as The Integrated Research Project on Seismic and Tsunami Hazards around the Sea of Japan since 2013, crustal architectures across the Toyama trough is characterized by three domains: (1) crustal thrust wedge comprising the northwestern flanks of the Hida Mountains, (2) Neogene sedimentary basin near the axis of the Toyama trough, and (3) reactivated normal faults as thrust (or obliquely slipping) faults beneath the Noto peninsula, comprising structural higher domain west of the Toyama trough. These structural patterns and permanent, late Quaternary crustal deformation recorded by tectonic geomorphology are quite similar to adjacent Neogene sedimentary basins in the backarc failed rifts in the Sea of Japan, including northern Fossa Magna, Niigata, and Akita.

Phase changes and temperature of the subducted crust of Philippine Sea slab beneath Kanto, Japan

ISHIKAWA, Masahiro[1*] ; NAKAGAWA, Shigeki[2] ; SAKAI, Shin'ichi[2] ; HIRATA, Naoshi[2] ; SATO, Hiroshi[2] ; KASAHARA, Keiji[3]

[1]Graduate School of Environment Information Sciences, Yokohama National University, [2]Earthquake Research Institute, The University of Tokyo, [3]Association for the Development of Earthquake Prediction

The Philippine Sea plate subducts beneath the Greater Tokyo Area of Japan. Devastating M8-class earthquakes occurred on the upper surface of the Philippine Sea plate, examples of which are the Genroku earthquake of 1703 (magnitude M8.0) and the Kanto earthquake of 1923 (M7.9). A M7 or greater (M7) earthquake in this region may occur either on the upper surface or intra slab of Philippine Sea plate. To evaluate seismic hazard in the Greater Tokyo Area of Japan we need to clarify the lithological properties of Philippine Sea slab. This study presents an interpretation of the crustal and mantle structure of the Philippine Sea slab beneath Kanto based on recent MeSO-net seismic tomography data. The seismic tomography reveals that P wave velocity of the subducted crust of the Philippine Sea slab increases stepwise at 30 km and 40 km depths beneath the Kanto area. The cause of these two stepwise increases in P wave velocity of subducted crust is expected to correspond to metamorphic phase changes. Mineralogical assemblages of forearc basalt composition of the Izu arc was calculated by Theriak-Domino software, and the phase diagram shows that phase changes to garnet amphibolite and eclogite can account for these two stepwise increase in P wave velocity of the subducted crust of the Philippine Sea slab.

Geologic structure in and around the Beppu Bay estimated by gravity analysis

YAMAKITA, Satoshi[1*] ; KUDO, Takeshi[2] ; ITO, Tanio[3]

[1]University of Miyazaki, [2]Chubu University, [3]Teikyo-Heisei University

Seismic profiling in the Beppu Bay and the Bungo Straight performed by Kyoto University and JGI inc. from 1988 to 1990 (Yusa et al., 1992) raised new progresses of studies on the geologic structure of the Median Tectonic Line (MTL) in Kyushu and the development of the Beppu Bay Sedimentary Basin (BSB) accompanying it (Yamakita et al., 1995; Ito et al., 1996). The P-wave velocity assumed by Yusa et al. (1992) for the rocks in Ryoke Belt, however, was too low for granitic and metamorphic rocks constituting this Belt, and it is likely that the dip of the MTL beneath it was underestimated. Besides, the structure of the basin in the innermost part of the Beppu Bay has remained uncertain because this part is located in the terminal part of the seismic lines. On the other hand, there are plenty of gravity data in and around the Beppu Bay (Yusa et al., 1992; GSJ, 2000; Gravity Research Group in Southwest Japan, 2001). It can be expected that these gravity data clarify the structure of BSB, combined with correct seismic profiles. Fortunately, a profile reprocessed with re-estimated P-wave velocity along the Bungo straight (J-line) was presented last year (Abe et al., 2013). Using this reprocessed profile and gravity data, we tried to determine the subsurface structure along the G-line of Yusa et al. (1992), trending N70E, 35 km long, from on-land area, across the Asamigawa fault (AF) and the Beppu Bay Central Fault (BCF), to the mouth of the Beppu Bay (Fig. A), occupied by Sanbagawa metamorphic rocks (Sm, ρ=3.0g/cm^3), Ryoke granitic and metamorphic rocks (Rk, ρ=2.8g/cm^3), lower (Bl, ρ=2.6g/cm^3) and upper (Bu, ρ=2.4g/cm^3) sediments of BSB. Assuming only the depth and form of the MTL estimated from the reprocessed profile of J-line and geologic constraints, and the position of the AF on the surface, we determine other subsurface structures to fit with the gravity data through traial and error (Fig. B). In this profile, the upper surface of the Ryoke basement almost coincides with that in the Yusa et al. (1992)'s profile. This fact suggests high reliability of this profile. We concluded the structure of BSB from this and Yusa et al.(1992)' s profiles as follows.

1. The innermost part of the BSB was formed by two listric normal fault systems, NE-dipping Asamigawa Fault System (AFS) and SW-dipping Beppu Bay Central Fault System (BCFS). Both systems formed roll-over structure in the sediments of BSB.
2. The AFS consists of three faults (I, II, III), which converge to the MTL. It is uncertain whether the fault AFS-II reaches the uppermost part of the sediments. The total amount of the vertical displacement of ASF may be up to 3000m, although it depends on the thickness of sediment in the SW-side on AF and the amount of erosion of Ryoke basement
3. Two faults BCFS-I and BCFS-II vertically displaced the bottom of the Bu in 250m and 150m respectively and reach the uppermost part of it, although it is difficult to recognize in this figure because of its highly reduced scale. Both, however, did not displace the bottom of the Bl (= the upper surface of the Ryoke basement).
4. BSB is inferred to be formed and developed by eastward movements of the hanging wall (Ryoke basement), strike-slip on the MTL and downward on the AF. The BCFS was secondarily formed in eastward moving sediments.

These results are almost concordant with the model of a strike-slip basin proposed by Yamakita and Ito (1999), which assume a not vertical but moderately dipping strike-slip fault with a releasing bend. This model ignored the effects of secondary listric normal faults in sediments, dipping toward the main oblique normal fault forming the oblique ramp, but they contributed to the development of BSB to some extent. Their effects, however, are rather small as indicated by the fact that they did not displace the basement.

Structure and evolution of the lower crust constrained from alkaline basalts and xenoliths in southwest Japan

IGATA, Eri[1*] ; OMORI, Soichi[2] ; IWAMORI, Hikaru[3]

[1]Department of Earth and Planetary Sciences, Tokyo institute of technology, [2]The open university of Japan, [3]Japan Agency for Marine-Earth and Technology

The continental crust is unique to the Earth and, in spite of its small mass, is geochemically an important reservoir, concentrating about half of the radiogenic heat producing elements. In order to understand the differentiation history of the Earth, it is essential to decipher how and when the continental crust has been formed.

In contrast to the upper continental crust, which has been well surveyed with direct means, the lower continental crust is largely unknown in terms of composition, mineralogy and age distribution of formation. In this study, we investigate the xenoliths that have been derived possibly from the lower crust, in terms of petrology (mineral assemblages and their composition, modal abundances and bulk composition) and geochronology (zircon U-Pb age dating of both the xenoliths and the host basalt). Study area is located on the Kibi Plateau in southwest Japan. The xenoliths are classified into 4 types by petrography and EPMA analysis; Type 1, pyroxenite; Type 2, eclogitic gabbro; Type 3, anorthosite: Type 4, kyanite/garnet-bearing felsic granulite. Pseudosection and mineral stability analyses were performed by a thermodynamic program "Perplex". These analyses have revealed that pyroxenite is stable beneath the Moho and its seismic velocity estimated from pseudosection ranges from 7.23 to 7.65 km/s. Therefore pyroxenite corresponds to the olivine-pyroxenite layer under the Moho. Gabbro was formed at 8-10 kbar and 873-940 K and its velocity is higher than pyroxenite. Granulite is stable at 7.5- kbar and about 1000 K and its velocity is very low. In spite of the density gap between the eclogitic gabbro and granulite (3900 and 2740 kg/m^3), the analysis suggests that the felsic granulite exhibits a higher equilibration pressure and may even underlay the eclogitic gabbro. Moreover, composition of the lower crust becomes more felsic than previously thought.

Ages of the eclogitic gabbro xenolith and the host basalt coincide, showing 70 Ma. It is argued that the subducted sediments (now appear as felsic granulites) were subdcuted and underplated to the bottom of the lower crust during the last 30 million years or so. If such a mechanism operates worldwide, then the continental crust may have an intermediate to felsic composition even without a hypothetical process of lower crustal delimitation.

The authors thank T. Hirata, K. Tani, Jl. Kimura and Q. Chang for U-Pb zircon age dating.

Three-dimensional seismic velocity structure beneath East Asia using adjoint tomography

MIYOSHI, Takayuki[1*] ; OBAYASHI, Masayuki[1] ; TONO, Yoko[1] ; TSUBOI, Seiji[1]

[1]JAMSTEC

East Asia is the complicated region where tectonic plates meet. In many studies, travel-time tomography based on ray theory has clarified three-dimensional (3D) velocity structure of the Earth. On the other hand, the recent studies show waveform inversion based on wave theory can construct realistic 3D structure (e.g. Obayashi et al., 2010 SSJ; Miyoshi et al., 2013 SSJ). In the present study, we have inferred 3D heterogeneous structure precisely beneath the eastern Asia region by using adjoint tomography method. We selected 161 earthquakes (M >5.5, half duration <5 second) occurred in the region based on Global CMT catalog. Displacement seismograms used in this study were recorded at broadband seismic stations in the region. The average number of stations used in inversion is about 180. Theoretical waveforms were calculated using the spectral-element method (Komatitsch and Tromp, 2001). We used GAP-P2 mantle tomography model (Obayashi et al., 2009) as an initial 3D model of inversion. Both observed and theoretical waveforms were filtered between 12.5 and 100 second to extract time windows of P- and S-waves, and between 30 and 150 second to extract time windows of surface waves. We applied adjoint method (Liu and Tromp, 2006) for calculating the misfit kernel, which is related to velocities, and performed inversion by using the steepest descent method. The parallel computing of theoretical waveforms and misfit kernels were used 256 CPU cores of supercomputers, such as K computer at Riken. The computing time was required 0.1 million CPU hours in each iteration. We have iterated four times on inversion. The VR value was improved about 10% by using the revised model. The Vp and Vs of improved model showed a few percent slower than the initial model. The ratios of the velocity perturbation show slightly large value than the initial model at a depth of 100 km in a wide area of the eastern Asia region. Acknowledgements: We used F-net seismograms of the National Research Institute for Earth Science and Disaster Prevention. This study was supported by the strategic Programs for Innovative Research ”Field 3” Advanced prediction Researches for Natural Disaster Prevention and Reduction.

Seismological evidence for a transition from ”hydrous” oceanic crust to typical oceanic crust in the Lau back-arc basin

ARAI, Ryuta[1*] ; DUNN, Robert[1]

[1]University of Hawaii

The Lau back-arc basin, associated with subduction of the Pacific plate beneath the Indo-Australian plate at the Tonga Trench, provides a superb study area to understand the interaction between plate subduction and back-arc spreading: Subducting oceanic lithosphere induces mantle corner flow within the mantle wedge above the subducting plate and releases a large amount of water and other elements into this wedge, producing heterogeneous chemical compositions and fluid gradients beneath the back-arc basin. While petrological studies suggest that the heterogeneity in the mantle source composition, mainly caused by slab-derived fluids, plays an important role for melt supply to the back-arc ridges, variations in thickness and internal structure of crust formed along back-arc ridges are poorly documented. On the basis of seismic tomography analyses, we present a structural model of crust formed along the Eastern Lau Spreading Center within the Lau back-arc basin as evidence for a transition from a “ hydrous ” type of oceanic crust to a more typical oceanic crust. The seismic data indicate that as the back-arc spreading center moved away from the active arc, the crust thinned from 8-9 km to ˜7 km, the lower crust changed from high P wave velocity values (7.2-7.4 km/s) to typical values for oceanic crust (7.0-7.2 km/s), and the upper-crustal volcanic layer changed from a thick low-velocity layer to a thinner layer with more typical wave speeds. The seismic results, in combination with other geophysical and geochemical data, suggest that crustal formation along the ELSC is strongly controlled by the influence of slab water: When a spreading center is near the active arc, water from the downgoing slab is entrained in the melting zone beneath the back-arc ridges where it enhances melting. Thereafter, the water enhances crustal differentiation within sub-ridge magma chambers. This creates an anomalous “ hydrous ” form of oceanic crust with a thick felsic volcanic layer and a mafic/ultramafic lower crust - features that are not typically observed in crust formed at mid-ocean ridges. The Lau basin has a zoned structure with an abrupt transition from this type of oceanic crust to more typical oceanic crust, which resulted from a rapid change in the influence of slab water as the ridge moved away from the arc. The unique geodynamic setting of the Lau basin, such as proximity of the back-arc ridges to the volcanic arc (<100 km), the relatively low subduction angle of the slab (˜45 degrees), and the fast subduction rate at the Tonga trench (>20 cm/yr), probably operate to effectively deliver slab-derived water far beyond the volcanic arc to the back-arc ridges and produce this “ hydrous ” oceanic crust in the back-arc basin. The abundance and high rate of production of the “ hydrous ” crust suggests that such crust may make up a significant proportion of the arc-like crust that forms continents.

