Global Data Framework and Japanese Contribution

MURAYAMA, Yasuhiro[1*]

[1]National Institute of Information and Communicatoins Technology

Open data is not only the subject discussed in the last G8 meeting 2013, but also can be a wide-spread argument and can become substantially important factor in conducting science. Of course we cannot make all the research data publicly open immediately after its creation. But also data and paper are important in the modern science scheme, for validating results of a scientific research, e.g., its reproduction or statistical significance particularly in fields such as physics, earth science, or so. Recently there are found scientific results in certain percentage of original papers which are not necessarily reproducible in life science fields. Today's society has increasingly big concern with climate change and huge earthquake etc., where scientific research may directly affect real worlds like political and people's decision making. Validation of scientific papers is important since it may affect mutual trust between science and society. Here electronic data which can be linked to scientific papers in data citation scheme, are part of evidence of our scientific truth. In comparison to the history for a couple of hundred year of the printing culture in scholarly communications, the modern technology like Internet, hard disk drives, etc., have only the tens-of-years history. Human beings are now challenging this new system of electronic way to conduct science with society, seeking the right strategy for management of scholarly information. International data management activity like ICSU-WDS from the academic side, and RDA related to governmental arrangement are part of such big challenges of the international community. Furthermore Future Earth, the international 10-year transdisciplinary research programme are promoted by ICSU, UN bodies, Belmont Forum, etc. for future of the planetary earth and human beings, where ICSU-WDS and CODATA are required to support Future Earth's international scientific data management. We need careful discussions to promote those activities, but with a bright hope for the human society who has the indispensable intellectual infrastructure called "science".

Importance of Future Earth in Asia

YASUNARI, Tetsuzo[1*]

[1]Research Institute for Humanity and Nature

Future Earth (FE) has been launched as an international initiative to promote research for global sustainability by the international science and technology alliance with partnership of the International Council for Science (ICSU), the International Social Science Council (ISSC), the Belmont Forum of funding agencies, the United Nations Educational, Scientific, and Cultural Organization (UNESCO), the United Nations Environment Programme (UNEP), the United Nations University (UNU), and the World Meteorological Organization (WMO) as an observer (Future Earth, 2013). Future Earth will provide a single overarching structure for researchers, funders, service providers, and users, and integrates the existing Global Environmental Change (GEC) programmes. The GEC programmes have provided foci for several extensive international and multi-disciplinary networks of researchers investigating key human-environmental dynamics. Future Earth would develop a new generation network building on these. Future Earth proposes national and regional level committees, in addition to the regional nodes. The most essential issue for the overall FE activity towards global sustainability will be how to integrate efforts and activity of solving environmental problems and achieving sustainability for local to regional scales.

This paper introduces a strategic science plan for FE in Asia, which should be a guideline for implementing the overall FE activity in the whole of Asia, including a comprehensive archive of data in natural science as well humanity and social science fields.

Integrated Data System on Climate, Water and Disaster Risk Reduction

KOIKE, Toshio[1*]

[1]School of Engineering, The University of Tokyo

Increased water cycle variability impacts primarily through water, biological processes and human dimensions with implications for land use and societal development. It is critically important to recognize the fundamental linkages among water; land use, including deforestation; carbon cycle and ecosystem services; and food-, energy- and health- securities. By sharing coordinated, comprehensive and sustained water cycle and related Earth observations and information for sound decision making, we are now in developing effective interdisciplinary collaborations for working together based on coordinated and integrated efforts and subsequently to both mitigation and adaptation benefits at a river basin scale. Reducing disaster risk and building resilience to the climate change and variability is essential for establishment toward the final goal, the sustainable development of Earth societies and ecosystems.

Synergetic approach of bottom-up/top-down studies on CO2 and CH4 emissions from biomass burning and rice paddy in East A

IMASU, Ryoichi[1] ; TAKEUCHI, Wataru[2] ; SEKIYAMA, Ayako[2] ; SAITOH, Naoko[3] ; MATSUMI, Yutaka[4*] ; KAWASAKI, Masahiro[4] ; HAYASHIDA, Sachiko[5] ; ONO, Akiko[5]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, [2]Institute of Industrial Science, The University of Tokyo, [3]Center for Environmental Remote Sensing, Chiba University, [4]Solar-Terrestrial Environment Laboratory, Nagoya University, [5]Nara Women's University

There has been still a large discrepancy in estimations between bottom-up and top-down approaches for both CO_2 emissions from biomass burning and CH4 from rice paddy in East Asia. The purpose of this study is to update the emission inventory databases as to be more consistent between these two approaches through a synergetic usage of satellite data, ground-based remote sensing measurements, and in situ data. The most important parameter to estimate total CO_2 emissions from biomass burning is the biomass amount of the forests. In this study the amount is estimated based on the normalized vegetation index (NDVI) observed by satellites and, CO_2 emissions from burning area are estimated by multiplying the fire strength evaluated from hot spot data with some auxiliary data such as soil moisture and groundwater level. As for the top-down approach, CO_2 concentration data observed from space are useful for constraining the inverse analysis of CO_2 emission strength. The greenhouse gas observing satellite (GOSAT) dedicated to observe atmospheric CO_2 and CH_4 concentrations was launched in 2009 and has been operated for more than five years. The main band of its sensor can measure the columnar CO_2 concentration, however, it cannot be directly converted into the concentration near the surface. One of our attempts is to develop a retrieval method to estimate CO_2 concentration in the lower troposphere, particularly in the boundary layer, from a synergy of spectrum data in a wide spectral range covering from short wavelength infrared to the thermal infrared. In order to validate this method we have carried out CO_2 sonde observations around Tokyo city where GOSAT has been operated in a specific observation mode (targeting mode) to obtain sufficient number of data over this area. Based on the validated results, this method will be applied to analyze the data observed in biomass burning areas. One of our important targets is Kalimantan (Indonesia) where peat fire is the main CO_2 emission source. We started the ground-based measurement of columnar CO_2 concentration using an optical spectrum analyzer (OSA), and expect that these temporally continuous data would be effective for achieving the consistency between bottom-up and top-down approaches. Also started are observations of columnar CH_4 concentration using the same type of spectrometer in Sichuan basin (China) and Karnal (India) where are identified as the extremely high CH_4 concentration area based on the almost decadal record of observations by SCIAMACHY and GOSAT. It is expected that the synergetic analysis of data from satellite and ground-based measurements could contribute to make clear the cause of high concentration of CH_4 in these areas.

Estimation of Ecological Function based on Biodiversity and Ecosystem Information

ITO, Motomi[1*]

[1]Graduate School of Arts and Sciences, University of Tokyo

In the Green Network of Excellence (GRENE) - environmental information project, we are working on collecting biodiversity and ecosystem information, and developing methods to use them for evaluation. In the past three years, more than 500,000 plant distribution information and information of more than 10,000 localities of vegetation had been databaed, and now they become available for users. Based on those information, together with several kinds of environmental information and land use data, it is possible to estimate distribution probability of each plant species, and to estimate some ecosystem functions of the forests with higher accuracy by considering composition of tree species. Here, I will present some examples of estimation of ecological function in Japanese forests, such as forest biomass, CO2 FLUX, and amount of pollination services for crops by insects. I also discuss a way from those ecosystem function to estimating Ecosystem Services, which is a total benefits for us provided by biodiversity and ecosystems function.

Environmental Monitoring of Soil contaminated by Radiocaesium in Iitate Village using FMS developed in GRENE project

MIZOGUCHI, Masaru[1*]

[1]Graduate School of Agricultural and Life Sciences, The University of Tokyo

Most of radiocaesium released from Fukushima Daiichi nuclear power plant has been accumulated in the topsoil within 5 cm. For decontamination of the top soil, Japanese government (Ministry of Agriculture, Forestry and Fisheries) has authorized three methods: topsoil stripping method, puddling method, and plowing method to replace surface soil with subsoil. Among three methods, the topsoil stripping method is being carried out and a lot of flexible container bags containing contaminated topsoil are piled up in the paddy field. We have not yet found the final disposal site of the contaminated soil. For agricultural regeneration and early return village, it is urgent and important to find a feasible decontamination method that farmers can conduct by themselves. Therefore, we are challenging a field test that buried the contaminated soil in the ground by a combination of the topsoil stripping method and the plowing method in Iitate Village in Fukushima Prefecture. We named this method ”Madei-method” that means we treat contaminated soil carefully. Currently, we are monitoring the radiation level from the buried contaminated soil by using a soil radiation sensor combined to the Field Monitoring System (FMS) that we developed for agricultural use in GRENE project. At the moment, leakage of radiocaesium has not been confirmed from the buried contaminated soil despite rapid changes in ground water due to rainfall and irrigation to the paddy. In the presentation, I explain outline of the FMS we developed in GRENE project and would like to propose to build a useful soil radiation database in Fukushima as one of important global data.

Framework of Applications of Environmental Information for Realizing Resilient and Sustainable National Land Design

HAYASHI, Yoshitsugu[1*] ; KATO, Takaaki[2] ; SUZUKI, Yasuhiro[1] ; TANIKAWA, Hiroki[1] ; SATO, Shinji[3] ; SHIBASAKI, Ryosuke[4] ; TSUKAHARA, Kenichi[5] ; KATO, Hirokazu[1] ; KAWAZOE, Yoshiyuki[2] ; SHIBAHARA, Naoki[1] ; AKIYAMA, Yuki[6] ; KACHI, Noriyasu[5]

[1]Graduate School of Environmental Studies, Nagoya University, [2]Institute of Industrial Science, The University of Toyko, [3]Graduate School of Engineering, The University of Tokyo, [4]Center for Spatial Information Science, The University of Tokyo, [5]Faculty of Engineering, Kyushu University, [6]Earth Observation Data Integration and Fusion Research Initiative, The University of Tokyo

1. Introduction

This research project, GRENE-City, aims to construct a methodology to design and realize ”resilient and sustainable national land” with mitigation and adaptation measures against vulnerabilities of national land and society. This ”resilient” concept is derived from an understanding of ”natural providence”. The proposed system takes advantage of a broad range of information includes disaster risk caused by meteorological phenomena and others from DIAS (Data Integration and Analysis System) by the Earth Observation Data Integration and Fusion Research Initiative (EDITORIA), the University of Tokyo. As such the system will be developed as a ”Progressive Integrated Database” based on various environmental information infrastructures provided by DIAS. In addition, this project aims to cultivate experts who can construct and utilize this database in actual policy making fields.

To achieve this goal, a re-design of national land and society for a reduplicative system in both normal and emergency situations is necessary. Both a ”safety and security” concept, which takes account of damage reduction, and a ”sustainability” concept which tackles low carbon, energy saving, and prevention of climate change, are needed in order to keep pace with the threats of predicted huge earthquakes and climate change.

2. Contents

Natural hazards caused by climate change, earthquakes and other disasters may be increasing, and could strike in the near future our vulnerable society which is characterized by with declining birth rate and a growing proportion of elderly people, population decline, urban sprawl and etc. Based on the common recognition on these problems, this research project sets out to construct a methodology to lead to safer peaceful mind and sustainable national land and society by using DIAS.

The system needs to use data on natural and social situations. The data on natural situations includes earthquakes, climate change and disasters. The data on social situations include population structure, economic conditions, infrastructure, and land use. Additionally, not only the present data, but also historical data, such as land use and infrastructure change, record of disasters, population structures, and other information, are collected. Therefore ”four-dimensional GIS” will be constructed to allow quantitative prediction and to evaluate policies considering historical faces, past place names, and other qualitative information.

In consequence, the system will analyze the vulnerability of national land and society caused by social, geographical, and other conditions, and natural variations and disaster risks. This system supports the examination of various policies, especially, the effectiveness of ”Smart shrink” which could stop urban sprawl.

3. Results and future works

1) Information archives

This project collected historical data on earthquakes, tsunamis, and other natural disasters from old documents and other resources. In particular, records of tsunami damages of the Great East Japan Earthquake are stored. A prototype Web-GIS is developed to show these photos and tsunami height with map information.

2) Analysis and design

This project offers the evaluation of national land and cities with a view to safety, security, and sustainability. The system introduces QOL (Quality of Life) indicators. Data about accessibility, amenity, and disaster vulnerability to calculate QOL indicators are collected and added to the system. This will be utilized to illustrate conditions of residential amenity and disaster vulnerability in each area of the national land.

3) Utilization and deployment

This evaluation system will be applied to case study cities and regions. The problems and demands of the system will also

be clarified. As a result, the system and database will be developed to accommodate requests from policy planning of city and national land.

Population health and global data sciences in Grene Ecohealth project

KANEKO, Satoshi[1*] ; WATANABE, Chiho[2] ; MOJI, Kazuhiko[3] ; NISHIMOTO, Futoshi[4] ; TIENGKHAM, Pongvongsa[5]

[1]Institute of Tropical Medicine, Nagasaki University, [2]School of International Health, Graduate School of Medicine, The University of Tokyo, [3]Graduate school of international health development, Nagasaki University, [4]Research institute for humanity and nature, [5]Savannakhet Provincial Health Department, the Lao People's Democratic Republic

Age of global and big data has come. The amount of data explosively increase and the expectations of exploring such data and effective utilization of data analysis results go wide of the mark. We enjoyed somehow the benefits from the big data analysis in daily life and some of the field in sciences; however, how can it be delivered to the health field, especially in areas or regions where the data collection is difficult due to the luck of data collection system? In developed countries, we can have data related to health and it has been already used for improvement public health service system. Furthermore, it has been linked to environmental data to know the results from climate and environmental changes. But this is only limited to developing countries and data or information from developing countries or regions, where the most vulnerable people from climate changes live and no information exists even on population, is still lack in identifying and monitoring the real situation. To sort out such information lack situation, the GRENEcoH project, a GRENE-Ecohealth project that is running under the GRENE-environmental information program, has started data collection of population health in areas in the Lao People's Democratic Republic using up-to-date technology to collect and link individual data. The system called in general as Health and Demographic Surveillance System (HDSS), which collect information about residents in the certain given areas for research. The HDSS programs are run in different areas and by different organization in African and Asian countries, however, in Japan; the HDSS is not paid enough attention. In this presentation, the introduction and the scientific and social values of HDSS and our technology will be presented.

Development of DIAS Metadata System

YOSHIKAWA, Masatoshi[1*] ; SHIMIZU, Toshiyuki[1] ; LI, Jiyi[1] ; NAKAHARA, Yoko[1] ; KINUTANI, Hiroko[2]

[1]Graduate School of Informatics, Kyoto University, [2]Institute of Industrial Science, The University of Tokyo

We are developing a metadata system in the Data Integration and Analysis System (DIAS) project sponsored by Japan Ministry of Education, Culture, Sports, Science and Technology. A major goal of the DIAS metadata system is to collect all metadata of earth observation data produced under the projects sponsored by Japanese government. The DIAS metadata system is comprised of metadata registration system, metadata retrieval system, and download system.

Cooperation with other data centers is also an important goal of the DIAS metadata system. We have imported metadata from JAMSTEC (Japan Agency for Marine-Earth Science and Technology) data catalog and JaLTER (Japan Long Term Ecological Research Network) database, and supported integrated metadata search through the DIAS retrieval system. On the other hand, by exporting DIAS metadata, DIAS is now listed in the Earth Observation Catalogs of GEOSS Portal. We are developing a metadata coordination system to make it possible more comprehensive exchange of metadata among data centers.

Keywords: earth observation data, metadata

Design and proposal of operational DIAS

NISHIMURA, Hajime[1] ; KAKUTA, Shinya[1*] ; KOIKE, Toshio[2] ; FUKUDA, Toru[3] ; NOJIRI, Yukihiro[4]

[1]Japan Agency for Marine-Earth Science and Technology, [2]Department of Civil Engineering, School of Engineering, The University of Tokyo, [3]Earth Observation Research Center, Japan Aerospace Exploration Agency, [4]National Institute for Environmental Studies

Data Integration and Analysis System (DIAS) is intended to create new scientific knowledge and public benefits through integration of various data under collaboration with stakeholders, in order to become a social infrastructure to make new innovations and social growth. DIAS will provide information toward resilient society and mitigation on social problems related to global environment, including resource management, bio-diversity, and natural hazards, by utilizing data on earth observation, climate-variability prediction, socio-economy, and so on.

Data Integration and Analysis System Program (DIAS-P) started in 2011 as the second phase, aiming at (a) designing and proposing an operational scheme (operational DIAS) to realize public benefits through its operational application for global-scale solutions with sustainable scientific cutting-edge advancement, as well as (b) prototyping the operational regime with intelligent infrastructure to create new value, and (c) enabling stakeholders in various fields to together leverage the fusion of super-large-scale various data sets and information.

Japan Agency for Marine-Earth Science and Technology (JAMSTEC) is collaborating with the University of Tokyo EDITORIA, Japan Aerospace Exploration Agency (JAXA), and National Institute for Environmental Studies (NIES) to design the operational DIAS and present a tentative reference model including its roles. The infrastructure and schemes shown in the reference model will be the first practice if realized. This reference model has been designed in consideration with relevant progresses in relating research programs, and will be annually amended.

To achieve the above-mentioned objectives, DIAS comprehensively manages and publishes metadata as an integrated portal to provide and distribute the following data; (1) observation data listed in ”Japan Earth Observation Implementation Plan,” (2) observation data collected in each state to contribute toward nine social benefit areas of ”Global Earth Observation System of Systems” (GEOSS), (3) observation data available in partner states under bilateral or multilateral collaboration, (4) data obtained through Application Workbenches, which are intelligent infrastructure to support projects toward application to each field, and (5) data provided by Function-Improvement Partners, which are inter-organization partnership to sustainably improve functions of DIAS. Their targeted fields include socio-economy, agriculture and fishery, land use and land cover, transportation network on roads and ports, landscape, and hazards. It is to be discussed how to create an environment where archives are acknowledged as research results.

The core infrastructure of DIAS will consist of large-scale storages to archive the data, and of analysis space and tools to analyze large-scale data.

The operational DIAS expects decision-makers (in domestic and developing countries) on resource management, disaster-protection, etc. to be the major users. The major users of integrated data and analysis function of DIAS will be not only researchers (science communities) who provide decision-makers with evidence but also stakeholders who collaborate on Application Workbenches. Moreover, end-users, social movements, and civilian services are also expected to use DIAS through access to the DIAS portal site.

For the above-mentioned purposes, we developed a remote collaboration system (ubiDIAS) utilizing open sources, and studied various policies and United Nations’ Sustainable Development Goals.

The Laud Use Information System (LUIS) Database which has been developed under the GRENE-ei biodiversity area

NAKAJIMA, Hideaki[1*] ; HIMIYAMA, Yukio[2] ; SAIGUSA, Nobuko[1] ; NOJIRI, Yukihiro[1]

[1]National Institute for Environmental Studies, [2]Hokkaido University of Education, Asahikawa Branch

We, the Office for Global Environmental Database, at the Center for Global Environmental Research (CGER), in National Institute for Environmental Studies (NIES), has been developing a new database called the Land User Information System (LUIS). LUIS is a database which was provided from NIES as one of the databases of GRID-Tsukuba before. LUIS is a database to visualize the land use in Japan which was extracted from the topographical maps of the Geospatial Information Authority of Japan in three different eras, i.e., Meiji-to-Taisyo era (around 1900s), early Syowa era (around 1950s), and late Syowa era (around 1985). The land use information was extracted in each 2x2 km mesh of 1:50,000 topographical map for the upper left corner, the maximum land use, and existing land use. We have developed a program to plot the land use, on a simple Japanese map and on Google Earth view screen. The figure shows the distribution of broadleaf trees in 1900s and 1985. Red area represents the existence in both era, blue represents the extinction, and yellow represents the appearance. We are thinking of distributing the map from the CGER's Database Web server in future. Current status and future plan of the LUIS database will be presented.

Arctic Data archive System(ADS)

YABUKI, Hironori[1*] ; SUGIMURA, Takeshi[2]

[1]Japan Agency for Marine-Earth Science and Technology, [2]National Institute of Polar Research

Of all the regions on the planet, the Arctic currently shows the biggest rise in average temperature due to global warming, and is one of the regions expected to become most affected by climate change on the Earth in the future. The change in the Arctic area brings a profound impact to the global climate system through changes in interactions between the atmosphere, ocean circulation, and the cryosphere. These climate changes not only impact upon human activities, but also the Arctic flora and fauna ecosystem.

Large parts of the observations and mechanisms of the environmental change, including the climate of the Arctic region, are still not well understood. In order to further our understanding of these complex systems, an integrated study carried out with continuous observations in the Arctic is proposed. In the Arctic Environmental Observation Center in the National Institute of Polar Research, operations began on the Arctic Data archive System (ADS) in March 2012, in order to promote the mutual use of scientific data.

The purpose of the Arctic Data archive System is to archive and distribute multiple observational (atmosphere, ocean, terrestrial, and ecology) and model simulation datasets, and promote utilization of these datasets. ADS is the central repository of archived data on Arctic research in Japan.

JAXA's contributions for Earth and Planetary research using earth observation data

FUKUDA, Toru[1*]

[1]Earth Observation Research Center, JAXA

JAXA's earth observation satellites play an important role in providing essential information for Earth science and applications regarding global warming, climate change, water cycle change, agriculture, public health and disaster management.

JAXA have been operating Greenhouse gas Observing SATellite (GOSAT), and Global Change Observation Mission-Water 1 (GCOM-W1) successfully. These satellites are collecting geophysical data of the earth's surfaces and atmosphere those are important for the earth and planetary researches.

In addition to those ongoing earth observation satellite missions, new satellites will be added to the line.

One is GPM (Global Precipitation Measurement), the successor of TRMM focusing to measure precipitation. Another one is ALOS-2 (Advanced Land Observing Satellite) carrying an L-band synthetic aperture radar. Those new generation satellites will contribute to observe disaster, earth resources, climate change, water cycle, etc.

JAXA will make continuous efforts to create and provide satellite-based information for not only scientists but also decision makers and stakeholders in order to contribute to solving global and regional issues. In order to make such information useful, close collaboration with various players in various sectors is essential.

IUGONET project and its products for multidisciplinary study on upper atmospheric physics

ABE, Shuji[1*] ; YATAGAI, Akiyo[2] ; KOYAMA, Yukinobu[3] ; TANAKA, Yoshimasa[4] ; SHINBORI, Atsuki[5] ; UENO, Satoru[6] ; UMEMURA, Norio[2] ; SATO, Yuka[4] ; YAGI, Manabu[7] ; HORI, Tomoaki[2]

[1]International Center for Space Weather Science and Education, Kyushu Univ., [2]Solar Terrestrial Environment Laboratory, Nagoya Univ., [3]Data Analysis Center for Geomagnetism and Space Magnetism Graduate School of Science, Kyoto Univ., [4]National Institute of Polar Research, [5]Research Institute for Sustainable Humanosphere, Kyoto Univ., [6]Kwasan & Hida Observatories, School of Science, Kyoto Univ., [7]Planetary Plasma and Atmospheric Research Center, Graduate School of Science, Tohoku Univ.

In order to investigate the mechanism of long-term variations in the upper atmosphere, it is crucially important to make cross-cutting studies with various kinds of data observed between Sun and Earth region. Thus, it is needed to combine databases which maintained by each institute and to accelerate to make data-sharing network in the STP community. The IUGONET (Inter-university Upper atmosphere Global Observation NETwork) project was established in 2009 as a six-year research project supported from the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan. It consists of the five Japanese universities and institutes (NIPR, Tohoku University, Nagoya University, Kyoto University, and Kyushu University, that have been leading ground-based observations of the upper atmosphere for decades), and collaborates with many domestic (for example, the National Institute of Information and Communications Technology (NICT), the National Astronomical Observatory of Japan (NAOJ), and the Kakioka magnetometer observatory, Japan Meteorological Agency) and overseas institutes/projects (for example, ESPAS in EU). One of our products in the IUGONET data management framework is developing systems for searching metadata of these observational data, and the metadata database (MDB). In the STP community, there are various kinds of archived data observed by many instruments, for example radars, magnetometers, photometers, radio telescopes, helioscopes, and so on. The IUGONET MDB is based on DSpace as a metadata registering system, which is mainly used in literature management. It also adopts an extension of the SPASE data model as a metadata format, which is widely used in the upper atmospheric community in USA. As a result, this system can deal with all kind of data belonging to IUGONET institutes, including cosmic ray, meteorological information observed by automatic weather station, etc. The system can also get flexibility to other type of data including the satellites and the numerical simulation which are used in the STP community. It is one of our challenges to apply the IUGONET system to many kinds of data in other communities. This MDB system is in operation since 2011 with over 10 million metadata. Other challenge of the IUGONET is developing software which can use for scientific research and publication. The iUgonet Data Analysis Software (UDAS) is a plug-in software of Themis Data Analysis Software (TDAS), which is upgraded to Space Physics Environment Data Analysis System (SPEDAS). The UDAS provides many routines for loading the ground-based observational data from various types of instruments, and performing scientific data analysis. This platform made it easier for STP community to analyze a various kind of data in a unified way. The IUGONET project will be closed at the end of fiscal year 2014. In this presentation, we will introduce the achievements and problems of our six-year project and discuss futures for global data sharing and research.

Introduction of NICT ionospheric data archive system

ISHII, Mamoru[1*] ; MARUYAMA, Takashi[1] ; TSUGAWA, Takuya[1]

[1]NICT

NICT has a long history of operational ionospheric observation with ionosondes since IGY 1957. On the beginning, we had four domestic observatories, Wakkanai, Akita, Kokubunji and Yamagawa. After that Akita was closed and Okinawa joined and we operate these four observatories continuously. In addition, Syowa station in Antarctica has been observing ionosphere by NICT since IGY, too. In addition as the World Data Center for ionosphere, we have a lot of number of ionospheric data obtained by foreign institutes.

The present ionosonde system named 10C provides digital image of ionogram. However, all other previous systems provide analog image and recorded on films. Now it becomes a serious problem to lose data by corrupted of films. The only solution of this issue is to digitize the film image but usually the cost is very high. We search the way to keep low cost and comfortable quality for future analysis and find a method named ribbon scanning. In this method we keep whole of one film data in one file, which makes cost low and avoid losing data by frame skipping. We had trial of resolution of digital image and confirm the quality is same level of original image.

We already had some fruitful results using these data archive. Maruyama et al. [2012] shows the statistic results of ionospheric variation after large earthquakes. Other than these kinds of study we expect the archive is useful for discussion of long-term variation of ionosphere with climate change. For improving the use of these dataset we need to solve another issue. Film-digitized images are suitable to manual scaling with naked-eye but we cannot use these data automatically because the axes vary in each image. To solve the issue we need to try image analysis to detect the axes automatically.

Making Dynamic Data Citable: Approaches to Data Citation within the Context of the RDA Working Group

RAUBER, Andreas[1*]

[1]Vienna University of Technology

Being able to reliably and efficiently identify entire or subsets of data in large and dynamically growing or changing datasets constitutes a significant challenge for a range of research domains. In order to repeat an earlier study, to apply data from an earlier study to a new model, we need to be able to precisely identify the very subset of data used. While verbal descriptions of how the subset was created (e.g. by providing selected attribute ranges and time intervals) are hardly precise enough and do not support automated handling, keeping redundant copies of the data in question does not scale up to the big data settings encountered in many disciplines today. Furthermore, we need to be able to handle situations where new data gets added or existing data gets corrected or otherwise modified over time. Conventional approaches, such as assigning persistent identifiers to entire data sets or individual subsets or data items, are thus not sufficient.

In this talk we will review the challenges identified above and discuss solutions that are currently elaborated within the context of the working group of the Research Data Alliance (RDA) on Data Citation: Making Dynamic Data Citable. These approaches are based on versioned and time-stamped data sources, with persistent identifiers being assigned to the time-stamped queries/expressions that are used for creating the subset of data. We will further review examples of how these can be implemented for different types of data and see how this fits into the larger context of activities on Data Citation.

Recent activity of DOI-minting to database by WDCs in Japan

NOSE, Masahito[1*] ; KOYAMA, Yukinobu[1] ; IYEMORI, Toshihiko[1] ; ISHII, Mamoru[2] ; MURAYAMA, Yasuhiro[3] ; KADOKURA, Akira[4] ; SHINOHARA, Iku[5]

[1]WDC for Geomagnetism, Kyoto University, [2]WDC for Ionosphere and Space Weather, NICT, [3]WDS Scientific Committee, NICT, [4]WDC for Aurora, National Institute of Polar Research, [5]WDC for Space Science Satellites, JAXA

Recent electronic journals are published with DOI (digital object identifier) such as doi:10.1029/2012SW000785. DOI is a persistent name that is resolved into URL, where readers can obtain digital objects of the journal articles; for example, abstract, figures, and pdf files. The DOI system was launched around 2000 and becomes popular these days so that DOI is ordinarily indicated in references and citations.

The next development of the DOI system is to extend it to database. It makes possible for researchers to cite the data used in a scientific publication, which is called ”data citation”. Data citation provides the following benefits:

• Readers can more easily locate the data used in the paper, obtain necessary information of the data (i.e., metadata), and validate the findings of the paper.

• Readers can also easily discover datasets which are relevant to their interests but has not been noticed.

• Data contributors can gain professional recognition and rewards for their published data in the same way as for traditional publications.

• Data centers can measure the impact of individual datasets and receive proper credit of their work.

Recognizing the importance of data citation, World Data Centers (WDCs) in Japan including WDC for Aurora (National Institute of Polar Research), WDC for Geomagnetism (Kyoto University), WDC for Ionosphere and Space Weather (National Institute of Information and Communications Technology), and WDC for Space Science Satellites (Japan Aerospace Exploration Agency) started discussion to mint DOI to their own database in August 2013. The discussion finds that Japan Link Center (JaLC) is a proper agency to register DOI-URL mapping, because JaLC aims at public information services to promote science and technology in Japan and it handles scientific and academic metadata and content from holders nationwide, including national institutes, universities. Two representatives of the above 4 WDCs are working closely with JaLC to define a registration scheme to implement the DOI-URL mapping. We are also developing a web-based system to register metadata with JaLC and create landing pages for database. We expect to start a pilot program to mint DOI to the database from the middle of 2014.

Open Science Data Discovery Platform

ZETTSU, Koji[1*]

[1]National Institute of Information and Communicatoins Technology

Technology and use case studies of ”Open Science Data Discovery Platform” will be introduced. So far we have harvested approximately 0.6 million metadata of data citation (DOIs and related metadata given to datasets) from publicly open databases of ICSU-WDS, PANGEA, ICPSR, etc., and have been developing new technology to leverage those data-citation link information and scholarly article archives. This technology, including linguistic, time-space, and ontological analysis techniques, is expected to have potential to enable new knowledge finding from various relations between datasets and articles, as well as analysis of higher-class clustering and grouping structures of relationships and links between science-technology information sources and even various communities which are related to science and technology data and articles. Through this process, perhaps to be like easy user-interface in future (like Web of Science), even international perspectives will be easily captured of more general science and technology research information pieces, links, and inter-relations to each other. For example, regarding climate change prediction and related decision making we may be able to find easily by an online search system how different earth observation datasets are used in political papers and meteorological papers.

Construction of spatio-temporal data mining system for time-series satellite imagery using Hadoop

NISHIMAE, Kou[1] ; MIYOSHI, Tomoya[1] ; HONDA, Rie[1*]

[1]Kochi University

A large number of spatio-temporal data have been stored in various fields of science, such as remote sensing, numerical simulation, and astronomical observation, in which data often appears as time-series images. To extract spatio-temporal knowledge from spatio-temporal data including time-series images, spatio-temporal cross section relevant to a target task has to be extracted from a mass of data. Since these data are stored as a large number of files, utilization of distributed processing framework such as Hadoop or Gfarm is promising.

We constructed distributed data mining system for time-series satellite images using 53 nodes (3 masters and 50 slaves at maximum) of iMac and Hadoop which enables distributed file system and distributed processing using MapReduce. We evaluated the scalability and performance of the system for the task extracting time-series data from a large number of images carefully and found that partitioning the images into optimum numbers and reducing the data between map phase and reduce phase is essential.

The system was then applied to two different tasks focusing on time-series data analysis extracted from satellite imagery: statistical modeling of seasonal changes in vegetation index and spatio-temporal correlation analysis of weather satellite images. The tasks were successfully implemented on the system and the computational time was decreased in inverse proportion to the number of slave nodes, thus usefulness of the distributed system to spatio-temporal data mining for time-series images.

This paper is to propose a cloud system for science, which has been developed at NICT (National Institute of Information and Communications Technology), Japan. The NICT science cloud is an open cloud system for scientists who are going to carry out their informatics studies for their own science. The NICT science cloud is not for simple uses. Many functions are expected to the science cloud; such as data standardization, data collection and crawling, large and distributed data storage system, security and reliability, database and meta-database, data stewardship, long-term data preservation, data rescue and preservation, data mining, parallel processing, data publication and provision, semantic web, 3D and 4D visualization, out-reach and in-reach, and capacity buildings.

Global spectral crustal model

TENZER, Robert[1*] ; CHEN, Wenjin[1]

[1]School of Geodesy and Geomatics, Wuhan University

We compile the harmonic coefficients, which describe the Earth crustal density structure with a spectral resolution complete to degree/order 180. These coefficients can be used in gravimetric studies of the Earth lithosphere structure, isostasy, crustal loading, sedimentary basins and related topics. The global spectral crustal model is separated into 9 specific layers of the topography, bathymetry, polar ice sheets, sediments (3-layers) and consolidated crust (3-layers). The harmonic coefficients describe uniformly the geometry and density (or density contrast) distribution within each crustal component. The topographic and bathymetric coefficients are generated from the topographic/bathymetric model ETOPO1 and the global geoid model GOCO03s. A uniform density model is adopted for the topography. The ocean density distribution is approximated by the depth-dependent seawater density model. The ETOPO1 topographic and the DTM2006.0 ice thickness data are used to generate the ice coefficients, while assuming a uniform density of the glacial ice. The geometry and density distribution within sediments is described by the 3 stratigraphic layers of a laterally varying density model, and the same structure is used to describe the density distribution within the consolidated crust down to the Moho interface. The sediment and consolidated crust coefficients are generated from the global crustal model CRUST1.0. The density contrasts of the ocean, ice, sediments and remaining crustal structures are taken relative to the reference crustal density.

Muographic observations in Satsuma Iwojima, Japan

TANAKA, Hiroyuki[1*]

[1]Earthquake Research Institute, The University of Tokyo

Satsuma-Iwojima volcano continuously discharges large amounts of volcanic gasses without significant magma discharge. One of the proposed mechanisms of this continuous gas discharge is conduit magma convection. In this hypothesis, a magma conduit is connected to a deep magma chamber and a ”degassing” phenomenon drives convection. Once the volatile component is released (by degassing) at the top of the magma conduit, the degassed magma sinks through the non-degassed magma occupying the pathway. A continuous supply of non-degassed magma from the magma chamber ensures that there is compensation for the degassed magma and the cycle continues. In 2008, a muography detector was placed at the foot of Satsuma-Iwojima volcano, and it captured an image of a large, shallow depth, low-density region existing beneath the crater floor. Degassing magma, with its high proportion of bubbles, has been interpreted as being the low-density region, and its dimension (location and size) was compared to the results from other field measurements, laboratory and theoretical studies. In 2013, an improved muography detector was developed and placed at the same location as the 2008 observation to exploit advanced muographic images in Satsuma-Iwojima. The recent progress in muographic observations will be reported.

Conduit magma convection: Constraints from Muography

SHINOHARA, Hiroshi[1*] ; TANAKA, Hiroyuki[2]

[1]GSJ, AIST, [2]ERI, Univ. Tokyo

Muographic imaging is a powerful tool to radiographically reveal density structure of a shallow volcanic edifice with high energy muons and was applied to the rhyolitic dome of Iwodake, Satsuma-Iwojima in order to understand the conduit magma convection in this volcano. In this paper, we will discuss the constraints obtained by the muographic measurements performed in 2008 and their implication to the conduit magma convection model.

Conduit magma convection is a model to explain persistent degassing, that is continuous emission of large amount of volcanic gases without eruption and is driven by the density contrast between the ascending non-degassed magma and the descending degassed magma that is created by outgassing at the top of a magma column (Kazahaya et al., 1994). This model is commonly applied to less viscous basaltic magma systems but the application to andesitic or rhyolitic magma system is a matter of debate, because the large viscosity of these magmas can slow down the magma flows in the conduit. Although theoretical evaluation indicated that a larger diameter of a conduit can compensate the larger magma viscosity and can cause the rapid magma flows in the conduit, it is difficult to prove its occurrence under the ground, as the conduit magma convection is a steady state process with few seismic signals nor deformation. In contrast, the conduit magma convection suggests that intensive degassing occurs at top of a magma column, which is likely detectable as a low density zone in a shallow magma conduit system. Therefore the density structure survey the muon-radiography is an ideal method to reveal the size, shape and magnitude of density anomaly at the shallow volcanic edifice.

Quantitative re-evaluation of the muon radiography data at the Iwodake rhyolitic cone obtained by Tanaka et al. (2009) confirms the existence of a low-density body of 300 m in diameter and with 0.9-1.0 g cm^{-3} at depths of 135-190 m from the summit crater floor. The low-density material is interpreted as rhyolitic magma with 60% vesicularity on average, and existence of this unstable highly vesiculated magma at shallow depth without any recent eruptive or intrusive activity is considered evidence of conduit magma convection. The structure of the convecting magma column top was modeled based on density calculations of vesiculated ascending and outgassed descending magmas, compared with the observed density anomaly. The existence of the low-density anomaly was confirmed by comparison with published gravity measurements, and the predicted degassing at the shallow magma conduit top agrees with observed heat discharge anomaly distribution localized at the summit area. This study confirms that high viscosity of silicic magmas can be compensated by a large size conduit to cause the conduit magma convection phenomena. The rare occurrence of conduit magma convection in a rhyolitic magma system at Iwodake is suggested to be due to its specific magma features of low H_2O content and high temperature.

Development of coupled Stokes–DEM simulation scheme for geodynamical magmatic studies

FURUICHI, Mikito[1*] ; NISHIURA, Daisuke[1]

[1]Japan Agency for Marine-Earth Science and Technology

For geodynamical magmatic studies such as crystal settling at the melting roof of a magma chamber, we develop a robust and efficient simulation scheme for solving high-viscosity fluid and particle dynamics in a coupled computational fluid dynamics and discrete element method (CFD–DEM) framework. The high-viscosity fluid is treated by the Stokes-flow approximation, where the fluid interacts with particles via the drag force in a cell-averaged manner. The particles are tracked with contact forces by DEM. To efficiently solve such Stokes–DEM coupled equations, we propose two key techniques. One is formulation of particle motion without the inertial term, allowing a larger time step at higher viscosities. The other is a semi-implicit treatment of the cell-averaged particle velocity in the fluid equation to stabilize the calculation. We will explain some details of our model developments in the presentation. A series of numerical experiments shows that our proposed scheme can handle sinking particles in a high-viscosity fluid; such problems are difficult for the conventional CFD–DEM method. Then we will discuss our targeting geodynamical problems tackled with this simulation method.

Recent updates on the DIAPHANE project of muon tomography

MARTEAU, Jacques[1*] ; GIBERT, Dominique[2] ; DE BREMOND D'ARS, Jean[2] ; JOURDE, Kevin[3]

[1]Institut de Physique Nucleaire de Lyon, Univ Claude Bernard, UMR 5822 CNRS, Lyon, France, [2]Geosciences Rennes, Univ Rennes 1, UMR 6118 CNRS, Rennes, France., [3]Institut de Physique du Globe de Paris, Sorbonne Paris Cite, Univ Paris Diderot, UMR 7154 CNRS, F.

Density radiography with atmospheric muons aims at determining the density variations or the absolute densities of geological or large volume bodies. The density is measured through the screening effect on the incident muons flux induced by the presence of matter, like for the X rays in a standard medical radiography. We will present recent updates on the DIAPHANE project which studies volcanoes with this technique since many years and is now deployed in the Lesser Antilles (Guadeloupe, Montserrat), Italy (Etna), the Philippines (Mayon) and in underground sites (France and Switzerland). Time-of-flight techniques have been developed to improve the data analysis and provide significant results.

Muon radiography by nuclear emulsions - Report on activity in Italy

BOZZA, Cristiano[1*]

[1]University of Salerno and INFN

The nuclear emulsions technology has entered the field of muon radiography of volcanic edifices and faults in the last decade, and progressively attracted the interest of nuclear emulsion laboratories and experts from various countries. The historical first muographic image of a volcano was indeed generated by using this nuclear emulsion technology. In earlier times, large-scale application was limited by the readout time and manpower needs as the emulsion films had to be scanned by eye; modern fast automatic microscopes solved both issues with limited cost, and the readout and analysis speed increased by several orders of magnitude, opening the door to access muography that requires large statistics. The Italian nuclear emulsion groups of the Universities of Salerno, Napoli and Padova and the Laboratori Nazionali del Gran Sasso (INFN) have built an Italian network of scientists working on muography, establishing tight collaboration links with the Tokyo University Earthquake Research Institute; more Italian groups could join in the near future. The network performs many activities, from the preparation of emulsion film exposure, on-site data taking campaigns, to readout and data analysis.

Nuclear emulsions are usually cast in the shape of thin films (thickness in the range of 20-100 micrometers) coating transparent plastic bases. Even a single film can provide 3D tracks marking the passage path of ionizing particles, when observed by a dedicated microscope. Normally emulsions films are exposed in stacks, piling several sheets, so that a single particle, after development, leaves several aligned tracks, one in each film.

Automatic emulsion readout systems allow track detection and measuring on several m^2 of surface in few weeks, collecting large statistics, which is needed to investigate regions of high cosmic muon absorption. Angular resolution of the order of a few milliradians is commonly achieved, which gives the ability to discriminate relatively small details, depending on the distance between the detector and the observed volume. Currently, one line of research aims at developing faster and cheap film readout systems, based on commercial hardware, to increase the current data-taking speed by a factor 10 or better.

Emulsions are continuously sensitive, since the time of their production: while this is an advantage because they need no power supply, the lack of time discrimination makes data analysis for such detectors a delicate task. The high combinatorial background of 3D tracks, due to many months' pile-up, can be greatly reduced by exploiting the micrometric alignment precision of emulsion tracks. Application of nuclear emulsion data to muon radiography requires also particle identification. Multi-film stacks with interleaved slabs of dense scatterers (such as iron or lead), allow distinguishing soft particles, typically electrons/positrons from electromagnetic showers, from hard muons with 1 GeV/c momentum or higher. Dedicated simulation of the passage of hard muons through rock and in the emulsion-instrumented volume allows optimizing selection criteria and estimating purity and efficiency of the selection. Systematic errors on the predicted integrated flux, which is compared to the measured integrated flux, should be kept as small as possible; in turn, this requires proper modelling of the expected cosmic-ray muon flux, which demands specific efforts in some regions of the angular and energy spectrum, where the statistics is intrinsically lower. Simulation and modelling activities require specific software and sizeable computing resources and are shared amoung the collaborating groups.

Accounts are given of the status of muon radiography campaigns in which the Italian groups are mostly involved. The cases covered are Stromboli, Teide and the La Palma fault. For each case, the present situation, possible developments and future plans are also envisaged.

Development of Nuclear Emulsion Detector for Cosmic-ray Muon Radiography and Its Applications

MORISHIMA, Kunihiro[1*] ; NISHIO, Akira[1] ; KATO, Yoshito[1] ; NAKANO, Toshiyuki[1] ; NAKAMURA, Mitsuhiro[1]

[1]Nagoya University

We are developing nuclear emulsion and its automatic analysis system for cosmic-ray muon radiography (muography). Nuclear emulsion is very high-sensitive photographic film for detecting 3-demensional trajectories of charged particles like muon in its volume with the very high position resolution (sub-micron), which gives us the very high angular resolution (a few mrad). In addition, nuclear emulsion does not require electronic power, the size is very compact and the weight is very light. And also, it is easy to perform the tomographic analysis using multiple detectors placed around the target. These features have advantages in the field observation for the measurement of geoscience object, archeological object, or in the disaster area like Fukushima Dai-ichi nuclear power plant.

In the case of Fukushima Dai-ichi nuclear power plant, high radioactivity shielding and lack of electronic power supplies should be taken into account. Nuclear emulsion is the powerful candidate used in such area. We have conducted the basic study of muon radiography of reactor core at fast reactor Joyo, which belongs to Japan Atomic Energy Agency (JAEA), in order to demonstrate the imaging of the reactor core. The result validates the observation of the reactor core with high resolution.

We will present technical developments of nuclear emulsion, latest scientific results including other observed objects and future prospects.

Muon radiography Monitoring for Structural Survey of the Prambanan World Heritage Temple

HANAZATO, Toshikazu[1*] ; TANAKA, Hiroyuki[2] ; KUSAGAYA, Taro[1] ; OKAMOTO, Yumiko[1]

[1]Mie University, [2]University of Tokyo

Muon cosmic-ray can penetrate rocks and soils and give us projection of the path' density, therefore, muography technology has been successfully developed in the geological field for disaster prevention of volcano explosion 1). Furthermore, it was utilized to survey the inner condition of a blast furnace in a steel mill during its operation time. On the other hand, non-destructive tests are required, in general, to conduct structural survey of heritage structures with cultural and historical values. In particular, when World Heritage Monuments are surveyed, we have to follow this principle strictly. There are a number of World Cultural Heritages of masonry in seismic regions in the World. When their seismic safety is assessed, seismic structural survey is conducted by employing non-destructive tests. Considering that muography technology can be useful for structural survey of massive masonry structures as a non-destructive test, we installed the muon detecting system at the Prambanan Temples, World Cultural Heritage in Indonesia and monitored the muon cosmic-ray for 5 months. Here, the Prambanan Temples of stone masonry structures were severely damaged by Central Java Earthquake of 2006. We have been successfully involved in architectural and structural survey project conducted by an international and interdisciplinary team. The damaged masonry monuments have been restored after the earthquake, however, restoration work of Candi Siva, the oldest and highest monument of the Prambanan Temples, was not started yet, as its inner structural condition was unknown. If the inner structural conditions are revealed, 3-D finite element model is available for seismic structural diagnosis of such massive masonry structures. The scope of the present paper is to describe this challenge of non-destructive test utilizing muography technology for the Prambanan restoration project and to demonstrate applicability of this advanced technology to structural survey of World Cultural Heritages of masonry. The muon data obtained at the site indicated that the monument must have inner chambers that had been unknown. The date also indicated their sizes and locations. This information will be useful to provide analysis model for seismic evaluation.