Tectonic province of the northern Fossa Magna region based on the crustal movement and seismic activity

IMAI, Yuki[1*] ; TAKEUCHI, Akira[2]

[1]Graduate school of Science and Engineering for Education, University of Toyama, [2]Graduate school of Science and Engineering for Research, University of Toyama

The northern Fossa Magna region is located in an area where the Niigata-Kobe tectonic zone (Sagiya *et al.*, 2000) and geological strain concentration zone along the eastern margin of the Japan Sea (Okamura, 2002) is duplicated. In the past, inland crustal earthquakes, such as the Zenkoji earthquake in 1847 (M7.4) and the Niigata-ken Chuetsu earthquake in 2004 (M6.8), have occurred in this region. In order to discuss the current tectonics of the northern Fossa Magna region that has active crustal movement and seismic activity, it is necessary to clarify the characteristics of ”tectonic province”. The purpose of this paper is to reveal a detailed three-dimensional tectonic province model from the crustal movement and seismic activity of this region in the recent years. In order to clarify the characteristics of crustal movement and seismic activity, we have analyzed the GEONET observation data (from October 2007 to March 2011) using the GAMIT 10.4 software, and made the E-W cross-sectional view of the JMA hypocenter data.

The horizontal strain distribution for three and a half years just before the 2011 Tohoku-Oki earthquake shows that strain concentration zone with NW-SE directional contraction extends from the Niigata plain to the Matsumoto basin continuously. Moreover, the eastern margin of this zone corresponds roughly to the position of the Shibata-Koide tectonic line (Yamashita, 1970) running NNE-SSW direction in the eastern margin of the Niigata plain. The strain rate in the Echigo mountain range is smaller than in the Niigata plain. Takeuchi (1999) showed tectonic province based on the activity and characteristics of active faults. The strain distribution revealed from GPS data corresponds approximately to active faults provinces. The large and small strain region corresponds approximately to the reverse fault province (Shin’etsu ˜Niigata sedimentary basin) and strike-slip faults province (Central upheaval zone and Echigo mountain range) respectively. Focusing on the depth distribution of the seismogenic layer in the E-W cross-section, the depth of the lower limit of seismogenic layer is shallow (D = 10-15 km) in the strike-slip province but is deeper (D = 20-30 km) in the reverse fault province. The seismogenic layer is located beneath the low P-wave velocity zone corresponding to the thick sediments layer in the sedimentary basin.

According to the above results, there is obvious spatial variation of the depth of seismogenic layer and strain distribution at the boundary of the sedimentary basin and Central upheaval zone. It is conceivable that two different tectonic provinces are adjacent along the tectonic boundary where characteristics of the crustal activity are changing greatly. The moderate-large crustal earthquakes around the northern Fossa Magna, such as the Zenkoji earthquake in 1847, the Niigata-ken Chuetsu earthquake in 2004 and the Nagano-ken Hokubu earthquake in 2011, have occurred on or near the tectonic boundary. Stress concentration is likely to occur due to large changing of the physical properties in the tectonic province boundary, and a large crustal earthquake tend to occur at the tectonic province boundary than at the inside province.

Results of 2013 Off-Kanazawa and Noto peninsula survey for the integrated research project on seismic and tsunami hazard

SATO, Hiroshi[1*] ; ISHIYAMA, Tatsuya[1] ; SHIRAISHI, Kazuya[2] ; ABE, Susumu[1] ; KATO, Naoko[1] ; IWASAKI, Takaya[1]

[1]Earthquake Research Institute, Univ. Tokyo, [2]JGI. Inc.

To estimates Tsunami and seismic hazards along the coastal area of Sea of Japan, more detailed survey to identify source faults are needed. A new research project funded by MEXT named ”the integrated research project on seismic and tsunami hazards around the Sea of Japan” began in FY 2013. To obtain the information of source faults, we performed deep seismic reflection profiling off-Kanazawa and Noto area in the central part of Honshu, Japan. The source faults were estimated together with the results of seismic sections in the epicentral area of the 2007 Noto peninsula earthquake (Sato et al., 2007, BERI). We used two vessels; a gun-ship with 3020 cu. inch air-gun and a cable-ship with a 2-km-long, streamer cable with 156 channels and 480 cu. inch air-gun. Common-mid point reflection data were acquired along 4 seismic lines with total 245 km in length. The seismic profiles portray the reactivation of normal faults, which formed during syn-rift periods, associated with the opening of the Sea of Japan. 2007 Noto peninsula earthquake occurred by the oblique motion on source fault dipping 60 degrees, which is favorable normal faulting. The back arc side of the SW-Japan arc experienced NS trending shortening deformation in the latest Miocene. From the Noto peninsula to the west, undeformed Pliocene sediments covers folded Miocene. Some normal faults reactivated as active strike-slip and reverse faults in Quaternary. The survey results contributed to construct source faults models of Tsunami and seismic hazards estimation.

A new research project funded by MEXT named ”the integrated research project on seismic and tsunami hazards around the Sea of Japan” began in FY 2013. To obtain the information of source faults, we performed deep seismic reflection profiling off-Joetsu area in the central part of Honshu, Japan. The seismic lines were located in the offshore extension previous onshore seismic lines forming onshore-offshore integrated seismic lines. We used two vessels; a gun-ship with 3020 cu. inch air-gun and a cable-ship with a 2-km-long, streamer cable with 156 channels and 480 cu. inch air-gun. Common-mid point reflection data were acquired along 3 seismic lines. Two offshore seismic lines are connected to the onshore seismic sections. The survey area consists of stretched continental crust, such as Noto peninsula and Sado island, and failed rift area with large amount of large mafic intrusive rocks, such as Sado strait and Toyama trough. Stretched continental area is marked by densely distributed syn-rift normal faults. On the other hand, in the Sado strait and Toyama trough, fault-related folds were developed, which show small amount of vertical displacement. Along the boundary between continental crust area and oceanic crust, thrusts with rift axis vergent well imaged by seismic reflection profiles. The survey results contributed to construct source faults models of Tsunami and seismic hazards estimation.

To estimates Tsunami and seismic hazards along the coastal area of Sea of Japan, more detailed survey to identify source faults are needed. A new research project funded by MEXT named " the integrated research project on seismic and tsunami hazards around the Sea of Japan " began in FY 2013. To obtain the information of source faults, we performed onshore offshore deep seismic reflection profiling across the Toyama trough. The seismic line extends from Unazuki at the foot hill of the Hida mountains to the shoreline for 15 km and connected with bay cable of 3 km in length. Seismic signals produced by four vibroseis trucks were recorded by onshore receivers and bay cable. For offshore, we used two vessels; a gun-ship with 3020 cu. inch air-gun and a cable-ship with a 2-km-long, streamer cable with 156 channels and 480 cu. inch air-gun. The P-wave velocity profile by refraction tomography, suggests that the upper surface of Vp 5 km/sec is located 5 km below the mean sea level at the Toyama trough. Vertical offset of Vp 5 km/sec layer is about 8 km. Trough fill sediments beneath the Kurobe alluvial fan show northward dipping. Beneath the apex of this fan, velocity profile and reflection profile suggest the existence of south dipping thrust at 4 km in depth. This fault extends northward as a blind thrust. The seismic section suggests the reverse fault at the northern edge of Toyama trough. Based on the distribution of 5e coastal terraces along the southern part of Noto peninsula, the reverse fault prayed a significant roll for the uplift of Noto peninsula. Such basin structure is analogues to the Niigata sedimentary basin, and northern Fossa magna basin. The survey results contributed to construct source faults models of Tsunami and seismic hazards estimation.

Structure analysis of the Ryukyu arc by the receiver function

ARASHIRO, Yasuhisa[1*] ; NAKAMURA, Mamoru[1]

[1]Graduate School of Science,Ryukyu University

The Ryukyu arc have converted plate boundary and back arc basin. The volcanic front in Tokara Islands is the main volcanism. Moreover, The activity of shaped Trough is supposed (Kimura, 1985). In addition, by the survey of igneous activity, the Okinawa Trough have upper flow mantle. Analyzed by receiver function in the Ryukyu arc, McCormack et al., (2013) ware anisotropy structure of slab beneath F-net station.

The Ryukyu arc have converted plate boundary and back arc basin. The volcanic front in Tokara Islands is the main volcanism. Moreover, The activity of shaped Trough is supposed (Kimura, 1985). In addition, by the survey of igneous activity, the Okinawa Trough have upper flow mantle. Analyzed by receiver function in the Ryukyu arc, McCormack *et al.,* (2013) ware anisotropy structure of slab beneath F-net station.

However, it was unknown how changed the structure in the slab and wedge mantle structure changed in the subducting direction. Therefore we clarified I sank by making a receiver functional analysis section at right angles to an errand, the trench including a seismometer record in addition to F-net broadband seismometer record in a short period of the Japan Meteorological Agency,(JMA) and how a Slavic angle changed into the direction.

In the receiver function analysis, we use 8 of short-period seismograph by JMA and 3 of broadband seismometers by NIED F-NET established in central Ryukyu . An analysis period is 2002 to 2013. and used 113 remote earthquake events more than M6.0 for analysis.

In receiver functional analysis, the discontinuity imaging depth is as same as JMA , in Okinawa-honto beneath 40km.

Superflares on Solar-Type Stars

SHIBAYAMA, Takuya[1*] ; MAEHARA, Hiroyuki[2] ; NOTSU, Yuta[3] ; NOTSU, Shota[3] ; HONDA, Satoshi[4] ; NOGAMI, Daisaku[3] ; SHIBATA, Kazunari[3]

[1]Nagoya University, [2]University of Tokyo, [3]Kyoto University, [4]University of Hyogo

Stellar flares emit harmful UV and high-energy particles such as protons. Although the atmosphere protects the surface of the planets, certain amount of UV penetrates the atmosphere and high-energy particles reach the ground as secondary radiation. These radiations are thought to affect habitability and evolution of life.

High precision photometry of Kepler spacecraft enables us to detect superflares on G-type dwarfs. By extending Maehara et al. (2012, Nature), we found 1547 superflares on 279 G-type dwarfs detected from light curves of 500 days (Shibayama et al., 2013, ApJS). In the case of the Sun-like stars (with surface temperature 5600 - 6000 K and slowly rotating with a period longer than 10 days), the frequency of superflares with energy of 10^{34} - 10^{35} erg (100 - 1,000 times larger than the largest solar flare) is once in 800 - 5000 years. No hot Jupiters were found in these superflare stars. These superflare stars often show quasi-periodic brightness variation, which might be evidence of the large star spot. Rotational period can be estimated from the brightness variation period. It is interesting that superflares are detected on slowly rotating stars (P $>$10 days) like the Sun. Using these data, we studied the statistical properties of superflares. We compare the flare frequency distribution of the superflare and solar flare, and study the similarity of them. We also found that some G-type dwarfs show very high activity and exhibit superflares once in ~ 10 days. In the case of Sun-like stars, the most active stars show one superflare in ~ 100 days.

Survey Observations of A Glycine Precursor, Methylenimine (CH2NH)

SUZUKI, Taiki[1*] ; OHISHI, Masatoshi[2] ; HIROTA, Tomoya[2] ; SAITO, Masao[2]

[1]Department of Astronomy, the Graduate University for Advanced Studies (SOKENDAI), [2]National Astronomical Observatory of Japan

It is widely thought that prebiotic chemical evolution from small to large and complex molecules would have resulted in the Origin of Life. The interstellar medium (ISM), where more than 170 molecules ranging from simple linear molecules to COMs were detected, show chemically rich environment. Ehrenfreund et al. (2002) argued that exogenous delivery of COMs to the early Earth by comets and/or asteroids could be more than their terrestrial formation by two orders of magnitude; molecules delivered from the Universe might have played an important role in early Earth chemistry. From this point of view, many observations were conducted to search for prebiotic molecules in the ISM, which might turn into the " Seeds of Life " when delivered to planetary surface. Especially, great attention was paid to amino acids, essential building blocks of terrestrial life; many surveys were made unsuccessfully to search for the simplest amino acid, glycine (NH_2CH_2COOH), towards Sagittarius B2 and other high-mass star forming regions (e.g., Brown et al. 1979; Snyder et al. 1983; Combes et al. 1996, ...).

In these days, the Atacama Large Millimeter/submillimeter Array (ALMA) is expected to break through such difficulties associated with glycine survey. Garrod (2013) used her chemical reaction network simulation and argued the possibility in detecting glycine with very high spatial resolution (~0.1 ″) and the collecting power of ALMA. It would be important to know which are potential glycine-rich sources for future surveys. However, the chemical evolution of N-bearing molecules, including glycine, is poorly known. We would need to better understand formation mechanisms of N-bearing COMs including amino acids and to have carefully selected good candidate sources for amino acids before conducting searches for amino acids by ALMA.

Although the chemical evolution of interstellar N-bearing COMs is poorly known, methylamine (CH_3NH_2) has been proposed as a precursor to glycine. Theoretical and laboratory studies have demonstrated that glycine is formed on icy grain surface from CH_3NH_2 and CO_2 under UV irradiation (Holtom et al. 2005). It is suggested that CH_3NH_2 can be formed from abundant species, CH_4 and NH_3, on icy dust surface (Kim & Kaiser 2011). Further methyleneimine (CH_2NH) would be related to CH_3NH_2. Another possible route to form these species is hydrogenation to HCN on the dust surface (Dickens et al. 1997; Theule et al. 2011).

However, a source number of such precursor molecules is very limited. In order to increase the number of CH_2NH sources and to better understand formation paths to CH_2NH, we conducted survey observations of CH_2NH, with the NRO 45 m telescope and the SMT telescope towards 11 high-mass and three low-mass star-forming regions. As a result, CH_2NH was detected in eight sources, including four new sources. The estimated column densities were roughly 10^{14}-10^{15}, 10^{15}-10^{16}, and 10^{16}-10^{17} cm^{-2}, respectively, for extended, 10 ″ , and 2 ″ sources. G10.47+0.03 and Orion KL are found to be especially CH_2NH-rich sources. We used chemical reaction network simulations to investigate formation process of CH_2NH in the ISM. Under the dark cloud condition, the simulated CH_2NH abundance in the gas phase is more than 10 times lower than our observations even if we conservatively estimate the CH_2NH abundance with an extended source. On the other hand, if we include hydrogenation reaction to HCN in our model, the CH_2NH abundance increased about by two orders of magnitude, enabling us to reconcile the observed abundance of CH_2NH. We also showed that this reaction is dominant in the early, low temperature phase of cloud evolution.

As a wide variety of organic compounds have been found in meteorites and comets, their relevance to the origin of life is discussed. Many kinds of amino acids have been identified in extracts of carbonaceous chondrites, their origin is controversial. Possible carriers of organic compounds to the Earth were meteorites, comets and interplanetary dust particles (IDPs). It is said that IDPs could deliver organics more safely than meteorites and comets, the nature of organics in IDPs are little known since they have been collected usually in terrestrial biosphere. In addition, IDPs are directly exposed to cosmic and solar radiation, which might destroy organics in IDPs.

When possible interstellar media (a mixture of carbon monoxide or methanol, ammonia and water) was irradiated with high-energy particles, amino acid precursors were formed in high energy yields. We are planning to irradiate possible interstellar media with high energy heavy ions from a newly developed Digital Accelerator in KEK to confirm it. It suggested that amino acid precursors could be formed in interstellar space in prior to the formation of the solar system. Before the incorporation of interstellar organic compounds into comets or parent bodies of meteorites, they could be altered with high energy photons from the yound Sun. Soft X-rays irradiation of simulated interstellar organics resulted in the formation of hydrophobic compounds as seen in comets.

We are planning a novel astrobiology mission named Tanpopo by utilizing the Exposed Facility of Japan Experimental Module (JEM/EF) of the International Space Station (ISS). Two types of experiments will be done: Capture experiments and exposure experiments. In the exposure experiments, organics and microbes will be exposed to the space environments to examine possible alteration of organic compounds and survivability of microbes. Selected targets for the exposure experiments of organic compounds are as follows: Amino acids (glycine and isovaline), their possible precursors (hydantoin and 5-ethyl-5-methyl hydantoin) and complex precursors (CAW) synthesized from a mixture of carbon monoxide, ammonia and water by proton irradiation. In capture experiments, we will collect space dusts by using ultra-low density silica gel (aerogel), and will analyze them after returning them to the Earth. Amino acid enanthiomers will be analyzed after HF digestion and acid hydrolysis, as well as characterization of complex organic compounds in space dusts. The mission is planned to be started in 2015.

Polymerization of methionine: Ignition of sulfur metabolism?

KAKEGAWA, Takeshi[1*]

[1]Graduate School of Science, Tohoku University

Methionine, sulfur-bearing amino acid, is one of protein-forming 20 amino acids. On the other hand, peptide formation using methionine is known to be difficult, because of large thermal stability of methionine. Incorporation of methionine into peptide has importance to form metal-sulfur-cluster in protein or other biologically important molecules, such as taurine. In order to overcome difficulties to make methionine-bearing peptide, new series of experiments were performed in the present study. Experiments were performed at 175 C and 150 MPa, using various mixtures. Methionine-trimers, which were not formed by previous investigators, were produced in the present study. Surprisingly a part of methionine was converted into glycine and then glycine-methionine peptide was newly formed. Those results demonstrated that high T and P conditions were suitable for not only methionine-peptide formation but also making multi-component peptide. Sulfur isotope compositions were determined on run products of the present study. Run products were enriched or depleted in 32S compared to starting materials. Hydrogen sulfides were preferentially released from methionine for the 32S-depleted samples. The 32S-enriched samples are explained by loss of sulfate from methionine, although oxidants of methionine-sulfur are still unclear. Modern living organisms metabolically produce sulfide and sulfate from methionine and cysteine. Such metabolic path is similar to the abiological production of sulfide and sulfate in the present study. This may imply that course of sulfur metabolism was most likely established early in the prebiotic age when methionine was incorporated in prebiotic protein.

As one of research groups on ”Astrobiology in the Solar System” (a proposal submitted to MEXT), our group will study the origin of icy satellites around giant planets, and the origin and evolution of the interior ocean(s) of those icy bodies and their universality. Outside the so-called snowline of H_2O, the mass of protoplanets could be large enough to collect surrounding gas rapidly to form massive gaseous giant planets. Icy satellites would have been formed or trapped by the circumplanetary gas disks around giant planets. In multisatellite cases, orbital resonances may stabilize satellite migration and tidal dissipation would provide heat for sustaining interior oceans. Even when surface temperature is lower at a further distance from the sun, additional ice component (NH_3, CH_4, CO, etc.) would decrease the melting temperature. As a result, the more extended condition for presence of liquid water can be considered in comparison with the conventional habitable zone (with surface water).

Tanpopo, a dandelion in Japanese, is a plant species whose seeds with floss are spread by wind. We propose this mission to examine possible interplanetary migration of microbes, and organic compounds at the Exposure Facility of Japan Experimental Module (JEM: KIBO) of the International Space Station (ISS). The Tanpopo mission consists of six subthemes: Capture of microbes in space (Subtheme 1), exposure of microbes in space (Subtheme 2), analysis of organic compounds in interplanetary dust (Subtheme 3), exposure of organic compounds in space (Subtheme 4), measurement of space debris at the ISS orbit (Subtheme 5), and evaluation of ultra low-density aerogel developed for the Tanpopo mission (Subtheme 6). 'Exposure Panel' for exposure of microbes and organic materials and 'Capture Panels' for capturing micro particles with aerogel will be launched. The panels will be placed on the Exposed Experiment Handrail Attachment Mechanism (ExHAM) in the ISS. The ExHAM with the panels will be placed on the Exposure Facility of KIBO (JEM) with the Japanese robotic arms through the airlock of KIBO. The panels will be exposed for more than one year and will be retrieved and returned to the ground for the analyses.

Rock Magnetic Constraints on the origin of putative biological magnetite in the Martian ALH84001 Carbonates

KIRSCHVINK, Joseph[1*] ; KOBAYASHI, Atsuko[2] ; BUZ, Jennifer[1] ; THOMAS-KEPRTA, Kathie[3] ; CLEMETT, Simon[3]

[1]California Institute of Technology, Pasadena USA, [2]Earth/Life Science Institute, Tokyo Tech., [3]ESCG at NASA/Johnson Space Center, Houston TX

McKay et al. (1996) discussed 4 lines of evidence that were consistent with the possible presence of ancient life on Mars. Although none of these have been falsified, the one that has triggered the most intense debate concerns the claim that some of the fine-grained magnetite crystals embedded in small carbonate deposits might have been formed by the magnetotactic bacteria. These magnetite particles, when examined by high-resolution transmission electron microscopy, are indistinguishable from particles only produced by magnetotactic bacteria on Earth (Thomas-Keprta et al., 2001). Unfortunately, the magnetic and microscopic analyses done to date do not allow us to provide a direct statistical test of the probability that these particles are of biological origin, vs. the hypothesis they form from high-temperature decomposition of siderite (FeCO3).

In the past decade, developments in superconducting magnetometry and electron microscopy now provide new experimental approaches that can be applied to this problem. First, the new Ultra-High Resolution Scanning Magnetic Microscopes (UHRSMMs) can detect magnetic moments 3 to 4 orders of magnitude below the sensitivity of the best superconducting rock magnetometers, and robust dipole-fitting routines allow the 3-D vector magnetic moment of tiny particles to be resolved quantitatively. We have shown recently that individual fragments of the famous ALH84001 carbonate blebs can be imaged clearly using this technique, opening the possibility of experimental tests that should distinguish low-temperature (biological) from high-temperature (thermal decomposition) magnetite. Magnetite produced by thermal decomposition of carbonate during shock heating should carry a relatively strong Thermo-Remanent Magnetization (TRM), whereas biological magnetite trapped during carbonate growth should have a much weaker detrital magnetization (DRM). Fuller et al. (1988) reported a simple technique that compares the relative intensities of the Natural Remanent Magnetizations (NRMs) to Isothermal and Anhysteretic magnetizations (IRMs and ARMs) that can easily distinguish TRMs from DRMs; this new sensitivity now be applied to these particles. Second, because the magnetotactic bacteria use genetic control to manufacture their magnetite crystals, particles within the same cell are of very similar size and shape. When these cells die and leave their magnetite crystals in the sedimentary record as magnetofossils, they produce clumps of similarly-sized crystals because they stick together magnetically with very strong force (Kobayashi et al., 2006). Sediment transport and removal processes cannot disaggregate them, but they do get scrambled together during extraction and high-resolution TEM studies. We therefore need to do very high-resolution studies that can demonstrate the position of these crystals within the carbonate matrix of the ALH 84001 carbonate precipitates. We propose to use the new focused ion-beam (FIB) milling techniques available at the Earth-Life Science Institute of TiTech to make 3-dimensional reconstructions, at a 5 to 10 nanometer scale, of rectangular chunks of the ALH84001 carbonate. At this resolution, the putative magnetosomes will be represented by up to 500 voxel elements, each with definitive elemental composition. We should be able to determine whether clusters of particles within these carbonates are of similar size and shape, as expected from collapsed magnetosome chains. It will then be very simple to do statistical tests to determine whether these clumps are non-random assemblages sampled from the background crystal size distribution. The debate about life on Mars may rise again!

Cu-Zn ores in 2.7 Ga komatiite-basalt assemblages in Abitibi Greenstone Belt, Canada, and their associations to microbs

KAKEGAWA, Takeshi[1*]

[1]Graduate School of Science, Tohoku University

Archean greenstone belts are hosting many massive sulfide ores. In particular, komatiite-basalt sequences are hosting Ni-Cu ores, which are mostly considered as a magmatic in origin. Some Ni-Cu ores are associated with serpentinization near seafloor. Such serpentinization may have been important for early life as hydrogen donors with alkaline fluids. Cu-Zn-Pb ores are also reported from the same komatiite-basalt sequences, although the origin of these ores are still uncertain. One representative 2.7 Ga komatiite-basalt sequence appears in the Munro area of the Abitibi Greenstone Belt. In order to understand the origin of Cu-Zn-Pb ores, mineralogical and geochemical studies are performed on ores at Munro area. Sulfide ores are essentially developed in black shale zones, and some ores are disseminated in altered volcanic rocks. Chalcopyrite, sphalerite, pyrrhotite are major minerals associated with minor galena, electrum, pentlandite, etc. Sulfur isotope compositions of those sulfides are ranging are not magmatic values. Some ores are rich in Se and As. Host volcanic rocks are extensively hydrated (followed by metamorphism) forming tremolite, chlorite and talc. Those features are similar to the modern submarine hydrothermal deposits, rather than magmatic ore deposits. Therefore, Cu-Zn-Pb ores in komatiite-basalt sequences were formed by black smoker type submarine hydrothermal activities. Carbon isotope analyses of organic matter in ore-associated sediments suggest that methanogens were active when komatiite became serpentinite, followed by submarine hydrothermal activities.

Microbial community development in deep-sea hydrothermal vents in the Earth, and the Enceladus

TAKAI, Ken[1*] ; SHIBUYA, Takazo[1] ; SEKINE, Yasuhito[2] ; RUSSELL, M. J.[3]

[1]Japan Agency for Marine-Earth Science & Technology, [2]Department of Complexity Science & Engineering, University of Tokyo, [3]Jet Propulsion Laboratory, California Institute of Technology

Over the past 35 years, researchers have explored seafloor deep-sea hydrothermal vent environments around the globe and studied a number of microbial ecosystems. Bioinformatics and interdisciplinary geochemistry-microbiology approaches have provided new ideas on the diversity and community composition of microbial life living in deep-sea vents. In particular, recent investigations have revealed that the community structure and productivity of chemolithotrophic microbial communities in the deep-sea hydrothermal environments are controlled primarily by variations in the geochemical composition of hydrothermal fluids. This was originally predicted by a thermodynamic calculation of energy yield potential of various chemolithotrophic metabolisms in a simulated hydrothermal mixing zone. The prediction has been finally justified by the relatively quantitative geomicrobiological characterizations in various deep-sea hydrothermal vent environments all over the world. Thus, there should be a possible principle that the thermodynamic estimation of chemolithotrophic energy yield potentials could predict the realistic chemolithotrophic living community in any of the deep-sea hydrothermal vent environments in this planet. In 2005, a spacecraft Cassini discovered a water vapour jet plume from the sole pole area of the Saturnian moon Enceladus. The chemical composition analyses of Cassini's mass spectrometer strongly suggested that the Enceladus could host certain extent of extraterrestrial ocean beneath the surface ice sheet and possible ocean-rock hydrothermal systems. An experimental study simulating the reaction between chondritic material and alkaline seawater reveals that the formation of silica nanoparticles requires hydrothermal reaction at high temperatures. Based on these findings, we attempt to built a model of possible hydrothermal fluid-rock reactions and bioavailable energy composition in the mixing zones between the hydrothermal fluid and the seawater in the Enceladus subsurface ocean. The physical and chemical condition of the extraterrestrial ocean environments points that the abundant bioavailable energy is obtained maximally from redox reactions based on CO_2 and H_2 but not from with other electron accepters such as sulfate and nitrate. In the low-temperature zones, the available energy of the Enceladus methanogenesis and acetogenesis is higher than those in any Earth's environment where the methanogens sustain the whole microbial ecosystem. Our model strongly suggests that the abundant living ecosystem sustained by hydrogenotrophic methanogensis and acetogenesis using planetary inorganic energy sources should be present in the Enceladus hydrothermal vent systems and the ocean.