An Application of Muography to Exploring Gigantic Masonry Architectures: Evolution in Pyramid ConstructionTechnique

OHSHIRO, Michinori[1*]

[1]Komazawa University

Since the technique of Muography was used for the pyramid of Khafre (second pyramid of Giza) by L. W. Alvarez in 1970, academic researches using non-destructive testing methods have been applied to some huge stone structures (ex. the Pyramid of the Sun in Teotihuacan, Mexico, by A. Menchaca-Rocha). Although Alvarez and his team attempted to find a new chamber in the pyramid, they couldn't find any hidden chambers. However, now it is thought that the result was unreliable because their muon detector was an old type. After Alvarez the muon detector was developed and contributed to the elucidation of mechanism of a volcanic eruption in recent years (e.g. Asama volcano and Satsuma-Iwojima Volcano by H. Tanaka et al). Applying this technique, the internal structures of the Shiva temple in the Prambanan temple compounds (Indonesia) and the Parthenon (Greece) is explorable. On the basis of those results, we are going to go back to the roots of Muography by Alvarez by revisiting the pyramid.

It is assumed that if it is possible to use Muography for the pyramids in Egypt (the oldest huge stone building in the world), in terms of the usage and volume of differing density of the stone (limestone and granite), it would make clear the developmental sequence and construction way of pyramids which has been impossible to know until now. Therefore, we can confirm the human ingenuity of earthquake-proof structures by ancient Egyptians. Most of the pyramids were made of limestone. Harder granite was sometimes used to encase the pyramids. If it can be made clear where two different kinds of stones were used and how much stone were used for the pyramids, we can take possession of previously-unattainable new information in the study of earthquake-proof structures of pyramids.

The developmental sequence of burial of ancient Egyptian kings and the transition of the outer shape are as follows:1.Simple graves, 2.Mastabas, 3.Step Pyramids, 4.Bent Pyramid, 5.Red Pyramid (true pyramid), 6.Pyramid of Khufu (true pyramid), 7.Pyramid of Khafre (true pyramid), 8.Pyramid of Menkaure (true pyramid).

Judging from the above-mentioned process, it is assumed that there were further stages in the development of pyramids. However, it is still not clear. If we have the opportunity to use muongraphy to the above pyramids (from the step pyramid of Netjerykhet to three true pyramids in Giza), we can put an end to speculation as to the evolution theory of the pyramid from the viewpoint of earthquake-proof structures and advancement of civilization.

Overview of Neutrino Geoscience

DYE, Steve[1*]

[1]Hawaii Pacific University

Radiogenic heating is a key component of the energy balance and thermal evolution of the Earth. Geo-neutrino observations from Japan and Italy are now measuring the radiogenic power of our planet. Although the error on the present measurement is too large to significantly constrain geological models, the potential of geo-neutrino observations is clearly demonstrated. This contribution traces the development of neutrino geosciences and discusses the prospects for geo-neutrino observations to inform geology.

KamLAND: geo-neutrino result

SHIMIZU, Itaru[1*]

[1]RCNS, Tohoku University

Geo-neutrinos are anti-neutrinos (elementary particles) produced in radioactive decays within the Earth. Those anti-neutrinos can be detected in a terrestrial experiment using interaction via weak force, however, due to extremely low reaction probabilities, there were no feasible experiments for a long time. Owing to the development of large-size anti-neutrino detectors, the observation of geo-neutrinos has been finally made, and then composition models of the Earth are constrained from the radiogenic heat estimate. In this talk, a precise measurement of geo-neutrino flux from the Kamioka Liquid-scintillator Anti-Neutrino Detector (KamLAND) in Japan will be presented. In addition, the recent situation of KamLAND anti-neutrino data will be reviewed. Following the Fukushima nuclear accident in 2011, the most of Japanese nuclear reactors has been subjected to a protracted shutdown, resulting in the low reactor anti-neutrino background. It provides a unique opportunity to measure the geo-neutrinos with an improved sensitivity. Based on this low background data, prospects of geo-neutrino sensitivity with KamLAND data in the near future will be shown, and discuss the ability of discriminating between Earth models.

Borexino: geo-neutrino results

SUVOROV, Yury[1*]

[1]Yury Suvorov

Geo-neutrinos are the electron anti-neutrinos produced by long-lived radioactive isotopes (such as U, Th and K) in the earth crust and mantle. Geo-neutrinos can be detected in kiloton scale organic liquid scintillator detectors located in underground laboratories. The detection reaction is the inverse-beta decay, which has a particular signature given by two correlated in space and time prompt and delayed signals.

In spite of the strong signature geo-neutrino can only be detected in massive low background set-ups designed for low energy (1 MeV) neutrinos.

Borexino at the GranSasso underground laboratory in Italy has been in operation since 2007 to search for sub-MeV solar neutrinos.

At present experimental studies of geo-neutrinos are carried out with Kamland at the Kamioka mine in Japan and with Borexino at GranSasso. The first attempt of a geo-neutrino measurement was done in Kamland in 2005. Only in 2010 and 2011 both Borexino and Kamland observed at more the 4sigma C.L. a signal from geo-neutrinos. The search of geo-neutrinos likewise the one of solar neutrinos for the sun provides a unique tool to probe the interior of the earth. Uranium and thorium from the crust and the mantle make the geo-neutrino flux on surface. The energy spectrum of the detected geo-neutrinos depends on the abundance of uranium and thorium and on the different beta decays in the two radioactive chains. A spectroscopy determination of the geo-neutrino signal can be done. This has been recently shown by Borexino. By means of this analysis the ultimate goal of the geo-neutrino search will be the determination of the uranium and thorium content in the mantle. For this purpose a combined analysis of more than one experiment results will be necessary. In this talk we will review the present status of geo-neutrino research. We elaborate on the recent results from Borexino and Kamland. The experimental difficulties and background sources will be discussed.

A reference Earth model for geoneutrinos

HUANG, Yu[2] ; MANTOVANI, Fabio[1*] ; RUDNICK, Roberta L.[2] ; MCDONOUGH, William F.[2]

[1]University of Ferrara - INFN of Ferrara - Italy, [2]University of Maryland, College Park, MD, USA

Geoneutrino data from the KamLAND and Borexino experiments provide insights into Earth's energetics and global radiogenic heat production. In 2014, SNO+ will begin to collect data; the era of the exploration of our planet through geoneutrinos is definitely open.

Detection of geoneutrinos provides quantitative information about the total amounts of U and Th in the Earth and their distribution within the different reservoirs (crust, mantle and possibly core). One of the greatest potentials of geoneutrino is to discriminate among the different models for the bulk composition of the Earth, which are based on cosmochemical arguments and geochemical and geophysical observations. In order to determine the U and Th concentration of the deep Earth from the geoneutrino signal, the regional and crustal contribution to the geoneutrino flux needs to be determined from detailed geological studies.

We developed a geophysically based, three-dimensional global reference model for the abundances and distributions of U and Th in a Bulk Silicate Earth (BSE) model. The structure and composition of the outermost portion of the Earth, the crust and underlying lithospheric mantle, are detailed in the reference model; this portion of the Earth has the greatest influence on the geoneutrino fluxes. The structure of the crust is based on 1^{o} x1^{o} surface map of the Earth discriminating layers of sediments, upper, middle and lower crust. For the first time three geophysical global crustal models based on reflection and refraction seismic body wave (CRUST 2.0), surface wave dispersion (CUB 2.0), and gravimetric anomalies (GEMMA) are studied with the aim to estimate the contribution of geophysical uncertainties to the reference crustal model.

On the base of new compilations of geochemical data for sediments, oceanic and continental crust, we estimate the expected geoneutrino signal and its uncertainties for the crust of the Earth. Evaluating the U and Th abundances and their uncertainties in middle and lower crust are a focus of this model, along with using seismic velocity data to determine the lithological nature of these layers. The fraction of felsic and mafic rocks in the deep portions of the continental crust has been estimated by comparing the velocities of longitudinal and transverse seismic waves reported in the crustal model with the laboratory values obtained for ultrasonic velocities of different rock types.

An updated xenolithic peridotite database is used to represent the average composition of continental lithospheric mantle. The geoneutrino signal from this reservoir is calculated for the first time and it exceeds that from the oceanic crust at all three existing detectors.

Geoneutrino signal at Earth's surface is calculated in TNU (Terrestrial Neutrino Unit) (see figure) and Monte Carlo simulation is used to track the asymmetrical uncertainties of different crustal inputs. The combination of the global crust model, detailed local crust models, and the measured signal for each detector provides the critical inputs needed to assess the global mantle signal and its uncertainty. Thus, the mantle signal at each detector and its uncertainty can be independently combined to place limits on acceptable models for the mantle's radiogenic power.

Can noble gas reservoirs in Earth's mantle be identified from the geoneutrino distribution?

SUMINO, Hirochika[1*] ; BALLENTINE, Chris[2]

[1]Geochemical Research Center, Graduate School of Science, University of Tokyo, [2]Department of Earth Sciences, University of Oxford

Noble gas isotopes in mantle-derived samples are key tracers of chemical heterogeneity in the Earth's mantle and of the origin of the atmosphere. Samples of mid-ocean ridge basalt (MORB) and ocean island basalt (OIB) provide a comprehensive understanding of mantle noble gases. MORBs show relatively uniform $^{3}He/^{4}He$ ratios and in a $^{21}Ne/^{22}Ne$-$^{20}Ne/^{22}Ne$ diagram form a mixing line between the atmospheric composition and the MORB-source endmember. The latter is formed by the addition of nucleogenic ^{21}Ne to the primordial Ne ("solar" or "Ne-B" composition, Ballentine et al., 2005; Honda et al., 1991; Trieloff et al., 2000; Mukhopadhyay, 2012). In contrast, OIB samples, which are derived from a deeper region of the mantle, can exhibit higher $^{3}He/^{4}He$ ratios and less nucleogenic Ne isotope compositions. The OIB characteristics provide evidence for a mantle source in which primordial He and Ne has been less diluted by addition of radiogenic ^{4}He and nucleogenic ^{21}Ne produced by the decay of U- and Th-series elements. Therefore, noble gas isotopic evolution in the mantle is directly related to the U and Th contents in their reservoirs. However, the reasons for the less-radiogenic/nucleogenic character of the plume source are under debate; it may be less degassed (e.g., Allegre et al. 1983; Kaneoka, 1983; Kurz et al. 1982; Porcelli and Ballentine, 2002; Porcelli and Elliott, 2008), re-gassed through volatile recycling (Holland and Ballentine 2006; Ballentine and Holland 2008), or depleted in U and Th by ancient melt extraction events (Parman, 2007; Albarede, 2008). Recent finding of different $^{129}Xe/^{130}Xe$ ratios (^{129}Xe is a product of extinct isotope ^{129}I, while ^{130}Xe is primordial) in the MORB and Icelandic plume source requires that a portion of the latter has been isolated from the MORB-source mantle over geological timescales (Mukhopadhyay, 2012). This finding is consistent with that the less degassed nature is essential for the high $^{3}He/^{4}He$ ratio of the plume source because high noble gas concentrations in the plume source is required to preserve Xe isotope heterogeneity against dilution by depleted or surface-recycled material with atmospheric or MORB-like $^{129}Xe/^{130}Xe$. If the plume source corresponds to the large low-shear-wave-velocity provinces (LLSVPs) or D" layer at the base of the mantle, it may indeed have existed since the formation of the Earth and cannot exclusively be composed of subducted slabs (Mukhopadhyay, 2012). This is consistent with high $^{3}He/^{4}He$ (primordial) and low $^{3}He/^{4}He$ (recycled) components in Polynesian OIBs (Parai et al., 2009). The geoneutrino distribution will shed light on this issue; the less degassed (i.e., primordial) plume source is expected to contain 30-40% of the total mantle U and Th and if the LLSVPs is dominated by undiluted primordial material this feature will generate a significantly higher geoneutrino flux than a LLSVPs dominated by ancient subducted slabs with U and Th contents most likely lower than the convecting mantle.

Subcontinental lithospheric mantle (SCLM) exhibits slightly lower $^{3}He/^{4}He$ ratio and more nucleogenic Ne feature (Gautheron and Moreira, 2002; Buikin et al., 2005), indicating it is enriched in U and Th relative to noble gases. Although U and Th concentrations in SCLM is estimated as 10-30 times those in the convecting mantle, its small volume fraction (ca. 1.5%) results in insignificant contribution to global geoneutrino flux. However, it may be significant for existing detectors located in or close to continental region such as KamLAND (Japan) and Borexino (Italy). An ocean-based or transportable detector like Hanohano (Sramek et al., 2013) is therefore expected to have a great advantage to reveal geoneutrino flux from the deep mantle.

On the origin of large-scale heterogeneity in the deep mantle: Thermo-chemical mantle convection in a spherical geometry

NAKAGAWA, Takashi[1*]

[1]IFREE, JAMSTEC

The origin of large-scale heterogeneous structure in the deep mantle, that is, large low shear velocity provinces (LLSVP) is still debated, which is between thermo-chemical [e.g. Nakagawa et al., 2012] and purely thermal [e.g. Davies et al., 2012]. If the large-scale heterogeneous anomalies in the deep mantle are generated by basaltic piles, the large-scale anomalies such as LLSVP may be enhanced for huge amount of heat source compared to the ambient mantle. Current efforts of geoneutrino observations attempt to detect the large-scale anomalous region of radioactive elements in the deep mantle [personal communication with H. Tanaka], which may have large-scale enhanced region of radioactive element in the deep mantle beneath the southern Pacific from test simulations of geoneutrino detectors. In addition, this approach could give an answer for the origin of large-scale heterogeneous structure in the deep mantle. Here we introduce our current numerical modeling of thermo-chemical mantle convection in a spherical geometry with self-consistently calculated mineralogy. The advantage of this approach is to include all phase transitions in the mantle without any linearization of physics of phase transition in mantle minerals and calculate seismic anomalies from thermo-chemical structure obtained from numerical modeling directly. In this presentation, we will show several important information on resolving this issue.

Anti-Neutrino Directionality with KamLAND

XU, Benda[1*]

[1]RCNS, Tohoku University

KamLAND holds its novelty in the observation of reactor anti-neutrino disappearance. After the great Tohoku earthquake in 2011, almost all nuclear power plants of Japan are closed for safety inspection. This Reactor-Off period offers a unique opportunity to study the directionality of anti-neutrinos from the earth and the remaining nuclear reactors with the liquid scintillator detector.

Tracking geo-neutrinos towards the future geo-neutrinography

WATANABE, Hiroko[1*]

[1]RCNS, Tohoku University

Directional sensitive neutrino detectors contributed to astronomy and particle physics. The solar neutrino problem was firmly believed by the directional measurement of solar neutrinos, and the atmospheric neutrino oscillation was confirmed by the zenith angle distribution for two types of neutrinos. Liquid scintillator detectors are marked by the ability to detect low energy neutrino signals, such as reactor, geo, and extraterrestrial neutrinos. On the other hand, liquid scintillator detectors do not have sensitivity of neutrino direction.

KamLAND (Kamioka, Japan) and Borexino (Gran Sasso, Italy) have showed the geo anti-neutrino detection realized by the event rate and energy spectra. We have begun to use neutrinos as " probe " to observe the Earth's interior. Geo-neutrino measurement does not have the sensitivity of its direction, so we can not distinguish the crust and mantle contribution.

It is hoped the development of new measurement technology to measure neutrino direction. Lithium-loaded liquid scintillator has the potential to have the high sensitivity of coming anti-neutrino direction. Directional sensitive detectors will contribute to the better understanding of the earth interior using geo anti-neutrino flux information. Other motivations are the earlier determination of supernova direction and improvement of oscillation sensitivity for reactor anti-neutrinos.

Geophysical Inversion of Geo-Neutrino Flux Data: Formulation for Reveling Chemical Structure in the Earth

TAKEUCHI, Nozomu[1*]

[1]Earthquake Research Institute, University of Tokyo

Observation of geo-neutrino flux enables us to constrain distribution of radiogenic heat sources in the Earth (e.g., Enomoto et al. 2007, EPSL). Although the data provides unique information, resolution was limited because the observed data has been just one scalar quantity (geo-neutrino flux at the observational site). However, recent challenge to directional measurements by the RCNS group will greatly improve the resolution, because the observed data becomes a vector quantity with large dimension (geo-neutrino flux as a function of incident angle and azimuth).

In this study, I will formulate geophysical inverse problem to effectively constrain where and how much we have radiogenic heat sources in the Earth. Following procedures by Enomoto et al. (2007), we first categorize reservoirs of radiogenic elements (e.g., crust, bulk mantle, slab and LLSVP) and develop a reference distribution model of radiogenic elements in the Earth. We then compute a synthetic geo-neutrino flux pattern (as a function of incident direction) for each reservoir category. We assume that the observed flux can be expressed by linear combination of synthetic patterns and define their coefficients as model parameters.

The optimal coefficients can be obtained by solving an inverse problem. If the reference model is perfect, every coefficients should be equal to one. If the optimal coefficient deviates from one, it suggests that the assumed concentration was not appropriate for that reservoir category. This formulation should be useful for geophysical interpretation. For example, if the coefficient for LLSVP is large, we can suggest that a large amount of crustal material is accumulated in the LLSVP.

At the time of presentation, besides the details of the above formulation, I plan to show expected resolution when we use data obtained by the ongoing KamLAND experiment.

Hanohano: Future deep ocean geo-neutrino measurement

LEARNED, John[1*]

[1]University of Hawaii

Neutrinos from the decay chains of Uranium and Thorium from within the Earth's mantle constitute a vital signature of the origin of most of the heat thought to be driving all of geodynamics. The only means conceived as yet to study the magnitude and geographical distribution of the flux of mantle geo-neutrinos is from a large and mobile deep ocean detector. This study cannot be done from crustal locations due to the ovewhelming flux of neutrinos from local rocks. We present a description of the Hanohano Project, aimed at opening this new discipline.

Prospects of Earth Composition Measurements via Neutrino Tomography at Next-generation Neutrino Detectors

ROTT, Carsten[1*]

[1]Sungkyunkwan University

The Earth matter density is well determined through seismological measurements, however the chemical composition of the Earth has not yet been measured and only been inferred from meteorite samples. The Earth interior composition could be determined using neutrino tomography. Neutrinos are naturally produced in the Earth atmosphere and can be detected at neutrino telescopes. Neutrinos are elementary particles that are extremely light and only rarely interact, so that they can traverse the entire Earth without being absorbed. For the measurement, one can utilize a unique property of neutrinos, which is known as matter induced neutrino oscillations. This effect changes the neutrino properties based on the electron density of the medium through which the neutrino travels.

The dependence on electron density is what allows us to get a handle on the composition of the Earth. While seismological measurements determine the matter density, so to speak the average mass of nuclei, the oscillation effects depend on the electron density. In combination we can determine the average Z/A, where Z is the proton number (number of protons per nucleus) and A is the atomic mass (number of protons and neutrons per nucleus). The talk will introduce the measurement and discuss prospects at next-generation neutrino detectors like PINGU and Hyper-K, that could perform it.

The Hyper-Kamiokande Project

YOKOYAMA, Masashi[1*]

[1]The University of Tokyo

In this paper, we present the baseline design and expected performance of the Hyper-Kamiokande detector (Hyper-K)[1,2], a next generation underground water Cherenkov detector proposed in Japan. Hyper-Kamiokande is a successor of Super-Kamiokande (Super-K), which has been producing epoch-making results in particle physics and astrophysics, most notably the discovery of neutrino oscillation, since 1996. A water Cherenkov detector measures properties of elementary particles by detecting Cherenkov light, which is emitted when a charged particle travels faster than the velocity of light in water. Although neutrino itself does not emit Cherenkov light, it can be detected via particles produced in interaction with matter. Because the interaction probability is very small, a gigantic detector is necessary for the study of neutrinos. Water Cherenkov technique is the only solution to realize a Megaton scale detector with currently available technology. The design of Hyper-K is based on the highly successful Super-K, taking full advantage of a well-proven technology. The science goals of Hyper-K include not only the study of neutrino properties, but also broad topics in particle physics, astrophysics and geophysics.

Hyper-K consists of two cylindrical tanks lying side-by-side, the outer dimensions of each tank being 48 (W) 54 (H) 250 (L) m^3. The total (fiducial) mass of the detector is 0.99 (0.56) million metric tons, which is about 20 (25) times larger than that of Super-K. The inner detector region is viewed by 99,000 20-inch PMTs, corresponding to the PMT density of 20% photo-cathode coverage (one half of that of Super-K). In order to enhance the performance of the detector and to reduce the construction cost, new types of photosensors are under development. The design of critical components such as excavation of large caverns, mechanical structure of the tank, and water purification system is established. Further R&D towards detailed technical design, together with study of science cases, is ongoing by an international working group consisting of more than hundred scientists from eleven countries over the world.

Hyper-K presents unprecedented potential for precision measurements of neutrino oscillation parameters and discovery reach for CP violation in the lepton sector. Hyper-K can extend the sensitivity to nucleon decays beyond what was achieved by Super-K by an order of magnitude or more. The scope of studies at Hyper-K also covers high precision measurements of solar neutrinos, observation of both supernova burst neutrinos and supernova relic neutrinos, and dark matter searches.

Although the main motivation of the Hyper-K project arises from particle physics and astrophysics, thanks to its large volume and excellent performance, Hyper-K will be also able to contribute to geophysics by detection of neutrinos coming through the inside of the earth as discussed in [1]. The prospects for geophysics using Hyper-K will be discussed.

Testing Geological Hypotheses Using Particle Physics

HERNLUND, John[1*] ; TANAKA, Hiroyuki[2]

[1]Earth-Life Science Institute, Tokyo Institute of Technology, [2]Earthquake Research Institute, Tokyo University

Installations of muon and neutrino observatories are yielding an increasing spirit of collaboration between particle physicists and Earth scientists interested in leveraging their resources and techniques and to apply them to major outstanding scientific problems in both fields. This comes at a very good time, as experimental methods and seismological analysis has increasingly illuminated the frontier of Earth's deep geological structure, leading to new ideas and hypotheses regarding the evolution of Earth since its formation. Particle geophysics offers unique new tools to test hypotheses regarding the geological evolution of the entire Earth, some of which should help to break through non-uniqueness hurdles that arise using more traditional approaches. Here we discuss some of the frontier problems in Earth science, and describe some potentially novel approaches that may lead to breakthroughs in our understanding of our planet. One already well-known application involves detection of anti-neutrinos generated by naturally occurring radioactive decay processes in Earth's interior, the strength and distribution of which is sensitive to different hypotheses regarding Earth's origin and evolution. Other approaches, which will be made possible using the high energy detectors in Antarctica, is the determination of the electron density inside the Earth. This is especially useful, since the electron density is sensitive to the molar fraction of elements in solution inside bodies like the core, while seismology is only sensitive to the weight percent of those solutes. Here we show how combining this independent information will help to solve major questions such as the composition of the core.

Review of the recent muon radiography observations by using nuclear emulsion detector

MIYAMOTO, Seigo[1*]

[1]The University of Tokyo

Nuclear emulsion is one of three dimensional particle tracker which have micron position resolution and the feature that no electricity so we can put this detector everywhere easily and also this is suitable for non-fixed point observation.

Several observations for volcanoes were done and will be done from 2011 to 2014. The imaging the of Unzen lava dome, which was formed from 1991 to 1995, was done by Miyamoto et al and they found the detector got many back ground particles and the amount is more than several times than expected muon signal. this implies that we are on the stage of background particle study.

The emulsion cloud chamber (ECC) is a modular structure made of a sandwich of passive material plates such as lead interleaved with emulsion film layers. Nishiyama et al studied the source of background noise in cosmic-ray muon radiography using ECC. They found that the origin of background is expected to be electromagnetic components of air-showers or cosmic-ray muons scattered in topographic material whith momentums is less than 2GeV/c.

The shallow conduit shape of Stromboli will provide the important information for eruption dynamics modeling by Tioukov et al. Hernandez et al put the emulsion detector near the top of summit of Teide volcano to investigate the past eruption histroy of Teide. Teide volcano is located in Teferife, Canary Islands, Spain. They are also under observation of the fault appeared in La Palma, Canary Island, in 1949, which is the sign of huge land collapse or not. The width of the fault is expected to be 1 meter or less, so high position resolution of emulsion detector is suitable for this observation. They will measure the width, delth and the porosity of this fault.

Simultaneous inversion of muon radiography and gravity anomaly data for 3-D density structural analysis of lava domes

NISHIYAMA, Ryuichi[1*] ; MIYAMOTO, Seigo[1] ; OSHIMA, Hiromitsu[2] ; OKUBO, Shuhei[1] ; TANAKA, Hiroyuki[1]

[1]Earthquake Research Institute, University of Tokyo, [2]Usu Volcano Observatory, Hokkaido University

Cosmic-ray muon radiography (muography) has been utilized for obtaining the density profiles of volcanoes (eg. Tanaka et al., 2007; Lesparre et al., 2010; Cârloganu et al., 2013). Since gravity measurement is also sensitive to the internal density of the Earth, a combination of muography and gravimetry is expected to provide density profiles with fine resolutions (Okubo and Tanaka, 2012). Nishiyama et al. (2014) has developed a simultaneous inversion method of both two data for determining the 3-D density structures of volcanoes and has presented the feasibility of the hybrid measurement through a case study of a small (500 m in diameter) lava dome, Showa-Shinzan, Hokkaido, Japan. This study revealed that a vent extends downward beneath the dome.

We are now planning another hybrid measurement at Tarumai Lava Dome on the Shikotsu caldera, Hokkaido, Japan, in order to perform a comparative study on the internal structures of lava domes. The Tarumai lava dome has formed at the top of Mt. Tarumai during the 1909 eruption. We conducted gravity measurements at 23 stations spanning 1.5 km (NS) x 1.5 km (EW). We are preparing the muography detector for the coming measurement. We report the possible detector sites and the result of the resolution test of this new hybrid measurement.

Introduction about test measurement of the muon detection system for monitoring a groundwater (With some observations)

SANNOMIYA, Akira[1*] ; TANAKA, Hiroyuki[2] ; SUENAGA, Hiroshi[3] ; SUZUKI, Kouichi[3]

[1]Electric Power Development Co., Ltd, [2]Earthquake Research Institute,U of Tokyo, [3]Central Research Institute of EPI

The technique to radiographically image the internal structure of gigantic objects by utilizing muon's significant penetration power (muography) enabled us to investigate the internal structure of volcanoes and the city foundation with higher spatial resolution than possible with the conventional techniques.

This observation technique is applicable to exploring a large-scale civil engineering structure, the internal state of a base rock, etc. However, feasibility of muographic application to monitoring inside the large-scale civil engineering structure has not confirmed yet. Therefore, we decided to carry out test measurements in order to explore the possibility of muography for monitoring groundwater levels.

We are currently investigating the response of the groundwater levels to major rainfall events in the landslide area. We selected this area as an observation area. The measurement was carried out from the inside of a scupper tunnel in the base rock. Our muon detection system consists of plastic scintillator, photomultipliers (PMTs), and a high voltage (HV) power supply.

The muography detector was installed to the observation site in August, 2012 and measurement was started on the same date.

The result will be compared with the independent measurement results of groundwater levels and soil resistivity in order to quantitatively assess the technological limit of muography.

So far, we obtained the preliminary result that showed variations in the penetrating muon intensity; hence the density as a response of major rain fall events by plotting a moving average of the 48-hour observation time at different time intervals of one hour, two hours, three hours, and six hours. It showed a clear rainfall effect when the time interval is 6 hours. The future prospect includes further case studies for different rainfall-underground water coupling scenarios.

A Historical View on the Degradation on Seismic Performance of The Parthenon, Greece and Muography as the Potential Eval

AOKI, Shimpei[1*] ; TANAKA, Hiroyuki[2] ; OHSHIRO, Michinori[3] ; YAMASHITA, Maria[4]

[1]Faculty of Letters, Kansai University, [2]Earthquake Research Institute, the University of Tokyo, [3]Faculty of Letters, Komazawa University, [4]Graduate Division of Arts and Sciences, Komazawa University

To reinforce the Parthenon against earthquakes, the process of disassembling and reassembling Doric columns is obligatory. For this, the column strength and durability is required to withstand the reconstruction process. Wooden rods in the dowels of each drum provide the mechanical strength of each column, however some of these rods may have been damaged during the Venetian bombardment of the Acropolis on September 26, 1687. Due to the size of the Parthenon's Doric columns, muography is more appropriate to image the internal structure than conventional radiographic techniques. Muography may be utilized as a non-destructive technique targeting the inside composition of the Parthenon's Doric columns, potentially providing the following information: (1) the durability of the columns against future earthquakes, and (2) the magnitude of the internal damage sustained during the Venetian bombardment. The results of this muographic survey would aid conservator's efforts to protect the Parthenon along with the possibly of applying to other cultural properties. Secondly, the state of the wooden rod inside the column will provide evidence for the time and temperature around the column (based on the geometrical structure and thermal conductivity of the column) which would contribute further evidence to historical discussions particular to the Parthenon, such as estimates of the amount of gun powder stored in the Parthenon by the Ottoman Empire and information on the aforementioned siege. Muography may supplement efforts to preserve and protect the Parthenon as well as contributing to our understanding of the historical events that have occurred in this ancient structure.

Geo-neutrinos and reactor anti-neutrinos expected in Daya Bay II and in LENA

BALDONCINI, Marica[1*] ; ESPOSITO, Juan[2] ; LUDHOVA, Livia[3] ; MANTOVANI, Fabio[1] ; RICCI, Barbara[1] ; XHIXHA, Gerti[1] ; ZAVATARELLI, Sandra[4]

[1]University of Ferrara, [2]INFN, Legnaro National Laboratories, [3]University of Milan, [4]University of Genova

Geo-neutrinos produced by beta decays occurring in ^{238}U and ^{232}Th decay chains are presently detected via inverse beta reaction in liquid scintillation detectors (KamLAND and Borexino). Geo-neutrinos are a unique direct probe of our planet's interior since they instantaneously bring to the Earth's surface information concerning the total amount and distribution of U and Th in the crust and in the mantle, which are thought to be the main reservoirs of these elements. The geo-neutrino spectrum allows to discriminate the different Th and U components. Measuring geo-neutrino fluxes and spectra can shed light on the radiogenic contribution to the terrestrial heat power and on the Earth's nowadays composition, providing a direct test of the Bulk Silicate Earth models and giving additional constraints on the Earth's evolution models.

A better discrimination among different Earth's global models can be reached combining the results from several sites: new measurements of geo-neutrino fluxes are highly awaited from experiments entering operation, such as SNO+, or proposed to the scientific community, as LENA or Daya Bay II. In particular, LENA and Daya Bay II would provide a substantial increase of the detection sensitivity and of the event rate thanks to their large target masses (50 kton and 20 kton, respectively) compared to the 1 kton mass of KamLAND and SNO+ and to the 0.3 kton of Borexino.

The main background in geo-neutrino measurements is due to the electron anti-neutrinos produced by nuclear power plants, which are the strongest man-made anti-neutrino sources. Many fission products decay through beta processes with the consequent emission of electron anti-neutrinos, the so called reactor anti-neutrinos. The reactor anti-neutrino spectrum covers an energy range extending up to about 8 MeV, which results in a significant overlap between geo-neutrino and reactor anti-neutrino signals in the geo-neutrino energy window (1.8 $-$ 3.3 MeV). The events of reactor anti-neutrinos are strongly dependent on the distance of the closeby commercial nuclear power plants. Therefore, a careful analysis of the expected reactor anti-neutrino event rate at a given experimental site is mandatory.

In this framework, we estimate the expected reactor anti-neutrino signals at ongoing geo-neutrino experiments sites, in particular at Pyhasalmi and JUNO (Jiangmen Underground Neutrino Observatory), which are the candidate sites for hosting the LENA and Daya Bay II experiments, respectively. The inputs required to evaluate the reactor anti-neutrino flux come from neutrino properties, nuclear physics in the reactors and features of nuclear power plants. In our calculation we take into account the three neutrino oscillation mechanisms in vacuum, the most updated reactor anti-neutrino spectra and standard fuel compositions. According to the International Atomic Energy Agency (IAEA) database, we use detailed information on the locations and on the monthly time profiles of the thermal power for each nuclear core.

In Table 1 we report the expected geo-neutrino and reactor anti-neutrino signals for different locations, expressed in TNU (Terrestrial Neutrino Units). Nuclear power plants data refer to IAEA database reporting information of year 2012, when all of the Japanese nuclear power plants were still switched off. The ratio between the expected reactor anti-neutrino signal in the geo-neutrino energy window (R_G) and the expected geo-neutrino signal (G) is calculated all over the world in order to produce a R_G/G map. The values of R_G/G for future sites (Phyasalmi and JUNO) are almost comparable to the operating ones (LNGS and Kamioka), with a slight preference for the Finnish location. The total uncertainty on the reactor signal predictions is on the order of 5%: among all the accounted sources of uncertainties, the ones giving the main contributions originate from the θ_{12} mixing angle, the anti-neutrino spectrum, the fuel composition and the thermal power.

Keywords: geo-neutrino, anti-neutrino from reactor, neutrino detector

Sites	R [TNU]	R_G [TNU]	G [TNU]	R_G/G
LNGS	85.8 ± 4.6	22.8 ± 1.1	$40.3^{+7.3}_{-5.8}$	0.6
KAMIOKA	70.1 ± 3.7	18.7 ± 1.1	$31.5^{+4.9}_{-4.1}$	0.6

Towards a refined regional geological model for predicting geoneutrinos flux at Sudbury Neutrino Observatory (SNO+)

STRATI, Virginia[1*] ; HUANG, Yu[2] ; MANTOVANI, Fabio[1] ; SHIREY, Steven B.[3] ; RUDNICK, Roberta L.[2] ; MCDONOUGH, William F.[2]

[1]University of Ferrara, [2]University of Maryland, [3]Carnegie Institution of Washington

The SNO+ detector is the redeployment of the illustrious Sudbury Neutrino Observatory (SNO) at SNOLAB in Ontario (Canada). After the substitution of heavy water (D_2O) with liquid scintillator (CH_2) inside the inner vessel, in 2014 the 1 kton detector will come on-line and together with KamLAND in Japan and Borexino in Italy will accumulate geoneutrino events. Geoneutrinos are electron antineutrinos originating from beta decays of natural radioactive nuclides in the Earth interior. A fraction of them, generated from ^{214}Bi and ^{234}Pa of ^{238}U decay chain and from ^{228}Ac and ^{212}Bi of ^{232}Th decay chain, are above the threshold for inverse beta reaction on free protons and can be detected by SNO+. Geoneutrinos are a real time probe of Earth interior, because the flux at the terrestrial surface depends on the amount and distributions of U and Th in the Earth's reservoirs. To extract global information such as terrestrial radiogenic heat power or to test compositional models of the Bulk Silicate Earth (BSE), the regional contribution to the geoneutrino signal has to be controlled by study of regional geology.

We present the 3-D refined geological model of the main reservoirs of U and Th in the regional crust extended for approximately 2×10^5 km^2 around SNOLAB, including estimates of the volumes and masses of Upper, Middle and Lower crust, together with their uncertainties. According to the existing global reference model (Huang et al., 2013), this portion of the crust contributes for 43% of the total expected signal at SNO+. The remaining contributions come from the far field crust (34%), from continental lithospheric mantle (5%) and from the mantle (18%). Since SNO+ will accumulate statistically significant amounts of geoneutrino data in the coming years, the calculated signal that is predicted to be derived from the lithosphere can be subtracted from the experimentally determined total geoneutrino signal to estimate the mantle contribution.

The main crustal reservoirs are modeled by identifying three main surfaces: the Moho discontinuity, the top of the Lower Crust and the top of the Middle Crust. About 400 depth-controlling data points obtained from deep crustal refraction surveys and from teleseismic receivers are the inputs for the spatial interpolation performed with the Ordinary Kriging estimator. This method takes into account the spatial continuity of the depths and it provides the uncertainties of the crustal volumes. The Upper Crust is further modeled in detail combining information from vertical crustal cross sections and Geological Map of North America at 1:5,000,000 scale. Seven sub-reservoirs with distinctive characteristics lithologies, metamorphism, tectonic events and chemical composition are identified. The density and the abundances of U and Th in the seven sub-reservoirs are evaluated from the published litho-geochemical databases, including analyses of representative outcrop samples. The Middle and Lower Crust densities and radioactivity contents are evaluated from seismic constraints.

The numerical 3D model consists of about 9×10^8 cells of 1 km $\times$ 1 km $\times$ 0.1 km dimensions. For each of them geophysical information, such as latitude, longitude, depth and reservoir type, are combined with estimates of the U and Th abundances to predict the geoneutrino signal at SNO+ originated from the regional crust. The total geoneutrino signal at SNO+ is about 12% less than that calculated using the global reference model (Huang et al., 2013).

Upgrade plan of the KamLAND detector for improvement of sensitivity to geo-neutrino

OBARA, Shuhei[1*]

[1]RCNS, Tohoku University

Neutrino, which is a kind of elementary particles, interacts with other particles only via weak interaction. RCNS, Tohoku University, researches the neutrino science with the large neutrino detector, KamLAND. Measuring the geo-neutrinos that are produced in beta decays within the Earth ′ s interior, is only way to estimate the Earth ′ s radiogenic heats production and constrain composition models of the Earth.

The KamLAND detector is marked by the ability to detect low energy electron-type anti-neutrinos. Radioactive isotopes, such as ^{238}U and ^{232}Th decay as follows, and produce the electron-type (anti-) neutrinos (geo-neutrino).

^{238}U$\rightarrow$ ^{206}Pb+8 ^{4}He+6e^{-}+6$\nu^{bar}{}_{e}$+51.7[MeV]

^{232}Th$\rightarrow$ ^{208}Pb+6^{4}He+4e^{-}+4$\nu^{bar}{}_{e}$+42.7[MeV]

Geo-neutrino flux directly informs us the radiogenic heat generation. In fact, previously, the KamLAND experiment has given the result; the radiogenic heat production in the Earth ′ s interior by ^{238}U and ^{232}Th is estimated to be $20.1_{-9.1}{}^{+9.1}$ TW through measuring the geo-neutrinos, and it is obviously smaller than the Earth ′ s total heat flow (44 ± 1TW).

In order to improve the sensitivity of the KamLAND detector, the upgrade plans (KamLAND2 experiment) are in progress. Large light intensity liquid scintillator, light collection mirror, high quantum efficiency photomultiplier, imaging device, scintillation film, etc...

In the KamLAND2 experiment, improving energy and vertex resolution are expected. Therefore it will be possible to observe geo-neutrinos with higher accuracy and statistics. This experimental improvement will have higher ability to discriminate between models and separate contributions from ^{238}U and ^{232}Th. The KamLAND2 will play a contribution to the geo physics in that way.

In this presentation, future prospects and R&D are discussed.

The next-generation KamLAND electronics

HAYASHIDA, Shingo[1*]

[1]Research Center for Neutrino Science, Tohoku University

KamLAND was constructed to detect the low energy anti-neutrinos. And then, KamLAND detected reactor neutrinos and solved solar neutrino problem on 2003. And furthermore, KamLAND detected geo-neutrinos for the first time in the world on 2005. Currently, KamLAND has already been beginning to search several new physics. However, searching new physics in the detector of 10 years ago is difficult. So, it is necessary to update the detector. We are planning to update the KamLAND. As this updating, KamLAND electronics will be renewed using the latest technologies. The next-generation KamLAND electronics will certainly contribute to geoscience.

Imaging detector

MITSUI, Tadao[1*]

[1]RCNS, Tohoku University

Geo-neutrinos are emitted from radioactive elements, such as Uranium and Thorium, in the Earth's interior. Those elements contribute about one half of Earth's heat source. With high transmissivity of neutrinos, geo-neutrino may enable us to measure heat sources in the deep mantle. Since 1-kton liquid scintillator detector "KamLAND" detected geo-neutrinos in 2005, it has been expected as a new probe of Earth's interior. At present, an Italian detector "Borexino" is also observing geo-neutrinos, realizing a "stereo observation". However, observation points are still not enough. In addition, lack of the directional information of geo-neutrinos are serious disadvantage in making the data more precise. We are now developing a new detector for directional measurement of geo-neutrinos, aiming at installing it in KamLAND in the near future. Geo-neutrinos are electron antineutrinos being detected with an inverse beta decay channel with a free proton. Directional information of the neutron, emitted in the inverse beta decay channel, should be measured, in order to measure the direction of the incoming electron antineutrino. To this purpose, we are developing liquid scintillators doped with Lithium-6, which has large neutron capture cross section, and imaging detectors, which detect the vertex position of neutron capture precisely. In this poster, imaging detectors, that we are developing, are reviewed. To detect feeble light emission of the scintillator (actually one photon level), and determine the emission position precisely, optics with large acceptance and small aberration, together with a light detector with high quantum efficiency and positional sensitivity should be employed. In our current R&D, a hopeful design is that with a mirror of diameter 50 cm, and a 256-channel multi-anode photomultiplier tube. Highlighting that design, we will review the latest progress, plan of installing it, expected geophysical results.

Li loaded liquid scintillator for directional measurement

SHIRAHATA, Yutaka[1*]

[1]RCNS, Tohoku University

By the detection of the electron antineutrino using the current liquid scintillator, we can suppress the large background by the delayed coincidence of positron and neutron released by the inverse β-decay that proton and electron antineutrino cause. And we can observe electron antineutrino in the low energy scale.

On the other hand, we cannot know the coming direction of the electron antineutrino like the water Cerenkov method with the existing detector.But we can know the coming direction of the electron antineutrino by observing both reaction point of positron and capture point of neutron.If we could observe the coming direction of the electron antineutrino in the low energy scale, we would distinguish a neutrino every observation object and be able to expect observation with high precision.

There are three necessary conditions to detect the coming direction of the electron antineutrino by a liquid scintillator; (i)capture a neutron before losing directional information, (ii)cause luminous phenomenon at a neutron capture point, (iii)develop a new detection technology with the high position identification performance to detect the reaction points.

In current liquid scintillator, it takes about 200μs until a positron captures a thermal neutron released by inverse β-decay and this reaction emits 2.2MeV gamma ray. The released thermal neutron scatters about 10 cm, and so the neutron loses antineutrino $'$ s directional information. The neutron produces 2.2MeV capture gamma ray and it obscures the neutron capture point. To solve this problem, we developed ^{6}Li loaded liquid scintillator. ^{6}Li has large neutron capture cross section (940barn) and when ^{6}Li captures neutron, it releases alpha ray that it cannot move a long distance in the liquid scintillator. We can expect to solve two problems by using this new liquid scintillator and also to detect the coming direction of the electron antineutrino using imaging detector that has high position resolution.

In presentation, I will talk about the lithium loaded liquid scintillator developed by an original method.

Tomography of the earth with large-scale neutrino experiments

HOSHINA, Kotoyo[1*]

[1]Earthquake Research Institute, the University of Tokyo, [2]Wisconsin IceCube Particle Astrophysics Center

Experimental techniques to study inside of the Earth have been developing remarkably in the past decades. For example, in-situ x-ray diffraction measurements under high-pressure and high-temperature opened new era for studying about possible chemical components and structures of deep Earth. In the next ten years, we will obtain yet another technique for direct measurements of the Earth's interior.

Probing inner structures of the Earth with neutrinos has been discussed for more than 30 years. Neutrinos are chargeless particles and have very small cross-sections. They normally penetrate the Earth without any interaction, and from the rare interactions that do occur we obtain information on the density profile of the Earth's interior. However, the elusive characteristic of neutrinos poses a challenge for detecting them at experimental sites. To compensate for the small interaction cross-section, one needs a large volume neutrino detector.
The IceCube[1] neutrino observatory, completed in 2011 and has 1 cubic kilo-meter volume of detector size, is a possible candidate for this study. Current status of a study for measuring the core density of the Earth with atmospheric neutrino will be presented.

Another characteristic of neutrino is that they change their flavor periodically (neutrino oscillation). These oscillation patterns are affected by the density profile of electrons along the path of the neutrino. Comparisons between the Earth's mass-density profile and the electron-density profile give us ratio profiles of atomic number vs mass number (A/Z), which contains information of chemical composition of the Earth.

It is crucial to use a specific energy range for source neutrinos in order to perform the neutrino oscillation tomography. For Earth's core, the energy range is ˜1GeV to 30GeV. To detect the GeV-range neutrinos with sufficient statistics, next-generation experiments Hyper Kamiokande[2] and PINGU[3] have been proposed. Possible discrimination powers of some chemical models of the Earths core will be discussed.

Fig.1
Left: Exclusion of a pyrolite core model with respect to a pure iron core a time range of ten years. Right: The accuracy, measured in units of sigma, of the Z/A measurement for the assumption of an iron core. Calculated for PINGU[3].