Light absorption and energy transfer in photosynthesis: Toward extending our current biosignatures

KOMATSU, Yu[1*] ; UMEMURA, Masayuki[1] ; SHOJI, Mitsuo[1] ; KAYANUMA, Megumi[1] ; YABANA, Kazuhiro[1] ; SHIRAISHI, Kenji[2]

[1]University of Tsukuba, [2]Nagoya University

In the recent success in detecting for extrasolar planets, several habitable planets, which can sustain liquid water, have already been discovered. From reflection spectra on exoplanets, what and how to detect signs of life, biosignatures, have been controversial (Kiang et al. 2007). One of proposed biosignatures is vegetation red edge (VRE), which is observed from reflectance spectra on the Earth. VRE is identified as a sharp contrast in about 700 - 750 nm due to the absorption in visible region by photosynthetic pigments like chlorophylls and the reflection in NIR region. However, VRE is an effective as biosignature only if exovegetation shows the same spectral feature to that on the Earth (Seager et al. 2005). Therefore, the criterion as biosignature needs to be extended when the primary stars are totally different. Because in future missions searching for a second earth, the M type stars (cooler than Sun) will be the main targets, as the first step, we focused on the fundamental properties of purple bacteria which absorbs longer wavelength radiation (1025 nm).

We investigated light absorptions and excitation energy transfers (EETs) based on quantum dynamics simulations for light harvesting complexes (LHCs), which contain array of photosynthetic pigments. After light reaches in LHCs, effective EET is accomplished by corporative electronic excitation of the pigments. We used theoretical models for LHCs in purple bacteria (LH2s). LH2 is made of 2 rings: inner ring (B850) and the outer (B800), as shown in Figure. In our model, a dipole-dipole approximation was used for the electronic excitations. The low-lying electronic excited states of a LH2 were computed by using transition dipole moment of first excited state of each pigment calculated at time-dependent density functional theory. Corresponding to the light absorption process, the oscillator strength in the system could be computed. The oscillator strength of one LH2 was in a good agreement with the experimental value. Subsequently, quantum dynamics simulations were performed by Liouville equation to examine the EET process. In this model, the densities relaxed according to energy gradient. This treatment corresponded with the EET process. The relaxation parameters were determined based on the energy transfer time from B800 to B850 (0.8 ps). The calculated transfer time between two LH2s was determined to 2.72 - 3.67 ps in good agreement with the experiment values (2.0 - 10.0 ps). In order to deal with more realistic system, we calculated at a macro structural model. The calculated systems were composed of 7 LH2s and 19 LH2s, where LH2s were aligned in triangle lattice. As the system size increases, the oscillator strength shifted longer and the transfer velocity became faster. In photosynthesis, collected energies are efficiently transferred to lower energy sites where redox reactions take place, very efficiently by EET. When two pigments in central LH2 in the system were exchanged to pigments absorbed longer wavelength radiation (850 nm to 890 nm), the transfer velocities became faster. Moreover, in order to examine for what environments the absorption spectra of purple bacteria were optimized, the absorption efficiency was calculated from blackbody spectra expected in typical extrasolar planets. As a result, the absorption efficiency was maximum at the emission spectrum of a black body at around 200 K. Furthermore, the Light absorptions and EETs in purple bacteria, cyanobacteria and plants will be examined by using our methodology.

Ancient Habitable-Trinity Mars and Future Targeting of potential Signs of Life

DOHM, James[1*] ; MARUYAMA, Shigenori[1]

[1]Earth-Life Science Institute, Tokyo Institute of Technology

Mars, the most Earth-like planet in our solar system, once had Habitable-Trinity conditions: an interfacing ocean, atmosphere, and nutrient-enriched primordial crustal materials with energy circulation driven by the Sun. Mars is thus considered the best target to search for life beyond Earth, as there are no other planetary bodies in our solar system that record Habitable-Trinity conditions. Following the termination of Habitable Trinity conditions nearly 4.0 Ga, when a strong dynamo shut down prior to the post-heavy-bombardment Hellas and Argyre impact events, the atmosphere was thinning, and plate tectonism was ongoing though waning, life would have found it increasingly difficult to survive at or near the surface, and thus would have migrated to the subterranean to persist. Vent structures, such as those located in the western part of Elysium Planitia where oceans once occupied the Martian surface and long-term magma-water interactions (billions of years) may be still ongoing, as evidenced through pristine lavas, faults that cut youthful surfaces, and geologically-recent flood events, are thus considered to be optimal targets to search for signs of life on Mars. The vent structures were formed by the transferal of subterranean materials to the surface likely due to magma-water interactions. The geologically youthful vent structures could be readily investigated in situ through current mission design.

Origin of life component of the Earth

MARUYAMA, Shigenori[1*] ; KOUCHI, Akira[2]

[1]ELSI Tokyo Institute of Technology, [2]Hokkaido University

The Earth is highly depleted in volatile in general. Water is one of them and only 0.023wt% among mass of the solid Earth. If the parental chondrite is carbonaceous with 2.3wt% water, the Earth must have been covered by 380km thick ocean, where too much amount of water was present, hence no life was born because of no supply of nutrients (Maruyama et al., 2013). Origin of water is critical to control the birth of life on rocky planet. Snowline is a concept of the boundary whether solid ice or vapor (gas) is stable at 2.7AU. If the Earth was formed at 1.0AU, the Earth must have been dry, no atmosphere and no ocean.

By this reason, there are several ideas to make the Earth with thinly covering ocean. One of such ideas is that Earth was born as a dry planet with Moon at 4.5-4.6Ga, followed by late bombardments to transport water components to the Earth at 4.4Ga (Maruyama et al., 2013).

Here we propose that late bombardment delivered not only water component but also carbon and nitrogen together at 4.4Ga. The organic lines are present within a narrow region around 2.1AU which is much closer to the Earth than the snowline. Asteroids derived from chondritic materials were transported to the Earth at 4.4Ga, and their organic matters turned to be primordial atmosphere from which primordial ocean was born. C and N with respect to O and H are enriched to make reduced atmospheric composition which could be favorable to synthesize complex organic compounds at the interface between atmosphere and ocean.

Theoretical investigation of amino acid formations on interstellar dusts

KIDACHI, Kaori[1*] ; UMEMURA, Masayuki[1] ; KOMATSU, Yu[1] ; KYANUMA, Megumi[1] ; SHOJI, Mitsuo[1] ; YABANA, Kazuhiro[1] ; SHIRAISHI, Kenji[2]

[1]University of Tsukuba, [2]Nagoya University

Molecular evolution in the interstellar space remains unsolved. Formations of molecules in space have been extensively studied by experiments and space observations. Formations of complex organic molecules are expected in the interstellar space. In fact, some amino acids were found in meteorites and amino acids were detected after UV irradiation of interstellar ice analogs.

In the amino acid formation in space, many precursors and molecular evolution pathways are expected. Among these possible pathways, it is very important to know the energy profiles and molecular structures in the major formation pathways. In this study, possible amino acid formation pathways are investigated by using accurate quantum chemistry methods at the density functional theory levels.

Two formation pathways of glycine and alanine were examined: (1) hydrolysis of aminoacetonitrile and (2) hydrolysis of hydantoin derivatives. In the aqueous solution model, Polarizable Continuum Model was used.

Calculated formation energy of glycine is the most stable in the formation pathway in vacuum and no excessively stable intermediates existed. In aqueous solution, hydantoin pathway was slightly unstabilized. In conclusion, glycine production is considered to be occured easily if the components exist. Similar trend is expected for the alanine production.

Introduction: Organic matter in interplanetary dust particles (IDPs) records the primitive chemical history in the early Solar System as well as it is thought to have delivered the building blocks of life to the early Earth (Chyba and Sagan, 1992). The Japanese Astrobiology working group, Tanpopo, is planning to collect the IDPs using a low-density silica aerogel (0.01 g/cm^3) (Tabata et al. 2011) on the International Space Station (Yamagishi et al. 2009). The mission has a great advantage that collection of the pristine IDPs without atmospheric entry heating and terrestrial contamination will be expected. One thing that has to be considered is a possible modification of the chemical composition of organic matter in IDPs upon their high velocity impact to the aerogel. This issue has been also concerned in the Stardust cometary dust sample return mission. Although the laboratory simulations have been conducted to study the alteration of minerals (Okudaira et al. 2004; Noguchi et al. 2007), the alteration of organics under a realistic condition has not been well understood. As a ground-based experiment, we have conducted a laboratory experiment of aerogel capture of Murchison meteorite powder at 4 km/s using a two-stage light gas gun, in order to evaluate the extent of modification of organic matter in the meteorite.

Experimental: The Murchison meteorite powder (˜500 ug) of a particle diameter of 30-100 um in a polycarbonate sabot was shot at ˜4 km/s using a two-stage light gas gun at JAXA/ISAS. The penetrations of the meteorite powder formed ˜70 tracks of ˜10 mm length in aerogel. Six terminal particles were extracted from the aerogel tracks using a tungsten needle and were pressed between two Al foils. The particles on the Al foils were analyzed by micro-Fourier transmission infrared (FTIR) spectroscopy at the beamline 43IR, Spring-8 and Osaka Univ., and micro-Raman spectroscopy at Osaka Univ. For a comparison, pre-shot Murchison meteorite powder was analyzed by these micro-spectrometers.

Results and discussion: The IR imaging detected the regions of absorptions of aliphatic carbons, CH3 at 2960cm^{-1} and CH2 at 2920cm^{-1} within the two Murchison terminal particles captured by aerogel. Thus, organic matter is survived through the high velocity impact at 4 km/s. The spectral intensities of aliphatic carbons in the terminal particles are slightly lower than those in the pre-shot Murchison meteorite. CH2/CH3 ratios obtained from the IR spectra of the terminal particles were 0.3 ? 3, while those of the pre-shot sample were 1.3 ? 2. The difference in the ratios may be reflected by modification of aliphatic chains of organic macromolecules in the meteorite, e.g., demethylation, methylation, or cracking, due to the high velocity impact heating. From the two terminal particles, D- and G- bands, which are derived from carbonaceous matter, were detected by micro-Raman analyses. Peak widths and positions of the two bands showed similar values to those for pre-shot Murchison meteorite. Thus, modification of aromatic structures after the aerogel capture is unlikely. Although relative amounts of organics were low in the four other terminal particles, this may be reflected by original heterogeneity of the meteorite.

Possibility of production of amino acids by impact reaction using a light-gas gun as a simulation of asteroid impacts

OKOCHI, Kazuki[1*] ; MIENO, Tetsu[2] ; KONDO, Kazuhiko[1] ; HASEGAWA, Sunao[3] ; KUROSAWA, Kosuke[4]

[1]Dept.Physics, Shizuoka Univ., [2]Grad.School of Sci. and Technol, Shizuoka Univ., [3]ISAS/JAXA, [4]Planetary Exploration Research Center, Chiba Institute of Technology

We are interested in the production process of amino acids in space. Especially, asteroids coming to Titan satellite have made impact reaction on the surface including nitrogen gas, water ice and methane. On the Titan surface, various material, produced by the impact reactions, have been stored under low temperature and dark condition. To do the simulation experiment, a JAXA 2-stage light-gas gun has been used. A projectile with 6.5km/s of speed hits a water + iron target in 1 atm of nitrogen gas, causing an impact reaction. Figure 1 shows a crater on the target. Figure 2 shows produced black soot which deposited onto the aluminum sheet. The samples produced are carefully collected and analyzed by HPLC, FTIR, TOF-MS. As a result of HPLC, peaks suggesting the existence of glycine and alanine in the samples produced were confirmed.

Amino acid formation from simulaed mildly-reducing primitive atmospheres by spark discharges and proton irradiation

ISE, Jun-ichi[1*] ; KANEKO, Takeo[2] ; OBAYASHI, Yumiko[2] ; FUKUDA, Hitoshi[3] ; OGURI, Yoshiyuki[3] ; KOBAYASHI, Kensei[4]

[1]Grad. School of Eng., Yokohama Natl. Univ., [2]Faculty of Eng., Yokohama Natl. Univ., [3]Grad. School of Sci. & Eng., Tokyo Inst. Tech., [4]Yokohama National University, NINS

Miller (1953) reported that amino acids were abiotically formed in a gas mixture of methane, ammonia, hydrogen and water. However, It is suggested that the primitive Earth atmosphere was less reducing, and its major components were carbon dioxide and nitrogen. It is quite difficult to form amino acids from such non-reducing gas mixtures. If it is mildly reducing, i.e. it contained some carbon monoxide or methane, amino acid production could be expected.

We examined possible formation of amino acids from mildly reducing gas mixtures by spark discharges or by proton irradiation. A mixture of carbon dioxide and methane (total 50 %) and nitrogen (50 %) was introduced into a glass tube with liquid water. Spark discharges in the gas mixtures were performed with a Tesla coil for 12 hours. Proton beams (2.5 MeV, 2 mC) were irradiated to the gas mixtures from a Tandem accelerator (TIT). The resulting products were acid-hydrolyzed, and amino acids were determined by ion-exchange HPLC with post-derivatization with o-phthalaldehyde and N-acetyl-L-cystein.

A mixture of methane and nitrogen gave amino acids in high yields by either spark discharges or proton irradiation. When carbon dioxide was added to the gas mixture, amino acid yields decreased. In the case of spark discharges, amino acids could not be detected when methane ratio in total carbon sources (carbon dioxide + methane) was less than 30 %. In the case of proton irradiation, the mixture with the methane ratio was 5 % still gave amino acids. Thus, it was suggested that, in the case that the primitive Earth atmosphere was only slightly reducing, a major energy source for the production of amino acids was not thundering but cosmic rays.

Stability and reactions of amino acids in simulated submarine hydrothermal systems

AKAMATSU, Ryota[1*] ; BALASANTHIRAN, Kuhan C.[1] ; OBAYASHI, Yumiko[2] ; KANEKO, Takeo[2] ; KOBAYASHI, Kensei[2]

The discovery of hydrothermal systems in the late 70s brought a new hypothesis to the origin of life. Previously, the Urey-Miller experiment had made waves in this new field, indicating that a reducing atmosphere could form amino acids from basic chemicals. The further discovery of hydrothermal systems with earth prebiotic conditions added another notion to the field. Since then, different kinds of simulation were conducted to test the hypothesis. Initially and autoclave was extensively used due to its robustness and durability, however this system was not an ideal system, hence a flow-type simulator was proposed instead. We tested the stability and reaction of several amino acids using a flow reactor simulating submarine hydrothermal systems at 200 — 250 ℃. This study generally showed that there is a variation in the individual amino acids survivability in the simulators. This is mainly attributed to the following factors; heat time, cold quenching exposure, metal ions and also silica.We observed that, in a rapid heating flow reactor, high aggregation and/or condensation of amino acids could occur even during a heat exposure of 2 min. We also monitored their stability in a reflow-type of simulator for 120 min at 20 min intervals. The non-hydrolyzed and hydrolyzed samples for this system showed a similar degradation only in the absence of metal ions. We also tested the possible condensation that could be forming peptide bonds among the amino acids in one of the flow rectors. We utilized the Lowry protocol to determine the concentration of the peptide bonds in several hydrothermal temperatures. Concentration of peptide bonds was significantly higher when the temperature was at 300 ℃. This is despite the decomposition of amino acids by more than half. However, the contribution of peptide bonds in the combined amino acids was less than 10%, even in the 300 ℃ sample, which showed the highest contribution of peptides. The major heat products were non-peptide amino acid condensates (NPACs) that only possess partial peptide bonds. The role of NAPCs should be examined though they were often ignored in the classical chemical evolution scenario so far.

We experimented with Gly, Ala, Asp and Val in the SCWFR at 200 ℃, 250 ℃ and 300 ℃. We recorded the recovery of the samples and performed the Lowry method to quantify the peptide bond concentration. Peptide bonds ' concentrations are significantly higher when the temperature is at 300 ℃. This is despite the decomposition of amino acids by more than half. The highest peptide bond concentration among the samples constitute only about 10% of the total product yield of the amino acid mixture.

We also examined possible formation of amino acid condensates by using single amino acid (Gly, Ala, Asp or Val) and compared the results with those with all of four amino acids.

Scanning electron microscopic observation of organic microspherules formed by Maillard-type reaction

TAKAHASHI, Ayako[1*] ; YABUTA, Hikaru[1]

[1]Osaka University, Department of Earth and Space Science

It has been suggested that organic microspherules played a role as a physical container to maintain catalytic molecules and their reaction intermediates at concentrations high enough to sustain catalysis in prebiotic chemistry on the early Earth (Weber, 2005). Experimental studies on the formation of organic microspherules from a variety of organic compounds, such as amino acids (Fox and Harada, 1958), gelatin and gum arabic (Oparin, 1976), organic extracts from meteorite (Deamer, 1985; Deamer and Pashley, 1989), interstellar organic analogue (Dworkin et al. 2001), fatty acids and polycyclic aromatic hydrocarbons (Groen et al. 2012), formaldehyde and ammonia (Cody et al. 2009; Kebukawa et al. 2013) have been reported. However, the formation process and stability of these organic microspherules have been unexplored. In this study, sizes, shapes, and distributions of organic microspherules formed during the progress of Maillard-type reaction of formaldehyde and ammonia were investigated.

Experimental:
Paraformaldehyde (120mg), glycolaldehyde (120mg), ammonium hydroxide (54ul), calcium hydroxide (30mg) in 2ml of water in a glass tube was heated at 50-90 degrees C for 71-720 hours. For comparison, the samples without ammonium hydroxide were heated under the same conditions. After heating, the sample solutions were centrifuged. The precipitated material were rinsed with 2N HCl to dissolve calcium, and dried at 50 degrees C to obtain organic solids. The organic solid samples were pressed on a indium plate, gold-coated, and observed by a scanning electron microscopy (SEM).

Results and discussion:
After several minutes in heating, all the sample solutions turned yellow and eventually turned brown to black. Organic solids were produced at 90 degrees C but 50 degrees C. The yields of organic solids from sample solutions with ammonia were 10 times higher than those without ammonia. The yields gradually increased during heating. While distorted-shaped aggregates are produced from the samples heated for 71-120 hours, micron-sized organic microspherules (0.4-4.0 um) were observed from those heated for 240-720 hours. The samples with ammonia show perfectly round shapes of microspherules. Some microspherules are large and oval in the sample heated for 480 hours. The sizes of the microspherules increased with heating time. Organic solids produced by the same reaction as this study's at 90 degrees C for 72 hours consist of approximately equal abundances of aromatic and aliphatic carbons (Kebukawa et al. 2013). This molecular composition could result in amphiphilicity that is related to formation of the stable microspherules observed in this study. Formaldehyde and ammonia are thought to have been commonly present on the early Earth, and thus the organic microspherules formed by these molecules which proceed polymerization efficiently under mild conditions, could have played a role as a precursor of prebiotic cell membrane.

We previously proposed an experiment (the Tanpopo mission) to capture microbes and organic compounds on the Japan Experimental Module of the International Space Station. An ultra low-density silica aerogel will be exposed to space for one year. After retrieving the aerogel, particle tracks and particles found in it will be visualized by fluorescence microscopy after staining it with a DNA-specific fluorescence dye. In preparation for this study, we simulated particle trapping in the aerogel so that methods could be developed to visualize the particles and their tracks. During the Tanpopo mission, particles that have an orbital velocity of about 8 km/s are expected to collide with the aerogel. To simulate these collisions, we shot *Deinococcus radiodurans*-containing Lucentite particles into an aerogel from a two-stage light-gas gun (acceleration 4.2 km/s). The shapes of the captured particles and their tracks and entrance holes were recorded with a microscope/camera system for further analysis. The size distribution of the captured particles was smaller than the original distribution, suggesting that the particles had fragmented. We were able to distinguish between microbial DNA and inorganic compounds after staining the aerogel with the DNA-specific fluorescence dye SYBR green I as the fluorescence of the stained DNA and the autofluorescence of the inorganic particles decay at different rates. The developed methods are suitable to determine if microbes exist at the International Space Station altitude.

Studies on life detection methods by using enzymatic activities: Phosphatase and Catalase

AOKI, Kohei[1*] ; KURIZUKA, Taihei[1] ; OBAYASHI, Yumiko[1] ; OGAWA, Mari[2] ; YOSHIMURA, Yoshitaka[4] ; MITA, Hajime[3] ; NAVARRO-GONZALEZ, Rafael[5] ; KANEKO, Takeo[1] ; KOBAYASHI, Kensei[6]

[1]Graduate School of Engineering, Yokohama National University, [2]Faculty of Education, Yasuda Women's University, [3]College of Agriculture, Tamagawa University, [4]Faculty of Engineering, Fukuoka Institute of Technology, [5]National Autonomous University of Mexico, [6]Yokohama National University and Natural Institutes of Natural Sciences

We have recognized that microorganisms can survive in such extreme environments as polar environments, deserts, hot springs and stratosphere. It is quite difficult to evaluate microbial activities in extreme environments, since most microorganisms in extreme environments are hard to cultivate. We are discussing how to detect microorganisms in extreme environments including Mars. In MELOS mission, a proposed Japanese Mars exploration, fluorescence microscope will be applied to life detection. In addition to the technique, we examined amino acid analysis and enzyme assay as possible chemical strategies for life detection in terrestrial and extraterrestrial extreme environment.

One of the most well studied enzymes in environments is phosphatase. Phosphatases hydrolyze phosphate esters to produce phosphate that is essential for terrestrial life, and they are known to be stable in environments. We assayed rocks and soils in extreme environments such as submarine hydrothermal core samples and Antarctic soil samples, and found that it can be a good indicator for microbial activity. Here we analyzed phosphatese activity in Atacama Desert soil samples. Atacama desert is know to be one of the driest and harshest environments on the Earth, and regarded as Mars simulant. Samples were collected in 2002 by USA-Mexico team. Phosphatase activity was correlated to precipitation rate.

Such extreme environments as Mars, Antarctica and deserts have commonalities. Strong UV causes formation of peroxides that will damage bioorganics. Thus, we supposed that catalase and peroxidase are quite important for the survival of organisms living there, and it would be a good biomarker. We are now studying the assay methods for catalase in soil samples.

Molecular approach to the characterisation of Sri Lanka red rain cells

MIYAKE, Norimune[1*] ; MATSUI, Takafumi[1] ; WICKRAMASINGHE, Chandra[2] ; WALLIS, Jamie[3] ; WALLIS, Daryl[2] ; WICKRAMARATHNE, Keerthi[4] ; SAMARANAYAKE, Anil[4]

[1]Planetary Exploration Research Center, Chiba Institute of Technology, Chiba, Japan, [2]Buckingham Centre for Astrobiology, University of Buckingham, Buckingham, UK, [3]School of Mathematics, Cardiff University, Cardiff, UK, [4]Medical Research Institute, Colombo, Sri Lanka

The recent mysterious phenomenon that has attracted much attention is that of the red rain which fell in Polonnaruwa, Sri Lanka, on 13 November 2012. The microbial content in red rain shows generic similarities to that of the Indian red rain which fell in 2001. The morphological property of those microbes has been well documented [1,2]. Various microscopic analyses of our Sri Lankan red rain sample indicate that the defining red rain cells (RRC) exist in the presence of other microorganisms including diatoms. In our past paper, the ultrastructure of RRC shows that it is possibly a spore-form and so allowing them to thrive in the extreme upper biosphere conditions [3]. We also show the presence of uranium in the abnormally thick cell wall of RRCs.

In this report, we present the molecular approach to the characterisation of microbial communities in red rain and reveal the genus of RRCs. A beads-beating protocol is carried out for the efficient extraction of DNA and denaturing gradient gel electrophoresis (DGGE) for the analysis of microbial communities.

The mechanism that had formed the oldest organic carbon with the banded ironstone formations

KARASAWA, Shinji[1*]

[1]Miyagi National College of Technology (Professor emeritus)

The band iron layers were formed about 3.8 billion years ago. M. T. Rosing reported that the oldest organic carbon was found in the sedimentary rock from west Greenland that formed at the same period [1]. That is, the value of carbon isotope ratio ($^{12}C/^{13}C$) on 2- to 5-micrometers graphite globules in the rock is larger than that of inorganic carbon. Since photosynthesis is realized by a system of molecules with chain of reactions, the production of that carbon by the photosythesis is difficult. The author proposes the mechanism that a slightly large amount of ^{12}C was incorporated in the floating substances which were produced with the banded ironstone formations (BIF).

We can observe the phenomena by adding fine iron particles in carbonated water as shown in the [photograph 1]. Bubbles were produced at the surface of iron in the bottom of water. The bubbles transfer the fine particles of iron from the bottom to the surface. Since the electronegativity of carbon is larger than that of hydrogen, the carbon atom released from carbonated water by oxidation of iron was adhered to iron particle. The intermolecular bonding of iron with carbon beomes floating substance. The iron atom will be released from the floating substance as the form of iron oxide. So, the carbon atom that was released from the iron will constitute the floating substances [2].

At about 3.8 billions years ago, earth's surface was covered with compounds such as oxides, sulfides and carbonates. Although there were carbon dioxide gasses in the atmosphere, the seawater at mild temperature became dissolve the carbon dioxide. There occurred volcanic eruptions frequently. Iron particles were emitted by the volcanic eruption and the iron oxides were deposited at the bottom on the sea. that is the process of BIF. On the other hand, the carbn dioxide molecules in the syk smashed into surface of the sea water frequently. It is possible to produce an organization of molecules from the floating substance of intermolecular bonds by the energy that comes from outer world such as ultraviolet ray. The floating substances will accuulate at surface of water. At last, the substances deposited at bottom of the sea. That is, the carbon atoms those were included in sedmentary rocks fromk west Greenland had come from the sky.

Ocean Acidification and its effect on calcification since the late 19th century revealed by d11B of Ogasawara coral

KUBOTA, Kaoru[1*] ; YOKOYAMA, Yusuke[1] ; ISHIKAWA, Tsuyoshi[2] ; SUZUKI, Atsushi[3]

[1]Atmosphere and Ocean Research Institute, University of Tokyo, [2]Japan Agency for Marine-Earth Science and Technology, [3]National Institute of Advanced Industrial Science and Technology

Boron isotopes ($d^{11}B$) of coral skeleton are known as a pH meter in the seawater. As pH of seawater is closely related to partial pressure of CO_2 (pCO_2) in the atmosphere, it is expected that $d^{11}B$ becomes pCO_2 indicator in the geological past too. However, $d^{11}B$-pH is under scrutinized since coral calcification itself probably affects the relationship. Although many studies have focused on $d^{11}B$ measurements for cultured corals under pH-controlled aquarium, those for living corals outdoors have rarely measured, which are limited to, for example, Great Barrier Reef and Guam. Here we show 125 years-records (AD1873-1998) of $d^{11}B$ and boron concentration (B/Ca ratio) for long-lived massive coral (Porites sp.) that was sampled at Chichi-jima, Ogasawara Islands, North West Pacific. They clearly reveal Ocean Acidification after the industrial revolution. We will discuss a relationship between ocean acidification and coral calcification from a slope of pH decline that is obtained from observational data. We will also discuss how B/Ca of calcium carbonate skeleton that is produced by marine calcifiers is reliable proxy for seawater pH, which is being paid a great attention mainly due to relative easiness to measure compared to isotopes.