Muographic imaging of Usu volcano with a multilayer detector

KUSAGAYA, Taro[1*] ; TANAKA, Hiroyuki[1] ; OSHIMA, Hiromitsu[2] ; MAEKAWA, Tokumitsu[2] ; YOKOYAMA, Izumi[3]

[1]Earthquake Research Institute, University of Tokyo, [2]Graduate School of Sciences, Hokkaido University, [3]The Japan Academy

Usu volcano is one of the most active volcanoes in Japan and has erupted for four times in the recent 100 years (1910, 1943, 1977-1978 and 2000). In the 1977-1978 eruption, 18 craterlets and a U-shaped fault were formed in the summit crater. The eruption also caused the deformation in the summit crater area with a diameter of 1.8 km and formed an upheaval called Usu-Shinzan.

Preceding studies suggested that the cooling magma intrusion with a height of 600 m and a width of 300 m was located below the Usu-Shinzan by magnetotelluric soundings (e.g. Ogawa et al., 1998, Matsushima et al., 2001). And Yokoyama and Seino (2000) built a tilt model to interpret the formation of Usu-Shinzan. In this model, a block with a width of 800 m tilted approximately 11^o on a pivot at a depth of 800 m. So, in the present work, we conducted the muographic imaging (radiography with cosmic-ray muon) of Usu volcano to confirm the existence of magma intrusion beneath Usu-Shinzan.

But there is the issue of background (BG) noise of muographic imaging for a large volcano (>1 km thick). Since the integrated intensity of traversing cosmic-ray muons steeply decays as a function of the thickness of the target, the signal-to-noise (S/N) ratio also decreases seriously as the size of target becomes larger, and thus the density distribution cannot be accurately measured at a large volcano. The background (BG) noise that reduces the S/N ratio mainly consists of the fake tracks that are generated by the accidental coincidence of the electromagnetic (EM) shower particles. The values of BG noise were 10^{-6} cm^{-2} sr^{-1} s^{-1} (Lesparre et al., 2012) and 10^{-7} cm^{-2} sr^{-1} s^{-1} (Carloganu et al., 2013). BG noise of 10^{-7} cm^{-2} sr^{-1} s^{-1} corresponds to integrated cosmic-ray muon intensity after traversing 1 km of 2.65-g cm^{-3} rock.

In order to solve this problem, we developed a novel muon detection system that consists of multiple layers of position sensitive detectors (PSDs) in conjunction with a trajectory analysis method to effectively reduce the BG noise. In this method, the EM shower-originated fake tracks are rejected by requesting a linear trajectory for a muon event (linear cut method) since EM shower particles randomly hit each PSD layer and make a non-linear trajectory in the detection system. This detection system was applied to Usu volcano, Hokkaido, Japan to image its internal density structure (the spatial distribution of the density). In this measurement, we utilized a muon detection system that consisted of 7 layers of PSDs. One PSD consisted of x- and y- arrays of plastic scintillator strips with an active area of 1.21 m^2 and a segmented area of 10x10 cm^2. The angular resolution was +/- 3^o. The measurement duration was 1977 hours (82 days).

In this measurement, we compared the integrated cosmic-ray muon intensity traversing 2500 m of 1.5-g cm^{-3} rock with observed data at an elevation angle of 55.6 mrad. Assuming that the residual between the calculated intensity and data is BG noise, we obtained the BG noises of 5.4x10^{-5} cm^{-2} sr^{-1} s^{-1} with two PSDs and 1.9x10^{-6} cm^{-2} sr^{-1} s^{-1} with seven PSDs. The multilayered muon detector was effective to reduce the BG noise. However, BG noise remains and they may be attributed to another source of BG noise such as upward-going particles(Jourde et al., 2013). This measurement yielded the following results: (A) by analyzing the region that has a thickness of more than 1000 m, we confirmed that our detection system is sensitive to a density variation of 10% in 1300-m rock; and (B) there are high- and low-density anomalies beneath between Oo-Usu and Usu-Shinzan peaks, which is consistent with the magma intrusion and the resultant fault generation suggested by Yokoyama and Seino (2000), Ogawa et al. (1998) and Matsushima et al. (2001).

For the future prospect, we will try to use the shield in order to distinguish the upward-going particles from muons arriving from a volcano side.

Open Access Issues in Physics Journals

UEDA, Ken-ichi[1*]

[1]Institute for Laser Science, University of Electro-Communications

I introduce some of Open Access activities in Physics journals.

1. arXiv, INSPIRE, SCOAP3

Open Access activities in Physics area have a long history and culture. The standard of judgement of physics papers is based on whether they give new knowledges or informations on human or not. We developed open access databases like arXiv and INSPIRE in 1991 at the beginning of WWW technology. High energy physics (HEP) has been a front runner of open data and open articles. SCOAP3 is a challenging program to serve OA services for top existing HEP journals not only to readers but also to the authors; most of the authors are poor theoretical physicists. Redirection of budget flow from subscription to SCOAP3 scheme is proposed. SCOAP3 started and challenge to stablish a long term sustainable model.

2. Public Access activities

Physics communities have delivered charge-free access to the journal database of societies via public libraries and high school libraries since early 90's. All physics papers are open to the people in US when they visit these libraries. Researchers and teachers of developing countries have a charge-free-acceess to the physics papers through International Center of Theoretical Physics (ICTP). Most of physical societies and publishing companies join the ICTP OA library. ICTP developed a lot of research support and educational programs under a support of UNESCO.

3. Charge-free Reading vs Charge-free Publishing

There are intense discussions on Gold-OA, which means charge-free reading journal. In 1997, the first Gold-OA journals such as Optics Express (OSA) and New Journal of Physics (IOP) were published. In 2003, Optics Expres reached breakeven point. Today OSA published more than 50% articles in Gold-OA journals with top IF in Optics. These Gold-OA journals demonstrated a sustainable model which satisfies high quality, article volume, and financial condition, altogether. Such a success was achieved by extraordinal efforts of editors group toward the new generation academic journals by online pubishing techniques. APS developed Gold-OA Physical Review X for the real top journal under a diffrect scope and vision. We understand Gold-OA is not a single issue, there are many variations in their scope and functions.

APS journals (Physical Review A-E, Physical Review Letters, etc) published more than 60% articles in Physics with high quality. The publicatin cost in APS journals is relatively low because authors send their manuscripts in REVTEX fromat. APS returned the benefit of electronic publication to the authors. The author-fee for Physical Review is zero when they send the manuscript in a manner of electronically acceptable format. The increase of subcriptions from Chinese institutions by WTO scheme contributed to their financial balance significantly.

How to share the scientific information with a reasonable cost, this is a main topics of OA movement today. However, we have to remind that the final target of information sharing is stimulation and activation of scientific activities. Physics communites have payed significant attention to the benefit of authors and readers in equal weight.

4. Try and Error, this is our principle.

Physics communities have made big efforts to improve the publication and access to the scientific informations last 20 years. Fortunately, Gold-OA journals in physics keep high quality by the effort of top societies like APS, IOP and OSA. The financial gain of Gold-OA is directly connected to the acception volume. This is an internal mechanism of Gold-OA. We need additional feedback mechanis to keep the scientific quality independently to the rejection rate. We have no rigid model for OA publishing and economical sustainability even now. It depends on the real situation of research and educational condition. Every academic community and every contry have to develop their own model accorting to their requirement, scope and decision.

Open Access to Academic and Scholarly Information and Scientific Data

MURAYAMA, Yasuhiro[1*]

[1]National Institute of Information and Communicatoins Technology

Scholarly and scientific information is the infrastructure of science and humanity in a broad sense. The first successful academic journal, Philosophical Transactions, in 17 century have resulted in open and sharing of academic literature or information. In modern Science and Technology research, information which cannot be expressed in a written journal paper, including numerical data, 3-dimensional geospatial information, voice and sounds, and movies. are increasingly being recognized important in international community. Considering that Open Access (OA) of academic journals is to support further advancement of science and technology in coordination with transition from printing culture to electronic media, scientific research data which can be open should be subject to the scientific information infrastructure. International data management activity like ICSU-WDS from the academic side, and RDA related to governmental arrangement are part of such big challenges of the international community. Data citation, using DOI as a persistent identifier attached to a data set, is promoted by international organizations such as WDS, RDA, DataCite, ICSTI, Force11, etc., jointly with science publishers such as Thomson Reuter, Elsevier, Wiley, and so on.

Toward the Founding of a Scholarly Publishing Consortium: UniBio Press Activities

NAGAI, Yuko[1*]

[1]The Zoological Society of Japan

This is a report on UniBio Press activities toward the founding of a scholarly publishing consortium as suggested by the Science Council of Japan Special Committee on Scholarly Publishing in August of 2012.

UniBio Press has, in collaboration with 8 other academic societies, adopted Strengthening International Dissemination of Information (A), and has spent this last year actively pursuing the creation of arenas for information sharing among, not only the participant academic societies, but for the whole of academic societies across Japan.

Renovation and future perspective of journal ”Earth, Planets and Space”

ODA, Hirokuni[1*] ; OGAWA, Yasuo[2]

[1]National Institute of Advanced Industrial Science and Technology, [2]Tokyo Institute of Technology

Earth, Planets and Space (EPS) is an academic journal published by the following five societies; The Society of Geomagnetism and Earth, Planetary and Space Sciences, The Seismological Society of Japan, The Volcanological Society of Japan, The Geodetic Society of Japan, and The Japanese Society for Planetary Sciences. The publication of EPS started in 1998 as continuations of the *Journal of Geomagnetism and Geoelectricity* and the *Journal of Physics of the Earth*. EPS is accepting scientific articles in the earth and planetary sciences covered by the five societies, in particular, geomagnetism, aeronomy, space science, seismology, volcanology, geodesy, and planetology. The 5-year publication project proposal on EPS to Grant-in-Aid for Publication of Scientific Research Results was accepted and open access publication has started from Jan. 2014. EPS is going to strengthen its international scholarly communication prioritizing letters, and will start publishing in cooperation with Japan Geosciences Union from Jan. 2016. Renovations of EPS including change of publishers and business model transition into open access carried out in FY2013 and the future perspectives will be presented.

Editorial policy and goal of Progress in Earth and Planetary Science

IRYU, Yasufumi[1*]

[1]General Chief Editor, Progress in Earth and Planetary Science

We at the Japan Geoscience Union (JpGU) launched a new open access e-journal called Progress in Earth and Planetary Science (PEPS) in October 2013. As its name suggests, the purpose of this journal is to publish papers that present new discoveries, ideas and unifying concepts in the various fields of earth and planetary sciences (space and planetary sciences, atmospheric and hydrospheric sciences, human geosciences, solid earth sciences, and biogeosciences). In addition to normal research papers and review articles we would also like to publish material based on the best presentations given at the JpGU Annual meetings, and we have asked and will ask session conveners from the meetings to recommend those presentations that they consider to be the most scientifically interesting.

Because PEPS is an open access journal, the following benefits can be provided to authors:
- All articles published by PEPS are made freely and permanently accessible online immediately upon publication, without subscription charges or registration barriers.
- Authors of articles published in PEPS are the copyright holders of their articles and have granted to any third party, in advance and in perpetuity, the right to use, reproduce or disseminate the article.

The authors will benefit from the e-journal as follows:
- No restrictions or limitations for pages, figures, tables, or additional files to enrich the content, including videos, animations, and large original data files.
- No cost for color figures/pictures.
- Fast publication?generally papers/articles can be published 3?4 months earlier in e-journals than in standard print publications.

By taking these advantages, we intend to make PEPS a top-level international journal, and therefore all submitted papers (including invited papers) will go through a full peer review process. In order to publish high level research papers and review articles, we have organized a strong editorial board composed exclusively of active scientists and asked them to ensure that the refereeing process is strict as well as fair.

The PEPS editorial team works and will work hard for PEPS. However success of this journal relies primarily on whether JpGU members submit many high quality manuscripts or not. We earnestly wait for your submission to PEPS.

Publication of Progress in Earth and Planetary Science by JpGU

KAWAHATA, Hodaka[1*]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo

JpGU started Open Access e-journal of Progress in Earth and Planetary Science (PEPS). The purpose of this new journal is to strengthen international communication in the field of geo- and planetary-science, and in particular: 1) To establish a geoscience open access leading e-journal; 2) To publish the best presentations from the JpGU Annual Meeting and the high quality of articles from authors based anywhere in the world, both those concerning specific areas of research and general unifying concepts and 3) To work on this together with the JpGU member societies. Efforts for the Promotion of PEPS are 1) to receive the list of the best presentation recommended by the session conveners at the JpGU annual meeting for PEPS submission and 2) to provide travel support and submission fee to submit a review (overview)/high quality articles. We will have the JpGU Journal special international session as part of the JpGU Meeting 2014, the JpGU Journal special symposium (relevant to JpGU research activity), invitation of big scientists recommended by each Science Section in JpGU, and enhancement of communication of the latest information on current research activity (e.g., published) among JpGU members and others. We are developing new application software that will be used at JpGU annual meeting place and at home. Also special effort is required to make PEPS recognized as a leading international journal by many scientists abroad. We will put an advertisement in AGU, EGU, AOGS and others. Our policy for JpGU journal is to publish high quality of articles in order to contribute to geoscience community globally. We present the latest information about JpGU journal and discuss its future development in this session.

Promotion of Scientific Research on Atmosphere and Climate System Using Aircrafts: Proposal of MSJ to SCJ

NIINO, Hiroshi[1*] ; KONDO, Yutaka[2] ; SATOH, Masaki[1] ; KOIKE, Makoto[2]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, [2]Graduate School of Science, The University of Tokyo

Aircraft observation systems along with artificial satellite and ground-based measurement systems are one of the most important tools for earth observations. Rapidly on-going climate change is already influencing our social and economic activities and water and food resources, which are bases for the civilization. Therefore it is important to understand the current status of the earth system and make reliable predictions of its future to avoid serious risks caused by the climate change.

The Working Group for Earth Observation Promotion, Subdivision on Research Planning and Evaluation, the Council for Science and Technology of the MEXT has summarized critical scientific issues for understanding of the global change in its annual guidelines in 2013. These include circulation and budget of the greenhouse gases, cloud and precipitation processes, changes in tropospheric species, climate change in polar regions, and changes in water circulation. The necessity of establishing aircraft observation system for conducting well organized long-term research of the global change is also mentioned. In-situ measurements by the state-of-the-art instruments on board aircraft provide accurate data of key parameters with high spatial resolutions, which lead to improved understanding of the critical processes.

The needs for research aircrafts have long been discussed among the Japanese research communities of atmospheric science and earth science. The Meteorological Society of Japan recently proposed a research project entitled ”Promotion of Scientific Research on Atmosphere and Climate System Using Aircraft” as a candidate for Master Plan of Large Research Project announced by the Japan Council of Science. This presentation gives a brief overview of the proposal. We plan to further polish up the research plans in the proposal and enrich the proposal by including possible subjects from other fields of earth science.

Long-term Observation of Atmospheric Greenhouse Gases using Aircraft

MACHIDA, Toshinobu[1*] ; MATSUEDA, Hidekazu[2] ; SAWA, Yousuke[2] ; MORIMOTO, Shinji[3] ; AOKI, Shuji[3]

[1]National Institute for Environmental Studies, [2]Meteorological Research Institute, [3]Graduate School of Science, Tohoku University

The more reliable prediction for future level of atmospheric greenhouse gases such as carbon dioxide (CO2) requires the quantitative understanding of global cycles in these gases. Comprehensive observation in atmospheric mixing ratios of trace gases can reduce the uncertainties of emission and absorption of these gases at earth's surface. The atmospheric observations, however, are not enough in several areas in the world, especially observations in upper atmosphere are quite limited compared to surface measurements.

Aircraft is one of the most reliable tools to observe the atmospheric compositions in troposphere and lower stratosphere. Several activities have been conducted to understand the 3-dimensional distribution and temporal variation of atmospheric greenhouse gases.

Mixing ratios of atmospheric CO2 have been measured from 200 to 10,000 m over Japan using chartered and commercial airliner since 1979 by Tohoku University (TU). Obtained data set is the longest record for CO2 mixing ratio in upper air. Latitudinal distributions of CO2 in upper troposphere are observed by commercial airliner operated by Japan Airlines (JAL) between Sydney, Australia and Narita, Japan, and Narita and Anchorage, USA from 1984 to 1985 by TU. The JAL observation in Australia-Japan route started again in 1993 using an Automatic Air Sampling Equipment (ASE) by Meteorological Research Institute (MRI). The new JAL observation named "Comprehensive Observation Network for Trace gases by AIrLiner (CONTRAIL)" have been done using improved ASE and Continuous CO2 Measuring Equipment (CME) since 2005 by National Institute for Environmental Studies (NIES) and MRI. Time series of CO2 mixing ratio in upper troposphere observed by old ASE and improved ASE are shown in the Figure. CONTRAIL-CME provides a large amount of CO2 data in upper air which contribute to solve global carbon cycle, atmospheric transport, model validation and satellite validation.

When dedicated aircraft is introduced in Japan, we propose to make a long-term observation for atmospheric greenhouse gases using above techniques and instruments.

Elucidation of atmospheric chemistry of reactive gases from airborne observations

KANAYA, Yugo[1*]

[1]JAMSTEC

Knowledge on spatio-temporal variations in the concentrations of tropospheric NOx, CO, and VOC is critical for closing the budget of OH radical, controlling oxidative capacity, and of O3, as a pollutant and a warming substance. Although recent satellite observations of tropospheric NO2, for example, have revealed regional/global distribution and seasonal features, they are based on column concentrations and thus limitation is present regarding information on vertical profiles and also on the spatial resolution.

In-situ airborne observations could provide complementary information with improved resolution in space, critical for validation of chemical transport model simulations. Validation of future satellite observations based on multi-spectral approach (e.g., O3 and CO), which could provide a piece of vertical profile information, is also important. Successful retrieval of near-surface concentrations, having impact on health and ecosystems, should be targeted.

Remote sensing from aircraft could enhance spatial (horizontal and vertical) coverage and resolution. For example, an airborne multi-channel imaging spectrometer in a nadir view could detect detailed inhomogeneity of NO2 and other gases present within cities at a 100-m resolution, contributing to studies on meso-scale atmospheric chemistry and physics. Limb observations in multiple angles could provide detailed vertical profile information.

In the presentation, observations of halogen and other unprecedented species, and observations to reveal air-sea or air-land interactions are also highlighted.

Aerosol measurements by aircraft and modeling studies

OSHIMA, Naga[1*] ; KONDO, Yutaka[2] ; KOIKE, Makoto[2] ; MOTEKI, Nobuhiro[2] ; TAKEGAWA, Nobuyuki[3] ; KITA, Kazuyuki[4] ; NAKAMURA, Hisashi[3]

[1]Meteorological Research Institute, [2]Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, [3]Research Center for Advanced Science and Technology, The University of Tokyo, [4]Faculty of Science, Ibaraki University

Most aerosol components scatter solar radiation; however, black carbon (BC) aerosols efficiently absorb it and lead to heating of the atmosphere. Because of these effects, the role of BC particles in the climate system has been recognized to be particularly important. However, there remain large uncertainties in the calculations of the spatial distributions of BC and its light absorption in current global models. One of the main causes is considered to be large uncertainties in the vertical transport and wet removal processes of BC adopted in aerosol models. Understandings of the vertical transport and wet removal processes of BC are critically important because they directly controls spatial distribution of BC and its radiative effects. To improve our understanding of these processes, aircraft measurements covering the entire altitude range of the troposphere are needed; however, there have been no aircraft observations of BC measurements covering the entire altitude range of the troposphere over East Asia since the ACE Asia and TRACE-P campaigns in spring 2001.

The Aerosol Radiative Forcing in East Asia (A-FORCE) aircraft campaign was conducted over the Yellow Sea, the East China Sea, and the western Pacific Ocean in March-April 2009 (Oshima et al., 2012; Moteki et al., 2012; Koike et al., 2012; Takegawa et al., 2013). During the campaign, 120 vertical profiles of BC particles, carbon monoxide (CO) concentrations, aerosol number concentrations, and cloud microphysical properties were measured at 0-9 km in altitude. The A-FORCE measurements showed that concentrations of BC were greatly enhanced in the free troposphere (FT) over the Yellow Sea. In this study (Oshima et al., 2012), the transport efficiency of BC (namely the fraction of BC particles not removed during transport) for sampled air parcels was estimated from changes in observed BC-to-CO ratios, because CO can be used as an inert combustion tracer within a timescale of a few weeks. The transport efficiency of BC decreased primarily with the increase in the precipitation amount that air parcels experienced during transport, and its value was about 70-90% and 30-50% at 2-4 km and 4-9 km levels, respectively.

Vertical transport and removal processes of BC over East Asia in spring were examined through numerical simulations for the A-FORCE campaign using a modified version of the regional-scale three-dimensional chemical transport model WRF-CMAQ (Oshima et al., 2013). The simulations reproduced the vertical distributions of the transport efficiency of BC observed by the A-FORCE campaign reasonably well, indicating the validity of the treatment of the wet removal processes of aerosols in the model. We identified three major transport pathways for BC export from East Asia to the western Pacific in spring. One pathway was the planetary boundary layer (PBL) outflow through which BC was advected by the low-level westerlies without uplifting out of the PBL (weak BC removal). The second pathway was through uplifting from the PBL to the FT by migratory cyclones over northeastern China and the subsequent eastward transport in the lower FT (moderate BC removal). The third pathway was orographic uplifting and/or convective upward transport from the PBL to the FT over inland-southern China followed by westerly transport in the mid-FT (strong BC removal).

We will introduce our studies with a particular focus on the importance of the aerosol measurements by aircraft and its importance for modeling studies in this presentation.

Aircraft measurements of aerosol-cloud interactions

KOIKE, Makoto[1*] ; MOTEKI, Nobuhiro[1] ; KONDO, Yutaka[1] ; TAKEGAWA, Nobuyuki[2]

[1]Graduate School of Science, University of Tokyo, [2]Research Center for Advanced Science and Technology, University of Tokyo,

1. Importance of aerosol ? cloud interactions

By serving as cloud condensation nuclei and ice nuclei, aerosols affect cloud droplet number concentrations and phase of cloud particles. These cloud microphysical changes cause cloud albedo changes and cloud adjustments (fast cloud response), such as changes in cloud liquid water path and/or cloud fraction. However, there are large uncertainties in estimations of these aerosol ? cloud interactions

2. Aircraft measurements

Satellite measurements can provide global view of the aerosol ? cloud interactions, however, quantities retrieved from satellite measurements are limited. Several artifacts are also known. Although aircraft measurements are limited in space and time, they can provide critical information to study aerosol ? cloud interactions, namely, aerosol and cloud droplet number size distributions. In fact, aircraft measurements have been intensively made over off the coast of California, Peru, and West Africa, tropical Pacific, Indian ocean, and Arctic ocean. Aircraft measurements act as a driving force to study aerosol ? cloud interactions.

3. Aircraft measurements in Asia

Aerosol concentrations in Asia are highest level in the world and they can potentially affect clouds forming over the Western Pacific. However, a number of aircraft measurements is limited. In this paper, results from aircraft measurements made over the Western Pacific during the A-FORCE-2009 and 2013S campaigns are shown. Future science of aerosol ? cloud interactions using aircraft is also discussed.

Evaluation of a result of a coupled atmosphere-ocean model around a tropical cyclone center using aircraft observations

SHINODA, Taro[1*] ; KUBO, Keishi[1] ; AIKI, Hidenori[2] ; YOSHIOKA, Mayumi[3] ; KATO, Masaya[1] ; TSUBOKI, Kazuhisa[1] ; UYEDA, Hiroshi[1]

[1]HyARC, Nagoya Univ., [2]JAMSTEC, [3]CAOS, Tohoku Univ.

Aircraft observations are enable us to understand the dynamical, thermodynamical, and microphysical structure of an inner region of TCs, such as their eye and eyewall. Numerical simulation is also a useful tool to clarify the structure of TCs, however, the reproducibility around the inner region of TCs could not be confirmed. This study shows an application of aircraft observations to evaluate the structure of a simulated TC using a coupled atmosphere-ocean non-hydrostatic model, Cloud Resolving Storm Simulator (CReSS) and Non-Hydrostatic Ocean model for Earth Simulator (NHOES), CReSS-NHOES.

The target typhoon is T1013 (Megi) developed over the tropical western Pacific Ocean in October 2010. During the Impact of Typhoons on the Ocean in the Pacific (ITOP), 200 dropsondes are dropped into and around T1013, including its eye and eyewall regions, from a height of about 2.5 km. Dropsondes can observe a vertical profile of pressure (height), temperature, humidity, wind direction, and wind speed. The profiles of these parameters are used to evaluate the simulation result using CReSS-NHOES. A simulation with horizontal grid resolution of 0.02 degree (approximately 2 km) is conducted for 7 days from 00 UTC on October 14, 2010, after one day of the formation of the T1013.

The simulation well reproduces its track and the tendency of the minimum central pressure. The reproduced minimum central pressure is 889 hPa and corresponds the observed one (885 hPa). To conduct the direct comparison between dropsonde observations and the simulation result, the target time of the simulation to compare with the observed one is determined to consider the value of minimum central pressure and its tendency. At the observed target time when conducted the dropsonde observations, the observed TC center is determined by the linear interpolation of the best track data provided by Japan Meteorological Agency. The simulated TC center at the target time is defined by the application to the Braun's method to the CReSS-NHOES output data. The location of the simulated profiles are determined by that of the dropsonde observations relative to the center of the TC at the simulated target time.

The eyewall region in this study is defined as the region that relative humidity of all layers is greater than 95% and maximum wind speed exceeds 25 m s^{-1} below a height of 2 km. The eye and outer region are defined by the inner and outer ones of the eyewall. The simulated potential temperature, mixing ratio of water vapor, and wind speed in the outer region are in the range of 1-sigma (standard deviation), thus, the simulated thermodynamic parameters are well reproduced statistically. After the rapid intensification of T1013, weak and maximum wind speed regions are reproduced in the eye and lower level of the eyewall, respectively. High potential temperature in the low-level of the eye is also reproduced. Thus, qualitative properties of the TC are well reproduced in the simulation. However, the simulated potential temperature is 3 K greater than that in the observation. And the simulated wind speed is 25 m s^{-1} lesser than that in the observation. The quantitative differences are expected to be caused by the difference of the structure of the eye. The problem on the structure of the eye appears in comparison with the application of the aircraft observations for the first time.

Aircraft observations over the Sea of Japan and the Sea of Okhotsk in winter

FUJIYOSHI, Yasushi[1*]

[1]Inst. Low Temp. Sci., Hokkaido Univ.

It is well known that the Sea of Okhotsk is one of the southernmost seasonal sea ice zones in the Northern Hemisphere. The importance of the relationship between the Sea of Okhotsk ice cover and regional/global climate has long been recognized. Indeed, recent research work has tied the extreme maximum and minimum wintertime extents of sea ice cover to large scale changes in atmospheric circulation patterns. Recent studies suggest that a possible origin of the North Pacific Intermediate Water (NPIW) is produced in the Sea of Okhotsk. Thus, there are important climate issues that are associated with the Sea of Okhotsk. It is also known that Japan, especially along the coast of the Sea of Japan, is one of the heaviest snowfall regions in the world. Snowfall is brought by banded snow clouds formed when winter monsoon air from Siberia is supplied latent and sensible heat from the Sea of Japan. These banded snow clouds are also frequently formed in the lee side of the sea ice over the Sea of Okhotsk, and play an important role in the growth of the sea ice.

Despite of the scientific importance of these areas in regional/global climate system, in-situ observations there are extremely few, especially in winter. This is due to the fact that the wintertime environment is generally harsh and is not conductive to making high quality measurements. However, in recent years instrumentation and technology have improved to the point where it is now possible to make the requisite wintertime measurements. In this regard, we conducted aircraft observations over the Sea of Okhotsk and the Sea of Japan.

We had deployed an X-band Doppler radar at Monbetsu on November of 2005, and started observation on 16 January of 2006. The height of sea-ice is different from place to place. Air-born laser altimeter is only the tool that can make horizontal distribution of the height of sea-ice. However, this method is very expensive and severely affected by weather condition. We tried to make a three dimensional display of sea-ice and suggested that our radar system could be used to study the irregularity of the height of sea-ice. Therefore, we measured horizontal distribution of height of sea-ice by using aerial cameras and compared it with 3Dimages of our X-band radar.

Use of Aircraft for Coastal and Oceanographic Research and Observations

ISHIZAKA, Joji[1*]

[1]Hydrospheric Atmospheric Research Center, Nagoya University

Aircraft should be useful to observe coastal and ocean environments, including physical, chemical and biological properties, especially under the raid, unexpected and dangerous conditions, such as typhoon or volcanic eruption, where ship operation is difficult. It is expected that there are two methods of observations from aircraft, other than seaplane, for oceanographic research; one is remote sensing and another is use of air-deployable sensors or platforms. Various remote sensing sensors are available using visible, infrared, microwave and sound waves. They have advantage to satellite-based remote sensors with high resolution and more flexible overflight, and they should be useful for coastal applications. Most of the remote sensing sensors can only obtain surface information; however LIDAR can detect vertical profiles of some parameters such as plankton distribution. Air-deployable sensors have been used for measurements of vertical profiles of temperature (AXBT; Airborne eXpendable BathyThermograph), salinity (AXCTD; Airborne eXpendable Conductivity Temperature and Depth probes), and current (AXCP; Airborne eXpendable Current Profilers). More recently, vertical profiling floats are developed and deployed for Argo project. There were attempts to deploy one of the vertical profiling floats, Electromagnetic Autonomous Profiling Explorer (EX-APEC), from airplane for typhoon observation and obtained profiles of temperature, density and currents. Autonomous profiling floats are now developing equipped with chemical, optical and biological parameters, and should be deployable from aircraft. Other various types of small autonomous underwater vehicles (AUV) are also underdevelopment and may be deployable from airplane in future. Combination studies of those physical, chemical, and biological parameters in coastal and ocean environments with atmospheric information, such as weather condition and chemical properties, are necessary to understand coupled atmospheric-ocean system.

Applicability of airborne remote sensing to terrestrial ecosystem sciences

SUZUKI, Rikie[1*]

[1]Japan Agency for Marine-Earth Science and Technology

Although the airborne remote sensing generally cannot be conducted repeatedly for a region during a multi-year long time period like satellite (space borne) remote sensing, the airborne remote sensing has many advantages in the observation of terrestrial ecosystem. One of them is, of course, the spatial resolution of the airborne remote sensing can be much higher than that of the satellite because the airborne platform flies at much lower altitude than satellite. Although WorldView-2 and GeoEye-1 provide high resolution images of land surfaces, it is practically hard to identify the individual tree in a forest, while the image of airborne remote sensing allows us to observe the tree crown structure and the forest floor condition. In 2000, an airborne remote sensing was conducted from spring to summer over forests around Yakutsk, eastern Siberia, and forest images were recorded by the onboard video camera from heights of 100 to 150m above the land surface. We examined the presences of green leaves in the crown of forest and the snow cover on the floor, and the spectral reflectance of the forest was investigated in relation to those conditions. The result suggested the reflectance from the forest floor significantly influenced the satellite-derived vegetation index (e.g. NDVI) in case of sparse boreal forests. The airborne remote sensing at a further lower height, several tens meters, enables us to indentify the individual leaf and insect, and subsequently, to study the biodiversity on individual basis. Recently, the remote sensing technique by airborne hyperspectral camera and LiDAR has explored a feasibility to identify species and retrieve the chemical trait and structure of vegetation. This methodology made a breakthrough for investigating the ecosystem function and biodiversity. Another advantage of airborne remote sensing is the capacity to select the observation geometry such as the incident angle of solar illumination and the view angle of the sensor. This capacity leads a robust development of radiative transfer model of vegetation based on the bidirectional reflectance distribution function (BRDF).

Ground Truth of Earth Observation Satellites using UAV

HONDA, Yoshiaki[1*] ; KAJIWARA, Koji[1] ; TANIGAWA, Satoshi[1] ; ONO, Yusaku[2]

[1]Center for Environmental Remote Sensing, Chiba University, [2]Earth Observation Research Center, Japan Aerospace Exploration Agency

Japan Aerospace Exploration Agency (JAXA) is going to launch new Earth observation satellite GCOM-C1 in near future. The core sensor of GCOM-C1, Second Generation Global Imager (SGLI) has a set of along track slant viewing Visible and Near Infrared Radiometer (VNR). These multi-angular views aim to detect the structural information from vegetation canopy, especially forest canopy, for estimating productivity of the vegetation. SGLI Land science team has been developing the algorithm for 10 standard products (above ground biomass, canopy roughness index, shadow index, etc).

In this paper, we introduce the ground observation method developed by using Unmanned Aerial Vehicle (UAV) in order to contribute the algorithm development and its validation. Mainly, multi-angular spectral observation method and simple BRF model have been developed for estimating slant view response of forest canopy. The BRF model developed by using multi-angular measurement has been able to obtain structural information from canopy. In addition, we have conducted some observation campaigns on typical forest in Japan in collaboration with other science team experienced with vegetation phenology and carbon flux measurement. Primary results of these observations are also be demonstrated.

New phase remote sensing stimulated by the use of airborne observation

KUZE, Hiroaki[1*]

[1]Center for Environmental Remote Sensing, Chiba University

Center for Environmental Remote Sensing (CEReS), Chiba University, is processing, archiving, and disseminating satellite data and related ground observation data to wide communities in remote sensing and environment-related areas. In the field of atmospheric remote sensing, we have established a radiometer network (SKYNET), which contributes to satellite data validation through characterization of atmospheric aerosols and clouds in East Asia. Also, the radiometer data are valuable for studying air pollutants due to anthropogenic activities when coupled with data from lidar and high spectral resolution spectroradiometer observations. Quantitative analysis of global biomass can be implemented by means of vegetation remote sensing. Methodology for obtaining highly accurate vegetation reflectance has been sought using satellite- and ground-based observations, as well as directional observation using unmanned helicopters. This approach has been exploited for developing an algorithm to be used for GCOM-C1, JAXA's next-generation satellite. In the field of microwave remote sensing, sensors based on circularly polarized synthetic aperture radar (CP-SAR) technique have been developed for both small satellites and unmanned aircraft applications.

Currently a new cooperative study plan is being discussed among university research institutes/centers based on chartering a manned airplane for scientific observation purposes. Through this initiative, it is expected that atmospheric science and climate system studies (University of Tokyo), cloud and precipitation system studies (Nagoya University), as well as high-level scientific application of remote sensing data (Chiba University) will be promoted. The primary goal of CEReS activity will be to achieve highly accurate remote sensing of vegetation, snow and ice fields, and coastal areas through the realization of high-precision atmospheric correction of satellite data, which would have been impossible without resorting to aircraft observation.

As more and more high resolution satellite data are becoming available, needs are growing for high-precision retrieval of physical quantities such as land or ocean surface reflectance. The largest obstacle for this improvement is the spectral changes due to atmospheric scattering and absorption. The influence of air molecules (Rayleigh scattering) can be corrected relatively easily. In contrast, correcting the effects of clouds and aerosols (Mie scattering) tends to be much more difficult, due to their temporal and spatial variability. Conventionally, network observation using a number of sunphotometers and skyradiometers has been implemented for measuring the optical properties of atmospheric aerosols and clouds. Also helicopter and unmanned air vehicle (UAV) measurements have been undertaken covering altitude ranges lower than 150 m above ground. Still, it is difficult to carry out the validation of satellite remote sensing imagery over an extended region.

The aircraft project currently under discussion will enable the measurements of radiation quantities and surface reflectance from high altitudes. The radiometer and hyperspectral camera measurements from both unmanned (low altitude) and manned (high altitude) platforms will allow us to improve radiative transfer algorithms indispensable for high-precision atmospheric correction. This, in turn, will contribute to dramatically improving the accuracy of algorithm for estimating biomass amount based on reflectance measurements. In addition, all-weather and both day- and nighttime surface observation can be demonstrated by equipping the CP-SAR instrumentation.

Aerosol particles collected using aircrafts from anthropogenic sources and biomass burning and electron microscopy

ADACHI, Kouji[1*]

[1]Meteorological Research Institute

Aerosol particles collected during four sampling campaigns using aircrafts were analyzed using transmission electron microscopes (TEM). The samples were collected from two A-Force campaigns in 2013 (winter and summer) conducted in Japan and Korea, BBOP campaign in 2013 in the USA, and MILAGRO campaign in 2006 in Mexico. These campaigns aim to characterize aerosol particles from regional transportation, biomass burning, and both. The samples collected using aircrafts are useful for characterization of particle agings, especially changes of their mixing states, from emissions as the aircrafts can chase plumes of different aging periods. An example of such aerosol-particle aging is tar ball formation in biomass burning smoke. Tar ball is spherical, organic aerosol particles commonly from combustion smoke of a wide range of biomass burning. At the early stage of the emission, tar balls are liquid but as they age in the smoke, they become solid and spherical. Sets of biomass burning aerosol samples with different aging stages collected using an aircraft revealed such processes in atmosphere. I will also discuss the samples collected over Japan during the A-Force campaigns.

Aerial observations for nitrogen compounds over the East China Sea

SADANAGA, Yasuhiro[1*] ; BANDOW, Hiroshi[1] ; ARAKAKI, Takemitsu[2] ; KATO, Shungo[3] ; KAJII, Yoshizumi[4] ; ZHANG, Daizhou[5] ; WATANABE, Izumi[6] ; FUJIMOTO, Toshiyuki[7] ; OKUYAMA, Kikuo[8] ; OGI, Takashi[8] ; SETO, Takafumi[9] ; TAKAMI, Akinori[10] ; SHIMIZU, Atsushi[10] ; HATAKEYAMA, Shiro[6]

[1]Osaka Prefecture University, [2]University of the Ryukyus, [3]Tokyo Metropolitan University, [4]Kyoto University, [5]Prefectural University of Kumamoto, [6]Tokyo University of Agriculture and Technology, [7]Muroran Institute of Technology, [8]Hiroshima University, [9]Kanazawa University, [10]National Institute for Environmental Studies

In order to clarify long-range transport of air pollutants from the Asian continent, we have conducted aerial observation over the East China Sea and measured air pollutants centering on aerosols, as part of Grant-in-Aid for Scientific Research on Innovative Areas " Impacts of Aerosols in East Asia on Plants and Human Health (ASEPH) " . In this presentation, the results of nitrogen compounds such as nitrate are mainly described.

The aerial observations were conducted in October, 2009 (autumn), December, 2010 (winter) and March, 2012 (spring) over the East China Sea. The flights were performed between Fukue Island and the southern offing of Jeju Island and the flight altitudes were 500, 1000, 2000 and 3000 m. Onboard measurements of gaseous total odd nitrogen species, gaseous nitric acid (HNO_3(g)), O_3, SO_2, CO and black carbon were made and particles were collected on filters for ionic and metal component analyses.

The concentration ratios of particulate nitrate (NO_3^-(p)) to inorganic total nitrate (T.NO_3 = HNO_3(g) + NO_3^-(p)) were less than 0.5 in most of the flights except under high concentrations of dust particles (Kosa) or transboundary air pollutants. Most of NO_3^-(p) would be $NaNO_3$ formed by the reaction of gaseous nitric acid (HNO_3(g)) with sea salt aerosols during the observations in autumn and winter except on October 17 and December 11, when high concentrations of Kosa were transported. In the spring observation, the fraction of $NaNO_3$ in NO_3^-(p) was low and a large part of NO_3^-(p) would be originated from reactions of HNO_3(g) with gas phase ammonia and soil dust particles.

O_3 concentrations decreased with altitude in autumn and increased in winter. Positive and negative correlations between NO_y-T.NO_3 and O_3 concentrations were observed throughout the flights in autumn and winter, respectively. This indicates that the major components of NO_y-T.NO_3 were secondary photochemical nitrogen oxides such as PANs and NO_x, in autumn and winter, respectively. The differences of vertical distribution and NO_y components between autumn and winter may be caused by the variation of solar radiation intensity.

Airborne lidar measurements of water-vapor profiles

ABO, Makoto[1*] ; NAGASAWA, Chikao[1] ; SHIBATA, Yasukuni[1] ; UCHINO, Osamu[2] ; NAGAI, Tomohiro[2] ; SAKAI, Tetsu[2] ; SHIBATA, Takashi[3]

Measurements of water vapor profiles are very important in studies of the atmospheric dynamics, aerosol growth effect and the eartlfs radiation effects. Water vapor is the predominant greenhouse gas and its vertical distributions are important parameters in model simulation of the global climate system. Passive remote sensing techniques from space provide global coverage of water vapor distribution but do not provide good vertical resolution, while lidar remote sensing techniques can provide high resolution measurements of water vapor distributions.

For future spaceborne water vapor DIAL systems, we developed a high power diode-pumped Nd:YLF laser and Ti:sapphire laser for water vapor DIAL. A Ti:sapphire laser is pumped by the SHG of the Nd:YLF laser. Tuning of the Ti:sapphire laser to a strong absorption line (ON1), a weak absorption line (ON2) of water vapor and an off line (OFF) is made by an injection seeder which consists of two single longitudinal mode laser diode modules. Two on-line laser diodes are locked to water vapor absorption lines using an absorption cell or a photo-acoustic cell. These three laser lines (ON1, OFF and ON2) are transmitted into the atmosphere with a triple pulse technique for measurements of water vapor profiles from the ground up to 10 km. The laser spectral width of the on line was 0.045 pm with a stability of 0.06 pm. The output energy of each laser line is more than 45 mJ. We have demonstrated airborne measurements of water vapor profile using this laser system.

Bioavailable energy distributions in the hydrothermal systems on Enceladus and early Earth

SHIBUYA, Takazo[1*] ; SEKINE, Yasuhito[2] ; RUSSELL, Michael[3] ; TAKAI, Ken[1]

[1]JAMSTEC, [2]University of Tokyo, [3]Jet Propulsion Laboratory

A recent research by Cassini spacecraft suggests that there are silica nanoparticles in Saturn ′ s E-ring derived from the Enceladus plume (Hsu et al., submitted). The findings of silica nanoparticles imply active water-rock reactions. Furthermore, an experimental study simulating the reactions between chondritic material and alkaline seawater revealed that the formation of silica nanoparticles requires hydrothermal reactions at temperatures higher than 100 deg. C (Sekine et al., submitted). Considering a short residence time of nanoparticles in the ocean, these studies imply geologically-recent or on-going hydrothermal activity in the Enceladus ′ subsurface ocean. Therefore, we modeled possible hydrothermal fluid/rock reactions and bioavailable energy in the mixing zone between hydrothermal fluid and seawater on Enceladus. The thermodynamic calculations of reactions between CI chondrite and alkaline NaCl-NaHCO3 seawater at 100 deg.C indicate that the pH of fluid increases up to about 10 and hydrogen concentration in the fluid is elevated up to 20 mmolal through the water/rock reaction. Based on the estimated fluid compositions, we calculated chemical property of the mixing zone between seawater and hydrogen-rich alkaline hydrothermal fluid, which revealed that the a certain level of bioavailable energy is derived from redox reactions based on CO2 and H2 in the mixing zone whereas there are unlikely other electron accepters such as sulfate and nitrate that are abundant in the terrestrial seawater. Thus, the CO2-H2 pair can be used for possible metabolic reaction, namely hydrogenotrophic methanogenesis and acetogenesis. In the low-temperature zone, the available energy of the Enceladus methanogenesis is higher than that of methanogenesis in the Rainbow field (Mid-Atlantic Ridge) where methanogens are certainly separated. It is therefore highly possible that H2-based energy metabolisms have been generated in the Enceladus hydrothermal vent system. Considering that the most ancient metabolisms in the Hadean terrestrial hydrothermal vent system could be also H2-based redox reactions, there is an energetic similarity between hydrothermal vent systems on Enceladus and Hadean Earth. The future exploration of Enceladus ′ plume would potentially provide clues to the origin of life on Earth.

Impact-induced D/L chiral changes of valine in early Earth's oceans

SEKINE, Toshimori[1*] ; TAKASE, Atsushi[1] ; FURUKAWA, Yoshihiro[2] ; KAKEGAWA, Takeshi[2] ; KOBAYASHI, Takamichi[3]

[1]Hiroshima University, [2]Tohoku University, [3]National Institute for Materials Science

It has widely known that proteins are composed of L-amino acid mononers and that nucleic acids contains exclusively D-sugars. Homochirality selection may be contributed to the consequence of life materials and their generation conditions. Regarding the enantiomeric excess in biomolecules, there are several proposals at present. Because the enantiomeric excess occurs in photoreactions by circularly polarized light, it has been believed that interstellar environments play an important role to the formation of chiral amino acids identified in chondrites and interstellar ices. However, it is also important to know whether the enantiomeric excess of amino acids occurs during oceanic impacts or not, because the enantiomeric enrichments are known under critical states of fluids due to density fluctuations.

We have investigated the shock-induced chiral changes of valine in aqueous solution coexisting with given solids. Powders of olivine, hematite, and calcite were selected to represent solids. Hypervelocity plane impact experiments were carried out using a propellant gun. Sample solution of each of L- and D-valine in sealed steel containers was subjected to impact at velocities of about 1 km/s. The calculated shock pressures are 5-6 GPa by the impedance match solution. The recovered solutions were analyzed with LC/MS (2695 separation module; Waters Corp. and Quattro micro API; Waters Corp) after the FDLA derivatization that makes a difference in hydrophobicity between D- and L-valine. The enantiomeric excess (ee(%)=100(L-D)/(L+D)), the yield of the initial valine, and shock pressure are plotted to see their relationship. The results indicate a difference among the solid. Although there was no significant change from the racemic valine solution, the reaction from L-valine to D-valine was significantly faster than that from D-valine to L-valine in calcite. The adsorption of calcite powders was checked to display no difference between D- and L-valine. These results may suggest that oceanic impacts may change the chirality of amino acids in oceans. However the enrichment of L-amino acids on the Earth need another mechanism.