Ocean acidification influences on coral growth of temperate species

KIM, So[1*] ; SUZUKI, Atsushi[2] ; HAYASHI, Masahiro[3] ; YAMAMOTO, Yuzo[3] ; HOTTA, Kimiaki[3] ; ISONO, Ryosuke[3] ; WATANABE, Yusuke[3] ; YAMANO, Hiroya[4] ; NOMURA, Keiichi[5] ; NISHIDA, Kozue[2] ; INOUE, Mayuri[6] ; ZHANG, Jing[1] ; NOJIRI, Yukihiro[4]

[1]Toyama University, [2]Geological Survey of Japan, AIST, [3]Marine Ecology Research Institute (MERI), [4]National Institute for Environmental Studies, [5]Kushioto Marine Park, [6]Atmosphere and Ocean Research Institute, The University of Tokyo

Carbon dioxide concentration in the atmosphere has steadily increased since the industrial revolution due to burning of fossil fuel and will cause the global warming and ocean acidification. It will raise the ocean temperature around Japan and reduce the seawater pH and then it may bring serious threat to corals dwelling around Honsyu Island, Japan. Last year, our research group did temperature-controlled culture experiments of temperate coral species from the Pacific side of Honsyu Island of Japan under the present level of the partial pressure of CO_2 (pCO_2). But, synergetic effect of the global warming and ocean acidification on these corals has not been tested yet in detail. In this study, we focus on the how the different pCO_2 levels (past, present, and future) can influence skeletal growth of temperate *Acropora* coral species under the different temperature setting using a precise control system. This system was used to generate six different pCO_2 levels: (i) pre-industrial, ˜300 μatm, (ii) present-day pCO_2, ˜400 μatm, and at four near-future conditions, (iii) ˜550 μatm, (iv) ˜750 μatm, (v) ˜1000 μatm and (vi) ˜1200 μatm at three temperature conditions (17, 25, and 27 deg C). Our early results suggested a negative influence of higher pCO_2 levels on skeletal growth of temperate *Acropora* corals, but not so sensitive compared to tropical and subtropical *Acropora* corals.

Projecting impacts of rising water temperature on the distribution of seaweeds around Japan

TAKAO, Shintaro[1] ; FUJII, Masahiko[1*] ; KUMAGAI, Naoki[2] ; YAMANO, Hiroya[2] ; YAMANAKA, Yasuhiro[1]

[1]Faculty of Environmental Earth Science, Hokkaido University, [2]National Institute for Environmental Studies

Using monthly mean sea surface temperature (SST) from 1950 to 2035 obtained by a high-resolution climate projection model (MIROC4h) and SST-based indices of the distribution of tropical-subtropical and temperate seaweeds (*Sargassum duplicatum* and *Ecklonia cava*, respectively), we evaluated the effects of SST rises on the potential distribution of the species in seas close to Japan. Estimated distributions from the 1950s to 2000s showed that the potential southern limit of the temperate seaweed shifted to higher latitudes due to rising water temperature-induced barren ground, while there was little change in the potential northern limit of them. In contrast, the tropical-subtropical seaweed *S. duplicatum* expanded their distribution polewards during the same period. Under the global warming scenario (RCP4.5), the potential distribution of *S. duplicatum* can replace the one of *E. cava* in coastal area of Kochi Prefecture by the 2010s. This replacement of the temperate seaweed species with the tropical-subtropical one could consequently change coastal productivity and food web structure, and therefore may affect ecosystem services around Japan.

Keywords: seaweed bed, global warming, climate model, Ecklonia cava, Sargassum duplicatum

Standing genetic variation of coral populations under changing environments

IGUCHI, Akira[1*]

[1]Department of Bioresources Engineering, Okinawa National College of Technology

How genetic diversities affect ecosystem functions is one of key questions to understand the maintenance of genetic diversities and their roles in ecosystem. To evaluate the functional genetic diversities of corals which are main composers of coral reefs, I genotyped 20 colonies (collected in front of Sesoko Station) of *Acropora digitifera* which is one of dominant coral species around the Ryukyu Archipelago where is the northern peripheral area of coral reefs, and performed common garden experiment using five clonal fragments from each colony (to reduce accidental response in each genotype) to estimate variations of growth and photosynthetic efficiencies among colonies, namely, genotypes. Genotyping was performed with microsatellite markers for coral host and ITS2 direct sequencing for symbiotic algae, indicating that all host colonies were genetically distinct and belonging to major populations around the Ryukyu Archipelago and mainly maintaining clade C symbionts which are dominant around this region. In common garden experiment, all colonies showed different growth patterns whilst the photosynthetic efficiencies showed similar optimal peaks among colonies. The experimental approach above suggests that there are standing genetic variations in host itself of *A. digitifera*, which might guarantee the adaptive potential of coral population for future global warming in northern peripheral reef area. These genetic variations might also contribute to the change of material cycles in future coral reefs.

Carbon flows in estuarine and shallow waters: blue carbon study

KUWAE, Tomohiro[1*] ; TOKORO, Tatsuki[1] ; WATANABE, Kenta[1] ; MIYOSHI, Eiichi[1] ; MOKI, Hirotada[1] ; TADA, Kazufumi[2]

[1]Port and Airport Research Institute, [2]Chuden Engineering Consultants Co., Ltd.

Blue Carbon, which is carbon captured by marine living organisms, has recently been highlighted as a new option for climate change mitigation initiatives. In particular, coastal ecosystems have been recognized as significant carbon stocks because of their high burial rates and long-term sequestration of carbon. However, unlike sequestration in terrestrial ecosystems, coastal carbon burial does not lead directly to an uptake of atmospheric CO_2. This is because the water column separates the atmosphere from benthic systems, and buried sedimentary carbon is composed of allochthonous sources in addition to autochthonous sources. Our research project is aiming to in situ measurements of carbon flows, including air-sea CO_2 fluxes, dissolved inorganic carbon changes, net ecosystem production, and carbon burial rates in estuarine and shallow waters.

Field investigation and the path analysis of air-sea CO2 flux in shallow waters of Ishigaki Island

TADA, Kazufumi[1*] ; TOKORO, Tatsuki[2] ; WATANABE, Kenta[2] ; MOKI, Hirotada[2] ; KUWAE, Tomohiro[2]

[1]Chuden Engineering Consultants Co., Ltd., [2]Port and Airport Research Institute

The Blue Carbon, which is carbon captured by marine living organism, is recently focused as an important option for climate change mitigation initiatives. The Blue Carbon is equivalent to approximately 55% of carbon fixed by photosynthesis activity of the earth. In particular, vegetated shallow waters have been recognized as significant carbon stocks due to the high burial rates and long term sequestration. However, the contribution of Blue Carbon sequestration to atmospheric CO_2 in subtropical shallow waters is unclear, because the investigation and analysis technologies are unmatured.

In this study, using an approach combining field investigations and path analysis, we examined the mechanisms by which environmental factors directly and indirectly affecting air-sea CO_2 flux. Field investigations were performed to examine air-sea CO_2 flux and environmental factors (e.g., wind speed, water temperature, salinity, total alkalinity (TA), dissolved inorganic carbon (DIC)) in shallow waters (Fukido, Shiraho, Nagura, and Kabira) of Ishigaki Island, July 2013. In addition, we implemented the path analysis to infer important environmental factors and interactions affecting the air-sea CO_2 flux.

Spatial distribution and its characteristics of stable nitrogen isotopic composition of macroalgae in Nagura Bay

TOMITA, Mami[1*] ; KAWACHI, Atsushi[2] ; MARUOKA, Teruyuki[2] ; TSUJIMURA, Maki[2]

[1]Graduate School of Frontier Sciences, The University of Tokyo, [2]Faculty of Life and Environmental Sciences, University of Tsukuba

This study, focusing on Nagura Bay in the west of the Ishigaki Island, conducted a field sampling and measurement of δ^{15}N values of macroalgae, *Padina* spp. and sea grass, *Thalassia hemprichii* in order to evaluate effects of land-derived nitrogen load on the coral reef ecosystem, and to discuss the reasons for the nitrogen load distribution in the bay.

In June 2013, 55 samples for each species were collected at about 50 m intervals on 7 transect lines, and their δ^{15}N and δ^{13}C values were measured in the laboratory. At the same time, water samples at stream, spring and sea were collected and their water qualities were measured. Moreover, areas for each land use in related watershed were calculated using GIS to examine the relationship between the nitrate concentration in river water samples and land use, and to identify the source of land-derived nitrogen.

As a result, most of the δ^{15}N values of macroalgae and sea grass linearly decreased from +6 to +2 ‰ with increasing distance from the shoreline. However, the transect lines around the river mouth of Nagura River relatively showed high δ^{15}N values by about 1 km away from the shoreline comparing with the other transect lines. One of the reasons is probably water flow condition around the river mouth. Some previous studies had showed that the water flow stagnates around there due to the south monsoon wind in spring and summer. Before this field sampling, the mode of wind direction for 3 months was surely south wind. This is why the land-derived nitrogen loads through Nagura River remained around river mouth due to water stagnation and lower dilution in seawater, and the plants could have higher δ^{15}N values.

On the other hand, NO_3-N concentrations have high correlations with ratios of farm land and cultivated areas. Thus, they were perhaps the main nitrogen sources in this study area. Additionally, NO_3-N flux [mg/s], which calculated by flow rate [m3/s] and NO_3-N concentration [mg/l], estimated 81.9 mg/s at the river mouth of Nagura River, and 59.4 mg/s at the upstream. Mangrove swamps and tidal flat exist between the two locations. Thus, the nitrogen source increasing the flux 22.5 mg/s could come from the swamps or their upstream.

Propagation of suspended matter from aquacultures as traced by stable C and N isotope ratios of bivalves

MORIMOTO, Naoko[1*] ; UMEZAWA, Yu[2] ; TANAKA, Yoshiyuki[3] ; REGINO, Genevieve L.[4] ; WATANABE, Atsushi[5] ; MCGLONE, Maria lourdes s.d.[4] ; MIYAJIMA, Toshihiro[1]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, [2]Faculty of Fisheries, Nagasaki University, [3]Mutsu Institute for Oceanography, Japan Agency for Marine-Earth Science and Technology, [4]Marine Science Institute, Unversity of the Philippines, [5]Graduate School of Information Science and Engineering, Tokyo Institute of Technology

Recently there is growing concern about the impact of densely-deployed aquacultures on coastal marine ecosystems in the Philippines. As suspension-feeding bivalves are expected to reflect local food sources, their effectiveness as an environmental indicator were examined by analyzing stable carbon and nitrogen isotope ratios of bivalves living in aquaculture and neighboring seagrass areas. As a whole, the δ^{13}C and δ^{15}N of bivalves collected in the seagrass areas ranged from -13.1 to -11.0 and from +4.0 to +6.6, respectively, but in seagrass area where water mass from aquaculture area passed through typically lower values (-18.9 ˜-16.1 and +2.7 ˜+5.2, respectively) were observed, and they were the lowest in the aquaculture area (-24.4 ˜-19.8 and +3.4 ˜+4.3, respectively). It suggests that bivalves mainly fed on sinking particles, and presumably also seagrass-derived particles in seagrass areas. Higher C/N ratio was observed at sites where impact of aquaculture was larger. Although the interspecies differences and food selectivity etc. may affect the variability of the bivalve δ^{13}C and δ^{15}N to some extent, these results demonstrated that stable isotope ratios of bivalves could be used as an effective indicator to evaluate propagation areas and actual effects of suspended matter resulting from anthropogenic source on ecosystems.

Large benthic primary producers such as seagrasses and seaweeds often exhibit extremely high CO_2-fixing ability and are expected to have a potential to mitigate the deteriorative influence of ocean acidification on local communities. In particular, the seagrass community has also a capacity of accumulating and sequestering organic carbon (OC) in the sediment underlying it, which implies that it functions as a self-complete, long-term CO_2 sink in the biogeochemical carbon cycle. This feature has been recognized as one of the major ecosystem services of the coastal marine ecosystem. In this study, we investigated the distribution, the physical state, and the potential origins of OC stored in the sediments from tropical, subtropical, and temperate seagrass communities.

The concentration of OC per salt-corrected dry weight of sediment normally ranged between 500 and 1300 μmol C g^{-1} in both temperate and subtropical seagrass beds, although extremely high values up to 4000 μmol C g^{-1} have been found in some tropical seagrass sediments that were affected by OC inputs from adjacent mangrove forest. The carbon isotopic composition (δ^{13}C) of OC varied broadly from -28 ‰ to -12 ‰ (vs. VPDB), although the majority of seagrass bed sediments exhibited -20 $\pm$ 3 ‰. The variability in δ^{13}C could be interpreted by varying contribution of multiple OC sources to the sediment, including seagrasses (c. -10 ‰), sinking particles derived from phytoplankton (c. -22 ‰), and allochthonous OC including terrestrial plant and mangrove detritus (c. -28 ‰).