The oldest remnant of life in 3.8 Ga old early Archaean rocks

OHTOMO, Yoko[1*] ; KAKEGAWA, Takeshi[2]

[1]Kochi Institute for Core Sample Research, JAMSTEC, [2]Graduate School of Science, Tohoku University

The suggestion that graphite in early Archaean rocks represents materials of biogenic origin has met with a degree of scepticism. Isotopic compositions of graphite in >3.7-billion-year-old rocks from the Isua Supracrustal Belt (ISB), western Greenland, which are believed to be of sedimentary origin, suggest that vast microbial ecosystems were present in early Archaean oceans. However, results of more recent studies suggest that most of graphite-bearing rocks were formed through interactions between crustal fluids and surrounding igneous rocks during later metasomatic events, thereby casting doubt on the existence of an extensive sedimentary sequence in the ISB and on the biogenic origin of constituents. In contrast, ^{13}C-depleted graphite globules, which are considered to form from biogenic precursors, have been reported from the metamorphosed clastic sedimentary rocks in the ISB. However, these were found at a single locality. It therefore remains unclear whether traces of life at other localities in the ISB were lost during metamorphism or were originally absent. The presence of additional clastic sedimentary rocks containing graphite may provide evidence for the preservation of organic constituents in early Archaean rocks, thus supporting the notion that microbes were active in early Archaean oceans.

We conducted a geological survey along the northwestern area of the ISB. Banded iron formations contain interbedded black to grey schist layers, typically 40-80 cm thick. Rare earth element patterns in samples lie close to that in Post Archaean Australian Shale, suggesting that the protoliths of the schist was clastic marine sediments. The black-grey schist samples contain abundant reduced carbon (0.1-8.8 wt%), identified as graphite by X-ray diffraction analysis. The range of δ^{13}C values was -23.8 to -12.5 per mil (average, -17.9 per mil), which is within the range of values reported in previous studies. Scanning transmission electron microscope and high-resolution electron microscope observations present different nanoscale morphologies between the graphite of metasediment and secondary vein samples. Examined metasediment included graphitic polygonal grains and nanotubes. Sheeted flakes were a dominant morphology of secondary graphite, whereas polygonal grains and nanotubes were absent from them, suggesting a different origin from the secondarily derived graphite.

We modelled the theoretical δ^{13}C values of fluid-precipitated graphites. The lowest δ^{13}C values exceed -16.4 per mil when Rayleigh-type isotope fractionation operates in the fluids. Therefore, ^{13}C-depleted biogenic organic matter in Isua clastic sediments is postulated as an initial carbon source to explain the lightest carbon isotope compositions (e.g., -23.8 per mil) in the present study. Distorted structures are common in pyrolysed and pressurized organic compounds. Such precursors commonly contain non-planar carbon ring compounds associated with abundant pores. Biogenic organic matter, which contains various molecules and functional groups, is suggested as the precursors of the graphite observed in metasediment.

In summary, the graphite in metasediment from the northwest ISB is distinct from the graphite in secondary vein samples. The combined information on geological occurrences, graphite morphologies, nanoscale structures, and isotopic compositions of the graphite in the metasediment suggests a biogenic origin of the graphite. High concentrations of ^{13}C-depleted graphite in these rocks would require widespread biological activity to support the high rate of production and sedimentary delivery of organic matter to the >3.7-billion-year-old ocean floor.

Mineralogical and geochemical study of clastic sedimentary rocks in Barberton greenstone belt, South Africa

KAWAI, Shohji[1*] ; KAKEGAWA, Takeshi[1]

[1]Graduate School of Science, Tohoku University

Cyanobacteria became active and oxidize surface ocean water in Archean. However, chronological constraint is still uncertain as to when ocean water became oxic. Some redox sensitive minerals in clastic sediments are often used to indicate the absence or presence of oxidative weathering, oxic sea water and diagenesis. Clastic sedimentary rocks in Barberton Greenstone Belt are studied by many previous investigators. However, detailed examination of redox sensitive minerals and elements are rare. Therefore, we set objectives of the present study (1) to investigate mineralogical and geochemical characteristics of clastic sedimentary rocks deposited in shallow water environments in ca.3.2Ga Moodies Group, (2) to discuss the origin of redox sensitive minerals in clastic sediments and (3) to decipher the redox conditions of the surface environments at the time of Moodies sedimentation.

We examined clastic sedimentary rocks (mainly sandstone) of the Joes Luck Formation in the Moodies Group. Samples were collected from drilled core collections of Sheba mine. All samples are belonging to Eureka Syncline blocks. Those samples are not affected by modern weathering.

The examined sandstones contained rounded quartz, K-feldspar, albite, minor zircon, and rutile. These minerals were detrital origins mainly from felsic crustal materials. Rounded chromite also occurs and we interpret that such chromite is a weathering product from mafic to ultramafic rocks. Rounded chromite is always surrounded by forming aggregates Cr-rich micas, and chromite never occurs without micas. We interpret that chromite was protected by micas, and survived from dissolution during weathering, transportation and diagenesis. Detrital pyrite and uraninite were not seen in these samples. Those mineral features indirectly indicate that presence of oxidative weathering, transportation and/or diagenesis at the sedimentation of Moodies Group. Geochemical analyses of the bulk samples indicate that most elements (e.g., Ti, Zr and V) are correlated to Al. Therefore, chemistry of examined samples are controlled by detrital components. On the other hand, Cu, Pb, Mn, and Mo are not correlated to Al, and apparently enriched in clastic sediments. Cu and Pb were mobilized in sediments during early to late diagenesis associated with late sulfide formations. Enrichment of Mn and Mo in the examined samples more reflected precipitation process from ocean water and diagenesis. In particular, enrichment of Mo is found in some samples with moderate amount of organic carbon. This suggests that Mo was dissolved in Moodies ocean water as oxidized species, and then reduced by microbial activities followed by sedimentation with organic matter. Overall results of this study suggested that oxygenic phototrophs already flourished in the photic zone of the 3.2 Ga ocean, making surface ocean water oxic.

Cerium stable isotopic fractionation as a potential paleo-redox proxy

NAKADA, Ryoichi[1*] ; TANAKA, Masato[1] ; TANIMIZU, Masaharu[2] ; TAKAHASHI, Yoshio[1]

[1]Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University, [2]Kochi Institute for Core Sample Research, JAMSTEC

Cerium (Ce) anomaly that appears in rare earth element (REE) pattern is a tool to estimate paleoredox condition and has been used for many studies. Discussion in previous studies, however, has been limited to qualitative one based on the REE pattern. This study, therefore, aims to provide more quantitative information on the redox condition in paleoenvironment by Ce stable isotope ratio related to the redox-sensitive property of Ce. If fractionations of Ce stable isotope responds differently to various geochemical processes such as (i) oxidative scavenging on Mn oxide, (ii) precipitation as $Ce(OH)_4$, and (iii) adsorption of Ce^{3+} without oxidation, it is possible that Ce stable isotope ratio can give more information on redox condition in paleoenvironment.

Cerium(III) chloride solution was added to manganese oxide and iron hydroxide, respectively, with the concentration of Ce systematically changed. In both systems, pH was adjusted to 5.00, 6.80, 8.20, and 11.0 ($\pm$0.05) and shaken for 6 hours before the filtration using 0.2 μm membrane filter. In addition, precipitation of Ce was obtained by bubbling of O_2 gas in the same $CeCl_3$ solution. Stable isotope ratios of Ce in both liquid and solid phases were determined using MC-ICP-MS at Kochi Institute for Core Sample Research. The $CeCl_3$ solution used in the adsorption experiment was employed as standard solutions and the isotope ratio of each element was expressed in delta notation relative to the average standards, which is shown in the equation as follows: δ^{142}Ce = [(142Ce/140Ce)$_{sample}$ / (142Ce/140Ce)$_{CeCl3}$ — 1] $\times$ 10^3.

Assuming equilibrium isotopic fractionation, the mean isotopic fractionation factor between the liquid and solid phases $\alpha_{Lq?So}$ of Ce adsorbed on ferrihydrite was within the analytical uncertainty for all the pH conditions. Meanwhile, the $\alpha_{Lq?So}$ of Ce adsorbed on δ-MnO_2 was gradually decreased with increasing pH. Most surprisingly, the $\alpha_{Lq?So}$ of spontaneous precipitation of Ce showed that, with increasing pH, the direction of the isotopic fractionation was in contrast to those in the adsorbed systems. These results suggests that the degree of mass-dependent fractionation of Ce can be used to clearly distinguish spontaneous precipitation from oxidative adsorption on δ-MnO_2, that occurs under more oxic conditions than the Ce(III)/Ce(IV) boundary. Our results suggest that the combination of the degrees of mass-dependent fractionation and chemical state of Ce can be used to classify the redox condition into the three stages based on Ce geochemistry, thereby offering a powerful tool for exploring redox conditions in paleo-ocean environments.

Decoding the Evolution of Early Atmosphere: Experimental Reconstraction of the D36S/D33S Chemostratigraphy

UENO, Yuichiro[1*] ; ENDO, Yoshiaki[1] ; MISHIMA, Kaoru[1] ; DANIELACHE, Sebastian[4]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [2]Earth-Life Science Institute (ELSI), Tokyo Institute of Technology, [3]Precambrian Ecosystems Laboratory, JAMSTEC, [4]Faculty of Science & Technology, Sophia University

Sulfur Mass-Independent Fractionation (S-MIF) has potential to monitor chemistry of the Earth's early atmosphere (Farquhar et al., 2000). Nonetheless, detailed mechanism of the S-MIF occurred in the Archean atmosphere is still poorly understood. Previous laboratory experiments indicate the anomalous isotopic fractionation depends largely on (1) wavelength or spectrum of the incident light source and (2) partial pressure of SO2, though none of these experiments have not yet succeeded to fully reproduce the S-MIF recorded in the Archean sedimentary rocks (e.g., Danielache et al., 2008; Masterson et al., 2011; Whitehill & Ono, 2012). We have developed a new photochemical chamber for determining isotopic effect of the SO2 photolysis under optically thin condition. Also, a new direct fluorination technique of carbonyl sulfide allowed us precise isotopic analysis down to 50 nmolS of photolysis product. The results indicate that the basic character of the S-MIF observed in the Archean record can be reproduced when SO2 column density is reasonably low (i.e. 10 to 50 times higher than preindustrial atmosphere). The results with a numerical modeling of the atmospheric reaction network suggest that the observed change in D36S/D33S ratio can be adequately explained by the two factors: (1) SO2 partial pressure and (2) amount of reducing gas (H2, CH4 and CO). In light of the new perspective, we have re-evaluated the geological record of the D36S/D33S ratio with additional analyses of Archean sedimentary sulfides from South Africa and India. Based on the magnitude of the S-MIF and the D36S/D33S ratio, the Archean period can be subdivided into four stages (i.e. › 3.0 Ga, 3.0-2.7 Ga, 2.7-2.5 Ga and 2.5-2.4 Ga). These changes probably reflect both intensity of volcanic SO2 emission and concentration of reducing gasses under the O2-free atmosphere. Particularly, the maximum scatter of D33S values observed in the stage 3 (2.7-2.5 Ga) requires high volcanic emission as well as very reducing atmospheric condition in the atmosphere at that time.

Archean Atmospheres Modeled with the KROME Chemistry Package

DANIELACHE, Sebastian[1*] ; UENO, Yuichiro[3] ; SIMONCINI, Eugenio[2]

[1]Sophia University, Faculty of Science & Technology, Department of Materials and Life Sciences, [2]INAF, Astrophysical Observatory of Arcetri, Italy., [3]Earth & Planetary Sciences, Tokyo Institute of Technology, [4]Earth-Life Science Institute (ELSI), Tokyo Institute of Technology

Sulfur isotopic fractionation has been used as a tool to understand the composition of reducing atmospheres. Our previous work (Danielache et al., 2008 and 2012) have shown that UV-light triggers a large Sulfur Mass-Independent Fractionation (S-MIF) on the SO_2 photodissociation products. However photodissociation of unshielded UV-light alone cannot reproduce the S-MIF signals reported for the Archean and Early Proterozoic (>2300 Ma) nor its large variability mainly at 2600 Ma (D33S = +11 ‰) (Johnston, 2011). In order to study a planetary-like chemical network capable of accounting for a sulfur cycle in reducing conditions we have introduced a high-order solver (DLSODES) administrated by the KROME (Grassi et al.,) chemistry package. The package automatically generates a set of FORTRAN subroutines with build-in rate equations and solves them with accuracy and e?ciency for sparse networks. This technique allows us to couple a detailed 4 sulfur isotopes chemistry to a 1D transport model capable of calculating the opacities influencing photochemistry and the temperature structure of an Archean atmosphere. We present preliminary results showing the ability of the code to deal with small isotopic fractionations and compare with already existing model studies of the Archean atmosphere.

Effects of atmospheric composition on apparent activation energy of silicate weathering

KANZAKI, Yoshiki[1*] ; MURAKAMI, Takashi[1]

[1]Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo

Silicate weathering is a major sink of atmospheric CO_2. Because CO_2 is an important greenhouse gas, silicate weathering regulates not only the partial pressure of atmospheric CO_2 ($P\mathrm{co}_2$) but also the surface temperature (T). The apparent activation energy of silicate weathering represents the temperature dependence of silicate weathering and thus interrelates the intensity of silicate weathering, $P\mathrm{co}_2$ and surface temperature. It has been reported that solution composition can affect the apparent activation energy of dissolution/precipitation of silicates (e.g., Casey and Sposito, 1992; Lasaga, 1995; Cama et al., 1999). However, the relationship between the solution composition and the apparent activation energy of silicate reaction is not yet fully understood.

To investigate the apparent activation energy of silicate weathering in a natural weathering system, we formulated the apparent activation energy of silicate weathering in three different scales, namely, (i) dissolution/precipitation of each mineral, (ii) elemental loss as the net reactions of the minerals and (iii) weathering flux from a weathering profile, based on the rate expressions in the three scales. It was found that, due to the effects of solution composition on the apparent activation energy, the temperature dependence of atmospheric CO_2 ($\Delta H^*\mathrm{co}_2$) affects the apparent activation energy of silicate weathering. Based on the formulated apparent activation energy, we estimated the apparent activation energy of silicate-weathering flux as a function of $\Delta H^*\mathrm{co}_2$. Then, the compensation law between the pre-exponential factor and the apparent activation energy of silicate-weathering flux was introduced from the literature, leading to the establishment of the relationship between silicate-weathering flux ($F\mathrm{co}_2$), T and $\Delta H^*\mathrm{co}_2$.

Based on the $F\mathrm{co}_2$-T-$\Delta H^*\mathrm{co}_2$ relationship and the greenhouse effects of atmospheric CO_2 in the literature, we calculated the ratio of change in $F\mathrm{co}_2$ to that in $P\mathrm{co}_2$ as an indicator of silicate-weathering feedback in the Precambrian. The calculation revealed that when $P\mathrm{co}_2 > \sim 10^{-0.5}$ atm, the feedback is negative and independent of $P\mathrm{co}_2$ and surface temperature. On the other hand, when $P\mathrm{co}_2 < \sim 10^{-0.5}$ atm, the feedback is independent of $P\mathrm{co}_2$ but dependent on surface temperature; at low ($< \sim 30$ ℃) and high ($> \sim 30$ ℃) temperatures, the feedback is negative and positive, respectively. Due to the positive feedback, the conditions of $P\mathrm{co}_2 < \sim 10^{-0.5}$ atm and $T > \sim 30$ ℃ are unstable, and immediately change, with a slight change in $P\mathrm{co}_2$, to either the conditions of $P\mathrm{co}_2 > \sim 10^{-0.5}$ atm or those of $P\mathrm{co}_2 < \sim 10^{-0.5}$ atm and $T < \sim 30$ ℃. When $P\mathrm{co}_2 < \sim 10^{-0.5}$ atm and $< \sim 30$ ℃, the feedback is not only negative, but also becomes more negative as temperature decreases, suggesting that global glaciations are harder to bring about than previously thought.

Kinetics and Mechanisms of Zeolite Crystallization at Hyperalkaline Conditions

FRANCISCO, Paul clarence[1*] ; SATO, Tsutomu[1] ; OTAKE, Tsubasa[1]

[1]Graduate School of Engineering, Hokkaido University

The predicted precipitation of zeolites in geologic barrier systems for radioactive wastes due to the alkaline alteration of bentonite may result in the modification or loss of favorable physicochemical properties of the bentonite as a suitable barrier material. Zeolites formation is typically preceded by an amorphous precursor, the transformation of which is seen as the rate-controlling step. However, the structure of the precursor phase and the rates and mechanisms by which it transforms into crystalline zeolites are poorly understood. In this study, we investigated the rates and mechanisms of zeolite crystallization from solutions.

Batch synthesis experiments were carried out over a range of solution compositions (Si/Al = 0.1 to 8.0), pH (9.5 to 13.5) and temperature (25C to 90C) conditions in order to clarify the effects of these parameters on zeolite crystallization. Solid products were characterized using XRD, SEM-EDX, FTIR spectroscopy, Raman spectroscopy and MAS NMR spectroscopy.

Zeolite crystallization proceeds by the rapid formation of an amorphous precursor phase, followed by the slower transformation of this precursor into crystalline zeolite. Depending on the Si/Al ratio of the parent solution, the species of zeolite may vary. At Si/Al >1, Faujasite forms slowly, whereas for Si/Al <1, Zeolite A forms more rapidly. Higher pH and temperatures favor transformation.

Morphological information from SEM shows intimate physical relationship between crystalline zeolites and the amorphous precursor phase. Spectroscopic results from FTIR, Raman and MAS NMR indicate that ring structures are present in both amorphous and crystalline phases, indicating structural similarity between the two phases. These data may suggest that amorphous phases transform directly into crystalline zeolites. The activation energy of crystallization suggests that solid-state processes occur alongside dissolution of the amorphous phase in order for the transformation of the amorphous phase into crystalline zeolite to proceed.

Effects on Phosphate Ion for the Phase Changes of Amorphous Calcium Carbonate

SUGIURA, Yuki[1*] ; ONUMA, Kazuo[2] ; YAMAZAKI, Astushi[1]

[1]Department of Creative Science and Technology, Waseda University, [2]National Institute of Advanced Industrial Science and Technology, Central 6

Under the biometric simulated environment, amorphous calcium carbonate (ACC) appears as initiation phase by reaction of calcium and carbonate ions. There is a strong relationship between the ACC phase and the forming crystalline polymorphs. We have shown a significant inhibit effect on the vaterite formation and calcite crystallized instead, and also stabilize ACC under higher PO4 concentration conditions. We hypothesized that PO4 ions incorporated in the ACC in that suspect that the adjusting the transfer mechanism of the amorphous phase. The structure and stability of ACC under various PO4 concentrations were examined using in situ ultra violet/visible spectroscopy (UV/Vis). Further, in order to observe in detail the coupling state, the ex situ measurement of ACC by Raman spectroscopy and by using a Ca ion electrode were performed to evaluation of the presence time of the ACC phase. The bicarbonate buffer was mixed with supersaturated solution of calcium chloride and sodium bicarbonate solution to precipitate the ACC, under conditions of pH ˜8.6. By mixing the potassium hydrogen phosphate at a concentration of any carbonate solution side during mixing, PO4 ions was adjusted between 0-50μM concentrations. The ACC contains no PO4 ions shows a spectrum similar to calcite. However the concentration of PO4 ions increase, UV / Vis absorption spectrum was carried out changed to spectrum like vaterite gradually. The similar behavior showed in the spectrum observed by Raman spectroscopy. By results of measurements of the molecular weight and particle size of the ACC by scattered light spectroscopy, the increasing both density and particle size of ACC was obsereved. Ion electrode measurements showed that the residence time of the ACC increased exponentially as increasing PO4 concentration.

In the presence of PO4 ion, ACC showed a structure similar to vaterite and its stability was increased. Moreover, the type of forming polymorphs greatly changes in variation of PO4 ions in μM scale, and stability amorphous structure is also highly variable. The results suggest a need to consider the effects of coexisting PO4 ions on ACC, when calcium carbonate tissue is formed in the organism.

Re-evaluation of mineral particles in geothermal fluid: Focus on polysilicic acid and adsorbed particles

YONEZU, Kotaro[1*] ; MASUDA, Chisato[1] ; MASUNAGA, Sachi[2] ; ETOU, Mayumi[2] ; WATANABE, Koichiro[1] ; YOKOYAMA, Takushi[2]

[1]Dept. of Earth Resources Engineering, Kyushu Univ., [2]Dept. of Chemistry, Faculty of Sciences, Kyushu Univ.

In geothermal system, the solubility of monosilicic acid concentration in geothermal fluid is controlled by physicochemical conditions. Once the supersaturated condition with respect to amorphous silica attained, the polymerization of silicic acid begins followed by the formation of the particles of polysilicic acid. In addition, the particles adsorbed on the solid surface can be a trigger for the further siliceous deposit. Therefore, in order to investigate the formation mechanism of siliceous deposit, the polysilicic acid particles formed by polymerization of silicic acid and the particles adsorbed on the solid surface in geothermal fluid are focused in terms of those size and chemical composition.

In this study, the polymerization mechanism of silicic acid is discussed based on the size variation of polysilicic acid in geothermal fluid as a function of time measured by dynamic light scattering (DLS) in addition to TEM observation of fractionated polysilicic acid. The filtered particles with different pore size and the adsorbed particles on the copper pipe are analyzed by SEM-EDX to characterize the particle size and chemical composition of the particles.

We expect that these results can be basic information for the prevention technology of siliceous deposit formation on the surface of heat exchanger during geothermal binary power generation.

Geomicroiology of Uranium - Challenges for the Deep Geological Environment

SUZUKI, Yohey[1*]

[1]Department of Earth & Planetary Science, The University of Tokyo

Our understanding of uranium mobility in the environment has been rapidly expanding in the past decades, especially due to problems associated with environmental remediation of uranium-contaminated sites and geological disposal of spent fuels composed mostly of UO_2. Although neither of these environmental problems was relevant in Japan, Fukushima Daiichi nuclear disaster has dramatically changed our situation. Despite the significant advancement, it is still difficult to predict the form, distribution and fate of uranium in the deep subsurface, as exemplified by studies of a Swedish geological disposal site where high concentrations of uranium was unexpectedly found in the granitic aquifer. In this presentation, the state of the art investigations of microbially mediated redox reactions and uranium mobility in the deep granitic aquifer at Mizunami Underground Research Laboratory (URL) will be presented to discuss factors controlling long-term uranium migration, as well as the relevance to the formation processes of Tono uranium deposit nearby the URL.

Haloarcula strains regulate transcription of two types of 16S rRNA genes by growth temperatures

SATO, Yu[1*] ; KIMURA, Hiroyuki[1]

[1]Graduate school of Science, Shiuzoka university

Translation is the process in which ribosome creates protein. The ribosome consists of two major components, the small and large subunits. In prokaryotes, small subunit of ribosome is composed of 16S rRNA and some ribosomal proteins. Many microbiologist use the 16S rRNA gene sequence for phylogenetic analysis and identification of prokaryotes. Previous studies have reported that the 16S rRNA gene sequence is naturally inscribed with the temperature adaptations of the prokaryotic host. This observation was based on the high correlation between the growth temperatures of prokaryotes and the guanine-plus-cytosine (G+C) contents of the 16S rRNA sequences. Thermophilic and hyperthermophilic prokaryotes generally have high G+C contents of 16S rRNA genes (56-69%). In contrast, mesophilic and psychrophilic prokaryotes have relatively low G+C contents of 16S rRNA genes (51-59%).

Haloarcula strains, belonging to a diverse group of salt-loving organisms in the archaeal phylum Euryarchaeota, have two types of 16S rRNA genes on the genome. These 16S rRNA genes indicate different sequences and G+C contents. Here, we proposed a hypothesis that *Haloarcula* strains preferentially expresses the high G+C contents of 16S rRNA gene (58%), having the stability to heat, during growth in high temperature, whereas they express low G+C contents of 16S rRNA gene (56%) during growth in low temperature. In order to verify this hypothesis, we surveyed transcriptional responses of *Haloarcula* strains in a wide range of temperature conditions by using RT-qPCR method. As the result, high G+C contents of 16S rRNA gene showed significant upregulation in high temperature conditions (40 to 55^{o}C). In contrast, low G+C contents of the 16S rRNA gene expressed at significantly higher levels in low temperature conditions (25 to 35^{o}C). The results suggest that *Haloarcula* strains regulate the transcription of two types of 16S rRNA genes by growth temperatures.

The effect of methane concentration on methanotrophic bathymodiolid mussels in the Okinawa Trough hydrothermal fields

MIYAZAKI, Yukari[1*] ; SUNAMURA, Michinari[1] ; ISHIBASHI, Junichiro[2] ; WATANABE, Hiromi[3] ; KONNO, Uta[3] ; SUZUKI, Yohey[1]

[1]Graduate School of Science, the University of Tokyo, [2]Graduate School of Science, the University of Kyusyu, [3]JAMSTEC

As methane (CH_4) is a greenhouse effect gas, the emergence and activity of CH_4-oxidizing organisms is suggested to have triggered global glaciation. Although the threshold concentrations of CH_4 for the growth of CH_4-oxidizing microorganisms under laboratory conditions are well known, CH_4-oxidizing organisms in the field is poorly constrained for the threshold concentration of CH_4 for growth. This information is critical to reconstruct atmospheric and oceanic CH_4 levels when the activities of methanotrophic organisms are indicated from geologic records with ^{12}C-enriched organic matter. We investigated sediment-hosted deep-sea hydrothermal fields in the Okinawa Trough where abundantly emitted $CH_4$is known to support methanotrophic ecosystem represented by Bathymodiolid mussels. The distribution of Bathymodiolid mussels and the CH_4 concentrations of their habitats were determined in five hydrothermal fields throughout the Okinawa Trough, and it is suggested that approximately 10μM is a threshold CH_4 concentration for the methanotrophic organism in the deep-sea ecosystem.

Biogeochemical cycles of iron and carbon in biogenic iron-rich sediment

KIKUCHI, Sakiko[1*] ; MAKITA, Hiroko[2] ; KONNO, Uta[2] ; SHIRAISHI, Fumito[1] ; TAKAI, Ken[2] ; TAKAHASHI, Yoshio[1]

[1]Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University, [2]Japan Agency for Marine-Earth Science and Technology

Biogenic iron oxides are the mixture of iron oxyhydroxides and organic materials which are produced by the metabolic activities of bacteria. These biogenic iron oxides work not only as adsorbent for various trace elements, but also as a source of iron and carbon for microorganisms. However, there is only little information about the degradation process of biogenic iron oxides and the effect to microbial activities after their sedimentation. Thus, the purpose of our study is to identify the spatial changes of iron species and microbial communities in biogenic iron-rich sediment (10 cm long).

We observed the existence sharp shifts for iron mineral species and microbial communities in the sediment. The dominance of ferrihydrite at the surface sediment (0-2 cm) subsequently turned into goethite and siderite at sediment depth 2-5 cm, corresponding to the iron reduction. However, iron reduction was depleted at depth deeper than 5 cm, as opposed to the remarkable increase of methane concentration. The microbial clone libraries were dominated by iron-oxidizing chemolithoautotrophic bacteria in the sediment 0-2 cm. In contrast, phylotypes represented by iron reducing and fermenting bacteria at 4 cm, and uncultured delta-proteobacteria and methnogenic archaea were recovered at 10 cm depth. These changes of iron mineral species, carbon metabolisms, and microbial communities only within a few centimeter intervals will also couple to the drastic change in cycles of trace element around the biogenic iron-rich sediment.

Interaction of nanoparticles with microorganisms

UTSUNOMIYA, Satoshi[1*] ; SHIOTSU, Hiroyuki[1] ; MASAKI, Shota[1] ; JIANG, Mingyu[1] ; OHNUKI, Toshihiko[2]

[1]Kyushu University, [2]JAEA

Nano-mineralization by microorganisms is a key process that can constrain the migration of actinides and REEs. This study demonstrates the REEs accumulation experiments to understand the effect of pH, coexistent REEs and the functional group of cells surfaces on the crystal chemistry of biogenic nanoparticle formation. During the experiment at 25 oC, all REEs were removed from the solution by 24 h at pH 4 and 5, while 50 % of the initial amount remained in the solution at pH 3 after 24 h. The nano-particles at pH 3 had monazite structure, while the particles forming at pH 4 and 5 were amorphous. The REE pattern at 24 h indicated the preferential uptake of LREEs. In case transuranic elements coexist, those elements should be preferentially incorporated into the particles compared to REEs. No cytotoxicity of CeNPs was detected; however, CeNPs induced an excess expression of two proteins: Eno2p and Rps24bp. The released organic substances enhanced anion adsorption and changed surface property of CeNPs. This leads to high colloid stability in solutions. This process is of great importance in the migration of radionuclides in the subsurface environment.

Microbial methanogenesis in coal seams and diatomaceous formations: Topics and application prospects

SHIMIZU, Satoru[1*]

[1]Horonobe Research Institute for the Subsurface Environment

1. Introduction

Microbial methanogenesis occurs in diverse subsurface environments. For example, biogenic methane has been detected from all representative ecosystems of the world and has been reviewed[1)]. However, the process of methanogenesis in those subsurface environments has yet to be revealed. Understanding the methanogenesis process is necessary for discerning the global-scale carbon-cycle and for a more effective utilization of biological methane as an energy resource from subsurface environments.

2. Methanogenic archaea from coal-beds and diatomaceous rock

Research topics on biogenic methanogenesis in the Ishikari (bituminous coal)[2)] and Tenpoku (brown coal) basin and the diatomaceous formations[3,4,5)] of northernmost Japan will be introduced in this presentation. We were successful in isolating and culturing methanogens from these habitats. In particular, the dominant methanogens isolated from diatomaceous shale formation[4,5)] will help in understanding some of the processes of methanogenesis in subsurface environments.

3. Biological methanogenic potential of coal-beds and diatomaceous rock formations as geobioreactors

The bottleneck of methanogenesis in subsurface environments is the production of suitable substrates for methanogens from persistent geomacromolecules. One of our approaches for eliminating the bottleneck is a geobioreactor for methanogenesis using hydrogen peroxide. Oxidation of low-rank coal using hydrogen peroxide produces a high yield of small-molecule substrates for methanogenic microorganisms (e.g., methanol, acetate, formate)[6)]. Substrate production from diatomaceous rock is considerably less than that from low-rank coal. However, the stratum thickness of diatomaceous rock (1 km or more) is much more than that of coal seams (several meters). Therefore, although the methanogenic potential of diatomaceous rock is low, by quantity, it constitutes an abundant resource. Furthermore, we have had success in microbial methanogenesis from small molecules produced from brown coal using hydrogen peroxide.

Transportation process of As in surface and shallow ground waters

MASUDA, Harue[1*]

[1]Osaka City University

Natural As contaminated groundwater has been a serious problem in the world. Instead of numerous studies, sources and pollution mechanism are still in debate. Most accepted source of As is Fe-oxyhydroxides that adsorb the As, and reduction-dissolution of the Fe-oxyhydroxides is believed to release the As into groundwater. Biotite and pyrite would be candidate sources of As, however, few studies assured the presence of As in those minerals. Here, transportation process of the As in surface water and As release mechanism in shallow sediments.

Arsenic is transported as dissolved components and suspended matters. Total As concentration of Red River water is ˜10 ppb, and dissolved As and As with suspended particles are 6:4. Although the Red River water contained gibbsite and goethite as suspended matters, those do not but clay minerals host the As as adsorbent. Concentrations of As of the riverbed sediments of Ganges-Bramaptra and Red Rivers are a few to 15 ppm, most of which are in insoluble detrital phases such as silicates and sulfides. Chlorite was the host phase of As in As contaminated groundwater aquifer in our study areas of Bangladesh and Pakistan, although different detrital minerals can host As in each rivers, of which tributaries As contaminated groundwater occurs. These results suggest that the transportation of As with detrital minerals is more important than that as dissolved components and adsorbed phases onto clay minerals and goethite.

In the shallow sediments, As concentration changes with redox potential and pH. Geochemical condition would be controlled by microbial activity in the aquifer. Dissolution of As occurs at the depths where detrital As host minerals are decomposed via oxidation. Newly formed Fe-oxyhydroxides would adsorb parts of the As but not all. Thus, the dissolution of As host minerals are the main reaction to cause As contaminated groundwater.

Adsorption behavior of organoarsenic compounds in soils

TANAKA, Masato[1*] ; TAKAHASHI, Yoshio[1]

[1]Graduate School of Science, Hiroshima University

The arsenic pollution is a world problem. Natural originated inorganic arsenic compounds are predominant cause of the water-related disease. In addition, anthropogenic originated organoarsenic compounds such as phenylarsonic acid (PAA) and diphenylarsinic acid (DPAA) are also pollution source. For example, DPAA polluted well water caused serious health problems in Kamisu, Japan [1]. These phenyl arsenic compounds are considered as a decomposition product of chemical warfare agents produced during World Wars I and II, and even now such compounds still remain in the ground [2]. Recently, adsorption and mobility of these aromatic arsenic compounds in agricultural soils have been investigated [3]. However, their adsorption mechanisms on soil are still unknown. In general, the adsorption property of chemical compounds influences its migration process in natural environments such as soil-water system. Thus, it is important to understand the adsorption mechanism of the arsenic compounds to predict future fate of them in environment. Recently, we reported adsorption structures of PAA and DPAA on ferrihydrite obtained by X-ray absorption fine structure (XAFS) analysis and quantum chemical calculations [4]. In this study, we conducted As K-edge XAFS measurements for organoarsenic compounds adsorbed on soil, as well as a sequential extraction, to understand their adsorption behavior in the soil. EXAFS analysis suggests that all arsenic compounds in this study adsorbed on Fe or Al (oxyhydr)oxide in the soil mainly regardless of the organic functional groups. This fact indicates that the Fe/Al (oxyhydr)oxide can control the mobility of organorasenic compounds in the ground.

Impact-induced produtcs from glycine polymers in early Earth's oceans

SEKINE, Toshimori[1*] ; KATSUKI, Yuto[1] ; SUGUMURA, Kousuke[1] ; KOBAYASHI, Takamichi[2]

[1]Hiroshima University, [2]National Institute for Materials Science

Early oceans may have contained appreciable amounts of prebiotic organic molecules, since previous studies have indicated that simple organic molecules are capable to be formed through oceanic impact processes by meteorites. Geologic evidence suggests that the root for the origin of life materials occurred just after or during the heavy bombardment period. At that time the impact energy is considered to have been important for molecules present in oceans to react. Shock reactions of organic molecules in aqueous solutions have been subject to few studies.

Here we investigate the reactions for glycine polymers (dimer G2, trimer G3, and tetramer G4) and alanilglyine (AG) in aqueous solutions in order to know their stability and reaction products during impacts. The starting G2 (>99.o% Tokyo Chemical Industry Co. Ltd), G3 (>98.0%, Tokyo Chemical Industry Co. Ltd), G4 (>95%, Tokyo Chemical Industry Co. Ltd), and AG (>98.0%, Tokyo Chemical Industry Co. Ltd) were used in the present study. Hypervelocity plane impact experiments were carried out using a propellant gun. Sample solutions of glycine polymers in sealed steel containers were subjected to impact at velocities of about 1 km/s. The calculated shock pressures are 5-6 GPa by the impedance match solution. The recovered solutions were analyzed with a hybrid Fourier transform mass spectrometer (Thermo Fisher Scientific LTQ Orbitrap XL) at Hiroshima University.

The analytical results for the recovered samples were compared with those for the initial sample. Limited numbers of amino acids of Glycine, alanine, and their polymers, amines from propylamine to octylamine, and carboxylic acids from acetic acid to decanoic acid were selected due to a measured range of their m/z values. The identification of a molecule was done by the presence of a peak with the calculated m/z value ($\pm$0.002). The results are discussed.

Effect of mineral species on the glycine polymerization

ONISHI, Hiroyuki[1*] ; KITADAI, Norio[2] ; FUKUSHI, Keisuke[3]

[1]Department of Nature System, Kanazawa Univ., [2]Earth Life Science Institute, Tokyokogyo Univ., [3]Inst Nature and Environmental Technology, Sci., Kanazawa Univ.

Protein is a major constituent of life on the earth, and is produced by polymerization due to dehydration condensation of amino acids. Polymerization of amino acids is an important process for the origin of life. The understanding of amino acid polymerization process in the earth surface environment is important for the origin of life. It is well known that polymerization of amino acids under the ambient condition is thermodynamically difficult. Therefore, how the amino acids polymerization in the early earth environment proceeded is still under debates.

Many model experiments for amino acid polymerization had been designed so far. Among them, one of the promising method is mixing the mineral powder with glycine solution with heating (e.g., Bujdak and Rode, 1997a). Bujdak and Rode, (1997b) was confirmed that alumina could promote alanine polymerization than Quartz. They suggested that the effect of mineral type is important on the polymerization of amino acids. However, it is not known which functions of the mineral affect the amino acid polymerization. After Bujdak and Rode, (1997b), amino acid polymerization experiments by using various type of mineral species has been widely examined. However, the experiment condition has not been unified among the studies. We cannot compare the effect of amino acid polymerization on each mineral. In present study, we conducted the experiments of amino acid polymerization using t various types of minerals (Rutile, Anatase, Amorphous silica, Quartz, gamma-Al2O3, Corundum, Hematite, Magnetite, Forsterite) under the unified experimental conditions. The purpose of the study is to clarify the factors for promoting the amino acid polymerization in mineral species.

Role of minerals for hydrogen generation in the interaction between ultramafic rocks and water

FUKUHARA, Naoki[1*] ; SATO, Tsutomu[1] ; OTAKE, Tsubasa[1]

[1]Laboratory of Environmental Geology, Hokkaido university, Graduate School of Engineering, Hokkaido U

Hydrogen generation by high temperature serpentinization is understood as hydration of mafic and ultramafic rocks, owing to the oxidation of reduced iron present in the olivine or pyroxene. On the other hand, in the Oman Ophiolite and Lost City Hydrotherrmal Field (LCHF) in the Mid-Atlantic Ridge, hydrogen is generated via low temperature serpentinization. Moreover, previous experimental study shown generating hydrogen at low temperatures (<100 degrees C). However, since even the rate of hydrogen generation by high temperature serpentinization is slow, the mechanism of hydrogen generation by low temperature in short period is yet to be explained. Therefore, the objective of this study is to clarify the mechanism of hydrogen generation via low temperature serpentinization for a short period. Batch experiments were conducted at 30 degrees C, 60 degrees C and 90 degrees C using minerals which constitute ultramafic rocks (olivine, Magnetite, Fe-Ni alloy), and serpentinite. Samples were taken after various reaction times (3h, 6h, 12h, 24h, and 1week). Liquid samples were analyzed by ICP-AES, ion chromatography, UV-Vis, pH, and ORP. Mineral phase changes in the solid samples were characterized by TG-DTA, SEM-EDX and XRD. The concentration of hydrogen gas was determined by GC-RGD.

Hydrogen generation was observed in all samples. Highest concentration of hydrogen gas was observed in the experiment using Fe-Ni alloy. In the experiment using Fe-Ni alloy, apparent surface change was not observed at the surface of Fe-Ni alloy. Therefore, hydrogen gas was generated by catalysis of Fe-Ni. The generation of hydrogen gas by this catalysis would be higher than that of generated hydrogen accomplished by the dissolution of olivine, which is the dominant mineral in the ultramafic rocks.

In this study, the hydrogen generation was confirmed at a temperature of less than 90 degrees C. The hydrogen generation process is catalyzed by Fe-Ni alloys or magnetite present in secondary minerals by serpentinization.

Spatial distribution of chromium enrichment in 3.2 Ga Moodies BIF, Barberton Greenstone Belt, South Africa

ISHIKAWA, Ko[1*] ; OTAKE, Tsubasa[1] ; KAWAI, Shohji[2] ; SATO, Tsutomu[1] ; KAKEGAWA, Takeshi[2]

[1]Division of Sustainable Resource Engineering, Graduate School of Engineering, Hokkaido University, K, [2]Department of Earth Science, Graduate School of Science, Tohoku University, Aoba 6-3, Aoba-ku, Senda

Geochemical data for ferruginous chemical sedimentary rocks (e.g., Banded Iron Formation: BIF) have been used to understand surface environments on early Earth. For example, enrichment of Cr relative to Ti in BIFs that occurred ˜2.48 billion years ago has been considered as a result of the chemical mobilization of Cr in acidic aqueous environments due to sulfide oxidation after the oxygenation of atmosphere. While the Archean sedimentary environments studied in most previous works are limited to deeper settings, the 3.2 Ga Moodies BIF in the Barberton Greenstone Belt, South Africa also indicated that Cr was enriched in the BIF and was therefore chemically mobile in a shallow marine environments. This finding could be significant because it may indicate the oxidation of, at least, some parts of the ocean and therefore, imply the emergence of oxygenic photosynthesis. However, spatial distribution of Cr enrichment in the BIF has not been well understood because the data were obtained from an outcrop and an underground mine. Therefore, the objective of this study is to investigate sedimentary environments and Cr enrichment of the Moodies BIF at another locality.

We conducted a geological survey of another outcrop of the Moodies BIF in the Eureka syncline located ˜10 km northeast of Barberton. The section of the BIF exposed in the outcrop was underlain by a conglomeratic quartzite, which is stratigraphically correlated with the BIF at Moodies Hills block in the previous study. Whereas the BIF at Moodies Hills block are 22m in the thickness and overlain by 122m thick silty sandstone and sandstone, the BIF in this study has a thickness of 36m and is overlain by a 103m thick layer of greywacke and silty sandstone. Petrographic observation of the BIF samples shows that the reddish layers are composed of microcrystalline quartz and fine grains of hematite (˜15μm), and that the black layers are composed of large grains of magnetite (˜50μm). These observations indicate that they are typical oxide-type BIF and therefore were originally formed as precipitates from seawater. Although chromite, which is a host mineral for Cr, was found in both BIF and clastic sedimentary rock (e.g., silty sandstone) samples, chromite in the BIF was always overgrown by magnetite. This observation is also consistent with results from previous studies. The chemical compositions of the chromite determined by FE-EPMA were low Mg# (0.001˜0.01) and high Cr# (0.76˜0.89). No significant difference in chemistry was observed in chromite between BIF and clastic sedimentary rock samples. Bulk chemical compositions of the samples were also analyzed by XRF. The results show that the Cr/Ti ratio was not significantly different between BIF and clastic sedimentary rock samples. Therefore, Cr enrichment was not observed in the BIF in this study. The apparent contradiction to the previous study at Moodies Hills block can be explained by the difference in (1) analytical method used or (2) the sedimentary environment. The Ti contents of BIF at Moodies Hills block were determined by ICP-MS after acid decomposition, by which the detection limit is one order of magnitude lower than XRF used in this study. Therefore, the high detection limit in this study may lose the sensitivity for Cr enrichment in samples in which Ti content was low. Alternatively, the BIF in this study could have been deposited in a deeper setting than that at the Moodies Hills block. Therefore, the results may suggest that oxygenated seawater was only localized in very shallow parts.

Change by a diagenesis of first minerals in 1.9 Ga sedimentary rocks of the Gunflint Formation

NIKAIDO, Emi[1*] ; KAKEGAWA, Takeshi[1]

[1]Graduate School of Science, Tohoku University

Some microfossils in the 1.9 Ga Gunflint Formation show clear morphology of aerobic microorganisms. However, carbon isotope compositions of microfossils and other geochemical characteristics suggest the activity of anaerobic microorganisms in the same rock sample. This leads to the skepticism if the 1.9 Ga surface ocean environments were essentially anoxic and oxic environments were very limited.

In order to examine if oxic world were more common or anoxic world were more common, shallow water sedimentary rocks were collected from Kakabeka (the bottom of the Gunflint) and Telly Fox (the top of the Gunflint) areas. The following features were found in the present study. (1) Chemistry of carbonate change into either Fe-rich or Mg-rich from calcite during diagenesis. Fe-rich feature is only found at the bottom of the Gunflint Formation, suggesting wide injection of reduced fluids in sediments. (2) Carbon isotope compositions were similar to cyanobacteria value, and feature of anaerobic bacteria were not detected. This suggests that previous report of carbon isotope compositions of anaerobic bacteria was limited in a few places and not widespread in the Gunflint Formation. Therefore, aerobic microorganism was the major life forms. (3) Sulfur isotope compositions of pyrite range from -2 to +15 per mil, suggesting closed system sulfate reduction. The closed system was most likely isolated oxic seawater from anoxic sediments, probably high sedimentation of SiO2 and CaCO3. In addition, isolated sediments were anaerobic bacterial world, where organic matter from the oxic world was largely consumed.

Origin of phosphate stromatolite formed after the snowball Earth

SHIRAISHI, Fumito[1*] ; OKUMURA, Tomoyo[2] ; TAKASHIMA, Chizuru[3] ; KANO, Akihiro[4]

[1]Hiroshima University, [2]JAMSTEC, [3]Saga University, [4]Kyushu University

The sedimentary rocks formed after Neoproterozoic snowball Earth distribute near Irece, Bahia, Brazil. Salitre Formation is one of them, and contains unique phosphate (apatite) stromatolites. They show dense columnar shape, and are surrounded by laminated dolomite. The relationship between stromatolite and dolomite is mostly sharply bounded, although some parts appear transitional. Stromatolite contains various shape of microfossils. Filamentous microfossil (5-10 μm diameter, about 300 μm long) is most abundant and resembles to filamentous cyanobacteria, and thus, photosynthetic microorganisms such as cyanobacteria are considered to be involved in the formation of stromatolite.