The specific surface area (SSA) of sediment grains ranged between 1 - 20 m^2 g^{-1} for seagrass bed sediments. In the case of temperate seagrass sediments, the concentration of OC was closely correlated to SSA (r = 0.9405), with the average OC/SSA ratio being 0.72 mg C m^{-2}. This trend, as well as the OC/SSA ratio, is consistent with the well-known sorptive preservation model of sediment OC originally proposed for shelf sediments (OC/SSA = 0.6 - 0.9 mg C m^{-2}; Keil et al. 1994, Mayer 1994). In contrast, no clear relationship between OC and SSA was detected for subtropical and tropical seagrass sediments. The OC/SSA ratio was generally higher for subtropical (up to 4.2) and tropical (up to 8.5) samples than temperate ones. Two clearly different trends of the δ^{13}C of OC vs. the OC/SSA ratio could be distinguished for tropical and subtropical samples. In one trend, the δ^{13}C converged to between -28 ‰ and -26 ‰ with increasing OC/SSA ratio. This trend was typically observed in mangrove-affected tropical seagrass beds and therefore could be ascribed to accumulation of mangrove-derived OC particles within seagrass sediments. The other trend, in which the δ^{13}C gradually increased up to -12 ‰ with increasing OC/SSA, was found mainly in subtropical seagrass beds. This trend indicates an accumulation of OC particles of relatively high δ^{13}C, putatively derived from the underground parts of seagrasses.

Overall, the above results demonstrated that the seagrass community actually has a large capacity to accumulate and store organic carbon of both autochthonous and allochthonous origins. However, the physical state of OC stored in the sediment seemed contrasting between temperate and tropical/subtropical seagrass communities. In the former, OC seemed to be stabilized by adsorption onto mineral particles as suggested by the consistent OC/SSA ratio. In the latter, accumulation of refractory detrital OC particles apparently played the major role in the OC storage in the sediment. The source of refractory OC particles could have been autochthonous (e.g. seagrass roots) or allochthonous (e.g. mangrove debris) depending on the environment. We are now investigating what causes such a difference in the accumulation state of OC depending on climatic and/or biological factors.

Inorganic carbon cycle at the Fukido estuary in Ishigaki Island

TOKORO, Tatsuki[1*] ; WATANABE, Kenta[1] ; MIYOSHI, Eiichi[1] ; MOKI, Hirotada[1] ; TADA, Kazufumi[2] ; HOSOKAWA, Shinya[1] ; KUWAE, Tomohiro[1]

″ Blue Carbon ″ , which is carbon captured by marine living organisms and about 55 % of biological captured carbon in the world, is an important carbon budget in the global carbon cycle. The Blue Carbon in coastal regions is recently focused as an effective option for the climate change initiatives because the part of the Blue Carbon is separated from the atmosphere for long periods as the sediment in the soil. The potential of the carbon sequestration in tropical-subtropical coastal regions is expected to be high due to the abundant vegetations such as seagrass meadows and mangroves. Meanwhile, there is the potential that the coastal regions release CO_2 to the atmosphere due to the high decomposition rate of organic matters in vegetations and from land.

The precise measurement of the carbon cycle including the air-sea CO_2 flux is necessary for the evaluation of tropical-subtropical coastal regions related to atmospheric CO_2. Because the temporal variation in tropical-subtropical regions is generally larger than that in other climate regions, the measurement should have a certain level of continuity for long periods. In this study, we analyzed the subtropical inorganic carbon flow base on the measurement of air-sea CO_2 flux by the eddy covariance method and the biomass of seagrass at an estuary in Ishigaki Island.

The measured air-sea CO_2 flux by the eddy covariance method (-1.00 $\pm$ 0.11 μmol/m^2/s; 95 % confidential limit) indicates that the estuary was atmospheric CO_2 sink during the measurement period; the value is almost the same as the flux measured by other method such as the bulk formula method or the floating chamber method. In addition, the measured flux shows different tendency before and after a typhoon approach at the site. Because the seagrass was autotrophic during the measurement period, the linkage between the Blue Carbon production and the absorption of atmospheric CO_2 was confirmed at the measurement site. The presentation will discuss about the potential of the Blue Carbon fixation at subtropical coastal regions based on the comparison of the carbon flow measurement in other climate zone.

Skeletal records in sclerosponges from Miyako-jima, Ryukyu Islands

MATSUMORI, Taketo[1*] ; ASAMI, Ryuji[1] ; SAKAMAKI, Takashi[2]

[1]University of the Ryukyus, Japan, [2]Tohoku University, Japan

Sclerosponges, living in dark environments of tropical to subtropical shallow oceans, precipitate calcium carbonate skeleton with growth bands. They grow slowly at an approximate rate of $<$1 mm/year unlike corals (about 1 cm/year) but can be so long-lived for several decades to hundred years like corals (e.g., Benavides and Druffel, 1986). Skeletal oxygen isotopic ratios (δ^{18}O) reflect variations in sea surface temperature and seawater δ^{18}O with the latter being closely related to salinity reflecting the precipitation-evaporation balance at the sea surface and changes in water mass transport (e.g., Wu and Grottoli, 2009). In contrast to zooxanthellate corals, which commonly show positive correlations between skeletal δ^{18}O and carbon isotopic ratios (δ^{13}C), there do not exist vital effects in the secretion of sclerosponge skeleton (Druffel and Benavides, 1986). Previous studies showed significant decrease trends in the δ^{13}C records toward the present, which is probably a result of $^{12}CO_2$ added into the atmosphere/ocean from fossil fuel burning (e.g., Bohm et al. 1996). Therefore, sclerosponges are shown to provide annually resolved time series of proxy records of ocean environments since the Industrial Revolution. However, longer ($>$100 year) proxy records from sclerosponges were derived only from the Atlantic Ocean.

Here we present δ^{18}O and δ^{13}C records from high-Mg calcite skeleton of two sclerosponges (*Acanthochaetetes wellsi*) collected at a water depth of about 10 m from Miyako-jima, Ryukyu Islands in the North Pacific. The samples were slabbed to a thickness of 5 mm parallel to the skeletal growth and subsamples for stable isotope measurements were taken every 1 mm. External precision of replicate measurements of interlaboratory calcite material throughout the stable isotope analysis using a continuous flow isotope ratio mass spectrometer system (Delta V Advantage and Gasbench II: Thermofisher Scientific Inc.) of Ryukyu University was $\pm$0.05 per mil for δ^{18}O and δ^{13}C. Soft X-ray images showed highly developed skeletal growth bands with $>$100 high/low density layers. The secular changes in δ^{13}C of the two sclerosponges were quite similar to previously reported δ^{13}C records from Atlantic and Pacific corals and sclerosponges. The long-term δ^{18}O trends of the two samples are characterized by slight depletions throughout their living periods, indicative of an overall trend toward warmer ocean environment around Miyako-jima. Our sclerosponge-based estimates of sea surface temperature and salinity may document thermal and hydrologic variations in the Ryukyu Islands, furthering a good understanding of northwestern tropical-subtropical Pacific climate change for the last several centuries in conjunction with coral-based long proxy records.

Paleoenvironmental analysis using Tridacnidae shells from archaeological sites in Okinawa-jima, subtropical southwestern

ASAMI, Ryuji[1*] ; KONISHI, Mika[1] ; TANAKA, Kentaro[1] ; UEMURA, Ryu[1] ; FURUKAWA, Masahide[1] ; SHINJO, Ryuichi[1]

[1]University of the Ryukyus, Japan

Symbiont-bearing Tridacnidae giant clams living in shallow waters of the Indo-Pacific tropical and subtropical regions can be a used as an archive for documenting high-resolution record of thermal and hydrologic variations in coral reef environments for the past. Their shells, composed of dense aragonitic increments, are less sensitive to diagenetic alteration than porous skeleton of corals. They have annually and daily banded shells structure, providing chronological controls (e.g., Bonham 1965). The oxygen isotope composition (δ^{18}O) of shells, which are precipitated isotopically equilibrium with seawater, can reflect the temperature and seawater δ^{18}O (e.g., Aharon & Chappell 1986). Several studies on paleoenvironmental reconstructions around the Ryukyu Islands were performed using geochemistry in fossil corals from Okinawa-jima (Mitsuguchi et al. 1998), Yonaguni-jima (Suzuki et al. 2001), Kikai-jima (Morimoto et al. 2007), and Kume-jima (Seki et al. 2012). However, only a δ^{18}O record has been published from 6.2 ka giant clams from Kume-jima (Watanabe et al. 2004).

Here we present seasonally resolved δ^{18}O time series of fossil Tridacnidae shells recovered from two archaeological sites (the Kogachibaru Shell Mound and the Second Aragusuku-Shichabaru Ruin) in Okinawa-jima, southwestern Japan to reconstruct subtropical coral reef environments of the past. The samples, mainly composed of aragonite shells with limited amounts of calcite cements, were selected for geochemical analyses. The radiocarbon dating results indicated that they lived during the early and middle Shell Mound periods in Okinawa-jima, corresponding to the middle-to-late Holocene, which is in good agreement with ages inferred from excavation (Okinawa Prefectural Board of Education 1987; Okinawa Prefectural Archaeological Center 2006). The shell δ^{18}O values roughly showed seasonal variations, coincident with the occurrence of annual growth bands. The averages of annual, summer, and winter δ^{18}O values of fossil shells were significantly lower than aragonite theoretically precipitated in present-day coral reef water of Okinawa-jima. These results demonstrate that the seawater temperature was higher and/or salinity was lower at the sites than today. It is likely that the giant clams lived in relatively small and/or closed coral-reef lagoons with less water circulation where seawater is highly susceptible to insolation-induced temperature increase and input of fresh water; the effect could be enhanced by the fisheries lifestyle that stonewalling would be constructed at shallow waters through the use of tidal variation during the Shell Mound period in Okinawa-jima.

Although it is extremely difficult to find well-preserved fossil Tridacnidae shells from carbonate sediments that are not fragmented, archaeological ruins and shell mounds can yield many fossils. Results of our study suggest that the use of fossil shells from archaeological sites can enable the reconstruction of temporal and spatial variations in coral reef environments and of the history of lifestyles and culture during prehistoric and protohistoric ages.

Evaluation of natural break water of coral reefs affected by typhoons in the near future

HONGO, Chuki[1*] ; KIGUCHI, Masashi[2]

[1]Dept. Physics & Earth Sciences, University of the Ryukyus, [2]Institute of Industrial Science, the University of Tokyo

Tropical cyclones are one of the most extreme natural catastrophic events over the world and devastate coastal areas affected by floods and coastal erosions. Ryukyu Islands in the northwest Pacific is especially prone to many typhoons every year (Emanuel et al. 2008 Bull Amer Meteor Soc). However, the region is moderately protected from storm surge and wave during typhoons because coral reefs play a role in natural break water. For the last several decades, coral cover and species diversity on coral reef have shown dramatic declines in the region, influenced by global and local stresses (e.g., Hongo and Yamano 2013 PLoS ONE). According to the numerical modeling of global warming at the end of 21 st century, moreover, the mean intensity of tropical cyclones will probably increase significantly in the near future (Meehl et al. 2007 IPCC 4th Report). It is thus of some interest to understand the impact of tropical cyclones on the coastal areas in the region and the evaluation of coral reefs as natural break water.

To calculate a hydraulic force on a natural break water, we measured 9 transects using the echo sounder system (HFD-1000; Hongo et al. 2013 The Quat Res) on from the coast to the reef crest at Ishigaki Island in Ryukyu Islands during November 2013. To evaluate a contribution to reef formation by corals, moreover, we observed species abundance (cover) of tabular corals at the island. We shows that a change of role in natural break water of coral reefs in the island from present to end of 21 st century. Furthermore, we suggest necessary information of corals (e.g., cover and species) for maintenance of natural break water in the near future. The information are like to be one of basic criterion for determination of species in terms of direct transplantation of juvenile or adult corals, if the coral reefs will decline in the near future.

This research was supported by Nippon Life Insurance Foundation and JSPS Research Fellowships for Young Scientists (24-4044).

Plant rhizopsphere is a hotspot for greenhouse gas emissions

MINAMISAWA, Kiwamu[1*]

[1]Consortium for Rhizosphere Biogeochemistry, Graduate School of Life Sciences, Tohoku University

Nitrous oxide (N_2O) is a greenhouse gas that also degrades stratosphere ozone. Marked N_2O emission were detected from soybean root systems with degraded nodules during late growth stage in field-grown soybeans. A model system developed to produce N_2O emissions from soybean fields. Soybean plants inoculated with *nosZ* mutant of *Bradyrhizobium japonicum* USDA110 (lacking N_2O reductase) were grown in aseptic jars. After 30 days, shoot decapitation (D, to promote nodule degradation), soil addition (S, to supply soil microbes), or both (DS) were applied. N_2O was emitted only in the DS treatment. Thus, both soil microbes and nodule degradation are required for the emission of N_2O from the soybean rhizosphere. The N_2O flux peaked at 15 days after DS treatment. A ^{15}N tracer experiment indicated that the N_2O was derived from N fixed in the nodules. As for nitrification, the addition of nitrification inhibitors significantly reduced N_2O flux. Both AOA and AOB were detected by PCR analysis with N_2O emission profile in soybean rhizosphere. The N_2O flux from the *nirKnosZ* mutant rhizosphere was significantly lower than that from *nosZ* mutant, but was still 30% to 60% of that of *nosZ* mutant, suggesting that N_2O emission is due to both *B. japonicum* and other soil microorganisms. Only *B. japonicum nosZ+* strains could take up N_2O. In particular, *Fusarium* spp., a soil fungus may contributed to N_2O emission in soybean rhizoshere. From these results, the organic-N inside of the nodules was mineralized to NH_4^+, and N_2O producing processes (nitrification and denitrification) simultaneously occur in the soybean rhizopsphere. We continue to examine which microbes really mediated N_2O methabolism using isotopic techniques including ^{15}N site preference of N_2O molecules. N_2O emissions from soybeans ecosystems can be mitigated by inoculting *B. japonicum* mutants with increased N_2O reductase activity (Nos++ strains). The mutation of *nasS* gene is responsible for the Nos++ phenotype. We propose that *nasS* mutation might be an effective strategy to induce higher Nos activities in N_2O-reducing rhizobia, such as indigenous isolates from local soybean fields or even from other important leguminous crops such as alfalfa, and thus to mitigate N_2O emission.