In order to understand the influence of microbial photosynthesis on apatite precipitation, saturation state of apatite after removing 200 μM of CO_2 from seawater was calculated by Phreeqc. The result indicated that photosynthesis can significantly increase saturation state of apatite, when the concentration of dissolved phosphate is at least1 μM. Although the saturation state of $CaCO_3$ is also increased by photosynthesis, its degree is much smaller than that of apatite. As a result, apatite is more likely to precipitate than carbonate, and phosphate stromatolite is formed.

The concentration of dissolved phosphate is extremely low at the surface ocean due to the uptake by phytoplankton, and its concentration is as high as several μM even at the deep ocean. At the time of post-snowball Earth, similar situation is expected for the surface ocean, while the concentration of phosphate in the deep ocean is considered to be much higher than today. If occasional upwelling transported such water mass to the shallow sedimentary basin where cyanobacterial mat is developed, phosphate stromatolite will be formed even if dissolved phosphate concentration is several μM.

Large Fe isotope fractionations in ferruginous sedimentary rocks above Kuroko deposits in the Hokuroku district

SUZUKI, Ryohei[1*] ; TSUBASA, Otake[1] ; YAMADA, Ryoichi[2] ; SHIN, Ki-cheoul[3] ; KON, Yoshiaki[4] ; YONEDA, Tetsuro[1] ; SATO, Tsutomu[1]

[1]Laboratory of Environmental Geology, Graduate School of Engineering, Hokkaido University, [2]Tohoku Univ., [3]Research Institute for Humanity and Nature, [4]National Institute of Advanced Industrial Science and Technology

The Hokuroku district in Akita Prefecture, Japan, hosts many large volcanogenic massive sulfide (VMS) deposits called Kuroko deposits formed around 15.3 million years ago by ancient submarine hydrothermal activity. VMS deposits were formed by the precipitation of metals from hydrothermal fluids and could have contacted with seawater in geological timescales. Because they are composed of sulfide minerals that are stable in a reducing environment, such as pyrite and chalcopyrite, an anoxic environment in the Hokuroku basin may play an important role in the preservation of the sulfide ores containing valuable metals in Kuroko deposits. However, geochemical evidence of such an environment occurring in Hokuroku district is currently lacking. Therefore, objective of this study is to investigate the distribution of REEs and the variation of Fe isotope compositions in the Fe-Mn-rich sedimentary rocks associated with VMS deposits in the Hokuroku district to understand the depositional environments and ancient sea-floor hydrothermal systems in the Hokuroku basin. Sedimentary rock samples obtained from both outcrops and mines in the Hokuroku district include ferruginous cherts occurring directly on or above a Kuroko deposit, manganese-rich siliceous mudstone, and amber in mudstone or tuff. Samples were analyzed by XRD, petrography, and SEM-EDS for mineralogy, by XRF and LA-ICPMS for chemical composition and MC-ICPMS for iron isotope composition (δ^{56}Fe (‰) = $1000*[(^{56}Fe/^{54}Fe)_{sample}/(^{56}Fe/^{54}Fe)_{IRMM-14}$ -1]).

The results of these analyses show the δ^{56}Fe values of mine samples occurring directly on and above Kuroko deposits were -1.5 to 0.5 ‰. These values are largely fractionated from δ^{56}Fe value that is similar with igneous rock ' s δ^{56}Fe. Iron isotopic fractionation occurs when ferrioxide precipitate part of the bivalent iron present in the reservoir. These values are largely fractionated from the δ^{56}Fe value of the standard (i.e., 0 ‰), which is a similar to that of igneous rocks. The samples that have a large negative value also bears negative Ce anomaly. These signatures indicate that partial oxidation of dissolved ferrous iron occurred by mixing ferrous iron-bearing anoxic water with oxygen-bearing seawater, and therefore that the sea-floor of the Hokuroku Basin was anoxic. On the other hand, δ^{56}Fe values of chemical sedimentary rocks formed during 2 -3 Ma after Kuroko deposits formed ranges from -0.8 to -0.3 ‰. These values are similar to that of dissolved ferrous ion in a modern sea-floor hydrothermal fluid. Therefore, the δ^{56}Fe values of the samples indicate near complete oxidation of dissolved ferrous iron in an oxic environment. Therefore, the results of this Fe isotope study suggest that the depositional environment in the Hokuroku basin shifted from anoxic to oxic after the formation of Kuroko deposit.

SEM and TEM observations of carbonate, Fe-oxide and silica minerals in Okuoku-hachikuro hot spring, Akita Prefecture

TERAJIMA, Shogo[1*] ; KAKEGAWA, Takeshi[1]

[1]Graduate School of Science, Tohoku University

Recent studies of biomineralization mainly treated biominerals produced by evolved life. It is uncertain if primordial microbes are capable to precipitate biominerals. If biomineralization by early life is well documented, it will help to understand the Precambrian environments more in details.

Abundant carbonates are precipitating at Okuoku-hachikuro hot spring, located in Kosaka, Akita Prefecture, Japan. We collected sinters, soft to solidified sediments and microbial mats. Then, those constituents were observed using field emission-scanning electron microscopy (FE-SEM). Minerals around microbial sheath were also observed by transmitted electron microscopy (TEM). Analyses of X-ray diffraction, pH, DO, dissolved amino acids, carbon isotope compositions and chlorophyll compositions were also performed.

Hot spring water does not contain appreciable amounts of dissolved oxygen, but Fe-oxides immediately precipitated after discharge. Chlorophyll analyses indicate no presence of anoxic photosynthesizing bacteria. These results suggest that Fe were precipitated by Fe-oxidizing bacteria dominantly, supported by SEM observation of characteristic morphology of the sheath. Cyanobacteria become more dominant in the distance.

Most samples contain radial aggregates of needle-shape aragonite. Such morphology was found in bubble in the ”first” discharging fluid. Each needle in radial aggregates seems to be bigger depending on a distance from the discharging point. Aggregates of coarser and random orientated needles of aragonite are found in lower stream zone, where evaporation and cooling of hot spring water are more visible. Because of no systematic correlation to biological activities (microbial mat, amino acid, organic carbon, etc.) to those morphological changes, all aragonites are formed inorganically. On the other hand, Fe-oxide covering sheath are found locally. Using dilute hydrochloric acid etching, Fe-oxide is observed clearly, especially in zone 1. It has 3 morphological types: sheath-like, agglomerated and needle in radial aggregates. It is noteworthy that Fe-oxides never grow in large crystals. This can possibly because microbial activities or organic molecules may prohibit the growth of Fe-oxides. Furthermore Si was detected in Fe-oxide. This result suggests that Fe-oxide probably adsorbs amorphous silica selectively. Such unique morphology may help to interpret the origin of hematite in Precambrian banded iron formations.

Microbial processes forming lamination in hot spring stromatolites by sulfur oxidizing bacteria and cyanobacteria.

OKUMURA, Tomoyo[1*] ; TAKASHIMA, Chizuru[2] ; HIRANO, Misa[2] ; KANO, Akihiro[3]

[1]JAMSTEC, [2]Faculty of Culture and Education, Saga Univ., [3]SCS, Kyushu Univ.

Travertines are carbonate precipitates from hot-spring water containing a sufficient amount of calcium and carbon dioxide. Most of travertines show sub-mm order laminations that were resemble to ancient stromatolites. Recently, daily microbial processes were identified in some travertines precipitated from some sulfide-poor and moderate temperature (<55 degree C) springs. In the process, daily growth of biofilms consisting cyanobacteria or heterotrophic bacteria, which inhibited inorganic mineral precipitation (1,2). While, lamination is less common in the travertines at higher temperature (>60 degree C) and sulfide-rich springs (3) likely because such daily microbe-mineral interaction might not be occurred. In order to understand the geomicrobiological system in high temperature and sulfide-rich spring, this study investigates a travertine in Sipoholon, Northern Sumatra, Indonesia.

Sipoholon hot spring forms the hugest travertine mound among the hot springs in Tarutung area located about 30 km south from the Lake Toba. The travertine mound spread in total area of 50,000 km^2. The actively precipitated region was separated 3 areas; A is natural mound without artificial effect, B is the mounds in a quarry, C is exposes the rim pools behind spa facilitates. In all area, sulfur-rich yellow sediments were formed near the vents, while white laminated sediment was formed from midstream to downstream. The surface color of the laminated travertine was changed with water temperature; pale pink around 55 degree C and green below 50 degree C. Lamination in the green travertine consisted of light colored crystalline layer and dark colored biofilm-rich porous layer in the interval of 0.5-1.0 mm. While, some lamination in the pink travertine was not clear.

12 sequences of water and travertine samples were collected at a green travertine and a pink travertine in Area C every 4 hours during 48 hours. Samples of both types of the travertine showed that the dark layer was formed during daytime and light colored layer was formed during nighttime without variation in pH, water temperature, Ca ion concentration, alkalinity, and flow. Only dissolved oxygen concentration showed the daily variation in the water chemistry, which was higher during the daytime and lower during the nighttime. Phylogenetic analysis on 16S rRNA gene showed that the pink and green travertines have a microbial composition dominated by obligatory chemolithoautotophic sulfur-oxidizing bacteria. Phototrophs, cyanobacteria and chloroflexus were more diverse in the green travertine than in the pink one. Epifluorescence microscopy showed that phototrophs were concentrated in the diurnal dark layer in the green travertine, while sparsely distributed near the surface in the pink travertine.

These results suggest that formation of phototroph biofilm in daily cycle was responsible for lamina formation in the green travertine same as previous study. On the other hand, formation of sulfur-oxidizer biofilm stimulated daytime increment of oxygen concentration was likely responsible for lamina formation in the pink travertine. The obscure lamination in the pink travertine possibly due to growth of chemolithoautotophs stimulated by extrinsic factor that is daily supplement of oxygen, in contrast to intrinsic daily growth of phototrophs. This novel microbial process could be occurred in ancient stromatolites formed under the anoxic sulfide-rich ancient ocean.

Influences of silica and embedding on thermal alteration of aliphatic hydrocarbons in cyanobacteria as evaluated by FTIR

IGISU, Motoko[1*] ; YOKOYAMA, Tadashi[2] ; UENO, Yuichiro[3] ; NAKASHIMA, Satoru[2] ; MARUYAMA, Shigenori[3]

[1]JAMSTEC, [2]Osaka University, [3]Tokyo Institute of Technology

To study influences of the presence of silica and embedding on thermal changes of aliphatic hydrocarbons in prokaryotic cells, cyanobacteria Synechocystis sp. PCC6803 were isothermally heated at 250-400 ℃ and the changes in IR signals were monitored by micro-Fourier transform infrared (FTIR) spectroscopy. The absorbance of aliphatic C-H decreased with heating time, indicating the degradation of aliphatic hydrocarbons. Both the presence of silica and embedding delayed the degradation of the aliphatic C-H. The absorbance ratios of 2960 cm-1 band (aliphatic CH3) to 2925 cm-1 band (aliphatic CH2) (R3/2 values) increased or changed little by the heating. Raman spectral features showed that some experimental products had a structural ordering similar to the Proterozoic microfossils, indicating that they were carbonized to a degree similar to the microfossils. These results reveal that the presence of silica and embedding affect the thermal degradation rate of aliphatic C-H in cyanobacteria but do not lead to the decrease in R3/2 values. The low R3/2 values of Proterozoic prokaryotic fossils from Bitter Springs and Gunflint Formations are not considered to be due to thermal degradation upon fossilization during diagenesis. Although other possibility cannot be ruled out, the results suggest that precursor lipids, having low R3/2 values, were selectively preserved in microfossils.

Role(s) of extracellular polymeric substance in microbial mineralization

NAKAMURA, Yuki[1*] ; SHIRAISHI, Fumito[1]

[1]Hiroshima University

Microbialites are defined as organosedimentary deposits that have accreted as a result of benthic microbial community binding detrital sediment or forming the locus of mineral precipitation. Most of microbialites are consisted of carbonate minerals, and considered to be formed by microorganism, such as cyanobacteria and sulfate reducing bacteria. Microbialite records the history of interaction between life and Earth environment, and therefore, it is important to understand their formation. Microbialites are formed mainly by three processes, including grain-trapping, mineral precipitation by metabolism and mineral nucleation by extracellular polymeric substances (EPS). Grain-trapping is locally important, but key processes are precipitation and nucleation. The knowledge of precipitation process by bacterial metabolism has increased, while that of EPS is still limited. Therefore, this study aims to investigate the influences of EPS on microbialite formation. We examined carbonate deposit developed at Kibedani hot spring, Shimane Prefecture. Calcite was despite of undersaturation in bulk water. Microerectrode measurement revealed that this deposit is formed as a result of photosynthesis-induced $CaCO_3$ precipitation. The result of EPS staing observation by Confocal Laser Scanning Microscope revealed that this deposit contains abundant acidic EPS, which is generally considered to have important roles in mineral nucleation. This deposit composed of two layers: the upper layer is consisted of empty EPS sheaths and the lower layer is of cyanobacteria with EPS sheaths. Both layers contain acidic EPS, while only lower layer was mineralized. This observation implies that acidic EPS cannot solely cause nucleation, and requires high mineral saturation state induced e.g.by photosynthesis.

Controlling factors of microbialite textures inferred by a tufa deposit

HANZAWA, Yuhsaku[1*] ; OKUMURA, Tomoyo[2] ; SHIRAISHI, Fumito[1]

[1]Hiroshima university, [2]Japan Agency for Marine-Earth Science and Technology

Microbialite is organosedimentary deposits that are formed by the interaction between life, water and mineral. It has accreted as a result of a benthic microbial community trapping and binding detrital sediment and/or forming the locus of mineral precipitation. Typical examples of microbialite are laminated stromatolite, and clotted thrombolite. In the Earth history, stromatolite appeared from about 3500 Ma, followed by its peak at 1300 Ma. At about 500 Ma, stromatolite rapidly declined, and thrombolite appeared. Although this transition is considered to reflect evolution of life and Earth environment, its detail is still not well understood. To understand the basic mechanisms forming microbialites, the geomicrobiological studies of recent samples are essential. While microbialite in modern marine environment is scarce, it is relatively common at freshwater environment as a tufa. The present study focuses on tufa for investigating the relationship between depositional structure and microbial composition. Tufa deposit usually has laminated structure resembling stromatolite. However, tufa deposit developed in Takahashi city (Okayama prefecture) exhibits both stromatolitic and thrombolitic structures by reflecting the difference of hydrodynamic condition. The chemical compositions of creek water at the sites where stromatolitic and thrombolitic tufa are depositing are almost the same, and similar to that of common tufa-depositing creek. Extracellular polymeric substances (EPS) staining observation applied for deposits surface by Conforcal Laser Scanning Microscope (CLSM) showed that the distribution patterns of phototrophs and EPS were different between stromatolitic and thrombolitic tufa. At the surface of thrombolitic tufa, coccoid cyanobacteria densely colonized to form small mounds (500 μm in diameter) and EPS located inner and marginal part of the mounds. On the other hand, at the surface of stromatolitic tufa, filamentous cyanobacteria distributed sparsely with EPS, and calcite was widely exposed. Vertical thin section observation revealed that there were large calcite crystals (500 μm in diameter) at the surface of thrombolitic tufa, and filamentous one colonized around them. Stromatolitic tufa, on the other hand, was consisted of fine grained calcite (10 μm in diameter) with filamentous cyanobacteria colonized perpendicular to the lamination. Microbial composition of both deposits was examined by 16S rRNA gene analysis. The result indicated that cyanobacteria were abundant and some strains were common between thrombolitic and stromatolitic tufa. However, the diversity of microbial population microbial population was higher in thrombolitic tufa than stromatolitic ones.

From the results above, it is inferred that the transition from stromatolite to thrombolite in $\sim$500 Ma was caused by microbial diversification and resultant EPS composition change.

Soil micromorphology and the effect of biotic activity

SUZUKI, Shigeyuki[1*] ; HATTORI, Tsutomu[2] ; HATTORI, Reiko[2] ; MIMURA, Kaori[3] ; ISHIGURO, Munehide[4]

[1]Okayama University, [2]Atic Laboratory, [3]Kanematsu-NNK Corporation, [4]Hokkaido University

Soil is formed on a boundary between geosphere and biosphere in relation with hydrosphere and atmosphere. The major component is quite very fine-grained particles which are not still unknown in detail. A great variety of microbes are associated in soil (e.g., Hattori, 1987). Hattori (2006) suggests that there is a possibility some bacteria produce very fine-grained mineral particles, silica-nano particle as a part of soil material. Micromophology is observed under petrological microscope. The technique for preparation to make thin section from unconsolidated soil is followed by method in FitzPatrick (1993). Soil fragments are examined by scanning electron microscope. Samples are collected from recent cultivated soil (Okayama University Farm), fluvial soil (Sendai City), rice field soil (150 to 2000 years old fluvial soil from Okayama University), paleosol (about 3000 years old organic rich fluvial soil from Dhaka City, Bangladesh).

The formation of microaggregates: The structure of soil macroaggregate (1∼2mm) which is composed of microaggregates (0.05∼0.3mm) and sand grains of mineral and rock fragments is observed in the recent cultivated soil from Okayama University Farm. Similar microaggregates (0.1∼0.5mm), structure with heterogeneous granular domains is observed in rice field soil from Okayama University. A paleosol from Dhaka, which is not considered to have artificial effects, also consists of microaggregate. The aggregates do not have distinctive boundary but are distinguished by different compositions (content of organic materials, deposited ferri-hydrite and .manganese dioxide, particles of mineral and rock fragment). Root pipes and cracks are associated in the soil. The compound structure is interpreted to be formed under effects of microorganisms, root and physical process as demonstrated by previous soil research (e.g., FitzPatrick, 1993).

The formation of silica-nano particle: Under scanning electron microscope, surface of mineral grain has structures caused by weathering, for example embayment, fracture and etch pit. Crystallized nano-sized minerals are formed on weathered surface of a mineral. A bacterial cell surrounded by radiate fibrous mineral is found. The feature indicates a possibility that some bacteria promote to form minerals. And also there is a possibility that a part of inorganic soil materials might be formed relation with organism.

A novel remediation method for nickel-bearing wastewater at neutral conditions

OKAHASHI, Haruko[1*] ; NISHIUCHI, Toru[1] ; SATO, Tsutomu[2] ; OTAKE, Tsubasa[2] ; YONEDA, Tetsuro[2]

[1]Graduate School of Engineering, Hokkaido University, [2]Faculty of Engineering, Hokkaido University

Advances in technology such as the electronics and metal plating industries have increased the demand of Ni year by year. On the other hand, the resources are unevenly distributed in a few countries and the supply is highly dependent on strategic policies. Moreover, since Ni is not produced in Japan and it is dependent on imports from foreign countries, the supply structures of Ni are vulnerable. Because of this, the necessity of recovering Ni from wastewaters and other waste forms has been increasing. Some industrial wastewaters contain large amounts of Ni. Generally, the removal of Ni from contaminated wastewater by adding antalkaline and flocculants to increase the pH to 10 or above would result in the generation of Ni-hydroxides after treatment. After that, it is necessary to adjust the pH below the effluent standard (pH 5.8∼8.6). However, this method suffers from some disadvantages, such as the high cost for chemical reagents, problems in the disposal of alkali sludge and inefficient treatment system. Therefore, a more sustainable remediation method must be developed to achieve sustainable wastewater treatment operations. This study focused on natural attenuation processes which are safer, cost-effective and more environmentally friendly than traditional methods. For example, at Dougamaru abandoned mine in Japan, high concentrations of Cu and Zn in wastewater are naturally incorporated in the structure of layered double hydroxides (LDH), which forms in the presence of Al ions, hence, natural attenuation of Cu and Zn occurs (Okamoto et al., 2010). Because LDH has the hydroxide structure, six-coordinated heavy metals such as Cu, Ni and Co can be incorporated into the structure during the formation process. Therefore the objective of this study is to develop a remediation method for Ni-bearing wastewaters at neutral conditions, and to clarify the behavior of Ni in the neutralization and precipitation process.

In this context, to check the applicability of LDH in the treatment of Ni-bearing wastewaters, synthesis experiments were carried out by co-precipitation of Ni-bearing LDHs containing SO_4^{2-} as the interlayer anion with different concentrations of dissolved Al ions. Analysis of water chemistry before and after the co-precipitation show that the removal efficiencies of Ni from the synthetic wastewaters increased with increasing dissolved Al concentration. The results further show that the presence of Al in the formation of LDH removed Ni at pH values lower than previous methods which precipitated Ni-hydroxides. It is expected that treatment costs will be reduced in actual wastewater treatment systems because Al addition leads to the reduction of antalkaline use and the neutralization process.

Ni adsorption experiments and extraction experiments were conducted to investigate the sorption behavior of Ni. Only a small amount of Ni was adsorbed to LDH and basaluminite (major minerals in coprecipitation experiments) as inner- and outer-sphere complexes. From the result of XAFS analysis, Ni was incorporated into the structure by being able to precipitate LDH selectively. This shows Ni is fixed securely in the structure of LDH and that the mobility of Ni will be governed by the solubility of LDH. Thermodynamic modeling suggests that the precipitation of LDHs with the optimum Al/Ni molar ratio (0.25∼0.50) is determined by the initial conditions (e.g. pH, Al, Ni concentrations). Furthermore, modeling results reproduce the experimental results such as removal efficiency and mineral species well, opening the possibility of its application in actual wastewater treatment operations.

Changes in water properties and microbial facies along a flow path of a travertine developed in northern Sumatra Island,

TAKASHIMA, Chizuru[1*] ; HIRANO, Misa[1] ; OKUMURA, Tomoyo[2] ; KANO, Akihiro[3]

[1]Saga Univ., [2]JAMSTEC, [3]Kyushu Univ.

Sumatra Island has many hot springs related with volcanoes belonged to the Ring of fire. Geothermal studies for these hot springs have been performed actively, but hot spring sediments including travertines have rarely been reported. Travertine is a useful modern analog for the Precambrian stromatolites (Takashima and Kano, 2008; Okumura et al., 2013).

We studied travertines at Sipoholon hot spring located about 30 km south from the Lake Toba which is the largest caldera lake in the world. The travertines spread in total area of 50,000 km^2, in which active deposition occurs mainly in three separated sites; Area A, B and C from north to south, respectively. This study focused on Area A that lacks artificial effect.

In this study, we measured chemical components and stable isotopes of water and observed textures and bacteria of the travertine. Based on these results, we cleared that relationship between water properties, travertine textures and distribution of bacteria.

The travertine deposit occurs along ~35-m-long flow path. The water from the vent first flows 15 m on a narrow (50 cm) and gentle passage and then widely on a steep slope on the travertine dome. Below the dome, the water passes on terrace-like rim pools and finally flows into a pool about 5 m in diameter.

The water with sulfurous smell emits from a vent at a rate of 286 L/min. This water is high temperature (61.4 degree Celsius), neutral pH (6.48) and microaerobic (DO of 0.6 mg/L). The water is rich in Ca^{2+} and $SO_4{}^{2-}$, and poor in Mg^{2+} and Cl^-. To the downstream, the water temperature decreases, pH increase, and conversely alkalinity and Ca^{2+} concentration decrease. These and increased carbon isotope of dissolved inorganic carbon indicate that CO_2 degassing increased supersaturation and induced deposition of calcium.

The travertine in Sipoholon hot spring is mainly composed of aragonite, but in one place, calcite coexists. It tends to become softer from the upstream to the downstream. This may reflect difference in crystal shape and texture. The harder travertines consist of tightly packed spherical aggregates of aragonite needles, while softer travertines have loose textures containing dumbbell-shape crystals.

Microbial facies on the travertine surface changes obviously from the upstream to the downstream. A white sulfur-turf in upper stream is composed of sulfur oxidizing bacteria with sulfur particles (Maki et al., 2004). It is known that the sulfur-turf prefers in high temperature, neutral pH and rich in hydrogen sulfide, which corresponds the conditions of the upstream. On high flow parts of the travertine dome, the travertine colored in pale pink likely due to the occurrence of purple sulfur bacteria. Green microbial mat covers the travertine deposited in in lower part with low flow rate. The mat is composed of filamentous bacteria with photosynthesis pigment identified in fluorescence observation. These are cyanobacteria. Water temperatures on the mat are all below 45 degree Celsisu. Thus, color change of travertine surface reflect that of microbial composition responded to water properties, such as water temperature, flow rate, flow volume, nutrient.

A study of irregular shaped tests formation of planktonic foraminifera

HORI, Masako[1*] ; SHIRAI, Kotaro[1] ; TAKAHATA, Naoto[1] ; SANO, Yuji[1] ; KURASAWA, Atsushi[2] ; KIMOTO, Katsunori[2]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo, [2]Japan Agency for Marine-Earth Science and Technology

Planktonic foraminifera are protist forming carbonate tests. They are used as useful index fossils, and moreover, the oxygen isotopic and trace element compositions in their calcite tests are recognized as a promised archive representing paleo-ocean environments. Foraminifera generally consist of multipul chambers, and each chamber forms spirally for the center of the first chamber. Culturing observations have contributed for understanding relationships between trace elements and isotopic indices, and environmental factors. However, the transfer of elements and trigger of test formation are poorly understood. Cultured specimens sometimes show irregular-shaped tests, which are unlikely formed under natural condition in the ocean.

In this study, we focused the test formation of planktonic foraminifera, and cultured two species (*Globigerina bulloides*, *Globigerinoides ruber*) collected at Sagami bay. Culturing temperature was controlled at 19, 21, 23 and 25 ℃. Calcium isotopic reagents were added to the culturing seawater to mark the timing of test formation. Moreover, we also investigated the other specimens cultured with seawater, whose calcium concentration was raised for 10% respective to the original concentration. In those cases, the pH of calcium reagents were adjusted to appropriate pH, and therefore, the seawater pH was kept at constant during the observation.

As a result, three of ten specimens of *G. ruber* have newly formed a regular test at 19, 21 and 23 ℃. On the other hand, 5 of 7 specimens of *G. bulloides* have formed new tests, three of which have formed irregular shaped tests. These three specimens are ones survived more than a couple of weeks after sampling. The water temperature of irregular test formation was 21 or 25 ℃, suggesting that the temperature was not a direct controlling factor of irregular test formation. Potential factors are concentrations of dissolved oxygen or dissolved organic matters. Foraminifera first forms organic layer called POM at the beginning of test formation. Anomalously high organic concentration in crystallization liquid may impede the regular formation of POM, consequently resulting in the formation of irregular-shaped tests.

For the specimens with increasing calcium concentration of seawater, the spines fell out within 12 hours. Because calcium is an essential element not only for test formation but also various biological reactions, rapid increase of calcium concentration might disturb the biofunction of planktonic foraminifera.

Anion adsorption and post-adsorption behavior of metastable iron hydroxides

KODAMA, Ritsu[1*] ; OKAHASHI, Haruko[1] ; YAMAMOTO, Takato[1] ; SATO, Tsutomu[1] ; OTAKE, Tsubasa[1] ; YONEDA, Tetsuro[1]

[1]Laboratory of Environmental Geology, Hokkaido university, Graduate School of Engineering, Hokkaido U

Pollution by dissolved anions has been a pertinent environmental concern in many areas around the world. For example, acid mine drainage from abandoned mines and contaminated waters resulting from the Fukushima nuclear power plant accident emphasize the importance of predicting the behavior of the dissolved trace elements on Earth ' s surface environments. Iron minerals may play a potentially important role in the control of dissolved trace elements in the environment. In particular, poorly crystalline iron minerals exhibit excellent adsorption capacities for toxic anions due to their high specific surface areas and reactivity. In order to evaluate the potential of poorly crystalline iron minerals as stable sinks of dissolved hazardous ions, it is necessary to investigate the adsorption mechanism on these minerals and their post-adsorption behaviors.

Adsorption experiments using arsenate, phosphate, chromate, sulfate, selenate, fluoride, and chloride were performed to investigate the selectivity of Schwertmannite and Ferrihydrite for various anions. Adsorption selectivity decreases in the following order: $H_2AsO_4^-$ › $H_2PO_4^-$ › $HCrO_4^-$ › $SeO_4^{2-} \fallingdotseq SO_4^{2-} \gg F^- \fallingdotseq Cl^-$. Schwertmannite and Ferrihydrite didn ' t have an ability to adsorb F^- and Cl^-.The adsorption mechanism of these anions was investigated using zeta potential measurements. The results indicated that $H_2AsO_4^-$, $H_2PO_4^-$ and $HCrO^{4-}$ formed inner-sphere complexes while SeO_4^{2-} and SO_4^{2-} formed outer-sphere complexes. The adsorption mechanism of these anions to both Scwertmannite and Ferrihydrite is generally similar, except in the case of $HCrO_4^-$.

Accelerated alteration experiments were performed to observe post-adsorption behaviors of Schwertmannite and Ferrihydrite. Oriented specimens loaded with varying amounts of adsorbed anions were aged under saturated water vapor pressure conditions at 50 ℃ for 30 days and analyzed by XRD. Results show that larger amounts of adsorbed anions delay the transformation of Schwertmannite and Ferrihydrite into more stable phases, indicating that adsorption of anions, particularly as inner-sphere complexes, stabilizes poorly crystalline iron minerals.

These results show that poorly crystalline iron minerals are capable of taking up a range of toxic anions from contaminated waters and that the stability of these minerals will be affected by the amount of anions sorbed on the surface. These suggest that poorly crystalline iron minerals may serve as stable, long-term sinks for toxic anions.

Anion adsorption and post-adsorption behavior of metastable calcium carbonate polymorph

YAMAMOTO, Takato[1*] ; KODAMA, Ritsu[1] ; SATO, Tsutomu[1] ; OTAKE, Tsubasa[1]

[1]Laboratory of Environmental Geology, Hokkaido University

In Japanese transuranic (TRU) waste disposal facilities, I-129 is the most important radionuclide that must be considered in long-term safety assessments of the repository. However, the degradation of cement materials used in the repositories can produce high pH pore fluids that can affect to anion transport behavior. Therefore, it is necessary to understand the behavior of anions such as I- in hyperalkaline conditions. Examples of I- behavior in natural hyperalkaline environments, such as in Oman, show that I^- is taken up by aragonite, opening up the possibility of calcium carbonates as inhibitors of I^- migration. This concept is currently being applied in the development of the Advanced Liquid Processing System (ALPS), which employs carbonate coprecipitation to treat contaminated waters resulting from the Fukushima Daiichi nuclear power plant accident. However, the stability of the carbonate phases precipitated in this system as well as the anion uptake capacities of these phases are poorly understood. In a previous study, (Kasahara, 2012), it was found that monohydrocalcite (MHC), a precursor of aragonite, affects the iodine capacity of aragonite, making it a possibly important material that can control the behavior of anions..The objective of this study therefore, is to investigate the sorption capacity of MHC for anions and its stability. MHC (Mg^{2+}/Ca^{2+}=6; $Ca^{2+}/{CO_3}^{2-}$=1) was synthesized and used for sorption experiments involving F^-, Br^-, I^-, ${IO_3}^-$, ${SO_4}^{2+}$, ${CrO_4}^{2-}$, ${HAsO_4}^{2-}$, and phase transformation experiments. Results show that Kd values of ${HAsO_4}^{2-}$ and F^- on MHC are high, while ${IO_3}^-$, ${SO_4}^{2-}$ are relatively low. On the other hand, Br^-, I^-, ${NO_3}^-$, ${CrO_4}^{2-}$ were not taken up. It is because MHC has high chemical reactivity and high specific surface (4 times large of aragonite, 15 times large of calcite), in addition MHC is most low density of calcium carbonate, so MHC can takes up relatively large amount of anions than other calcium carbonate. And other thing, MHC involves Mg^{2+} abundantly. This study indicates that Mg^{2+} form fluoride adsorption site. Results of the transformation experiments show that MHC with no adsorbed anions easily transforms into a stable phase, whereas MHC loaded with increasing amounts of anions transform after longer durations. It is because the driving force for the transformation decreases with the anions content in the solution. In conclusion, MHC can take up fluoride and oxyanions that ionic radii is similar to carbonate but larger than that. In addition, MHC is stabilized as a function of uptake amount of anions.

On activities in the interdisciplinary science of Hayabusa-2

KOBAYASHI, Naoki[1*] ; WATANABE, Sei-ichiro[2] ; THE INTERDISCIPLINARY SCIENCE TEAM, Hayabusa-2[1]

[1]ISAS/JAXA, [2]Division of Earth and Planetary Sciences, Graduate School of Science, Nagoya University

Hayabusa-2 is an asteroid sample return mission of which target asteroid is 1999JU3, a near Earth asteroid of type C, and it is scheduled to be launched late in this year. As on-board scientific instruments, Hayabusa-2 has a near infrared spectrometer (NIRS3), thermal IR imager (TIR), optical navigation camera (ONC-T) used as a multi-band imager with seven band-pass filters, laser altimeter (LIDAR), sampler (SMP), small carry-on impactor (SCI), separation digital camera (DCAM-D), and small lander (MASCOT). Using these instruments, we try to characterize the surface properties and materials of 1999JU3 and select three sampling points from which material samples will be obtained to reveal physical and chemical processes on the asteroid and its history from the formation to the present. Thus scientific success of Hayabusa-2 strongly depends on a strategy for characterizing the surface and selecting sampling sites, which can be achieved making the best use of data from the above all sensors. We, for this purpose, organize a working team called as the Interdisciplinary Science Team (IDST) of Hayabusa-2. In this presentation, we introduce the activity of the IDST.

The IDST was established in the first meeting held on Dec. 2012. Its purposes are to obtain the general picture of a scientific scenario of Hayabusa-2, define interdisciplinary science themes and contribution of individual instruments to the themes, define scientific constraints and validations on the mission scenario, and promote planetary sciences and think out planetary sciences from a standpoint of the asteroid mission. The discussion in the IDST is open to the project members. So far, we have discussed deeply a strategy in return sample analyses, heterogeneity detection by the remote sensing sensors, surface temperature detection, crater chronology, morphology produced by meteoroid impacts, reflectance spectra of C-type asteroids, space weathering, and so on. As a result of these discussion, we produce a logical flow chart to characterize the surface material and property. In the chart, mutual relations between basic observation quantities, quantities inferred by multiple sensors, their indexes, identified characters and general inferences on primitiveness are described. Contributions from each sensor are clarified in the chart. In addition, we also depicted an operational picture of SCI which is a grand experiment for an impact process in the low gravity space and exposes material in a depth that can be less suffered by space weathering, but SCI is wasteful of the satellite resources. It is necessary to polish up the operation plan of SCI from the view point of the system resources.

The logical flow chart is a guiding principle in the science of the Hayabusa-2 mission. We continue to refine the chart and complete the logic. For this purpose, we make several working groups to reinforce the logic flows. As closing the development phase of on-board instruments, we now rush up to make the IDST of Hayabusa-2 more active. We think that the activity in the IDST is a key point to succeed in the science mission and promote planetary sciences and explorations in Japan.

Detectability of 0.7 um absorption band of hydrous minerals using the Hayabusa2 ONC-T Flight Model

KAMEDA, Shingo[1*] ; AKITO, Takei,[1] ; SATO, Masaki[1] ; OKUMURA, Yu[1] ; CHO, Yuichiro[2] ; ONC, Science team[3]

[1]Rikkyo University, [2]The University of Tokyo, [3]JAXA

Hayabusa2 has three cameras for optical navigation to the asteroid 1999JU3. ONC-T is one of them and it can be used also for reflectance spectroscopy. The results of the ground-based observation suggested that hydrous materials might remain on the 1999JU3 but on the small part of the surface. To bring them to the Earth, we should perform reflectance spectroscopic observation near the asteroid using ONC-T to locate the point where hydrous mineral is rich.

In this presentation, we will report the result of final calibration test of ONC-T and discuss the detectability of hydrous minerals on 1999JU3.

[1]PERC/Chitech, [2]ISAS/JAXA, [3]NAOJ, [4]The University of Aizu, [5]ARD/JAXA, [6]Nihon University, [7]The University of Tokyo, [8]Osaka University, [9]Tokyo Institute of Technology, [10]NICT

The Japanese first asteroid mission, Hayabusa, visited at the small asteroid 25143 Itokawa in September, 2005. Images taken by Hayabusa are combined with other remote sensing observations and revealed that the asteroid as small as 500 m in the longest axis is the first rubble-pile body identified in our solar system. Despite of several serious failures of the spacecraft occurred during and after rendezvous, Hayabusa successfully retrieved samples from the surface of 25143 Itokawa to the Earth in 2010 to disclose unpredicted nature of a very small asteroid.

JAXA and collaborating scientists are now developing the second asteroid mission named ”Hayabusa-2”. Hayabusa-2 is based on a heritage of the first Hayabusa. At the same time, Hayabusa-2 is intended to improve engineering and scientific achievements of the first Hayabusa, and also to challenge new technologies. Furthermore, target asteroid is different from that of the first Hayabusa. The asteroid 25143 Itokawa is a silicate-rich S-type. On the other hand, Hayabusa-2 is visiting a C-type asteroid, (162173) 1999 JU3. Needless to say, C-type is more primitive than S-type, therefore is expected to be a key to understand chemical evolution of the early solar system.

LIDAR measures altitudes of the spacecraft from the surface of the asteroid by taking a time of flight of laser pulse. As a part of Attitude and Orbit Control System (AOCS), the LIDAR data are used for navigation of the spacecraft. The data are particularly important during touchdown operation. Besides, the LIDAR data are served for scientific analysis of the shape, mass, and surface properties of the asteroid in order to elucidate physical evolution of minor bodies such as impact fragmentation and coagulation. We also wish to expand outcomes of Itokawa exploration by examining uniformity and variation of porosity within rubble-pile body and detecting dusts levitating above the surface of asteroid. The remote sensing observations of Hayabusa-2 will be carried out from Home Position (HP), middle altitude, and low altitude whose distances from the asteroid surface are nominally 20 km, 5 km, and 1 km, respectively. We report recent progress of LIDAR development anticipating the launch in December 2014.

A strategy to estimate thermal properties using Thermal Infrared Imager on board Hayabusa-2.

SENSHU, Hiroki[1*] ; TAKITA, Jun[2] ; TANAKA, Satoshi[3] ; OKADA, Tatsuaki[3]

[1]PERC/Chitech, [2]Graduate School of Science, Tokyo University, [3]ISAS/JAXA

Thermal InfraRed imager (TIR) on board Hayabusa-2, an upcoming japanese mission to C-type asteroid 1999JU3, is non-cooled bolometer which image mid-infrared thermal emission from the asteroidal surface. The field-of-view (FOV) of TIR is 16x12 degrees and ts effective pixels are 320x240. So the spacial resolution, which depends on distance from the suface, is about 18m from an altitude of 20km (Home position) and less than 1m from an altitude of 1km.

By comparing the temperature distribution obtained by TIR and thermal evolution model, we can get thermophysical properties such as thermal inertia and emissivity. These parameters are diagnostic for the characteristic size of surafce grain.

In this presentation we will present our strategy to estimate the thermophysical properties from TIR observation.

Relationship on Surface Morphology of Small Asteroids and Geopotential

HIRATA, Naru[1*] ; MATSUMOTO, Koji[2] ; KIMURA, Jun[3]

[1]ARC-Space/CAIST, The University of Aizu, [2]RISE Project, The National Astronomical Observatory of Japan, [3]The Earth-Life Science Institute (ELSI) of Tokyo Institute of Technology

We compared the distribution of smooth terrains with the geopotential map of the asteroid Itokawa, and demonstrate that the distribution of smooth terrains on Itokawa is strongly controlled by the geopotential distribution. Because the geopotential distribution of an asteroid can be estimated from its shape, rotation state and density, we can predict the distribution of smooth terrains on the asteroid from these observations.

Spectral evolution of s-type asteroids suggested by principal component analysis of multi-band images of Itokawa

KOGA, Sumire[1*] ; SUGITA, Seiji[1] ; KAMATA, Shunichi[2] ; ISHIGURO, Masateru[3] ; HIROI, Takahiro[4] ; SASAKI, Sho[5]

[1]Graduate School of Frontier Sciences, The University of Tokyo, [2]Dept. of Earth and Planetary Sci., UC Santa Cruz, [3]Depertment of Physics and Astronomy, Seoul National University, [4]Depertment of Geological Science, Brown University, [5]Department of Earth and Space Science, Graduate School of Science, Osaka University

Objective

Itokawa is covered with materials from the same initial material with different degree of space weathering[1,2]. However, it has not been verified sufficiently if there is other factors that change the spectra. Our analyses of principal component analysis (PCA) using multi-band images taken by Hayabsa's AMICA (Asteroid Multi-band Imaging CAmera) so far have provided the results that a component of spectral reddening, a typical trend of space weathering effect, is the first principal component (PC1) with comparison to laser-irradiated meteorites spectra. The comparison with main-belt asteroids suggests how the spectra of the asteroids develop in their PC space with weathering (by micrometeorites bombardment[3])[4]. However, further analysis had been impeded by electromagnetic noise. In this study, we remove the noise and examine spectral change trends caused by processes other than space weathering.

Methods

We used 2 sets of images of six visible bands (Central wavelengths of 381, 429, 553, 700, 861, 960 nm) taken by AMICA. Periodic electromagnetic noise is imposed on most of the images. We removed it by subtracting superposition of sine waves. The images were calibrated following [4] and coresistrated. Normalized ratio images were obtained by dividing the images by those of 553 nm.

We performed PCA on the normalized reflectance spectra. We used a set of images of a Itokawa semisphere and another set including a dark rock (Black Boulder). Shock darkening is indicated as a possible origin of it [5].

We also performed PCA on spectra of main-belt asteroids obtained in ECAS [6] and each Itokawa spectrum superimposed. Because AMICA and ECAS filter wavelengths are approximately same, we can compare the Itokawa surface in the PC space defined by ECAS data set.

Results

The PC1 of spectra of only Itokawa had a shape rising to the right with a steep rise in 430-700nm. The PC1 score spatial distribution was consistent with the distribution of space weathering degree obtained by [7]. PC2 had positive coefficients at the wavelengths except 553nm, and the spectrum shape was upward to both sides. The PC2 is different from sillicate spectra, therefore interpretation in a context of material science is difficult. We found a feature that PC1 score is low and PC2 score high in boulder-rich regions, but the muximum area of PC2 score lay around a boulder where PC1 score were minimum. Proportion of variance of PC1 and PC2 was 60-75% and 20-30%.

In the ECAS-defined PC space, the spectra of Black Boulder were distributed apart from the cluster of the other parts.

Discussion

The proportions of variance of PC1 and PC2 would suggest that the heterogeneity in Itokawa surface spectrum is dominated by two processes. The PC1 and PC2 score distribution might suggest that the process which changes PC2 score occurs where space weathering has moderately developed. We have observed only a part of the surface, and features observed in a global analysis will be reported in our presentation.

The fact Black Boulder spectral trend is different from that of the other parts suggests that another process than space weathering (shock darkening is a candidate) is the origin of its peculiar spectrum.

In this analysis, another trend than the general space weathering was captured. Consideration of an evolution caused by larger impacts together as well as the space weathering caused by micrometeorites bombardment may enable us to constrain the spectral evolution processes of asteroids and derive relationships among asteroids of different spectral classes.

Small Carry-on Impactor of Hayabusa2

A Japanese spacecraft, Hayabusa2, the successor of Hayabusa, which came back from the Asteroid Itokawa with sample materials after its 7-year-interplanetary journeys, is a current mission of Japan Aerospace Exploration Agency (JAXA) and scheduled to be launched in 2014. Hayabusa2 is a similar sample return mission to Hayabusa, however the type of the target asteroid is different from that of Hayabusa. Asteroid Itokawa, explored by Hayabusa is a rock-rich S-type one. Hayabusa2 will go to a C-type asteroid. Both C-type and S-type asteroids consist of rocks, but C-type asteroids are considered to have organic and water materials. Hayabusa2 has two objectives to discover: organic matters and water in the solar system and relationship between life and ocean water. C-type asteroids are the most common variety and many of them are in the outer part of the asteroid belt beyond 2.7 AU. An asteroid, called 1999 JU3, is chosen as the target of Hayabusa2 mission because it is considerably easy to reach. It has a similar orbit as that of Itokawa and it is in the orbit that occasionally comes close to the earth orbit.

The design of Hayabusa2 basically follows Hayabusa. Its configuration, size and weight are almost same as Hayabusa and the touch-down operation will be performed in much the same way. However, it is planned to be equipped with some new components. Small Carry-on Impactor (SCI) is one of the new challenges. The observations by Hayabusa discovered that Itokawa was rubble-pile body with the macro-porosity. No direct observational data as for their internal structures and sub-surface materials were available, however. One of the most important scientific objectives of Hayabusa2 is to investigate chemical and physical properties of the internal materials and structures in order to understand the history of formation of small bodies such as small, un-differentiated asteroids. In order to achieve this objective, the SCI is required to remove the surface regolith and create an artificial crater on the surface of the asteroid. Different from other impact missions, Hayabusa2 can make a detailed observation of the resultant crater after the impact. Observing the size of the crater is very important to investigate the physical properties of the asteroid. Additionally, Hayabusa2 will try to touchdown near the crater to get the fresh material of the asteroid.

It is very difficult to create a meaningful crater on the asteroid. High kinetic energy (i.e. about 2km/s impact speed and 2kg impact mass) is required to make a crater, but the high speed is difficult to realize. The famous impact mission, Deep Impact was the direct impact mission, which used the interplanetary velocity for the impact speed. Consequently, the impact energy became very high. On the other hand, SCI of Hayabusa2 is a carry-on type impactor and it should accelerate itself after the separation from the mother spacecraft. Therefore, how to accelerate the impact body is a big challenge of SCI. The traditional acceleration devices such as rocket motors and thrusters are difficult to hit the asteroid without a guidance system because the acceleration distance is large. To overcome this difficulty, the powerful explosive is use in SCI. The special type of shaped charge makes it possible to accelerate the impact head in a very short amount of time (less than 1 millisecond) and it becomes possible to crash into the asteroid.

The development of SCI is now almost finished. A lot of tests were conducted during the development period. The overview of the small carry-on impactor system and the results of the development tests will be presented in the conference.

Small Carry-on Impactor Elucidates the Nature of Craters and the Evolution of our solar system

WADA, Koji[1*] ; SCI, Team[2] ; DCAM3, Team[2]

[1]PERC/Chitech, [2]Hayabusa-2 Project

Hayabusa-2, the Japanese next asteroid exploration mission, equips Small Carry-on Impactor (SCI) to launch a decimeter scale projectile on an asteroid surface. This is a novel apparatus to excavate the asteroid surface, and hopefully it will enable us to observe a fresh surface without space weathering and thermal alteration. Furthermore, we will be able to recover the asteroid sample excavated from several 10 cm depth at the deposit of the impact ejecta. The SCI impact on the asteroid is very good chance to examine the projectile scale on the crater scaling law in addition to the study on the gravity effect on the crater formation process. In this presentation, I will introduce the scientific goals of Hayabusa-2 mission using SCI and the scientific problems to be solved in the near future to maximize the scientific outputs of the SCI impact.

HAYABUSA-2(the next Japanese Aseroid Sumple Return Explorer) is now at the final integrated test. Before this test, all sub-systems experienced final test individually. The Small Carry-on Impactor:SCI has been adopted the new sub-system of HAYABUSA-2, it is one of the self forging fragment which will be able to eject the 2kg projectile by 2km/sec velocity by detonation.

In this paper we show the outline and results of the final performance test of the SCI explosive part on Oct. 2013. The test bodies have be made by the same rot of flight model, and experienced environmental stress tests. The projectiles formed explosion impacted on the sand target and made craters.

A point of view of understunding of impact phenomina, these tests are larger scale impact experiments than thats made in labolatory, between space scale and labolatory scale. Therefore we observed and measured the crater formation prosesses by two high-speed video cameras, a infrared video camera, accelerometers, geophons, and digital handy video cameras. We succeeded to obtaine five cratering prosesses.

Small Carry-on Impactor (SCI) is one of the instruments carried on Hayabusa-2 space craft. It will be used for an active exploration on the surface of asteroid 1999JU3. The SCI consists of a disk impactor made of copper. This disk will be accelerated to a velocity of ˜2km/s for the collision onto the asteroid surface, creating an artificial crater on 1999JU3. Then, samples in the crater and/or around the crater will be recovered by the Hayabusa-2 mother ship. Observation of the crater is expected to reveal the surface structure of 1999JU3. This SCI impact also has an aspect of an ”impact experiment” on an asteroid that elucidates the impact phenomena on small bodies.

A miniaturized optical camera unit (DCAM3) is being developed for observations of the SCI impact. DCAM3 will be detached from Hayabusa-2 mother ship and obtain a close-up image of the SCI impact. The detached part of DCAM3 has two cameras; one is an analog camera (DCAM3-A) and the other is a digital camera (DCAM-3D). The purposes of DCAM3-D are (1) the detection of SCI explosion and impact on the asteroid and (2) the observation of ejecta created by the SCI impact.

DCAM3-D optical system has to satisfy strict required specifications to fulfill these purposes: it requires a large view angle (74 deg) to detect both the SCI and the asteroid, high imaging capability for whole sensor area, a bright optical system (F $>$1.7) to detect dark SCI and ejecta, resistance to radiation, and limited size and weight . Moreover, these conditions have to be accomplished without active temperature control.

In this presentation we report the results of the optical performance verification of a flight model of DCAM3-D. The optical performance verification tests consist of electrical test, collimator test, and integration sphere test. The electrical test evaluated the performance of the CMOS sensor. In the collimator test, lens-sensor distance and lens-sensor angle were adjusted. Then, imaging capability (i.e., ensquared energy), spatial resolution, and distortion were evaluated under vacuum condition ($<$1 torr) with various temperatures, wavelength regions, and angles of view. In the integration sphere test, sensitivity, limb darkening, and stray light were evaluated. We confirmed that the results of these evaluations were favorable and that the strict required specifications of the optical system are almost satisfied.

The effect of substrate structure of rubble-pile bodies on cratering process

TATSUMI, Eri[1*] ; SUGITA, Seiji[1]

[1]Graduate School of Frontier Science, The University of Tokyo

Introduction: Hayabusa obtained many high-resolution images and revealed that this asteroid has many unique morphological features which are not seen on other small planetary bodies. One of the most symbolic configurations are quasi-circular depressions (QCD) on boulder-rich surfaces, which are inferred as impact craters (Hirata et al,. 2009). If the QCDs are impact craters, then the surface crater retention age of Itokawa can be estimated based on crater chronology approach. However, age estimates has great uncertainty: 75Myr-1Gyr (Michel et al., 2009). The uncertainty in age results mostly from the uncertainty in crater scaling formed on the boulder-rich surface observed on rubble-pile bodies. The impact energy required for forming a crater on a small body is much smaller than that on a large body because of the limitation of catastrophic disruption energy (Benz and Asphaug, 1999). Impact cratering with such small energy on rubble-pile bodies are expected to follow a scaling low between the strength-regime rates and the gravity-regime cratering. The impactor destroys a surface boulder and dissipates its energy, then leading to a smaller crater: an armoring effect.

Moreover, impact induced mass loss is a critical value for estimating the life time of small bodies. The escape velocity of small bodies is very small. For example, Itokawa has an escape velocity of 10-20cm/sec. Thus, small bodies can easily lose their mass upon impact cratering.

As mentioned above, crater size and ejecta mass are important parameters for calculating the life-time of small bodies. However, these values for the rubble-pile bodies are not constrained well. Cratering process may be influenced greatly by the substrate structure of small bodies. In this study, the effect of the substrate structure of the rubble-pile bodies on the impact process is examined experimentally.

Experiment: Sintered glass beads blocks crashed into 8-15 mm chips and 200 micro meter glass beads are used as boulder simulants and regolith simulant in our experiments, respectively. We employ two types of targets: one consists of all boulders simulants (target 1) and the other consists of a surface layer of boulders simulants and regolith substrate (target 2). Polycarbonate projectiles 10mm diameter were launched at 160-180 m/sec of velocities. The impact cratering process was observed by a high-speed camera. We also measured the size of final crater and the ejecta mass.

Result: Crater size of target 1 is smaller by $\sim$20% than target 2, and ejecta mass of target 1 is smaller than by a factor of five than target 2. High-speed camera observations revealed that the surface boulders are destroyed by the impactor more heavily in the target 1. This difference occurs because the shock impedance of boulder simulants are larger than that of regolith simulant by a factor of ten and much stronger reflected stress waves comes back to the surface boulders for target 1, but the stress wave transmits efficiently from surface boulders to legolith layer in target 2.

These results suggest that the substrate structure of small bodies changes the impact process greatly. Crater size varies by $\sim$20% depending on substrate layers: boulders or regolith. Crater forming on bodies consisting of only boulder is smaller than bodies with regolith substrate but still much larger than crater on monolith (i.e., the scaling in strength-regime scaling). Consequently, the surface age of Itokawa could be on the younger side of the previous estimates as 75Myr-1Gyr with the strength-regime crater scaling. Furthermore, the substrate structures of the rubble pile bodies change the ejecta mass by 5 times. Rubble-pile bodies consisted of boulders possibly live longer.

Computer Vision in Space: Optical Navigation Technology Development for Hayabusa-2

OHTA, Naoya[1*]

[1]Gunma University

Computer vision (CV) is a research field aiming to establish technologies by which information of objects is extracted from their images. Using CV technologies, our research group are developing methods to construct shape model of an asteroid for Hayabusa-2 navigation. We report this activity in this article. In addition, applying CV technologies to space environment has a potential to drive CV itself to a new research direction. We also touch on this observation.

For Hayabusa-2 navigation, we need to know shape of the destination asteroid, but the long distance between the asteroid and the earth prevent us from measuring it from the earth. Therefore we have to measure it after the arrival to the asteroid. Because active measurement methods need too much power, we are developing methods using images taken from the spacecraft.

Our project is mainly run by Dr. Seiji Sugita at Univ. of Tokyo and Dr. Naru Hirata at Aizu Univ., who are researchers in planetary science. However, because shape reconstruction techniques using images have intensively been studied in CV and CG (computer graphics) areas, the project is contributed by Dr. Hiroshi Ishikawa at Waseda Univ. and the author from CV area, and Dr. Shigeo Takahashi at Univ. of Tokyo from CG area.

We have applied a structure from motion technique developed in CV without modifications to the shape reconstruction of asteroids. We have had a minimum result required for Hayabusa-2 navigation, but more precise model is needed to make the navigation more certain and flexible. Therefore, we are combining photometric stereo to it.

Photometric stereo is a shape reconstruction method utilizing reflectance information of objects. However, we cannot directly apply such techniques developed in CV to the asteroid, because the conditions assumed in CV are fairly different from our case. The CV techniques assume that a number of images are taken from the same position, but the spacecraft cannot be controlled in such a way because it requires too much fuel. In addition, the reflectance models are different; Lambertian and Phong, for example, are used in CV, but we need algorithms based upon models such as Hapke and Minnaert, which describe reflectance of planet materials. Therefore, we are developing new algorithms that match the space environment for Hayabusa-2 navigation.

Looking at the origin of CV, it was regraded as a part of artificial intelligence research and has been motivated by artificially realizing functions of visual systems of human beings, or creatures in general. It seems that, from this reason, methods developed in CV tend to be general-purpose, and also that environments on the earth are implicitly assumed. Therefore, algorithms in CV are sometimes not applicable to problems in space science. However, viewing the situation from a different point, it may inspire CV itself to a new research direction by giving clear purposes.

When assuming usage in space, the following peculiarities are observed. The light source is usually only the sun, so it often suffice to consider only parallel light as the illumination. We can develop algorithms fully taking advantage of this simplicity. As mentioned above, reflectance models special to planet are used. If the process is executed in spacecrafts, the amount of computation is very limited, so the view point to develop a minimum algorithm to fulfill the objective becomes important. On the other hand, if images are transferred to the earth, the number of images is limited, but usually no limitation exists in amount of the computation. In such a case, CG-CV loop where a CG model is iteratively modified so that the generated images match to the observed images becomes to have reality. In addition to stated above, computing other information needed for space science than shape, estimating error information (variance), and so on, are important tasks for space science. We believe developing these techniques is an important direction of CV research.

Analytical chemistry of organic compounds in the Solar System: An attempt to link with planetary science

YABUTA, Hikaru[1*]

[1]Osaka University, Department of Earth and Space Science

Analytical chemistry of organic compounds in the Solar System small bodies is a microscopic approach for understanding of the origin and evolution of building blocks of the Solar System and life, which has a complementary relationship with macroscopic approaches such as observational and theoretical astronomy. This approach would provide a significance of considering organic compounds in the planetary formation theory, which has been constructed only by silicate and ice dusts. Indeed, significant roles of organic compounds in the early Solar System are explained by (1) high abundances of C, H, O, N in the Solar System, (2) major components of dusts in interstellar clouds, (3) high reactivity to heat, light, shock, water, and minerals (chemical indicator recording the processes in the Solar System), (4) possible contribution to accretion of dusts, due to their stickiness (Kouchi et al. 2002), and (5) possible contribution to redox imbalance in solar nebula (that determined the chemical compositions of chondrules) (Yurimoto and Kuramoto, 1998). Despite these significant roles, however, organic cosmochemistry was not a very popular field in planetary science until several years ago. One of the reasons may be because of difficulty in visualization of organic compounds, i.e., drawing of a big picture. In this point, I attempt to show a simple example. When starch-syrup is heated, how is it changed. One would tell that the color is changed from colorless to brown, the originally sticky syrup becomes less sticky candy, and water-soluble syrup becomes an insoluble solid. These descriptions are based on visuality and are easy to understand. On the other hand, if these phenomena are translated to organic analytical chemistry, the description becomes quite different from the former; hydroxyl groups of glucose changes to carbonyl groups via dehydration as well as aromaticity increases with heating. However, it should be noted that two ways of descriptions explain exactly the same phenomenon. That demonstrates that physical properties (color, stickiness, and solubility) are determined by molecular chemical structures. Likewise, analytical chemistry of organic compounds in the Solar System has a potential to reveal the molecular science that determines physics of macroscopic planetary formation, such as the color of asteroids (albedo). This will become possible by improvements of the in-situ organic analyses such as spectromicroscopy (e.g., STXM), electron microscopy (TEM), and ion probe mass spectrometry (e.g., nanoSIMS), through visualization of the distributions of organics and minerals in the Solar System materials which record the chemical evolution from dusts to planetesimals.

Formation Process of Complex Organic Molecules in Protoplanetary Disks

NOMURA, Hideko[1*]

[1]Tokyo Institute of Technology

It is believed that chemical reactions in protoplanetary disks will lead the origin of materials in our Solar System. Recently, many complex organic molecules (COMs) have been found in molecular clouds by radio observations of molecular transition lines. Meanwhile, amino-acids are found in a comet and meteorites in our Solar System. In this work we investigate the synthesis of complex organic molecules in protoplanetary disks using a large gas-grain chemical network together with a 2D steady-state physical model of a disk irradiated by UV and X-rays from the central star. We find COMs are efficiently formed on cold and warm grains in the disk midplane via grain-surface reactions through efficient migration of icy species on grain surface. Radiation processing on ice forms reactive radicals and helps build further complexity. We find the grain-surface abundances predicted by our calculations are consistent with those derived from cometary comae observations. We also predict line spectra of COMs, which are partly photodesorbed into gas from grain surface, will be observable in nearby protoplanetary disks with ALMA. In this talk I would like to discuss further on formation process of COMs on grains in the asteroid belt region, too.

Status report of curation of Hayabusa-returned samples

YADA, Toru[1*] ; ABE, Masanao[1] ; UESUGI, Masayuki[1] ; KAROUJI, Yuzuru[1] ; ISHIBASHI, Yukihiro[1] ; OKADA, Tatsuaki[1] ; SATAKE, Wataru[1] ; FUJIMOTO, Masaki[1]

[1]Japan Aerospace Exploration Agency

Hayabusa spacecraft returned samples from S-type Near-Earth Asteroid (NEA) Itokawa in June 2010. After the return, Extraterrestrial Sample Curation Team (ESCuTe) of JAXA have recovered particles from a sample catcher of Hayabusa, and more than 400 particles initially described have been presented in public (Yada et al., 2014a). In this presentation, we review the recovery and initial description of Hayabusa-returned samples and mention their future schedule.

A sample container had been extracted from the reentry capsule of Hayabusa and cleaned in cleanrooms of the Extraterrestrial Sample Curation Center (ESCuC) of JAXA. It was introduced into a clean chamber No.1 and opened in vacuo, and then a sample catcher, which enclosed samples captured on the surface of asteroid Itokawa, was extracted to be transferred to a clean chamber No.2 which is designed to handle Hayabusa-returned samples in highly purified nitrogen condition. The sample catcher is mainly composed of a rotational cylinder through which captured samples had been transferred, a room A in which samples obtained by the second touchdown on Itokawa and a room B in which captured those of the first one. At first, we had prepared quartz glass disks of the same size with covers of the room A and B, on which particles inside each room were fallen by tapping. The particles on the quartz disks have been picked up one by one with a specially designed electrostatically-controlled micromanipulator to be placed onto a SEM holder which can seal the samples in nitrogen condition and initially described by SEM-EDS. Then they sent back to the clean chamber No.2 to be placed onto gridded quartz glass slides to be given their ID and preserved. In fiscal year of 2013, we started to describe particles on a cover of the room B with SEM-EDS directly, utilizing a SEM holder specially designed for the cover of the catcher (Yada T. et al., 2014b).

The initial description method using the quartz glass disks has disadvantages in inefficiency and risk of particles transportation one by one with the micromanipulator. In order to resolve these disadvantages, we have developed metal disks which particles can be fallen on by tapping and can be set to the SEM holder designed for the covered of the catcher in fiscal year of 2013. We are planning to start sample recovery by the metal disks in fiscal year of 2014, and going to confirm vast majority of particles inside the catcher for more than two years (Yada T. et al., 2014a).

The ESCuTe of JAXA started the international AO for Hayabusa-returned samples in the beginning of 2012. In the international AO, worldwide researchers can apply their proposals and the committee composed manly of top scientists outside JAXA reviews the proposals to determine which proposal the precious samples should be distributed. The AO have been published approximately annually, and the third AO will be published in the beginning of fiscal year 2014. The research results of the AOs are presented in the international symposium held by JAXA, named as ”Hayabusa 2013: Symposium of Solar System Materials”, and its proceedings will be published in the international journal.

Particles having rare features have not been provided to the international AOs, but to consortium studies led by ESCuTe of JAXA until 2013. So far, four consortia, including the maximum-sized particle, a NaCl-bearing one, an iron sulfide one, and ones containing phosphates Uesugi et al., 2013; Yada et al., 2013; Karouji et al., 2013). Particles having other rare features will be provided to consortium studies in future.

Examination of the origin of carbonaceous particles in Hayabusa-returned samples

UESUGI, Masayuki[1*] ; NARAOKA, Hiroshi[2] ; ITO, Motoo[3] ; YABUTA, Hikaru[4] ; KITAJIMA, Fumio[2] ; TAKANO, Yoshinori[3] ; MITA, Hajime[5] ; KEBUKAWA, Yoko[6] ; YADA, Toru[1] ; KAROUJI, Yuzuru[1] ; ISHIBASHI, Yukihiro[1] ; SATAKE, Wataru[7] ; OKADA, Tatsuaki[1] ; ABE, Masanao[1]

[1]Japan aerospace exploration agency, [2]Department of Earth and Planetary Sciences, Kyushu University, [3]Kochi Institute for Core Sample Research JAMSTEC, [4]Osaka University, Department of Earth and Space Science, [5]Fukuoka Institute of Technoology, Faculity of Engineering, Department of Life, Environment and Mater, [6]Department of Natural History Sciences Hokkaido University, [7]Department of Earth and Planetary Science, University of Tokyo

Extraterrestrial Sample Curation Team (ESCuTe) recovered more than 50 carbonaceous particles from the sample catcher of the Hayabusa spacecraft. Those carbonaceous materials, named as category 3, were found in the form of particles with similar size range of the silicate particles those confirmed as Itokawa regolith particles. Initial description by the SEM-EDS analysis shows variable textures and chemical compositions of them, suggesting the multiple origins of the carbonaceous materials.

Preliminary examinations of category 3 particles were carefully processed in parallel with those of silicate materials. However, we could not obtain the information for the origin of category 3 particles before the opening of international announcement of opportunity (A/O). The ESCuTe and preliminary examination team of category 3 particles have continued the investigations. In this paper, we report the several recent results obtained from the sequential analyses.

Samples allocated for the preliminary examinations of category 3 are RA-QD02-0008, RA-QD02-0120, RA-QD02-0180, RB-QD04-0001, RB-QD04-0037-01 and RB-QD04-0047-02. RA-QD02-0008 was lost during the manipulation at first preliminary examination. Three samples, RA-QD02-0120, RB-QD04-0001, and RB-QD04-0047-02, were pressed on the Au plate and fixed without any adhesive materials. We analyzed H, C and N isotopic composition by nano-SIMS in the beginning of the sequential study, in order to investigate the isotopic anomaly which is a direct evidence of extraterrestrial origin of organic materials [8]. FT-IR and micro-Raman spectroscopy were also applied for the pressed samples [9]. After ToF-SIMS analysis of those particles, the samples were sliced by FIB in order to investigate the fine structure of the samples by XANES and TEM/STEM [10].

We performed those analyses with determining the effect on the subsequent analyses, such as sample damages and contaminations. The rest two particles, RA-QD02-0180 and RB-QD04-0037-01 were pressed on indium plates, because significant disturbance by Au on the ToF-SIMS analyses was found. We will also report the construction of the sequential analysis flow of tiny carbonaceous particles.

In parallel with the Hayabusa-returned particles, we processed observation and analysis of insoluble organic matter (IOM) of A881458 (CM2) and several possible materials of the origin of the category 3 particles, such as viton, silicon rubber, vectran and particles collected from the Hayabusa2 clean room.

We did not obtain any signature of extraterrestrial origin from category 3 particles so far. We are planning to continue the preliminary examination of category 3 by the end of March 2014. We are also planning to open the category 3 particles to the future International A/O, with the data of preliminary examinations before the end of 2014.

H, C and N isotopic compositions of HAYABUSA Category 3 organic samples

ITO, Motoo[1*] ; UESUGI, Masayuki[2] ; NARAOKA, Hiroshi[3] ; YABUTA, Hikaru[4] ; KITAJIMA, Fumio[3] ; MITA, Hajime[5] ; TAKANO, Yoshinori[6] ; KAROUJI, Yuzuru[2] ; YADA, Toru[2] ; ISHIBASHI, Yukihiro[2] ; OKADA, Tatsuaki[2] ; ABE, Masanao[2]

[1]Kochi Institute for Core Sample Research, JAMSTEC, [2]Japan Aerospace Exploration Agency, [3]Department of Earth and Planetary Sciences, Kyushu University, [4]Osaka University, Department of Earth and Space Science, [5]Fukuoka Institute of Technology, Department of Life, Environment and Materials Science, [6]Institute of Biogeosciences, JAMSTEC

Hayabusa spacecraft had brought back asteroid Itokawa particles to the Earth on June 2010. More than 1,500 mineral particles were identified on the Qz glass after the compulsive free fall, and most of them were very small ranging from 10 to 300 μm but are mostly smaller than 50 μm (Nakamura et al., 2011). In addition several amount of carbonaceous materials were found that is called Category 3. Based on FE-SEM and EDS observations at JAXA Extraterrestrial Sample Curation Team, those samples mainly composed of C, N, O and some of them contain NaCl and KCl (JAXA Hayabusa sample catalogue).

H, C and N isotopic compositions of extraterrestrial organic materials in Stardust cometary samples (McKeegan et al., 2006), IDPs (Messenger, 2000), IOM (Busemann et al. 2006) and nanoglobules in primitive chondrite (Nakamura-Messenger et al., 2006) provide a clue for understanding of origin and nature of the Solar System. Large D and 15N isotopic enrichments were observed, and C isotope is slightly enriched in 13C in extraterrestrial organic materials (Pizzarello, 2005). Those data suggest that extraterrestrial organics are probably interstellar material that was survived through formation processes (planetesimals) of the Solar System (Sanford et al., 2001), and may also have material that formed in the cold molecular cloud region of the protoplanetary disk (Aikawa et al., 2002).

Here we report H, C and N isotopic measurement of organic materials from Hayabusa Category 3 samples, RB-QD04-0047-02, RA-QD02-0120 and RB-QD04-0001, by an ion imaging with the JAMSTEC NanoSIMS ion microprobe. The purposes of this study are to evaluate terrestrial contaminations in the Hayabusa spacecraft and in the JAXA curation facility, and to find extraterrestrial organic materials on the basis of H, C and N isotope measurements.

Each Hayabusa organic sample was pressed on Au plate together with terrestrial organic standards of 1-hydroxybenzotriazole hydrate and BBOT with known H, C and N isotopic compositions. Following the SEM study to check the sample condition, texture and morphology, the samples were analyzed for H, C and N isotopic compositions by an isotopic imaging with the JAMSTEC NanoSIMS 50L at Kochi Institute for Core Sample Research.

We studied three Hayabusa organic samples, RB-QD04-0047-02, RA-QD02-0120 and RB-QD04-0001. All of the samples have been initially investigated by a FE-SEM and EDX observation at JAXA Hayabusa curation facility, and the EDX spectra of the samples contain C, N and O; the dominant elements are C, and N (Hayabusa sample catalogue).

Based on NanoSIMS isotopic images of H, C and N in RB-QD04-0047-02, RA-QD02-0120 and RB-QD04-0001, all three samples show homogeneous and terrestrial H, C and N isotopic compositions within an error (δD = 60 $\pm$ 13 permil, δ13C = 3 $\pm$ 3 permil and δ15N = -4 $\pm$ 2 permil for RB-QD04-0047-02; δD = 81 $\pm$ 54 permil, δ13C = -20 $\pm$ 8 permil and δ15N = 2 $\pm$ 2 permil for RA-QD02-0120; δD = 135 $\pm$ 32 permil, δ13C = -20 $\pm$ 9 permil and δ15N = 16 $\pm$ 12 permil for RB-QD04-0001).

The IOMs in CI and CM chondrites show heterogeneous distributions of delta-D at the molecular (Remusat et al. 2009) and micron scale level (Busemann et al., 2006). The IOMs of CR, CM and CI have D and 15N isotopic enrichments in micron-sized regions (hot spots). The IOMs in ordinary chondrites are heterogeneous, however, they do not show many micron-scale anomalies as IOMs in carbonaceous chondrite (Remusat et al., 2013). It is obvious that H, C and N isotope signatures of Hayabusa organic samples are different from those of IOMs in carbonaceous and ordinary chondrites: i.e., No hot spots, terrestrial values for H, C and N isotopes.

We have not found strong evidence of extraterrestrial origin because isotope compositions of H, C and N in Hayabusa organic samples show terrestrial values, and homogeneous distributions of H, C and N in the samples, which are unlike to IOM in various types of chondrites.

Albedo properties of main belt asteroids based on the infrared all-sky surveyors

USUI, Fumihiko[1*]

[1]University of Tokyo

Presently, the number of asteroids is known to be more than 620,000, and more than 90% of asteroids are classified as the main-belt asteroids (MBAs). The spatial distribution of compositions among MBAs is of particular interest, because the main belt is the largest reservoir of asteroids in the solar system. Asteroids are thought to be the remnants of planetesimals formed in the early solar system, and have a clue to study the formation and evolution of asteroids, origin of meteoroids and the near-Earth asteroids, as well as the formation of the solar system. Size and albedo are one of the most basic physical quantities of asteroid. Knowledge of size and albedo is essential in many fields of asteroid research, such as chemical composition and mineralogy, the size-frequency distribution of dynamical families and populations of asteroids, and the relationship between asteroids in the outer solar system and comets.

Several techniques have been developed to determine the size of asteroids. One of the most effective methods for measuring asteroidal size and albedo indirectly is through the use of radiometry, where a combination of the thermal infrared flux and the absolute magnitude as the reflected sunlight. Using radiometric measurements, a large number of objects can be observed in a short period of time, providing coherent data for large populations of asteroids within the asteroid belt. Infrared observations can be made still better under ideal circumstances, from space. The first space-borne infrared telescope is the Infrared Astronomical Satellite (IRAS; Neugebauer et al. 1984), launched in 1983 and performed a survey of the entire sky. To date, there are two other infrared astronomical satellites dedicated to all-sky survey: the Japanese infrared satellite AKARI (Murakami et al. 2007), and the Wide-field Infrared Survey Explorer (WISE; Wright et al. 2010). Based on the all-sky survey data obtained by IRAS, AKARI, and WISE, the largest asteroid catalogs containing size and albedo data were constructed (e.g., Tedesco et al. 2002; Usui et al. 2011; Mainzer et al. 2011). The total number of asteroids detected with size and albedo information with these three surveyors is 138,285, which is 22% of currently known asteroids with orbits.

In addition, several outstanding works have provided the taxonomic classification of asteroids (e.g., Tholen 1989; Bus & Binzel 2002; Lazzaro et al. 2004; Carvano et al. 2010), based on ground-based spectroscopic observations within optical and near-infrared wavelengths. Along with these taxonomic classifications, size and albedo data also contribute to our understanding of asteroid compositions. In general, the albedo of C-types is considered as low and that of S-types is high (e.g., Zellner & Gradie 1976). The relationship between taxonomic types and albedo is, however, complex and type determinations cannot be made on the basis of albedo values alone. Recently albedos of C- and S-type asteroids are found to vary widely, especially for sizes smaller than several tens km (Usui et al. 2013). Furthermore, in spite of the albedo transition process like space weathering, the heliocentric distribution of the mean albedo of asteroids in each taxonomic type is found to be nearly flat. In the total distribution, on the other hand, the mean albedo value gradually decreases with increasing the semimajor axis, presumably due to the compositional mixing ratios of taxonomic types.

In this talk, we present the details of data compiling of size, albedo, and taxonomy of MBAs, and discuss the compositional distribution in the main belt regions.

We have made the lightcurve observation of 13 vestoids ((1933) Tinchen, (2011) Veteraniya, (2508) Alupka, (3657) Ermolova, (3900) Knezevic, (4005) Dyagilev, (4383) Suruga, (4434) Nikulin, (4796) Lewis, (6331) 1992 FZ_1, (8645) 1998 TN, (10285) Renemichelsen, and (10320) Reiland).

Lightcurves in the R-band of rotation periods were found for (1933) Tinchen, (2011) Veteraniya, (2508) Alupka, (3657) Ermolova, (3900) Knezevic, (4005) Dyagilev, (4383) Suruga, (4796) Lewis, (6331) 1992 FZ_1, (8645) 1998 TN, and (10320) Reiland.

The distribution of rotational rates of 59 vestoids in the inner main belt, including 29 members of the Vesta family that are regarded as ejecta from the asteroid (4) Vesta, is inconsistent with the best-fit Maxwellian distribution.

This inconsistency may be due to the effect of thermal radiation Yarkovsky- O'Keefe-Radzievskii-Paddack (YORP) torques, and implies that the collision event that formed vestoids is sub-billion to several billion years in age.

Near-infrared spectral measurements of zodiacal light by CIBER rocket experiments

MATSUURA, Shuji[1*] ; ARAI, Toshiaki[1] ; ONISHI, Yosuke[1] ; SHIRAHATA, Mai[1] ; TSUMURA, Kohji[1] ; MATSUMOTO, Toshio[2] ; BOCK, James[3] ; CIBER, Team[3]

[1]JAXA, [2]ASIAA, [3]Caltech

We have observed the cosmic near-infrared background light as the integrated light along the line of sight, which is the near-infrared diffuse radiation in wide range of the cosmic structure from the solar system to extragalactic universe, with the CIBER (Cosmic Infrared Background ExpeRiment) rocket experiments. One of scientific objectives of CIBER is to measure the zodiacal light in the near-infrared, which is the scattered sun light by interplanetary dusts. From the results of CIBER, we first observed the zodiacal light spectrum and its polarization in the near-infrared range from 0.8 to 2 mincrons. In this paper, we present the observation results.

CIBER is an international collaboration study among Japan, US and Korea, and a sounding rocket program by NASA. In a term from 2009 to 2013, we have carried out four times of launch and obtained high quality data at the altitudes above 200 km with no contamination by the earth atmosphere. In order to measure the extragalactic background light, we selected the observation field to have solar elongation over 90 degrees with relatively low brightness. We extracted the zodiacal light component from the total sky brightness by using the ecliptic latitude dependence. As the result, we could obtain information of spectrum, polarization and seasonal variation of the zodiacal light.

The observed infrared spectrum shows neither ecliptic latitude dependence nor time variation, and reddened color compared with the solar spectrum at wavelengths below 1.5 microns. From this result, size of interplanetary dust is larger than the order of micron, and there may be absorption of dust minerals at shorter wavelengths. We found the polarization of 20-25% at the maximum at the north ecliptic pole, which is higher than that previously observed in the visible wavelength range. The polarization result also suggest that the majority of the dust size is much larger than the observation wavelength.

In this paper, we report the observation result, and we discuss the optical properties of interplanetary dust by comparing our result with the spectral reflectance of meteorites and cometary dust.

Reflectance Spectra of Jovian Small Satellites and Implication of their Origin

TAKATO, Naruhisa[1*] ; TERADA, Hiroshi[1] ; YOSHIDA, Fumi[1] ; OHTSUKI, Keiji[2]

[1]National Astronomical Observatory of Japan, [2]Kobe Univ.

Abstract

Jupiter has many small satellites other than the four giant Galilean satellites. Four of them revolve inside Io's orbit and others revolve outside Calisto's orbit. Based on the similarities of their photometric and orbital properties, these small satellites are thought to be captured asteroids. However, it is still unknown where and when these satellites were captured by Jupiter. We can reveal the dynamic history of our solar system evolution by investigating these questions.

Here, we have made optical spectroscopies of 11 small satellites which were not yet taxonomically classified by spectroscopy so far. We compared the number ratio of C- and X-type to D-type of the 11 satellites, and the Hilda and Trojan groups observed recently by Grav et al. (2012) as a function of diameter. We found that the diameter-(C,X)/D relation of the Jovian irregular satellites is similar to that of Hilda's, not Trojan's. This result suggests that the Jovian irregulars and the Hilda members originate from the same source of asteroids.

We also observed the 3.05 μm narrow-band photometry of the inner small satellite Thebe and found that there is absorption. This can be attributed to hydrated minerals.

Weathering effect of solar wind proton on hydrated silicate minerals

NAKAUCHI, Yusuke[1*] ; ABE, Masanao[2] ; KITAZATO, Kohei[3] ; TSUCHIYAMA, Akira[4] ; YASUDA, Keisuke[5]

[1]The Graduate University for Advanced Studies, [2]Japan Aerospace Exploration Agency, [3]University of Aizu, [4]Kyoto University, [5]The Wakasa Wan Energy Reserch Center

NIRS3 is an on-board near infrared spectrometer of Hayabusa-2 project which is aimed at returning samples from C-type asteroid 1999 JU3. In this project, it is important to characterize mineralogical and heterogeneities on the asteroid surface for the sampling site selection. Observing wavelength of NIRS3 is including the 3 μm band which is charactering C-type asteroid (*Rivkin et al. LPSC 2002, Milliken et al. 2007*). The NIRS3 will measure reflectance spectra of asteroid surface in the wavelength range of 1.8 - 3.2 μm. This wavelength region includes features mainly related to OH and H_2O.

The spectral properties of the surface, however, would have different trend to the subsurface, because the surface of asteroids would be exposed to solar wind and micrometeorite. As for the reflectance spectrum of the moon, the absorption feature from 2.8 μm to 3.0 μm was reported in M^3 data (*Pieters et al. 2009*). It is thought that the implantation of solar wind proton is one of the causes (*McCord et al. 2011*). The solar wind protons will affect the spectral shape of 3μm region of air less bodies. Thus we study effect of irradiation of solar wind protons on near-infrared reflectance spectra by laboratory experiment.

We executed the simulation of irradiation of solar wind protons using ion implantation device at the Wakasa Wan Energy Research Center (WERC), Fukui. This device can irradiate $H_2{}^+$ beam with 10 keV in a vacuum (under 1×10^{-5} Pa). The total amount of $H_2{}^+$ was about 10^{18} ion/cm^2. Three samples were prepared; olivine (San Carlos, Arizona), antigorite (Sangenchaya, Kyoto), saponite (synthetic: Kunimine Industries Co., Ltd.). Antigorite and saponite were sieved between 50 μm and 75 μm and olivine served between 75 μm and 105 μm, and then they were heated for 24 hours at 423 K. They were packed into Cu cups and formed pellets. After irradiated the spectra were measured using FTIR, which resolution was 2.0 cm^{-1} in wavenumber. We adopted the analysis method of *Ichimura et al. (2012)*, which is to compare the reflectance spectra of altered sample, R, with unaltered sample, R_0, to determine the alteration ratio of spectra, R/R_0, without absorption water.

The alteration ratios of irradiated samples were different between minerals. The alteration ratio of olivine showed increasing of broad absorption feature from 2.8 μm to 3.8 μm due to OH/H_2O production. In antigorite and saponite, the alteration ratio, additionally, showed characteristic change related to coupling state of -OH. In the alteration ratio of antigorite, stretching of -OH bonded water molecule (-OH $\cdots$ ^{H}OH) at 2.77 μm and stretching of -OH $\cdots$ ^{H}OSi at 2.85 μm was increased conspicuously. On the other hands, the alteration ratio of saponite was changed conspicuously at 2.77 μm.

We think that the difference of the bands which showed conspicuously change is related with structure of minerals. Antigorite have -OH into the crystal. Therefore the irradiated protons broke bonds of Si-O and produced newer hydrogen bonds which are -OH $\cdots$ ^{H}OH or -OH $\cdots$ ^{H}OSi. Saponite has H_2O as interlayer water. It would be similarly broken bands of Si-O and produced newer hydrogen bonds which are -OH $\cdots$ ^{H}OH. These spectral changes can explain same process. These features support that the irradiated protons react with bonds of Si-O in the crystal.

In this study, we showed that the alteration of feature related with OH/H_2O is different from each mineral. Next step, we will examine the other minerals against determination minerals and the amount of water from reflectance spectra.

The effect of coexisting iron sulfide on space weathering by nanosecond pulse laser irradiation

OKAZAKI, Mizuki[1*] ; SASAKI, Sho[1] ; HIROI, Takahiro[2]

[1]School of Science, Osaka University, [2]Brown University

High-velocity impacts of micrometeorites and solar-wind particles change the surface optical properties of airless silicate bodies such as asteroids and the Moon. This process is called ”space weathering”. Experiments using nanosecond pulse laser confirmed the prediction that the formation of nanometer-size metallic iron particles should cause darkening, reddening and attenuation of absorption bands in visible and near infrared reflectance. The space weathering may explain the spectral mismatch between S-type asteroids and ordinary chondrites.

Previously sulfur depletion from asteroid surface was advocated on the basis of low sulfur abundance on Eros.

Recently on the surface of dust particles from Itokawa’s surface returned by Hayabusa, a thin layer containing nano particles of FeS over amorphous zone containing nano iron particles. A 10 micron size FeS crystal is also found in one Itokawa-derived grain.

To examine the effect of FeS on the space weathering, we conducted simulation experiments of the space weathering of silicate-FeS mixture using nanosecond pulse laser irradiation.

Then S is rich in volatility, so we guessed if sulfur has a certain influence on space weathering at the astronomical surface, and the experiments on chondrites with S by using nanosecond pulse laser.

We prepared pellet samples of powdered olivine and pyroxene (45-75 micrometer) mixed with iron sulfide particles (of 10, 20wt%) with same (and smaller) size range. We also prepared olivine pellet samples containing metallic iron particles of 10 to 20 wt%.

We found that the addition of Fe should enhance reddening and also darken near infrared reflectance (about 20% in the case of 10-20wt % FeS)., as compared with the case of the addition of Fe.

Although it was space weathering which has so far attracted attention from reddening, such as reddening by weathering in case Fe is contained, in the case where FeS is added, darkening was also seen and it has checked that space weathering became strong. Although existence of nano iron particulates can be considered about reddening, about overall darkening, it is under examination.

The samples were irradiated by nano-second pulse laser.

Photometric Properties of (162173) 1999 JU3 in Preparation for JAXA Hayabusa 2 Sample Return Mission

ISHIGURO, Masateru[1*] ; KURODA, Daisuke[2] ; HASEGAWA, Sunao[3] ; HAYABUSA 2, Observation sub-group[4]

[1]Department of Physical and Astronomy, Seoul National University, [2]Okayama Astrophysical Observatory, National Astronomical Observatory of Japan, [3]Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency, [4]Japan Aerospace Exploration Agency

A near-Earth asteroid, (162173) 1999 JU3 (hereafter 1999 JU3), is a primary target asteroid for Hayabusa 2 sample return mission. We conducted a worldwide campaign to make photometric observations of the asteroid to determine the physical properties. 1999 JU3 is classified into C-type asteroid having a nearly spherical shape and the synodic rotational period of 7.6312±0.0010 hr.

In this presentation, we will report further information about 1999 JU3 determined since last JpGU meeting in 2013. We investigated the magnitude-phase angle relation. We obtained the parameters for IAU H-G formalism, H =19.20±0.12 and G=0.077±0.011 (V-band, 550nm), respectively. In combination of our result with infrared photometry, the geometric albedo is updated to be 0.05 (Mueller et al. in preparation), which is typical to but slightly smaller than the average of C-type asteroids in main-belt. We found that the magnitude-phase angle relation has a linear behavior in a wide range of the phase angles (5-80 degree) and show a possible non-linear opposition brightening within the phase angle of ‹ 5 degree. The phase slope is consistent to those of tens-km C-type asteroids, that is, 0.04 mag degree^{-1}. The opposition effect amplitude, ≈10% or less, is slightly weaker than that of a precursor C-type mission target body, (253) Mathilde, but the difference seems to reflect the diversity of C-type asteroids. Recently, Shevchenko & Belskaya (2010) reported that ˜20% of all studied low albedo asteroids did not show detectable opposition effect. We explore the significance of 1999 JU3 data with remote-sensing devices in terms of the opposition effect.

The Japanese asteroid explorer 'Hayabusa2' will be launched at end of 2014, and it will probe the near-Earth C-type asteroid '1999JU3'. In this mission, we have a plan to utilize the laser altimeter (LIDAR) to investigate the distribution of geometric albedo of 1999JU3 at laser wavelength (1064 nm). The LIDAR on-board Hayabusa2 has functions to measure the intensities of sending laser pulse and receiving laser pulse reflected from the asteroid surface in addition to measurement of distance between the spacecraft and the asteroid. We can evaluate the geometric albedo of the 1999JU3 using the measured intensities of sending and receiving pulses.

In this presentation, we will indicate results of the performance tests of the LIDAR and expected accuracy of the albedo evaluated from the results of the tests. We will also describe not only effect of characteristic of the LIDAR but also effects of inclination and roughness of the asteroid surface on estimation of the albedo.

In our study, three types of scientific topics using information of the albedo on asteroid surface estimated from the LIDAR data with other equipment data are considered; they are (1) rock and mineral category of 1999JU3, (2) degree of water content on asteroid surface and (3) variation of asteroid surface caused from space weathering and/or exterior material. We will report prospects to obtain information about these science topics applying the LIDAR which has our evaluated performance.

Performances of Flight Model of NIRS3: the Near Infrared Spectrometer on Hayabusa-2

IWATA, Takahiro[1*] ; KITAZATO, Kohei[2] ; ABE, Masanao[1] ; ARAI, Takehiko[1] ; NAKAUCHI, Yusuke[3] ; NAKAMURA, Tomoki[4] ; HIROI, Takahiro[5] ; MATSUOKA, Moe[4] ; MATSUURA, Shuji[1] ; OZAKI, Masanobu[1] ; WATANABE, Sei-ichiro[6]

[1]Institute of Space and Astronautical Science, JAXA, [2]University of Aizu, [3]Graduate University for Advanced Studies, [4]Tohoku University, [5]Brown University, [6]Nagoya University

NIRS3: the Near Infrared Spectrometer is one of the candidate scientific instruments which will be equipped on Hayabusa-2 mission. It aims to observe near infrared spectroscopy at the wave length band of 1.8-3.2 micrometer to detect specific molecular absorption lines, including the absorption by hydrated minerals at 3 micrometer, on the target C-type asteroid. The major purpose of NIRS3 is to observe the absorption bands of hydrated minerals in the 3 micrometer band on the candidate target C-type asteroid 1999JU3. C-type asteroids are thought to be mother celestial bodies of carbonaceous chondrites (C-chondrites). C-chondrites have been classified into sub-groups by their composition, organization, and isotope ratio of oxygen. The spectra of C-type asteroids have also been classified into sub-types by their inclination and the existence of absorption bands detected in ground observations. However, the relationship between the sub-groups of C-chondrites and the sub-types of C-type asteroids has not been clarified due to the effects of solar radiation and space weathering. Therefore, we will directly observe the surface of a C-type asteroid without the terrestrial atmospheric absorption in the 3 micrometer band using NIRS3. Detecting younger terrain by global mapping of the asteroid and the ejecta of new crater by the Small Carry-on Impactor (SCI) will also provide the spectra of surface less affected by space weathering. To estimate the quantities of the hydrated minerals with accuracies of 1 to 2 wt%, we designed the NIRS3 system to have a signal-to-noise ratio (SNR) exceeding 50 at 2.6 micrometer for global mapping.

The ground tests for NIRS3 flight model started in 2013. Results of the flight model tests implied that the dark current at the InAs sensor is much lower than that of the engineering model which improves SNR. The projected on-board SNR was confirmed to be sufficient during the one-year observation period of 1999JU3 assuming the asteroid surface temperature estimated from the heliocentric range and solar phase angle. The SNR exceeds 300 after 2.5 ms integration and 1024-stacking at the home position observations. The data obtained after the vibration tests and thermal-vacuum tests indicate that NIRS3 is sufficiently durable for the launching and on-orbit environments. The observed spectra for samples of serpentine, olivine, and C-chondrites (Murchison, Murray, and Jbilet Winselwan) demonstrated that the derived reflectances are almost the same as those obtained by Fourier-transform infra-red (FTIR) spectroscopy. These design results show that NIRS3 has sufficient performance for scientific objectives.

[1]ISAS/JAXA, [2]JSPEC/JAXA, [3]Hokkaido University, [4]Rikkyo University, [5]Chiba Institute of Technology, [6]University of Aizu, [7]Hokkaido University of Education, [8]AIST, [9]NIES, [10]University of Tokyo, [11]Sokendai, [12]German Aerospace Center (DLR), [13]Max Planck Institute for Extraterrestrial Physics (MPE), [14]Open University

Thermal Infrared Imager TIR onboard Hayabusa2 is to map thermo-physical properties of Near-Earth C-class asteroid (162173) 1999JU3 through thermal imaging. Scientific significance must be placed on physical properties of asteroids as well that imply the planetesimal formation in solar nebula and its mechanical evolution to current small bodies, although planetary material science is often more focused in small body missions.