Plants have mutualistic symbiotic relationships with rhizobia and fungi by the common symbiosis pathway, in which Ca_2^+/calmodulin-dependent protein kinase (encoded by *CCaMK*) is a central component. Although *OsCCaMK* is required for fungal accommodation in rice roots, little is known about the role of *OsCCaMK* in rice symbiosis with bacteria. Here, we report the effect of a *tos17*-induced *OsCCaMK* mutant (NE1115) on CH_4 flux in low-nitrogen (LN) and standard-nitrogen (SN) paddy fields as compared with wild-type (WT) Nipponbare. Growth of NE1115 was significantly decreased compared with that of WT, especially in the LN field. The CH_4 flux of NE1115 in the LN field was significantly higher (156?407% in 2011 and 170?816% in 2012) than that of WT, although no difference was observed in the SN field. The copy number of pmoA was significantly higher in the roots and rhizosphere soil of WT than those of NE1115. However, mcrA copy number did not differ between WT and NE1115. These results were supported by a ^{13}C-labeled CH_4-feeding experiment. In addition, the natural abundance of ^{15}N in WT shoots (3.05 permile) was significantly lower than in NE1115 shoots (3.45 permile), suggesting higher N_2 fixation in WT due to dilution with atmospheric N_2 (0.00 permile). Thus, CH_4 oxidation and N_2 fixation were simultaneously activated in the root zone of WT rice in the LN field, and both processes are likely controlled by *OsCCaMK*.

Does microbial ecology expand our understandings of nitrogen cycle in forests?

ISOBE, Kazuo[1*] ; OHTE, Nobuhito[1]

[1]The University of Tokyo

Forests cover approximately 70% of Japan's total land area, representing a largest reservoir of diversity of organisms including plants, animals, fungi protists and prokaryotes on land. These organisms are closely associated each other in material cycles if not directly. Thus, we need to know how materials are cycling between the organisms in order to address a fundamental question in ecosystem ecology: why do forests have the richest biodiversity on land? However, it is not easy to understand the material cycles in a forest because the forest has the various environmental heterogeneity which greatly affect the cycle. For example, nitrogen dynamics can be different in soils around hills and valleys in forests. Such spatial heterogeneity of the dynamics in the soils has been explained mainly from phenomenological perspectives using abiotic information such as soil moisture, soil temperature or litter quality. However, these perspectives have not fully explained the dynamics. Here, we suggest that such heterogeneity need to be explained in the context of ecology of microbial communities which mediate the nitrogen dynamics. More specifically, we suggest that understanding the nitrogen dynamics based on the physiology, population dynamics and diversity of the microbial communities can provide the mechanistic insights into the nitrogen cycle in forests.

We analyzed the spatial heterogeneity of nitrogen dynamics and associated microbial communities in natural and planted forest soils in Asia. Specifically, we focused on nitrification in which ammonium are oxidized to nitrate and found the close association between gross nitrification rates and population size of nitrifiers in the soils. Additionally, nitrification rates cannot be fully explained by using environmental properties including substrate supply, soil moisture and litter quality, but can be explained by using the population size of nitrifiers. This shows that the better understandings of the microbial ecology allows us to more accurately explain and even predict the spatial heterogeneity of material cycles. In this presentation, we will discuss how information on microbial ecology expands our understandings of nitrogen cycle in forests.

Diversity of microbial arsenic transformation pathways associated with arsenic cycling in the environment

HAMAMURA, Natsuko[1*] ; KATAOKA, Takafumi[1] ; FUKUSHIMA, Koh[1]

[1]CMES, Ehime University

Arsenic (As) is a naturally occurring toxic element that is widely distributed in nature. Although the concentrations of As in natural systems are generally low (~15 μg g^{-1} in soil and ~10 μg L^{-1} in surface waters), the elevated levels of As have been released via natural sources (i.e. volcanic activity) and anthropogenic activities due to its increasing industrial use. As can exist in four oxidation states (-III, 0, III and V), while they are mainly found as trivalent [arsenite; As(III)] and pentavalent [arsenate; As(V)] in natural systems. Depending on its oxidation state, As exhibit different mechanisms of toxicity to microorganisms and other biota. As(III) is highly reactive with thiol containing proteins and is considered more toxic than As(V). Despite its toxicity, microorganisms have developed mechanisms to tolerate As and/or utilize the element for respiratory metabolism. Although various microorganisms have been identified to catalyze As transformation including both oxidation and reduction, we have just began to unveil the full diversity of different microbial processes associated with the redox cycling of As in the environment.

To gain insight into microbial roles in the geochemical dynamics of As, the combined geochemical, physiological and molecular biological analyses were applied to examine As-impacted environments and microcosms. Microbial populations were analyzed using 16S rDNA-based molecular approach combined with metagenomic sequencing. The presence of indigenous microbial populations capable of As transformation was examined by using both molecular approach targeting As functional genes and cultivation approach. The genes coding for arsenite oxidase (*aioA*), which catalyzes the oxidation of As(III) coupled to O_2 reduction, have been recovered from geochemically distinct geothermal habitats (pH 2.6-8) as well as the soils from mine tailing. Successful cultivation of various As(III)-oxidizing bacteria confirmed the microbial attribute in As oxidation *in situ*. In contrast, from the As impacted lake sediments and soils, diverse sequences of anaerobic arsenite oxidase (*arx*) and arsenate respiratory reductase (*arr*) genes were detected, while no *aio* genes were recovered. The anaerobic arsenite oxidase, Arx, is known to catalyze arsenite-oxidation coupled to nitrate reduction or photosynthesis. Consistent with the molecular approach, the anaerobic arsenite-oxidizing nitrate reducer and arsenate-reducing bacteria were isolated from the lake sediments.

Our results showed that As redox metabolisms are widespread within phylogenetically and physiologically diverse bacteria, including both chemolithotrophic and organotrophic aerobes and anaerobes. This study revealed the diversity of As transformation pathways associated with geographically and geochemically distinct environments and presented the mechanisms behind microbial processes controlling the redox cycling of As.

Recently, many iron mats have been discovered at deep-sea hydrothermal fields in all over the world. It has been thought that microbes, especially iron-oxidizing microbes, are the key players for forming the iron mats. However, there was no direct evidence to this, due to cultivation difficulty of iron oxidizers. Recently, '*Mariprofundus ferrooxidans*' that belong to the Zetaproteobacteria was successfully isolated. From this isolation, it has been proved that this microbe can oxidize ferrous iron as the electron donor, and can widely be observed in various deep-sea low-temperature hydrothermal fields. Therefore we have investigated how these microbes contributed to the formation of the iron mat using mineralogical and culture independent approaches.

We tried to clarify mineralogical properties of natural or lab-prepared iron oxides of iron-oxidizing microbes by using XAFS, SEM and EDX. Natural samples were collected at 3 sampling sites: iron mats from deep-sea hydrothermal fields in the Mariana Volcanic Arc, Mariana Trough and the Okinawa Trough. Lab-prepared iron-oxide synthesis was carried out using chemoautotrophic bacterium Mariprofundus ferrooxydans PV-1 (ATCC BA-1020) and was cultured by diffusion cell's method (Kikuchi et al., 2011, 2014). SEM observation showed similar morphology to all samples, which have distinctive plait-like structure, and at where iron oxides precipitate around distinctive materials. Although each natural iron-oxide sample was precipitated at different environments and with different dominant microbial species within the natural samples, XAFS showed identical spectrum. Regardless of medium employed in the cultivation, lab-prepared iron oxides also showed similar spectrum to natural samples. XANES fitting suggested that iron mats consist of ferrihydrite and iron-organic complex being the same as the lab-prepared iron oxides. These results strongly supported the iron-oxidizing chemolithoautotrophs had significant ecological roles in producing the iron mat. These mineralogical analyses may help to find biosignature in the deep-sea environments.

The trench biosphere observed from the transect water sampling for the Japan Trench

NUNOURA, Takuro[1*] ; HIRAI, Miho[1] ; YOSHIDA, Yukari[1] ; NISHIZAWA, Manabu[1] ; KAWAGUCCI, Shinsuke[1] ; MAKITA, Hiroko[1] ; MIYAZAKI, Junichi[1] ; SUNAMURA, Michinari[2] ; TAKAI, Ken[1]

[1]JAMSTEC, [2]The Univ. Tokyo

We have discovered the presence of the trench biosphere that harbored distinct microbial populations comparing to those in the upper water masses in the Challenger Deep, Mariana Trench (Nunoura et al. in preparetion). The deep locates under the oligotrophic ocean and is isolated from the other trenches while the Japan Trench locates under eutrophic ocean and in a series of long trenches in north Pacific. Therefore, the Japan Trench has one of the best environments to test the universality of the occurrence of trench biosphere. In this study, we conducted CTD casts in 8 stations across the Japan Trench in 2011 after the big earthquake and analyzed microbial structures for each sample in order to examine the occurrence of the trench biosphere.

SUP05 contribution for Carbon and Nitrogen cycles in semi-closed water mass

SUNAMURA, Michinari[1*] ; TAKAKI, Yoshihiro[2] ; NUNOURA, Takuro[2] ; TAKAI, Ken[2]

[1]Earth & Planet. Science, The University of Tokyo, [2]JAMSTEC

In the deep sea hydrothermal plume, significantly elevated microbial biomass has been reported depending on chemolithoautotrophic activities by hydrothermal reduced chemicals. The potential energetic is sulfur, methane and hydrogen oxidation, and microbial production is up to date. The most important microbes in the plume is SUP05 phylotype (genus Thioglobes), which is known to have sulfur and H2 oxidation pathway, RubisCO carbon assimilation pathway, and denitrification pathways. In this study, we compared the bicarbonate and inorganic nitrogen species with SUP05 cell densities in the hydrothermal plume of the TOTO caldera hydrothermal field with half-closed water mass system in the Southern Mariana Trough. The cell densities of SUP05 is strong negative correlation with bicarbonate and nitrate, however, the correlation slope indicated the nitrogen assimilation but not the nitrogen respiration (denitrification). Only the nitrogen assimilation occurred in the plume is also supported by the lack of denitrification genes in the plume sample with the metagenomic analysis.

Microbial potential and carbon cycle in deep aquifer of the accretionary prism of Southwest Japan

MATSUSHITA, Makoto[1*] ; KIMURA, Hiroyuki[1]

[1]Department of Geosciences, Graduate School of Science, Shizuoka University

The accretionary prism situated along the Pacific side of Southwest Japan forms thick sediments. The sediment contains deep aquifers that anaerobic groundwater is accumulated. In addition to the anaerobic groundwater, it has been reported that dissolved natural gases composed mainly of methane are present in the deep aquifers. The groundwater and natural gases are collected from deep wells (150-1500 m depth) which are drilled at the accretionary prism. In the past study conducted in a deep well situated Shimada, Shizuoka Prefecture, Japan, it has been shown that methane has been produced by subterranean microbial community in deep aquifer associated with accretionary prism. However, microbial and geochemical studies have not yet been performed at other areas of accretionary prism. In this study, we collected groundwater and natural gases from 14 deep wells of Shizuoka Prefecture, and we performed measurements of physical and chemical parameters, anaerobic cultivations of microbial communities and 16S rRNA gene analysis to understand microbial potential and carbon cycle in subterranean environments of the accretionary prism.

The temperature of groundwater samples ranged from 24.2 to 49.3 ℃, and pH was weakly alkaline. Oxidation-reduction potential suggested -325 to -114 mV at all deep wells. Electric conductivity ranged widely from 92 to 2,110 mS m^{-1} at each groundwater sample. NO_3^-, SO_4^{2-} and S^{2-} in groundwater was below the detection limit. Dissolved organic carbon (DOC) ranged from <0.3 to 50 mg l^{-1}. From componential analysis of the natural gases, methane was predominant gas component at many sites (>90%). On the other hand, we detected several natural gas samples contained a large amount of N_2 (20-50%). Stable carbon isotopic analysis of methane in the natural gases and dissolved inorganic carbon (DIC) in groundwater suggested that methane of biogenic origin are contained in the natural gases at a lot of sites.

Anaerobic incubations using groundwater amended with organic substrates revealed the high potential of H_2 and CO_2 generation by H_2-producing fermentative bacteria. Furthermore, methane generation by syntrophic consortium of H_2-producing fermentative bacteria and H_2-using methanogen was also observed in 3-5 days after the start of incubation.

Bacterial 16S rRNA gene analysis indicated the dominance of H_2-producing fermentative bacteria. The presence of denitrifying bacteria was also observed at the sites where N_2 is contained in the natural gas samples. In archaeal 16S rRNA gene analysis, H_2-using methanogens dominant in the groundwater.