In the typical solar system evolution scenario, very fluffy porous bodies are formed in solar nebula and then become denser due to high-speed collision and thermal metamorphism. Some C-class asteroids are less dense, implying a highly porous assembly of densely compacted rocks or a loosely bound rubble-pile of porous rocks and soils. Those features will be identified by thermo-physical properties derived with TIR. Some C-class asteroids must have experienced dehydrated process whose clues might be found as veins or grooves on the asteroid. Those features are expected to be investigated by TIR. Granular flows which were found on asteroid Itokawa and ejecta sediments around impact craters will be measured by TIR as different thermal inertia zones because they have smaller particle size or higher porosity. Floating boulders (or moons), surrounding dust or vapor clouds ejected from asteroid surface could be detected by TIR if they exist sufficiently. Furthermore, on-site TIR observation will contribute to more confident and accurate determination of asteroid thermo-physical properties by ground observation.

TIR is a thermal infrared imager using two-dimensional micro-bolometer array, which has 328 x 248 effective pixels, 16 x 12 degrees field of view, and 0.05 degree per pixel, so that pixel resolution is 20m when observed from 20km altitude Home Position (HP), and less than 1m from 1km altitude covering 280m x 210m. The imaging feature is suitable for obtaining asteroid global feature from HP and investigating local geological context before and after sample collection. Hayabusa2 will observe asteroid 1999JU3 at the heliocentric distance from 0.96 to 1.42 AU and the dayside surface temperature is estimated -40 to 150 ℃ assuming the albedo is 0.05 and emissivity is 0.90 to 0.95. Detection range of TIR is 8 to 12 μm, which is best for observing thermal radiation from asteroid.

We have calibrated TIR performance for the target temperature ranging from -40 to 150 ℃. Goal is to construct the calibration curves for each pixel by 3 ℃ absolute temperature as well as 0.3 ℃ NETD. The apparatus for TIR calibration are the vacuum chamber for cold target and the clean-booth for hot target, with adjusting the optics and mounted panel temperatures. It is ideal that a single OFPN (Onboard Flat Pattern Noise) data is applicable for all the temperature range. Now efforts have been taken to improve its performance by interrelation between cold and hot calibration cases, adjusting bias levels due to different thermal energy input to detector, as well as geometric calibration. Instrumentation and results of calibration for TIR will be reported in detail.

Relationship between Regolith Particle Size and Porosity on Small Bodies

KIUCHI, Masato[1*] ; NAKAMURA, Akiko[1]

[1]Department of Earth and Planetary Sciences, Kobe University

Planetary small bodies are covered by a particulate layer called regolith. The particle size and porosity of the regolith surface of small bodies are important physical properties. The responses of the surface to solar irradiation are dependent on the particle size and porosity. The particle size and porosity have influences on the dynamic responses of the surface, such as cratering efficiency. By Apollo missions, the particle size was directly measured and estimated the mean porosity of the regolith 51% (Mitchell et al., 1974). The near-surface bulk porosity of asteroid was estimated using ground-based radar data to have a mean of 51∓14% (Magri et al., 2001). The angular width of opposition surge in optical reflectance was interpreted in terms of porosity and particle size distribution : surface porosities of S-class asteroidswere ranging from 40 to 80 % (Hapke, 1986; Domingue et al., 2002).

An empirical relationship between porosity and the ratio of the magnitudes of the interparticle force that was estimated as the capillary force and gravity which act on a particle was presented by Yu et al. (2003). The porosity was measured for the particles in the loose packing state and different porosities were interpreted as due to the difference of particle size. In this study we assume that the van der Waals force is predominant in the interparticle forces. A model formula of the van der Waals force in which the effect of adsorbate molecules is taken into account by a parameter is defined as

$Fv=AS^2r/48\Omega^2$ (1)

where A is Hamaker constant, r is particle radius, Ω is diameter of an O^{-2} ion, S is cleanliness ratio which shows the smallness of a number of the adsorbate molecules (Perko et al., 2001). It was shown that cleanliness ratio, S, is approximately 0.1 on the Earth, and is almost unity in the interplanetary space. In addition to the data of the several past studies, our own measurement result of micron-size fly ash particles in atmospheric condition.

We calculate Fv of all data using Eq.2, and obtain a revised relationship between porosity and the ratio RF of the magnitudes of the van der Waals force and gravity Fg , $R_F = F_V/F_g$. An empirical formula used in the previous study (Yu et al., 2003) ,

$p=p_0+(1-p_0)\exp(-mR_F^{-2})$ (2)

is applied to fit the data, where p_0, m and n are constants. Substituting Eq.1 to Eq.2 yields,

$p=p_0+(1-p_0)\exp\{-m(AS^2/64\pi\Omega^2\rho gr^2)^{-n}\}$ (3)

where $\rho$is particle density and g is gravitational acceleration.

We apply Eq. 3 to the conditions of small bodies ' surfaces to derive the relationship between particle radius and porosity. For example, we obtained the relationship for asteroid 25143 Itokawa surface. The particle size of Itokawa is ranging from millimeter to centimeter in the area of fine particles, smooth terrain of the Muses Sea (Yano et al., 2006). The result shows the range of porosity would be 0.55-0.8. Similarly, we can calculate the above relationships for other small bodies.

Gundlach and Blum (2013) estimated the particle size of small bodies by using the thermal inertia data and a heat conductivity model for regolith. By combining the relationship described for Eq.3 with those of Gundlach and Blum (2013), we can estimate the particle size and the porosity of regolith for the small bodies simultaneously.

How to detect a small crater produced by Small Carry-on Impactor (SCI) using Thermal InfraRed Camera (TIR)

WADA, Koji[1*] ; NAKAMURA, Akiko[2] ; KUROSAWA, Kosuke[1] ; SCI, Team[3] ; TIR, Team[3]

[1]PERC/Chitech, [2]Department of Earth and Planetary Sciences, Kobe University, [3]Hayabusa-2 Project

In Hayabusa-2 mission, a crater will be formed on the surface of a C-type asteroid 1999JU3 using Small Carry-on Impactor (SCI) and the crater should be quickly detected from the mother ship. The detection, however, will become difficult when the crater is very small with a diameter of only 30 cm, near to the resolution limit of on-board cameras. On the other hand, Thermal InfraRed Camera (TIR) mounted on Hayabusa-2 has a possibility to detect such a small crater even if the crater size is sub-pixel of TIR resolution, because the temperature on the surface of a small crater is expected to be different from that around the crater. We, therefore, have started examination about the possibility and method to detect a SCI-formed small crater using TIR. In this presentation, we introduce the basic idea and the preliminary results of our modeling.

SCI (Small Carryon Impactor" boarded on "Hayabusa 2" is a hollow Cu sphere with a mass of 15 kg, a diameter of 15 cm, which will impact a surface of asteroid 1999JU3. To estimate the conditions of the surface of the asteroid, such as composition and structure, we should investigate the results of the impact experiments with similar projectiles and various targets. We carried out impact experiments with gypsum and basalt targets and small hollow projectiles accelerated by a two-state light-gas gun at ISAS/JAXA, and sand targets and real scale projectiles at Kamioka. We report a summary of the results of these experiments.

Impact crater formation on quartz sand: the effect of projectile density on ejecta velocity distributions

TSUJIDO, Sayaka[1*] ; ARAKAWA, Masahiko[1] ; WADA, Koji[2] ; SUZUKI, Ayako[3]

[1]Graduate School of Science, Kobe University, [2]Planetary Exploration Research Center, Chiba Institute of Technology, [3]Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency

Introduction : Regolith formation and surface evolution on asteroid are caused by high velocity impacts of small bodies. The ejecta velocity distribution is one of the most important physical properties related to the crater formation and it is necessary to reconstruct the planetary accretion process among planetesimals. The surface of small bodies in the solar system has a various property on the porosity, strength and density. Therefore, the impact experiment on the target with the various properties is necessary to clarify the crater formation process applicable to the small bodies in the solar system. However, there have not enough studies on the effect of projectile density on the ejecta velocity distribution. Therefore, we would try to determine the effect of projectile density on the ejecta velocity distribution using 8 projectiles with different density by means of the observation of the each ejecta grain.

Experimental method: The cratering experiment was made by using a vertical type one-stage light gas gun (V-LGG) set at Kobe Univ. We used 3 types of targets: that is, they are the 100micron-glass beads target (porosity 37.6%), the 500 micron-glass beads target (porosity 37.6%), and 500-micron quartz sand (porosity 44.7%). These granular materials were put into the stainless steel container with the diameter of 30cm and the depth of 11cm. The target container was set in a large chamber with the air pressure less than 10^3 Pa or 10^5Pa. The material of the projectile that we used was a lead, a copper, an iron, a titanium, a zirconia, an alumina, a glass, and a nylon (1.1-11.3g/cm^3), and it had a diameter of 3mm and was launched at the impact velocity (v_i) of 24 to 217m/s.

We made an impact experiment using 8 types of projectiles on the 500-micron quartz sand target and observed each ejecta grain by using a high speed digital video camera taken at 2000-10000 FPS. Then, we measured the ejection velocity and the initial position of each grain. We successfully obtained the relationship between the initial position and the initial ejection velocity or ejection angle for the quartz sand grains.

Result: In (Eq.1), mu is proportional to density of projectile in the range less than 6g/cmˆ3. (Eq.2)

$v_e/v_i=a(x/R)^{(-1/mu)}$?(1)

, where ve is an ejection velocity of grain, x is the initial position of ejecting quartz sand grains and R is the crater radius.

mu=0.05ρ+038 -(2)

Moreover, we obtain the relation between crater size and projectile density.(Eq.3)

[R$*$(ρt/m)ˆ(1/3)]=11$*$[ρt/ρp]ˆ0.096 ?Eq(3)

The ejection angle of quartz sand grains is also obtained. For all projectiles, the grain that ejects from near impact point have high ejection angle and the more distant that grain ejects from, the lower the eject angle is. There are no effect of projectile density.

The obtained empirical equation between the ejection velocity and the initial position is as follows Eq(4),

$ve/vi=1.5*10^{-3}(x/R)^{-1.8}$ (0.3<x/R <0.9) -(4)

Impact cratering experiments on granular slopes

HAYASHI, Kosuke[1*] ; SUMITA, Ikuro[1]

[1]Graduate School of Natural Science and Technology

Impact cratering is an important process for the evolution of planetary surfaces. Many experiments of impact cratering into granular media have been conducted to understand its basic physics (e.g., Walsh et al., 2003, de Vet and Bruyn, 2007). These studies have shown that as impact energy becomes larger, simple craters transform into complex craters. In addition when gravity is more important than the target strength, the crater diameter increases in proportion to the 1/4 power of the impact energy. Peculiar craters on asteroids have been discovered in recent planetary missions. Some craters on asteroids are likely to be in the transitional regime between the gravity and strength dominated regimes. In order to better understand how such craters may have formed, we have recently conducted experiments around the transitional regime (Takita and Sumita, 2013). In addition, because asteroids have large topography relative to its size, some craters seem to have formed by impact on slopes (Jaumann et al., 2012). However, since most previous experiments were performed on horizontal targets, impact cratering on slopes is still poorly understood. In this study, we report the results of experiments to understand the effects of slope angle on crater formation.

The experiments in this study were performed by dropping spherical projectiles into an inclined granular target. Projectiles are made of stainless steel (density: 7.70g/cm^3) and their diameters are 11.0mm and 22.2mm. We use sand (mean diameter of 0.204mm, density of 2.66g/cm^3, angle of repose of 37.2○, volumetric packing fraction of 0.56) for the granular target. The slope angle ϑ was 0○,11○,16○,22○,34○. Impact energy E was 0.055 , 0.073 and 0.58 J. Crater formation process was recorded by a high speed camera. The 3-D topographies of the granular target before and after the impact were measured by a laser displacement meter which we move by a stepping motor. Resolution of the laser displacement meter is about 0.024mm for vertical direction, and about 0.1mm for horizontal direction. The stepping motor moves at 0.2mm intervals. We obtained the vertical displacement of the granular target caused by the impact by subtracting the topography of the target before and after the impact. We defined the maximum vertical displacement as the crater depth, the length of the crater in the dip direction projected to the horizontal plane as the crater length, and the width in the strike direction as crater width.

We find that the part of the crater rim disappears when ϑ is larger than about 20○. From studying the images recorded by high speed camera, we find that when ϑ becomes large, the slope above the impact point collapses and this causes the partial disappearance of the rim.

Comparing with the Vestan craters (Jaumann et al., 2012), we find that both laboratory and Vestan craters have common asymmetric shape with ejecta spreading down slope and the location of the maximum depth also shifted towards downslope. We find that the crater depth decreases with ϑ . On the other hand, crater length and crater width remains unchanged from 0○to 22○and increased when ϑ was larger than 22○. As a result, the depth / length ratio decreased from 0.25 to 0.05 with the increase of ϑ.

We also analyzed the impact energy dependence of the crater scales and fit them by a power law relation AE $\wedge$ α. We find that with the increase of ϑ, both the prefactor A, and the exponent α changes. This shows that the scaling law obtained for the horizontal granular target cannot be directly applied to impacts on slopes.

Size Dependence of Impact Disruption Threshold of Iron Meteorites

KATSURA, Takekuni[1] ; NAKAMURA, Akiko[1*] ; TAKABE, Ayana[1] ; OKAMOTO, Takaya[1] ; SANGEN, Kazuyoshi[1] ; HASEGAWA, Sunao[2] ; LIU, Xun[3] ; MASHIMO, Tsutomu[3]

[1]Graduate School of Science, Kobe University, [2]Institute of Space and Astronautical Science, [3]Institute of Pulsed Power Science, Kumamoto University

Iron meteorites and some M-class asteroids are generally understood to be fragments that were originally part of cores of differentiated planetesimals or part of local melt pools of primitive bodies. On these primitive bodies and planetesimals, a wide range of collisional events at different mass scales, temperatures, and impact velocities would have occurred between the time when the iron was segregated and the impact that eventually exposed the iron meteorites to interplanetary space.

In this study, we performed impact disruption experiments of iron meteorite specimens as projectiles or targets at room temperature to increase our understanding of the disruption process of iron bodies. Our iron specimens (as projectiles or targets) were almost all smaller in size than their counterparts (as targets or projectiles, respectively), with one exceptional shot. Experiments of impacts of steel specimens were also conducted for comparison.

The fragment size distribution of iron material is different from that of rocks because in iron fragmentation, a higher percentage of the mass is concentrated in larger fragments, probably due to its ductility. The largest fragment mass fraction is dependent not only on the energy density but also on the size of the specimen. We show the largest fragment mass fraction has a power-law dependence to initial peak pressure normalized by a dynamic strength, which is defined to be dependent on the size of the iron material.

This work was supported by the Space Plasma Laboratory, ISAS, JAXA, Japan and by the Global Center of Excellence Program of Pulsed Power Science, Kumamoto University.

The Japanese asteroid explorer Hayabusa-2, that is scheduled for launch in 2014, will be observe a near Earth C-type asteroid 1999 JU3 and will return to Earth with its samples. In this study, we model cratering and crater erasure processes on 1999 JU3 to provide an age estimate for 1999 JU3 based on high-resolution images that will be obtained by Hayabusa-2. The impact rate on 1999 JU3 is calculated from population models of main-belt asteroids (MBAs) and near-Earth asteroids (NEAs) and the average collision probabilities for the main belt and for NEAs. By converting the impactor size to the size of consequent crater based on crater scaling law and the average collision velosities for the main belt and for NEAs, the cratering rate on 1999 JU3 is calculated. For comparison, we use two population models of asteroids, two crater scaling laws and five conditions of surface of 1999JU3. In addition, two crater erasure processes, seismic shaking and saturation of craters, are considered in our model. As a result, our models indicate that age estimate of 1999 JU3 primary depends on crater scaling laws used and assumptions of surface conditions of 1999 JU3 rather than population models of asteroids.

Scaling analysis of cavity morphology and disruption threshold for highly porous targets

OKAMOTO, Takaya[1*] ; NAKAMURA, Akiko[1] ; HASEGAWA, Sunao[2]

[1]Graduate School of Science, Kobe University, [2]Institute of Space and Astronautical Science

The morphology of the cavity formed by an impact can be dependent on parameters such as porosity, bulk density and strength of target bodies and size, bulk density, strength and impact velocity of impactors. Laboratory impact experiments have been conducted and cavity diameter and depth have been studied in previous studies in which highly porous targets up to 60% in porosity were used (e.g. gypsum, sintered glass and snow). Based on recent spacecraft missions and ground-based observation, it is shown that small bodies have even higher bulk porosities up to 86% (Consolmagno et al., 2008). Experiments using further highly porous targets are necessary for understanding collisional evolution of such bodies in the formation period. We study cavity morphology of highly porous targets and compile the result with previous studies. We also study disruption threshold of targets and compile the results.

We prepared porous targets with three different porosities, which have porosity of 94%, 87% and 80% (Okamoto et al.,2013). Various projectiles with different density and strength were used; titanium, aluminum, stainless steel and nylon spheres of 1 and 3.2 mm in diameter, and basalt cylinder of 3.2 mm in diameter and 2.0 mm in height. The impact velocity was ranged from 1.7 to 7.2 km/s.

The track was long and thin, in carrot-shape, when the projectile was intact, while it was short and thick, in bulb-shape, when the projectile was fragmented. We report the results of bulb-shape cavity in this presentation.

We apply crater scaling law in strength regime for maximum diameter and entrance hole diameter of the cavity. We compile data of previous studies and ours to obtain empirical relationships. A correlation is shown between the distance from entrance hole to maximum diameter and characteristic depth where initial kinetic energy of projectile becomes 1/e. Characteristic length is a function of drag coefficient. Since the drag coefficient depends on the fragmentation degree of projectile, it is shown that disruption of projectile affects the distance from the entrance hole to the maximum diameter.

Volume, maximum diameter and depth of cavity during its growth were measured on flash X-ray images. Normalized cavity volume and time (Schmidt and Housen., 1987) are applied for the analyses of the results. They have a power law relationship. The power law index for shots with larger density ratio (target density / projectile density) is slightly larger than those with smaller density ratio. Similarly power law relationships between normalized depth of cavity, maximum diameter and normalized time were obtained, respectively. The power indices are consistent of the power index determined for the normalized volume and time. Thus the growth of cavity volume can be explained by growth of maximum diameter and depth.

The threshold energy density for disruption $Q^*$is defined by energy density leading to a largest remnant having half the mass of the target. Q^*increases slightly with porosity of the targets. $Q^*$for the targets with equal diameter-height ratio is slightly larger than those with longer shape (diameter /height=0.5). In this presentation, we will discuss scaling of $Q^*$with various previous study.

A consortium study of the largest particle of Hayabusa-returned samples

UESUGI, Masayuki[1*] ; KAROUJI, Yuzuru[1] ; YADA, Toru[1] ; ISHIBASHI, Yukihiro[1] ; SATAKE, Wataru[2] ; OKADA, Tatsuaki[1] ; ABE, Masanao[1]

[1]Japan Aerospace Exploration Agency, [2]Department of Earth and Planetary Science, University of Tokyo

Hayabusa-returned samples retrieved by the Hayabusa spacecraft were already distributed and investigated in the preliminary examinations and international A/Os. Through the investigations, several insights have been obtained on the formation process of 25143 Itokawa and surface processes occurred on the asteroid, as well as the confirmation that the particles were certainly regolith particles from there [1-6].

There are several particles, however, which have not been distributed for those examinations because of their rare features appeared in the initial description done by extraterrestrial sample curation team (ESCuTe) of JAXA. Though those particles will provide us further information for Itokawa and evolution of the asteroid, the samples should be investigated as carefully as possible to reduce consumption and damage of the samples. RA-QD02-0136-01 is currently the largest sample of Hayabusa-returned samples recovered from the sample catcher. The major axis of the particle ra is around 310 μm, and weight of the particles is estimated around 20 μg, assuming the volume V= $4/3\pi r_a r_b r_c \sim 4/3\pi/(2\sqrt{2})r_a{}^3$ and density of the particle as 3.4 g/cm^3, where r_a, r_b and r_c are major axis, semi-major axis and minor axis, respectively. The RA-QD02-0136-01 is mainly composed of Ca-rich pyroxene, and also contains minor amount of low-Ca pyroxene, olivine, plagioclase and troilite. In order to maximize scientific gain from the Hayabusa-returned samples, we decided to investigate this particle by constructing a specific consortium for the analysis.

6 teams were joined the consortium, and following analyses were proposed.
M. Uesugi and A. Tsuchiyama : CT observation of 3D texture and surface observation
J. Park and Rutger team : Ar age analysis to determine the shock ages
K. Nishiizumi and K. Nagao : Analysis of cosmogenic nuclides to estimate the erosion rate of Itokawa
N. Kita and D. Nakashima : O-isotope analysis of high-Ca pyroxenes and plagioclases by SIMS
F. Langenhorst : TEM observation of the dislocations for estimating shock effect by small impacts
L. Keller : TEM observation of the space weathering rims

Currently, we prepare the sample cutting method, and evaluate effect of the cutting and sample transfer on the subsequent analysis. We will report the sequential flow of the analyses and results of the rehearsals.

Present status of a consortium study of a NaCl bearing Itokawa particle

YADA, Toru[1*] ; UESUGI, Masayuki[1] ; KAROUJI, Yuzuru[1] ; NOGUCHI, Takaaki[2] ; ITO, Motoo[3] ; ISHIBASHI, Yukihiro[1] ; OKADA, Tatsuaki[1] ; ABE, Masanao[1]

[1]Japan Aerospace Exploration Agency, [2]Faculty of Science, Ibaraki University, [3]Japan Agency for Marine-Earth Science and Technology

Hayabusa spacecraft returned samples from S-type Near-Earth Asteroid (NEA) Itokawa in June 2010. After the return, Extraterrestrial Sample Curation Team (ESCuTe) of JAXA have recovered particles from a sample catcher of Hayabusa, and more than 400 particles initially described have been presented in public (Yada et al., 2014). Among them, some types of particles having rare features are assigned to consortium studies, because they are supposed to be applied by multiple proposals so that they could not be distributed. Members of the ESCuTe would lead consortium studies to ask for research plans from worldwide researchers, discuss a research flow for the particles with the researchers to maximize their scientific gain, and push the plan forward.

One of the consortium studies is for a silicate particle bearing NaCl. The sample ID RA-QD02-0129 is 40 micron in size, mainly composed of silicate similar to plagioclase in chemical composition, and have euhedral NaCl particles of 3-5 micron in size on its surface. This is the only silicate particle bearing NaCl among those initially described so far.

In planetary material samples, NaCl is very rare and unique component. It has been discovered only in Monahan and Zag H chondrites among all ordinary chondrites so far. Trace of extinct 129I was discovered in the NaCl in the meteorites, which means that it should have formed in their parent body(ies), H chondrite or other, in the early solar system and involved in the meteorites in some processes afterward (Zolensky et al., 1999; Whitby et al., 2000). The formation of NaCl should be linked with water in their parent bodies, so it could provide important information about the origin of its parent body. Additionally, water and salt should be closely linked with organic material revolution and might provide interesting suggestion for the origin of life.

One of the most important purposes of this consortium is to prove extraterrestrial origin of the particle (silicate) and NaCl. And next step is to clarify whether its parent body would be Itokawa and/or LL chondrite parent body or other ones. What can prove the extraterrestrial origin of the NaCl is (1) discovery of solar flare tracks in the NaCl, (2) detection of solar wind He on its surface, (3) presence of space weathering layer on its surface. Transmitted electron microscope (TEM) observation for ultrathin section of the NaCl made by focused ion beam (FIB) system will be necessary for (1) and (3), and a laser ionization mass spectrometer is necessary for (2). In the research plan so far, terrestrial NaCl with instrumentally implanted He and NaCl in Monahan meteorite will be prepared for the rehearsal analyses to establish analytical techniques and then we will try the real particle.

Three-dimensional structures of aggregate-type Itokawa particles

YADA, Toru[1*] ; UESUGI, Masayuki[1] ; KAROUJI, Yuzuru[1] ; UESUGI, Kentaro[3] ; TSUCHIYAMA, Akira[2] ; ISHIBASHI, Yukihiro[1] ; OKADA, Tatsuaki[1] ; ABE, Masanao[1]

[1]Japan Aerospace Exploration Agency, [2]Graduate school of science, Kyoto University, [3]Japan Synchrotron Radiation Research Institute

Regolith particles, which should have been formed by fragmentation and abrasion due to impact and impact-induced vibration, exist on surfaces of minor bodies. Their formation processes and causes will tell us physical and chemical condition of the surfaces of the minor bodies and their parent bodies.

Hayabusa spacecraft returned samples from S-type Near-Earth Asteroid (NEA) Itokawa in June 2010 (Abe et al., 2011). Among the returned regolith particles, we focus on aggregate-type particles composed of tiny component grains to analyze their three-dimensional (3D) structure in order to clarify their formation processes and environments.

In this study, we chose five aggregate-type Itokawa particles, which are 55-128 micron in size, assigned for JAXA's research among more than 400 particles initially described. They were firstly analyzed by synchrotron X-ray computed tomography (CT). Because they might be fragile, they were placed inside tiny, upside-down pyramid-shaped sample holder made of SiN. They were irradiated in beam line (BL) 47XU of SPring-8 by photon light source of both 7keV and 8keV in energy and obtained their transmitted X-ray images. The obtained images were calibrated by computers, and their 3D structure could be reconstructed. Mineral species in the particles could be estimated by the different X-ray adsorption factors of different energy X-ray in each of the minerals.

The obtained data are under calibration so far. We will clarify their 3D structure and discuss about their formation processes. Additionally, we are planning to make their ultrathin sections by focused ion beam fabrication system (FIB) and confirm detailed structures between the tiny component grains with transmitted electron microscope (TEM).

Consortium Study of Troilite and Phosphate-bearing HAYABUSA Returned Samples

KAROUJI, Yuzuru[1*] ; UESUGI, Masayuki[1] ; YADA, Toru[1] ; ISHIBASHI, Yukihiro[1] ; SATAKE, Wataru[2] ; OKADA, Tatsuaki[1] ; ABE, Masanao[1]

[1]Japan Aerospace Exploration Agency, [2]Department of Earth and Planetary Science, University of Tokyo

HAYABUSA returned samples have been shown as Itokawa origin by the preliminary examinations (e.g. Nakamura et al., 2011). Furthermore, international AO study has begun last year, and a formation process of asteroid Itokawa is becoming revealed.

HAYABUSA returned samples are described initially by JAXA Extraterrestrial Sample Curation Team (ESCuTe), and a sample catalogue is prepared based on the data of initial description (e.g. Yada et al., 2014). More than 400 returned samples were described so far. These described samples are classified into four categories. A number of samples of each category to be distributed for international AO are decided based on the sample catalogue. But it is difficult to distribute such samples with rare characteristics in composition, mineralogy, structure, or size, although those samples should maintain scientifically important information.

Therefore, in JAXA, ESCuTe started to organize the consortium studies in order to obtain the scientific information as many as possible from these samples (e.g. Yada et al., 2014; Uesugi et al., 2014). In this paper, we report the research plan for the particles mainly composed of FeS and which contain phosphate minerals.

RA-QD02-0245 composed mainly of FeS (40 micron) with smaller attached olivine and pyroxene grains. This particle was analyzed by X-ray CT at SPring-8 for 3D texture without atmosphere. Two ultra-thin section will be made from the edge of this particle by FIB. The ultra-thin sections will be examined by TEM in detail for space-weathering effect on FeS surface. The main mass of this particle will be analyzed for chemical composition. Especially, the siderophile element composition gives us information on the formation process of Itokawa parent body.

Some particles including phosphate mineral were found by the initial description. Because Ca-phosphate tends to be enriched in incompatible elements such as REEs, Th and U, we propose the investigation of U-Pb systematics using Nano-SIMS in order to study the history recorded in the phosphates. We will perform the U-Pb dating of the phosphates as many as possible and aim to understand the thermal history of Itokawa parent body such as crystallization age and the catastrophic collition if recorded.

Asteroid Shape Reconstruction by Structure-from-Motion Method with Bundler and PMVS2

HIRATA, Naru[1*] ; MORI, Yohei[1] ; HAYABUSA-2 SHAPE RECONSTRUCTION, Study group[2]

[1]ARC-Space/CAIST, The University of Aizu, [2]Hayabusa-2 project

Here we report results on application of open source shape reconstruction tools to an asteroid image data set. We test two tools that cooperatively work to reconstruct an object shape from images. Bundler is an open source implementation of a stereo shape reconstruction method called Structure from Motion (SfM). PMVS2 gives a more dense shape model, since Bundler only estimates 3D locations of a limited number of feature points. A global image data set of the asteroid Itokawa taken by AMICA on board the Hayabusa spacecraft is employed to our test data set. An obtained model satisfies that most requirements from the Hayabusa-2 mission on the shape model that used during the mission phase. An important advantage of these new tools compared to previous ones is its short processing time. This advantage will be effective in quick evaluation of observation data and decision making during the mission operations. More precise and high definition models will be reconstructed by other method such as shape-from-shading or photometric stereo.

Feature matching in planetary images with multiple spatial resolutions by using SIFT algorithm

KODAMA, Hiroyuki[1] ; HONDA, Chikatoshi[1*]

[1]The University of Aizu

This study uses feature matching in planetary images with multiple spatial resolution. To know where lower altitude images are taken in high altitude images is performed based on images without the position and attitude of spacecraft in this study. The lower altitude images of AMICA on-board the Hayabusa spacecraft, asteroid probe are found as a correspondence of image features (keypoint) in higher altitude images. We adopted the Scale Invariant Features Transform (SIFT) to represent a kind of key-point of image for image feature matching. In generally, the SIFT keypoint is robust to scale transition, change of lighting condition, parallel displacement, and rotation of image, so this keypoint is suitable to feature matching of planetary image which contains of scale and rotation between different images. As a result, for the improvement of accuracy of feature matching, it is important to have a preprocessing of image (e.g., equalizing).

Grooves on Phobos: Spatial distributions and their implications to the formational mechanism

KIKUCHI, Hiroshi[1*] ; MIYAMOTO, Hideaki[1]

[1]The University Museum, The University of Tokyo

Grooves are roughly-defined as trough-like depressions commonly found on asteroids and small satellites. Among the various features categorized as grooves, the most typical are considered as those found on the surface of Phobos. Grooves on Phobos are the most extensively-existing geological features on the satellite, and thus are documented and discussed for years. However, their formational processes remain controversial. Previously-proposed hypotheses are (1) grooves are some kind of intentional fractures and (2) they are results of impacts caused likely by linearly-aligned impactors ejected from Mars.

Former hypothesis has difficulty in explaining the geographical distribution of grooves (Murray 2011). In fact, because of this difficulty, Murray (2011) concluded that the latter (i.e., secondary impactors derived from Mars) could only be the reasonable explanation for the observed characteristics of grooves on Phobos, including their morphological features, distributions, and hemispheric coverage. Nevertheless, Ramsley and Head (2013) recently showed that, in order to form grooves well organized as those found on Phobos, each of fragments ejected from Mars should have no relative velocity, which is difficult to be achieved for ejecta from Mars. They also showed that most grooves on the northern hemisphere cannot be formed as secondary impacts from Mars because the impactors ejected from Mars do not impact in the directions normal to the equatorial plane of Phobos. Therefore, neither hypothesis remains satisfactory to explain the observational facts.

We carefully reevaluate previous hypothesis based on recently-acquired data, which are partly not available at the time of previous studies. We scrutinize all of the high-resolution images obtained so far to map them out on a numerical shape model. As a result, we identify 488 grooves, whose spatial distributions are precisely mapped three dimensionally. We newly find that each of grooves is always aligned on a certain plain even though it sometimes appears to be an undulating curved depression. We consider this strongly indicates that a groove is a result of a series of impacts of aligned fragments.

We statistically study the angle between the equatorial plane of Phobos and the plane, which contain each groove and find that the distributions of the angles have three peaks at 25, 90 and 155 degrees (hereafter we call A, B, and C type, respectively). Most of the B type grooves exist on the northern hemisphere.

To explain our mapping results, we propose a new hypothesis for the formation of Phobos as follows: (1) An asteroid of a collection of smaller fragments held together by self-gravity in the form of a rubble-pile is pulled apart and stretched straightly by tides during a close approach to Mars; (2) The asteroid (now separates into a train of fragments) is caught by the Mars gravity and revolves around Mars; (3) Every time it revolves around Mars, a part of the fragments hit Phobos and form a lineated depression, which is observed as a type A or C groove; (4) When the eccentricity of the impartor becomes low until the overlapping the trajectory of Phobos, type B grooves are formed.

Our hypothesis is along the idea that grooves are formed by aligned impactors as proposed by Murray (2011) but essentially different in the origin of the fragments, which can resolve the difficulty pointed out by Ramsley and Head (2013). Not only that, our hypothesis has advantage of completely satisfying both the morphological and geographical characteristics of grooves on Phobos. Furthermore, our hypothesis can also explain the deficiency of grooves on Deimos.

We present a unique data set of the taxonomic type of near-Earth asteroids (NEAs) accessible with available spacecraft.

The research on NEAs has entered a new phase thanks to sample-return space explorations together with state-of-the-art large ground-based telescopes. We made observations of twelve asteroids with Subaru, GEMINI-North, GEMINI-South and Okayama 188cm telescopes. They have low delta-v orbits with potential to be investigated by manned/unmanned spacecraft. Also, ten sub-km-sized bodies are included in them, and are one of remarkable characteristics in terms of an evolutionary scenario.

We find that eleven asteroids are classified as S-complex and one asteroid as V-type. Most S-complex asteroids (eight out of eleven, $\sim$70%) have spectra similar to subgroups of Q or Sq-type, suggesting that these objects are less matured against space weathering.

In this presentation, we show their spectra and discuss dominance of S-complex asteroids based on the previous research.

Development of a wide-band optical filter optimized for deep imaging of small solar-system bodies

OKUMURA, Shin-ichiro[1*] ; NISHIYAMA, Kota[1] ; URAKAWA, Seitaro[1] ; SAKAMOTO, Tsuyoshi[1] ; TAKAHASHI, Noritsugu[1] ; YOSHIKAWA, Makoto[2]

[1]Japan Spaceguard Association, [2]JAXA

We developed a newly designed wide-band optical filter and evaluated its performance. It is optimized for deep imaging of small solar-system bodies. The new filter, which we denote as *Wi*, is designed to reduce contamination by light pollution from street lamps, especially strong mercury and sodium emission lines. For the reasons that (1) much of artificial light pollution concentrates in the *V* band, (2) the photon numbers peak at a wavelength of 6350 $\AA$ in the spectrum of sunlight, and (3) many asteroids have their peak/plateau reflectance at around 7000 $\AA$ in the optical range, the new filter's cut-on wavelength is set to 5880 $\AA$ by using an OG590 Schott color glass filter. On the other hand, the cut-off wavelength, which is achieved by a short-pass interference coating, is set to 9380 $\AA$ in consideration of worst of the OH night sky emission and the atmospheric water vapor absorption band at 9400 $\AA$.

Compared with the use of a commercially available long-wave cut wide-band filter (*W* filter, 4900-9100 $\AA$), the sky brightness is 10-20 % reduced by the *Wi* filter under bright-sky conditions by not only artificial light pollution but scattered moonlight. In the detection of asteroids, the detected total flux of an asteroid through the *Wi* filter has been 3% larger than that through the *W* filter, though the width of the *Wi* filter response function is 16% narrower than that of the *W* filter. By using the *Wi* filter, the S/N ratios in the detection of asteroids were improved by about 6%, on average, compared with the use of the *W* filter, and the improvements were slightly larger in a brighter sky. The use of the CCD with high sensitivity at longer wavelength, such as the back-illuminated, fully-depleted CCD, will show a larger improvement in the S/N ratio by using the *Wi* filter.

Solidified and mixed materials on Asteroid body

MIURA, Yasunori[1*]

[1]In & Out University

The results of the present study are summarized as follows:

1) Study of the Asteroids provides characteristic formation processes of primordial terrestrial and extraterrestrial celestial bodies.

2) Identification of crystalline solids are almost similar between the Asteroids and Earth, though the Asteroid rocks might be formed by similar formation processes of terrestrial rocks based on the crystalline parts. However, extraterrestrial Asteroids show irregular mixtures of multiple states solidified amorphous solids.

3) Formation of non-spherical Asteroid body formed mainly by impact-related melting process is observed as heterogeneous and irregular distribution of impacted grains.

4) Local fluid-bearing depositions irregularly distributed on the surface and interior of the Asteroids might be based on storages on the interior formed by solidified mixtures of multiple states triggered by impact process on the Asteroids.

5) Different processes of solids between the Asteroids and Earth can be observed silica Si-O frameworks which can be obtained by the ion bombardment experiments. Crystalline rocks with hard silicate structures on Earth show higher ion-peaks of alkali ions (Na, K and Ca etc.), whereas solid-aggregates of the Asteroids show higher ion-peaks of Si and Al ions which are relatively destroyed by ion bombardments.

6) Ion-peaks by the sputtering of terrestrial impact-breccias are clearly higher than those of the Asteroid meteorites, which the main differences are not rock textures of breccias but atomic bonding of slow or rapid cooling process.

7) The air- and water-less Asteroids with solidified materials with multi-states are formed from nano-grains to macroscopic rocks by impact-related evolution process,

8) The primordial planet Earth with remained heterogeneous surface by impact-related process is considered to be cyclic system of three material states (air, liquid and solid) with macro-life activity which is formed by huge production from the interior triggered by huge collision process of the giant impact. On the other hand, the Asteroids without global cyclic changes of three materials states, microscopic quasi life-like materials might be locally found (mainly by high-resolution electron microscopy on in-situ or returned samples finally).

9) It should be avoided to collect artificial impacted samples, because irregular mixtures of solidified amorphous solids from vapor and liquid states are easily destroyed to be escaped to be exaggerated solids with less volatiles.

Keywords: Asteroids, solid aggregates, amorphous materials, fluid, ion bombardment run, micro quasi life-like materials

The Origin of The Moon and The Earth in Multi-Impact Hypothesis

TANEKO, Akira[1*]

[1]SEED SCIENCE Lab.

Origin of the moon and the earth in the multi-impact hypothesis

This new hypothesis to the origin of the Moon and Earth,This is the proposal of solutions that satisfy unified manner new hypothesis
to the origin of the Earth and the Moon, all of the following questions.

(1).Why, large biological extinction of five times or more were happened on the earth?
(2).The meteorite falling on Earth, why stony-meteorites, stony-iron meteorite, iron-meteorite, such as differentiated and undifferentiated chondrites, what mixed in there?
(3).The old theory, why cosmic dust or did not become a planet in the asteroid belt?I think Itokawa's aggregate piece of crust differentiated?
(4).We have proposed a theory of the origin of the original description to solve the problems of the giant planet collision theory, all of the earth and the moon and deep sea bottom.
(5).Why, protoplanetary Serra did they destruction? = The tragedy caused by tidal forces and deformation due to Jupiter orbit perturbation.
(6).Increase in the aspect ratio of Serra orbital perturbation by Jupiter, destruction by tidal force of the approaching Jupiter.
(7).Plate boundary formation of plate tectonics,I suggest the formation origin of the deep sea bottom crust by peeling.
(8).The origin of deep-sea bottom update and continental drift and Mystery of the driving force was solved.
(9).Why diamond pipe did formed in South Africa?
(10).Why core eccentric (about ten percent) of what is happening? Radiation anomaly of Brazil over the Van Allen belt.
(11).New hypothesis at the origin of Jupiter's Great Red Spot, I think about How and Why to that Mystery !
(12).Why is whether the silicate star (asteroid now) Pluto of the outer planets?

Until now, Giant impact hypothesis is a theory only for making the moon.Protoplanet is the result of accidental collision with the Earth there Mars core size to the Earth,
It only has to calculate the conditions formed by the mantle further moon.

It is the original collision hypothesis.

Protoplanetary Serra was born in Ceres position of Bode's law.The planet Serra that differentiated, elliptical orbit was flattened by the Jupiter perturbations.
Major axis is constant because of energy conservation law.Eccentricity of Serra increases, the orbit that focus of the solar get closer so as to extend to the point of near-side Jupiter.
Just before the collision with Jupiter, Serra was rupture in tidal forces of Jupiter.By the mantle debris collides with the Earth, the moon was formed.
Position Serra collides to the Earth becomes the Pacific Ocean, it becomes the origin of the plate boundary crack.In addition, deep-sea of multiple formed with Impact of Multi-attack which is the time difference.
Eccentricity of the moment of inertia is estimated to be the driving force of the seabed update theory and theory of continental drift.
Mantle debris energy is large becomes Pluto, heavy and high density Koaritchi debris became Mercury with scattered to the inner planet side.
I estimated that the debris of Serra collide to Jupiter, it became the origin of the Jupiter's Great Red Spot.
The fact that iron meteorites, stony-iron meteorites, stony meteorites are differentiated, and chondrite undifferentiated are mixed, Ceres is present in the asteroid belt, the origin of the meteorite is convinced straightforwardly with this hypothesis.
Multi-impact theory be the basis of large organism extermination repeated, it is also the reason sea accounts for 70%, it was possible to understand the origin of the plate boundary crack.
Multi-impact hypothesis can be explained in a unified manner present condition of the earth as well as make the moon in this manner.

It is believed that asteroid Itokawa could check a set? Like Serra crust, then it becomes even proof of this hypothesis.

Importance of Future Earth in Asia

YASUNARI, Tetsuzo[1*]

[1]Research Institute for Humanity and Nature

Future Earth (FE) has been launched as an international initiative to promote research for global sustainability by the international science and technology alliance with partnership of the International Council for Science (ICSU), the International Social Science Council (ISSC), the Belmont Forum of funding agencies, the United Nations Educational, Scientific, and Cultural Organization (UNESCO), the United Nations Environment Programme (UNEP), the United Nations University (UNU), and the World Meteorological Organization (WMO) as an observer (Future Earth, 2013). Future Earth will provide a single overarching structure for researchers, funders, service providers, and users, and integrates the existing Global Environmental Change (GEC) programmes. The GEC programmes have provided foci for several extensive international and multi-disciplinary networks of researchers investigating key human-environmental dynamics. Future Earth would develop a new generation network building on these. Future Earth proposes national and regional level committees, in addition to the regional nodes. The most essential issue for the overall FE activity towards global sustainability will be how to integrate efforts and activity of solving environmental problems and achieving sustainability for local to regional scales.

This paper introduces a strategic science plan for FE in Asia, which should be a guideline for implementing the overall FE activity in the whole of Asia, including part of the Pacific/Australasia and the Indian Ocean basin region.

Trade-offs in climate risks and societal risk decision

EMORI, Seita[1*]

[1]National Institute for Environmental Studies

The need to take mitigation measures in order to hold the increase in global average temperature below 2 degree C above pre-industrial levels are recognized in international negotiations of the United Nations Framework Convention on Climate Change (UNFCCC). According to the fifth assessment report by the Working Group I of Intergovernmental Panel on Climate Change (IPCC) which was published last September, attaining the temperature goal with a probability of 50% will require cumulative CO2 emissions from all anthropogenic sources to stay approximately 300 GtC from the present. If the current level of anthropogenic CO2 emission, 10 GtC yr-1, continues, the cumulative emissions will reach this upper limit in only 30 years. If we will seriously pursue the goal of temperature increase below 2 degree C, global CO2 emission should be turned to decline as soon as possible, and to be reduced at nearly zero by around the end of this century.

A great deal of research on climate change impacts and mitigation measures exist; however, large uncertainties remain in their overall pictures. So far, nobody can grasp clearly risks for human society and ecosystem associated with global warming exceeding ”2 degree C”, and risks for socioeconomics due to severe emission reductions of greenhouse gases. Furthermore, the risks will be realized in different ways by country, region, generation, and social attribution, and therefore, either if no specific response measures are conducted or if strong measures are conducted, a part of people in the world will have benefits and another part of people will make a loss. Climate change impact is not just an issue on benefits and losses of each person; but it relates to issues how we feel distress on risks for ecosystem, developing countries, and future generations. It relates to different value judgment among people. Deliberate work will be necessary in order to lead a decision-making which have both scientifically high rationality and socially high consensus, by connecting expert knowledge with social value judgment.

Integrated MRV system using Monitoring-Sensing-Modeling in Tropical Peatland and Wet/lowland

OSAKI, Mitsuru[1*] ; HIROSE, Kazuyo[2]

[1]Research Faculty of Agriculture, Hokkaido University, [2]Earth Remote Sensing Division, Japan Space Systems

The Earth ' s remaining tropical forests are found mainly in the peatlands of the Amazon, Central Africa, and Southeast Asia, especially in regions of Kalimantan, Sumatra, and Papua New Guinea, where rich biodiversity can still be found and large amounts of carbon are stored in peat soils. Also, Wet/low-land where locate especially in South-East Asia is globally one of most important Bioproduction Ecosystem on food production, livelihood, mitigation and adaptation on climate change. This kind of Bioproduction Ecosystem have been supporting to feed large population, because of sustainability of soil fertility and nature friendly production system, calling as human-nature coexistence such as Satoyama in Japan. This human-nature coexistence Ecosystem (Satoyama Ecosystem) in wet/low-land is widely distributed in South-East Asia and South Asia, such as Cambodia, Thailand, Myanmar, Malaysia, Indonesia, Philippines and Bangladesh. Thus, peatland and wet/low-land Ecosystem has a role to stock large amount of Carbon, especially in peat and organic soils, and Mangrove soil. However, this human-nature coexistence Ecosystem (Satoyama Ecosystem) has been gradually or quality degrading and breaking down because of human-impact and climate change. Thus Sustainability of this human-nature coexistence Ecosystem (Satoyama Ecosystem) is one of key issue in not only regional, but also global. As SBSTA38 and Workshop of UNFCCC in 2013 have been focusing on ”Ecosystem of High Carbon Resorvoirs” such as peatland, costal ecosystem including Mangrove and Coral, and Permafrost, South-East Asia is key in this aspect.

Focusing on carbon emission estimation related with the REDD (Reducing Emissions from Deforestation and Forest Degradation in Developing Countries) Mechanism, at COP15 in Copenhagen, MRV (Measurement, Reporting and Verification) focused on establishing reference emission levels, national monitoring systems. At COP15 of Copenhagen, it was declared that an MRV system that should be coupled with two components ? satellite sensing and grand truth- is urgently required. Presently, our JST-JICA Project (SATREPS) on ”Wild Fire and Carbon Management in Peat-Forest in Indonesia” is the only project in the world to propose all aspects of MRV in tropical peatlands, enabling it to contribute significantly to also in tropical wet/low-land. Actually, carbon stock mapping and carbon flux mapping in peatland were obtained. Therefore, this paper describes our MRV system as a sensing standard for REDD+, biodiversity, and LLULUCF in tropical peatland and Wet/low lands.

Keywords: Satoyama Ecosystem, MRV, REDD+, Tropical peatland, Wet/low lands, High Carbon Resorvoir Ecosystem

Current state of international governance on conservation and sustainable use of marine ecosystem services

YAGI, Nobuyuki[1*]

[1]Graduate School of Agricultural and Life Sciences, The University of Tokyo

Conservation and sustainable use of marine ecosystem services has been discussed internationally. For instance, discussions on EBSA (Ecologically or Biologically Significant Areas) are ongoing at meeting under the CBD (Convention on Biological Diversity). Likewise, the issues of VME (vulnerable marine ecosystem) are also discussed at FAO (Food and Agriculture Organization of the United Nations). In addition, General Assembly Ad Hoc Open-ended Informal Working Group to study issues relating to the conservation and sustainable use of marine biological diversity beyond areas of national jurisdiction has been held by the United Nations in order to discuss the need for creating an international instrument under UNCLOS to address the issue of the conservation and sustainable use of marine biological diversity of areas beyond national jurisdiction before the end of the 69th Session of the United Nations General Assembly (which is winter time in 2014).

The author has closely monitored the development of the discussions on the above meetings and found that their discussions were narrowly focused upon the control of fishing activities and they lacked considerations on the ecosystem services as a whole. This is most likely because stakeholder identifications, such as polluters and users of ecosystem services, are difficult and creating a legal framework is extremely hard. Under this situation, it can be argued that agreeing economical tools such as payment for ecosystem services would be more practical.

Global and regional platforms for integrated environmental and sustainability studies

TANIGUCHI, Makoto[1*]

[1]Research Institute for Humanity and Nature

Future Earth is a new 10 years initiative of international research program for global sustainability. The objectives of the Future Earth are to provide the knowledge required for societies in the world to face risks posed by global environmental change and to seize opportunities in a transition to global sustainability. Future earth was launched at 2013 by international academic, funding, organizations as alliances including ICSU, ISSC, IGFA, Belmont Forum, UNEP, UNESCO, and UNU. Future Earth focuses on co-design, co-production, and co-delivery, transdisplinarity, vertical (global-regional-local) and horizontal (multi issue with different sectors and stakeholders) integrations, and the involvement of young scientists. There are three themes, 1) Dynamic Planet, 2) Global Development, and 3) Transformation towards Sustainability. Researches on global environment and sustainability are urgent in Asia, because more than 50 percent of the world population lives in Asia, and drastic changes (both increase and decrease) of population, urbanization, material consumptions, environmental deteriorations, natural and social disasters, occurs in Asia, i.e. Asia is a hot spot area in terms of human and nature drives. Therefore core research hubs of the global environment and sustainability study such as Future Earth are needed in Asia, where is the hot spot area for global sustainability. Structures of the global and regional hubs for the Future Earth, core projects, and others are now under discussion during the interim period. Japan is expected to be Asian regional hub and a part of global hubs because many experiences and good practices on global environmental researches with stakeholders. Methodology, data, and knowledge for interdisciplinary and transdisciplinary researches, should be established in a platform and networking as regional hub of the Future Earth in Asia Pacific and others. Capacity building and education for global sustainability are also very important in Future Earth. Beyond the existing one-way capacity building and environmental education, knowledge transfers between different stakeholders may be a key for the next step of capacity building and education for global sustainability.

On Sustainability Initiative for Marginal Seas in East Asia

YAMAGATA, Toshio[1*] ; CRUZ, Lourdes J.[2] ; HASAN, Nordin M.[3]

[1]Application Lab, JAMSTEC, [2]National Research Council, the Philippines, [3]ICSU, Regional Office for Asia and the Pacific

The marginal seas of East Asia (MSEA hereafter) along the western Pacific, geologically as the interface between the Pacific Ocean and the Asian land mass, have islands spread from the Bering Sea down to the Indonesian seas consisting mainly of the Japanese, Philippine, and Indonesian Archipelagos. The MSEA is very important to international commerce and global security as linkage of heavily populated megacities with active societal, economical and industrial activities.

The MSEA is also the region of the highest marine biodiversity in the world, and its coral reefs and waters around atolls and small islands serve as the spawning ground and nursery of many marine species including tuna and other pelagic species that serve as very important food commodities in the Pacific islands, the Asia mainland and North America. To conserve the health of the MSEA under the pressure from the global change is of our urgent need. The region also lies along the path of destructive typhoons that originate in the western North Pacific and affect the Philippines, Vietnam, Hong Kong, China, Korea, and Japan. It is known that the western North Pacific is one of the most active basins where about 26 typhoons are generated annually, majority of which enter the Philippine area. The latest typhoon, Haiyan, the strongest storm recorded at landfall and the deadliest Philippine typhoon causing storm surges ever recorded, impinged heavily on human life, food security, energy supply, health, wellbeing, and transportation and communication systems in addition to extreme destruction of property, the economy and the ecosystem of Central Philippines. The outpouring of support from the international community to help the Philippines rise out of the disaster is well appreciated particularly by the victims of typhoon Haiyan and its storm surges. Many lessons now learned can be shared to minimize the impact, improve the resiliency of communities and to ensure protection of people against the anticipated increase in the number of future disasters due to global climate change. The cold phase of the Interdecadal Pacific Oscillation which brought the apparent hiatus of the global warming will eventually change and we expect a dramatic climate regime shift as observed in 1976.

In the spirit of the Future Earth initiative of ICSU, we are proposing a collaboration mechanism to share knowledge and expertise for better well-being among ICSU members around the MSEA to work for solutions of relevant problems in the region. While focusing on the maritime region, the researchers will aim to contribute to the attainment of the goals of Future Earth, namely: 1) to develop the knowledge for responding effectively to the risks and opportunities of global environmental change, and 2) to support transformation towards global sustainability in the coming decades. The main region of the proposed study will be the Exclusive Economic Zone beyond the territorial limit (generally 12 nautical miles from shore) in MSEA as well as international waters relevant to the sustainable use of common areas. The collaboration will involve joint researches and capacity building particularly of young scientist in developing countries. We had the brainstorming pre-scoping workshop for SIMSEA in February in Yokohama, of which purposes are:

1) To exchange information and knowledge on the existing discipline-oriented research programs on the marginal seas in Asia and the western Pacific for integrative sustainability research program involving natural, social, economic, engineering and technological sciences.

2) To discuss and co-design a collaborative interdisciplinary research program on the marginal seas of Asia and the western Pacific that meets the criteria of research toward global sustainability under the framework of Future Earth.

We will summarize the outcome of the pre-scoping meeting and envisage the future of SIMSEA in accord with Future Earth.

Digital Earth as a communication platform for Future Earth

FUKUI, Hiromichi[1]*

[1]International Digital Earth Applied Science Research Center, Chubu Univ.

As we can see in problematique, such as environmental issues and disasters, the various risks we face at both local and global scale are all interrelated to each other, and also tend to suddenly emerge at very local level. Conventional science has only been able to deal with parts of these problems. The first step to build a sustainable and disaster resilient society is to monitor, identify, store the data of phenomena on the earth, then process and interpret the raw data, turn them into understandable information to display, publish and distribute. We must share a common recognition of the issues. Therefore we need the Digital Earth (DE) that is a virtual representation of our planet on the internet, and enables a person to explore and interact with the vast amounts of natural, socio-economic and cultural information gathered about the earth. These infrastructures are using for the ESD (Education for Sustainable Development) that focus on systems thinking, critical thinking and holistic views. The Digital Earth can also facilitate collaborative, data-intensive studies for problematiques of Future Earth Project in the 21st century

It was reviewed Digital Earth concept, applications, and some of projects for promoting disaster resilient and sustainable society with information and communication technology in this paper.

We propose Digital Earth platform as the public information base which has cloud-based geospatial information system and services in cooperation with multi stakeholder as shown in Fig. These information systems should be autonomous, distributed and coordinated, interoperable as well. They work for ESD especially for the multi-risks, both mitigation and preparedness in ordinary time and emergency to reduce the vulnerability of our society. It would be a comprehensive facility and social system dedicated to disaster and environment management for sustainable future, with the capacity to supply the necessary staff and equipment such as sensor web supporting by a wide range of associated organizations.

Future Earth and Sustainable Development Goals

KANIE, Norichika[1*]

[1]Tokyo Institute of Technology

One of the next major challenges for research and policy in the field of sustainable development is the agreement of the post-2015 development agenda. This challenge is a direct result from the 2012 United Nations Conference on Sustainable Development (Rio+20), as well as from the formal ending of the Millennium Development Goals (MDG) in 2015. Governments, supported by civil society, now need to agree on a series of new global sustainable development goals and on the related governance mechanisms. At the Rio+20 Conference, governments decided on a process to develop such novel Sustainable Development Goals (SDG), to be integrated into the post-2015 global development agenda. Differently from the MDGs that target developing countries, the new Sustainable Development Goals are meant to apply to both developing and developed countries.

The research community that works in this field is faced with essentially two research tasks:
? First, we need to analyze the goal setting and implementation processes (governance questions);
? Second, we need to analyze and identify the goals and indicators themselves.

The first task entails an inquiry into who will be involved in setting these goals (Agency, Accountability), by which decision making mechanisms (Architecture, Adaptiveness), what these goals will be (Allocation and Access), and how to arrive at the framework for formulating the goals as well as an inquiry into how these goals will be translated into outcomes. The second task includes the question on how to elaborate the global development goals to facilitate achieving human well-being for all within resource constraints and environmental boundaries set by the earth system. A related question is the conceptual framework for the goals, and what goals, targets and indicators need to be developed. This in turn poses questions on enabling institutions and governance processes. We have witnessed in the past years that the development model that underpinned the post-1945 decades appears to be unable to handle the crises that many societies and institutions are struggling with (financial, demographic, environmental, etc.).

Therefore, questions related to the Post-2015 development agenda are not solely about SDGs, but are rather fundamental questions on how to achieve sustainability in the 21st century. To do so requires knowledge innovation, and it is possible through transdisciplinary research, one of the purposes of Future Earth, including co-design, co-production and co-design. This is a theme that should be explored in the year to come.

How will Humanity Survive and Flourish on Future Planet Earth?

DE MULDER, Eduardo[1*]

[1]Earth Science Matters Foundation

In the past half century the world has changed in an unprecedented way. For the first time ever humans observed their planet from outer space. Our species also has become a geologic factor while beginning to interfere with natural forces in the Earth to a scale which can no longer be ignored. These caused geographic modifications at the Earth' surface and geographic maps begin to show more and more distinct human imprints. Simultaneously, our knowledge about the Earth has increased to a level that the Earth crust's anatomy and composition is increasingly known and that we begin to understand how our planet works. Knowing the basic principles of the Earth processes paves the way to forward modelling and more and more accurately predicting the impacts of human interaction with planet Earth. That, in turn, provides tools to anticipate on both assets and threats for an increasingly large and complex human population. As long as we remain dependent on our home planet societies should benefit more from such rapidly increasing knowledge to balance development with the Earth' bearing capacity. Here, we describe recent progress in our knowledge of the Earth and some trends in human development. In combination, these may point to knowledge-based options on how human societies may cope with potentials and limitations posed by planet Earth in view with the ambitions expressed by the Future Earth science initiative.

Planet Earth by itself is not in danger and humans will never threaten its existence for another 5 billion years. But human activities will continue and possibly aggravate impacting the biosphere, the hydrosphere, and to a lesser degree, also the geosphere. Dimensions of such changes will be determined by physical factors in the first place but ability of human societies to cope with such changes also depends on cultural diversity.

Five global trends in human development are discussed: population, urbanisation, living standard, environmental awareness and science & technology. Together these trends point to a growing need for physical space to accommodate future human ambitions. Science and technology trends demonstrate accelerating potential abilities of human society to address such needs. As we proceed in the Anthropocene the need to integrate humanity issues and the geosciences will further increase while reconfirming the growing relevance of the discipline of the Human Geosciences.

So far, the Earth sciences play a modest role in the Future Earth initiative. That is in sharp contrast with global ambitions to arrive at a Green Economy, as expressed in Rio+20, to be developed in balance with the Earth' bearing capacities. Recent progress in geoscientific and technological research demonstrate the potential of such development. This has been widely exposed during the International Year of Planet Earth (IYPE, 2007-2009). This global initiative was proclaimed by the UN and was particularly successful in its outreach programme. In turn, the IYPE served as a model for developing the International Year of Global Understanding, spearheaded by the IGU, and for the UN Year of the Soil (2015).

Human ingenuity spurred discovery of larger natural resources than ever before to drive our economies to unprecedented heights. Future Earth might mobilize the brain powers accumulated in the heads of 400,000 Earth scientists around the world towards a sustainable economy.

Scientific Knowledge Creation Supported by Data Integration and Information Fusion

KOIKE, Toshio[1*]

[1]School of Engineering, The University of Tokyo

What is scientific knowledge? We create some hypothesis based on theories, develop models, and implement experimental observation for validation of the hypothesis. This approach is called deductive inference. Based on the accumulation of factual knowledge, we can form the hypothesis. This approach is called inductive inference. Scientific knowledge is called formal knowledge which can be transferred and shared among wide scientific communities. By publishing paper and promoting communication, we exchange the factual knowledge. Such widely shared factual knowledge is defined as scientific knowledge. We are doing science in this way. During past one hundred years, this scientific knowledge has been increasing explosively. Differentiation and systematization have proceeded, and then a large number of disciplines have been established.

However, it is very difficult to reflect accumulated sub-system knowledge to holistic knowledge. Knowledge on a whole system can be rarely introduced to a targeted subsystem. In many cases, knowledge in one discipline is inapplicable to others. We are far from solution of issues across disciplines. It is critically important to establish inter-disciplinarity and create scientific knowledge crossing disciplines. To realize the benefits of scientific knowledge in society, we need to combine scientific knowledge in the natural world, the socio-economic world and the recognition world and to develop trans-disciplinarity as well as inter-disciplinarity.

How can we develop inter-disciplinarity and trans-disciplinarity? We need to share the data and information and develop inter-linkage of our knowledge by developing models and exchanging tools. Based on this kind of scientific activities, we can corporate between science community and society by making effective use of opportunities.

Data Integration and Analysis System (DIAS) coordinates the cutting-edge information science and technology and the various research fields addressing the earth environment, constructs data infrastructure that can integrate earth observation data, numerical model outputs, and socio-economic data effectively, creates knowledge enabling us to solve the earth environment problems, and generates socio-economic benefits, aiming to create knowledge to be shared among different disciplines, to create knowledge to be shared throughout the world, and to disseminate data and information that brings awareness.

Geospatial data and Future Earth: a case of digital elevation models

OGUCHI, Takashi[1*]

[1]CSIS, Univ. Tokyo

Future Earth is related to the concept of Digital Earth, proposed by US Vice-President Al Gore in 1998. Digital Earth aimed to compile global geospatial data with various resolutions and make them open to public worldwide for efficient solution of environmental problems. Although some related projects were launched, such activities in the 21st century have been relatively limited, partly because Gore lost in the 2000 presidential election. However, some of the elements of Digital Earth have been realized in the form of Internet virtual globes such as Google Earth and Bing Maps. These services allow us to browse maps, satellite images and airphotos with various resolutions. Although Digital Earth planned to provide more varied geospatial data related to science and culture, compilation and broad distribution of such data have been more delayed. It is important to understand the current state of available geospatial data and utilize them for activities associated with Future Earth. This presentation deals with digital elevation models (DEMs), one of the most basic geospatial data. It introduces currently available DEMs and application examples related to Future Earth.

Keywords: Future Earth, geospatial data, digital elevation model, Digital Earth

Promoting Studies under Future Earth supported by Super-High Resolution Simulations on the Global Environment

OKI, Taikan[1*]

[1]Institute of Industrial Science, The University of Tokyo

The new terminology ”Anthropocene”, the geological era when anthropogenic activities substantially altering global environmental systems in which human beings are also a part of it, has been a popular word, but how the Anthropocene evolved? Population growth, economic development, and urbanization are inducing the climate change, the depletion of non-renewable resources, and the degradation of ecosystem services through the enhancement of the waste of resources, the emission of greenhouse gases, and the land use-land cover changes. Consequently, economic equity and the stable accesses to food, water, and energy are threatened, the potential risks to natural disaster are increased, and the minimum standards of wholesome and cultured living are in danger. How socio-ecological systems are changing and interacting with global and local environment?

In order to answer to these questions, it is necessary to understand the inter-linkages among factors of the socio-ecological systems through earth observations, field studies, data archive of social statistics and historical information on local and global changes, and the synthesis of them with integrated analysis and mapping. The study should have a scope with multi-spatial scale including Japan, Asia, and the globe, and with the target period of drastic changes for human beings in 300 years from the 150 years from the industrial revolution till now, and the 150 years from now on.

A research project of ”Super-High Resolution Simulations on the Global Environment” is proposed in order to promote various studies under Future Earth. Cycles and budgets of energy, water, and materials such as carbon, will be eventually simulated by 1km (30 arc second) over global continent for past 150 and future 150 years considering social and climatic changes. Past and projected changes will prevail the historic transition and future anticipations in sustainable energy, renewable resources such as food and water, impacts and transition of health and ecosystem services with super-high resolution.

Research components to enable the study are mostly ready to start feasibility studies. Motivated researchers are welcome to join.

Keywords: future earth, offline simulation, super-high resolution, anthropocene

Asian Economic Development and Global Environmental Sustainability

SUGIHARA, Kaoru[1*]

[1]National Graduate Institute for Policy Studies

During the last twenty years or so, growth economies of Asia collectively became the largest importer of resources (particularly of energy resources) in the world, as not only resource-poor countries like Japan but counties like Indonesia and China, which used to be resource exporters, turned to net importers. Meanwhile, East Asia historically pursued a path of economic development, different from that of capital- and resource-intensive industrialization developed in the West, by fostering relatively labour-intensive and resource-saving technology. The energy intensity (energy consumption per GDP) has been kept low in many Asian countries, and Japan's energy-saving technology still leads the world in a number of respects. Thus, growth economies of Asia (now including most of South and Southeast Asia) are major players in the global market of resources, influencing both demand and supply.

Needless to say, monsoon Asia creates the world's largest circulation of water and heat energy around the Himalayas (and the Tibetan Plateau), and about a half of world population live in this environment. It has formed a uniquely coherent civilization and economy, such as densely populated society based on rice farming, transcending the geospheric and biospheric boundaries between the tropics and temperate zones. Today, this region is going through comprehensive industrialization and urbanization, and the resource and energy use there is beginning to affect the health of the entire world economy.

In what ways has Asian economic development been affecting global environmental sustainability? If Asia has long fostered a path of economic development under the unique environmental outfit of monsoon Asia, how would it influence the region's ability to address global environmental issues? This presentation offers a review of recent history literature on these questions, with comments on its utility for the understanding of the future of global sustainability.

I am currently serving for the Future Earth Committee at the Science Council of Japan, to promote humanities and social science research for this global initiative. I hope to have an opportunity to exchange ideas with members of this Union, and to explore possibilities of interdisciplinary research, specifically designed for the activities of Future Earth.

Keywords: Asia, economic development, global environmental sustainability, path dependency

International Earth Science Olympiad from the viewpoint of Future Earth

TAKIGAMI, Yutaka[1*] ; HISADA, Ken-ichiro[2]

[1]Kanto Gakuen University, [2]Graduate School of Life and Environmental Sciences, University of Tsukuba

When considering the Future Earth-sustainable Earth, it is important to know the whole Earth and the international cooperation. As the study of the whole Earth is Earth Science, we consider International Earth Science Olympiad (IESO) which is the international competition for high school students from the viewpoint of Future Earth.

IESO was hold on 2007 (Korea), 2008(Philippine), 2009(Taiwan), 2010(Indonesia), 2011(Italia), 2012(Argentina) and 2013(India). In 2016, we will have IESO at Mie.

1) International Team Field Investigation (ITFI)

ITFI is the typical event which is not existed on other science Olympiads. This event is the presentation event after high school students from other countries investigated some subjects with international cooperation. At this event, communication language is English and sometimes subjects of this investigation include the regional social life. This experience will guide the consideration of Future earth to students in future.

2) Increase of participating countries

Participating countries were increased from about 6 (2007,2008) to over 20 (2011-). One of the reason might be due to the understanding the importance of Earth Science for Future Earth.

3) Examination questions at IESO

At present, questions are consisting from three disciplines; Geology and Solid Earth, Metrology and Oceanology, Astronomy. However, members of IESO want to include multidisciplinary questions which are important for considering Future Earth. At 2016 IESO at Mie, we want include these examination questions aggressively.

4) Japan Earth Science Olympiad (JESO)

The half of students for participating the JESO will enter the universities of art divisions and 30% of students are girls. This fact is good for consideration of Future Earth because many peoples, not scientist, have basic earth science knowledge. However, it is regret that more high school students study another science curriculum than earth science.

I think that it is very important for Future earth to learn Earth Science and to join the Earth Science Olympiad.

The education for sustainable earth - The International Geography Olympiad

IDA, Yoshiyasu[1*]

[1]University of Tsukuba

The International Geography Olympiad (iGeo) is a competition for the best 16 to 19 year old geography students from all over the world. Four students represent each country in a series of Geography tests in (generally) a four-five day program. An adult Team leader and International Board Member accompany each national team. The official language of the iGeo is English.(from iGeo home page)

There are three aims of iGeo. First is to stimulate active interest in geographical and environmental studies among young people, second to contribute positively to debate about the importance of geography as a senior secondary school subject by drawing attention to the quality of geographical knowledge, skills and interests among young people, third to facilitate social contacts between young people from different countries and in doing so, contribute to the understanding between nations.

The test questions in iGeo are presented from each country and are made. The international standard test is aimed by these questions. These questions are divided into three types that are multimedia, description, and fieldwork. The aim of each type test is to make students develop the ability to look the future society and earth on underlying knowledge, skills and view points of the geography. Particularly, in the fieldwork test, students can learn not only the present understanding but also the future by observing local natural phenomenon and the life of people, directly. Regarding geography education of our country, though present understandings more importance, a point of view to inquire the relation between nature and human in the future is not enough. In factually, the Japanese team in iGeo really tends that the point of the fieldwork test is low. As for this, the main factor would be that thinking the future is not educated in geography education in Japan. In addition, students have few chances to experience the fieldwork in geography class of our country.

In the geography education of Japan, it is necessary for the learning content including the consideration for the future based on geographical knowledge, skill and inquires.

Sustainable Future of Coastal and Marine Ecosystems in the Indo-Pacific Ocean

UEMATSU, Mitsuo[1*]

[1]Atmosphere and Ocean Research Institute, The University of Tokyo

The Indo-Pacific Ocean Region encompasses diverse coastal ecosystems, as represented by coral reefs, mangrove forests, seagrass beds, and even deep basin over 4000 m deep. These diverse environments harbor the unique and extremely high biodiversity of the region, known as the major biodiversity hotspot in the world. However, the region is also under serious threat of environmental decline from various human impacts due, for example, to loads of pollutants from land and habitat destruction associated with resort development and fisheries. There are also concerns about negative impacts of global climate change associated with ocean acidification.

As one of Future Earth initiatives, we should establish future perspectives and needs for strengthening sustainable ocean environment and development. A project aims at further expanding the network of the scientific and socio-economic studies and education on the Indo-Pacific Ocean Region, through (1) research collaboration applying new approaches and methodologies such as satellite remote sensing, molecular genetic analyses, and high-precision analyses of biogeochemical parameters, (2) integrative, inter-disciplinary ecosystem researches, and (3) establishment of core of coastal marine science and socio-economy in each country and multilateral network. Through these activities the project aims at enhancing education of researchers who will play major roles not only in domestic but also in international activities on global issues.

As a practical matter that impeded harmonized implementation of the program, there will be a large gap among the member countries in their funding capabilities, resulting in the shortage of funding in some countries. This may be partly due to the differences in political priorities for basic environmental and/or socio-economic research among countries. There are also problems that the importance and practical application of basic research to urgent environmental issues have not effectively been reflected in the response of funding organizations, policy makers, and/or popular audience, despite our efforts to demonstrate and disseminate these issues in various occasions.

Geoscientific Perspective for Sustainable Future Earth

HIMIYAMA, Yukio[1*]

[1]Hokkaido University of Education

The world global environmental studies are being re-organized under the flag of Future Earth led by ICSU, ISSC etc. Geoscience, which specializes in the dynamic nature and phenomena of the earth's surface, including lithosphere, hydrosphere, atmosphere, biosphere and human-geosphere, assumes unique responsibility in contributing to Future Earth. It was highly relevant for JpGU to establish Human Geoscience Section as one of its five academic sections when it was born in 2005 in response to the restructuring of the Science Council of Japan. The paper discusses the roles and the roadmaps of the geoscience community in general and those of the human geoscience in particular in implementing Future Earth.

Actions to the Eastern Japan earthquake disaster by SSJ and to disaster and environmental issues in academic communities

TADOKORO, Keiichi[1*]

[1]Graduate School of Environmental Studies, Nagoya University

The Seismological Society of Japan (SSJ) has organized the Investigation Committee for disaster. The committee corrected preliminary research outputs and opened them as a link correction on the SSJ ' s web site at the 2011 eastern Japan great earthquake disaster.

One of the important tasks of the committee is the contact point for other related academic societies dealing with earthquake and tsunami. The SSJ participated in the Liaison Committee on the off the Pacific coast of Tohoku Earthquake established with the related societies, as well as in the Environmental Hazard Countermeasure Committee of the Japan Geoscience Union (JpGU). The Outreach Committee of SSJ performed enlightening actions for general public and mass media. The SSJ cooperated the action also by the Science Council of Japan.

What we learn from the 2011 eastern Japan great earthquake and tsunami disaster is global environmental issues and natural disaster are inseparable. Earth and planetary sciences should integrate such problems that we have considered completely different problems in the past. For this purpose, cooperative action among our community is a matter of course. In addition, cooperation with the community outside of us is indispensable to earth and planetary sciences, studies about basis of the prosperity of the human, contribute for building sustainable human society. The JpGU is expected to be a core for such cooperative actions. It is important to make careful preparations to be successful in the actions and cooperation between the societies during the emergence period. I propose a workshop such as " global environmental issues among natural disaster " for brainstorming.

Activities of the Geological Society of Japan in support of reconstruction after the 2011 Tohoku earthquake disaster

TAKAGI, Hideo[1*]

[1]Waseda University (JGS Director of Outreach and Geopark Affairs)

I introduce the activities of the Geological Society of Japan (JGS) in support of the reconstruction after the 2011 Tohoku earthquake disaster on behalf of the Social Contribution Committee of the JGS. The JGS asked its members to submit proposals in support of the disaster recovery, and six of nine research programs in 2011 and one of two in 2012 were adopted and supported by funds of the Society. The seven projects can be categorized into three research categories: 1. recovery of specimens from museums destroyed by the tsunami, 2. development of methods of decontamination to help deal with the radioactive material spread by the Fukushima Daiichi nuclear power plant accident, and 3. surveys to recognize and quantify liquefaction caused by the Tohoku earthquake. The results of these studies were reported in poster presentations given at the JGS annual meetings and in newsletter articles published in 2012 and 2013. This report also introduces briefly the geopark activity that has been promoted by the JGS and its importance for local education in earth science including disaster prevention and mitigation in the eastern Tohoku coastal area (Sanriku area).

Reframing the academic responsibility of JSAF on the basis of its activities after the 2011 Tohoku earthquake

SHISHIKURA, Masanobu[1*]

[1]Active Fault and Earthquake Research Center, AIST

The Japanese Society for Active Fault Studies (JSAF) is devoted to the study of not only inland active faults but also offshore active faults including subduction zone mega-thrusts. The members of JSAF have been conducted emergently survey for every earthquake disasters related to active fault since the establishment of 2007. One of the important purposes of the survey is to identify and to describe any geological and geomorphological phenomena associated with earthquake and tsunami such as trace, geometry and displacement of surface rupture, coastal change and tsunami deposit. These modern analogues are key to reveal the past phenomena. And clarifying the past is key to estimate the future. This philosophy of paleoseismology and active fault study has been socially recognized in its importance for measuring low frequent great disaster after the 2011 great Tohoku earthquake (M9.0). However, as the lessons from the 2011 event and its triggered 2011 Fukushima Prefecture Hamadori earthquake (M7.0), we also recognized a limit of the current investigation technique of geological and geomorphological methods. The JSAF has an important role as a community for discussing new technique.

Activity of the AJG to the Great East Japan Earthquake Disaster: Role of academic societies at a big disaster

KUMAKI, Yohta[1*]

[1]Association of Japanese Geographers / Senshu Univ.

The activity of the Association of Japanese Geographers (AJG) responding to the Great East Japan Earthquake Disaster was as follows:

1) "The Headquarters for Disaster Response," the general manager of which was the chairperson of the executive committee of AJG, was set up just after the disaster occurrence. It performed correspondence to a various inquiries, liaison and information exchange with other associations, communication to geographers in the fields, uploading quick reports and proposals to the web site, etc.

2) Based on a geographical property to make much of air-photo interpretation and mapping, AJG organized a working group for clarifying the entire surface of the tsunami inundation and published the first report on March 28 (revised eight times until December).

3) AJG gave the geography teaching materials to damaged schools by the members' contribution.

4) Until March, 2014, ten symposia relating to the Great East Japan Earthquake Disaster were held. The theme were of physical geography (tsunami, liquefaction, slope disaster, disaster of land developed for housing, radioactive contamination, etc.) and of human geography (life of damaged inhabitants, the revival way, etc).

On the occasion of a big disaster, societies of geosciences should do not only the academic activity but also take a social role as follows:

1) dispatching the research results in a easily understandable way quickly and broadly

2) Supporting people and governments based on specialized intellect.

3) Supporting to school education.

It is important for JpGU to have an open window for the society for disaster outbreak as well as to support the researchers who act in the field.

Cartographic society's contributions to crisis resolution of environmental issues and disasters

ARIKAWA, Masatoshi[1*] ; MORITA, Takashi[1] ; KAMADA, Kouzou[1] ; KUMAKI, Yohta[1] ; SATO, Jun[1]

[1]Japan Cartographers Association

Maps are important for crisis management in environmantal issues and disasters, however it is not clear if the current situations of providing and using maps for crisis management are appropriate or not. We try to clarify contributions and problems on map provisions and uses for crisis management from the viewpoint of cartographic society in our talk. Particularly, we focus on the following points.

(1) prompt action and quality
(2) appropriateness of map provisoins to suffered communities
depending on their situation
(3) designing action plans of map provisions for levels of situations
(4) paper maps and digital maps
(5) appropriateness of current hazard maps
(6) weak map literacy in decision making, communication, and media
(7) international contributions
(8) volunteered geographic information, location-based SNS, and ubiquitous mappings
(9) use of spatio-temporal big data

Disaster Response Support Activity based on Geospatial Information

HATAYAMA, Michinori[1*]

[1]Disaster Prevention Research Institute, Kyoto University

In this presentation, the history of major disasters and progress of information communication technology related to geospatial information after 1994.

In 1995 Great Hanshin-Awaji Earthquake, GIS and Remote Senescing got a lot of attention to manage disaster information.

In 2004 Chuetsu Earthquake, GSI and voluntary base research group tried to share damage and recovery process information through Web GIS.

After launch of Google Earth, ordinary person can share his/her geospatial information though internet. And in 2011 Great East Japan Earthquake, most layers of geospatial information were shared.

Environmental pollution by the Fukushima Daiichi nuclear power plant accident and role of the atmospheric science

NAKAJIMA, Teruyuki[1*]

[1]Atmosphere and Ocean Research Institute

There are several past and future issues to be discussed regarding the role of the atmospheric science in the accident of the Fukushima Daiichi nuclear power plant. SPEEDI model results were not effectively used in the evacuation plan by the government. It was found, on the other hand, that the performance of atmospheric chemistry transport models are comparable to or better than that of SPEEDI, for simulation of distribution of radioactive material over the wide area contaminated by the accident. In that situation, a bottom-up process were useful to gather results of simulation and in situ measurements by volunteer scientists to be utilized in the decision process of the government. The Science Council of Japan is now under discussion of establishing an emergency action manual for gathering data and knowledge by scientists to be shared by professionals to make useful outputs to government and public. As also indicated by the IPCC assessment process for climate change, it is important to present uncertainties included in the scientific knowledge to be released. In this regard, it is important for the atmospheric science to contribute to reducing the uncertainties through a further progress of the atmospheric dynamics, physics, and chemistry modeling system and through establishing more robust monitoring system of weather and other quantities. I like to discuss these issues for improving our ability to reduce damage caused by future disasters that may happen.

Japan Geoscience Union Meeting 2014

How JAHS will manage the Great East Japan Earthquake?

KONDOH, Akihiko[1*] ; YASUHARA, Masaya[2] ; TSUKAMOTO, Hitoshi[2]

[1]CEReS, Chiba University, [2]The National Institute of Advanced Industrial Science and Technology

JAHS (Japanese Association of Hydrological Sciences) is an academic society that treat hydrological cycle on the Earth. Water is one of the most important component that makes feature of earth's surface. Water also is indispensable resources for human's life and activity, so hydrological sciences involves the relationship between hydrological cycle and human activities. JAHS have deep concern to human dimensions of environmental changes. To realize "Hydrological Sciences in the society" becomes important subject to be accomplished after the great earth quick in March 11, 2011.

After the great disaster, we carried out the studies both on Tsunami and on nuclear disaster. At a lecture, we will focus on the nuclear disaster in Fukushima District, because we think our knowledge and experiences on hydrology will be useful to understand the actual situation and future perspectives of radioactive contamination, and also useful to propose measures to restore the region contaminated by radioactive fallout.

The research works on the behavior of radioactive nuclides in the environment are divided into mechanism study and distribution study. In the latter, the distribution map should be discussed with the scales, because often what looks important at one scale is less important at another.

The small scale dose rate maps published by the government was useful to determine the evacuation area at the initial stage of the nuclear disaster, however, large scale map is necessary at the restoration stage. In the mountain village, the life and livelihood are strongly dependent to water and material cycles in SATOYAMA watershed. We have to know the distribution of radioactive materials, water and material cycles in the watershed. The knowledge and experiences in hydrology have great effect to make measures to cope with radioactive materials based on the SATOYAMA watershed scale. We are now conducting hydrological research in the small watershed in one of evacuation area. The outcomes are shared with local people and make them the materials to discuss the future of the region.

At the Fukushima Dai-ichi nuclear power plant, control of polluted water flowing from nuclear reactor buildings becomes an urgent issue to be solved. The buildings are located on the independent plateau. At this situation, local groundwater flow system, recharged on the surface and discharge to surrounding lowland, is the main system of hydrologic cycle. Groundwater from Abukuma Mountains belongs regional groundwater system, and its flux should be very low and residence time should be extremely long. This is hydrological knowledge, however, why accumulated knowledge does not apply to the field in problem?

Science is in the society, and supported by the society. We, scientists, have to consider how to use scientific knowledge in the framework that have common purpose.

Transfer of radionuclides to river by Fukushima Daiichi NPP

ONDA, Yuichi[1*]

[1]Center for Research in Isotopes and Environmental Dynamics, University of Tsukuba

A number of studies have been conducted to monitor and model the time series change of radiocesium transfer through aquatic systems after significant fallout, especially from the Chernobyl disaster. Our research team has been monitoring the environmental consequences of radioactive contamination just after the Fukushima Daiichi NPP accident in Yamakiya-district, Kawamata town, Fukushima prefecture. Research items are listed below.

1. Radiocesium wash-off from the runoff-erosion plot under different land use.
2. Measurement of radiocesium transfer in forest environment, in association with hydrological pathways such as throughfall and overlandflow on hillslope.
3. Monitoring on radiocesium concentration in soil water, ground water, and spring water.
4. Monitoring of dissolved and particulate radiocesium concentration in river water, and stream water from the forested catchment.
5.Measurement of radiocesium content in drain water and suspended sediment from paddy field.

Our monitoring result demonstrated that the Cs-137 concentration in eroded sediment from the runoff-erosion plot has been almost constant for the past 3 years, however the Cs-137 concentration of suspended sediment from the forested catchment showed slight decrease through time. On the other hand, the suspended sediment from paddy field and those in river water from large catchments exhibited rapid decrease in Cs-137 concentration with time. The decreasing trend of Cs-137 concentration were fitted by the two-component exponential model, differences in decreasing rate of the model were compared and discussed among various land uses and catchment scales. Such analysis can provide important insights into the future prediction of the radiocesium wash-off from catchments with different land uses.

Activities of JAGH relating to the earthquake disaster and disaster relief

NAKAGAWA, Kei[1*] ; TOKUNAGA, Tomochika[2] ; SUGITA, Fumi[3] ; KAIHOTSU, Ichirow[4] ; SHIMADA, Jun[5]

[1]Graduate School of Fisheries Science and Environmental Studies, Nagasaki University, [2]Graduate School of Frontier Sciences, The University of Tokyo, [3]Faculty of Commerce and Economics, Chiba University of Commerce, [4]Graduate School of Integrated Arts and Sciences, Hiroshima University, [5]Graduate School of Science and Technology, Kumamoto University

Followings are the activities of Japanese Association of Groundwater Hydrology (JAGH) relating to the 2011 off the Pacific coast of Tohoku Earthquake.

Program Committee (Chair: Makoto Nakashima) organized the symposium " The way of groundwater use as the emergency water source at the time of the earthquake " on May 26, 2012, at the Kashiwa Campus of the University of Tokyo. In the symposium, following presentations were given; " Ensuring safety and security of the water supply system " by Kenichi Yamamoto (Ministry of Land, Infrastructure, Transport and Tourism), " The securing water in areas affected by the Great East Japan Earthquake Tsunami " by Yoshiharu Ueno (Iwate prefecture), " About the use of groundwater as a domestic water at the time of the disaster in Nagoya " by Kazuhiro Takemoto (Nagoya City), " Investigation of the effect of tsunami induced by the Great East Japan Earthquake on groundwater " by Kei Nakagawa (Nagasaki University). Then, the panel discussion was coordinated by Makoto Taniguchi (Research Institute for Humanity and Nature). In this symposium, difference of water usage between emergency and non-emergency times, management method and registration system were discussed based on the presentations.

Editorial Committee (Chair: Tomochika Tokunaga) organized and published two special issues. In the special issue of " The 2011 off the Pacific Coast of Tohoku Earthquake and groundwater " (Vol.54, No.1, Feb, 2012), Technical Report of " Change in groundwater environment caused by the 2011 off the Pacific Coast of Tohoku Earthquake in the southern part of Sendai Plain " by Kazushi Mori et al. and Research-in-Progress of " Impact of Tsunami caused by the 2011 off the Pacific coast of Tohoku Earthquake on groundwater usage and quality in Asahi-city, Chiba Prefecture Japan " by Fumi Sugita are published. In the special issue of " Earthquake Hazard and Groundwater " (Vol.55, No.1, Feb, 2013), Review of " Importance of groundwater as security " by Makoto Taniguchi, Research-in-progress of " Field study on the damages of a well due to the Great East Japan Earthquake " by Kunio Ohtoshi et al., Data of " Effect of Tsunami induced by the 2011 off the Pacific coast of Tohoku Earthquake on groundwater " by Kei Nakagawa et al., Data of " Treatment and effective utilization of debris and tsunami deposits generated by the Great East Japan Earthquake " by Takeshi Katsumi et al., and Data of " Symposium, The way of groundwater use as the emergency water source at the time of the earthquake " by Makoto Taniguchi and Makoto Nakashima were published. All these papers have been published in the J-stage (https://www.jstage.jst.go.jp/browse/jagh/-char/ja/).

Prof. Ichirow Kaihotsu organized the joint investigation team of JAGH and JSHWR (Japan Society of Hydrology and Water Resources). They visited public water works offices and collected water samples at the wells of the city in Kamaishi city, Rikuzen Takata city, and Minami Sanriku town during June 16-19 and August 1-3, 2011. They also sampled water at the well for disaster in Wakaba-ku, Sendai City at that time. As a follow up of these investigations, the team of University of Tokyo and Nagasaki University sampled groundwater, river water and soil in Minami Sanriku town. In these investigations, we mainly focused on recovery from the salinization of groundwater due to tsunami induced by the earthquake.

Oceanic dispersion model intercomparison for the Fukushima accident

MASUMOTO, Yukio[1*]

[1]The University of Tokyo

There are several attempts to simulate oceanic dispersion of radionuclides discharged into the ocean after the accident of Fukushima Daiichi Nuclear Power Plant on March 11, 2011. In order to understand a present status of model capability to simulate the dispersion of radionuclide and uncertainty in the model simulations, detailed comparisons of model results with observations and also among the model results are necessary. A model intercomparison project, launched by a working group established under the Oceanographic Society of Japan, and then under Japan Science Council, compared results from several downscaling dispersion models focusing on Cesium 137 dispersion for the Fukushima case. Eleven model results from ten groups are participating in the project. Although there are general similarities in basic flow fields and dispersion patterns, significant differences among the simulated results also exist, due to differences in model settings and uncertainty in the forcing fields. This presentation introduces the model intercomparison activity and discuss some preliminary results of the comparisons.

Keywords: Oceanic Dispersion Model, Radionuclides, Model Intercomparison

Development of Composite Materials with Zeolite and Magnetite for Radioactive Cs Decontamination in Soil

AONO, Hiromichi[1*]

[1]Ehime University

1. Intorduction

The decontamination of radioactive Cs from the accident at the Fukushima No.1 nuclear power plant is an urgent problem. Zeolites are the most promising material for the Cs decontamination in water such as ponds and rice fields. The movement of the Cs^+ ions in the soil to the zeolite should be possible when the powdered zeolite mixes with the soil during the wet process using a K^+ or $NH_4{}^+$ ion-containing solution for ion exchange with the Cs^+ ions in the soil. However, the collection of the zeolite after the decontamination of the radio Cs^+ ions is impossible when the powder material mixes with the soil. Magnetic collection is one of the methods using a composite material composed of the zeolite and a magnetic material after the Cs^+ ion adsorption.

An Na-P1 type artificial zeolite ($Na_6Al_6Si_{10}O_{32}?12H_2O$) having a high cation exchange capacity (CEC) is able to be synthesized at a low cost using alkali from the waste coal fly ash of thermal power stations. On the other hand, the synthesis method using alkali for the nano-sized magnetite (Fe_3O_4) is very similar to that for the Na-P1 type artificial zeolite. We considered that a new composite material using alkali from a suspension of both starting materials would be a promising material for the Cs decontamination.

In this study, we synthesized the composite material (magnetic zeolite) of the Na-P1 type zeolite and nano-sized magnetite by alkali processing from a mixed solution of the fly-ash and iron chlorides for the magnetic collection of the zeolite after Cs^+ ion adsorption.

2. Experimentals

Fly ash (JIS II type) from thermal power stations (Shikoku Electric Power Co.) was used for the preparation of the Na-P1 type zeolite. For the preparation of the Na-P1 type zeolite, the fly ash and 2M NaOH were mixed and refluxed at 100 ^{o}C for 24 h. The powder was collected and washed several times by centrifugal separation, and then dried at 80 ^{o}C. For the preparation of the nano-sized magnetite, $FeCl_2?4H_2O$ and $FeCl_3?6H_2O$ (mole ratio=1:2) were dissolved in pure water. The mixed solution was placed in a water bath at 100 ^{o}C, and then a 2M NaOH solution was added with stirring and held at the same temperature for 30 min. For the preparation of the composite material (magnetic zeolite) of the Na-P1 type zeolite and magnetite, the synthesized magnetite in water and then fly ash was added to the mixed solution. A 2M NaOH solution was added to the mixed solution and refluxed at 100 ^{o}C for 24 h.

3. Results and discussion

For the material without magnetite , the main peaks for the XRD were the Na-P1 type zeolite with mullite ($Al_6Si_2O_{13}$) as the second phase. The peak intensity of the magnetite increased with an increase in the magnetite content. The peaks of the magnetite were very broad due to its small crystalline size. The particle size for the magnetic zeolite was 5˜30 μm for a SEM observation. These particles of the magnetic zeolite were easily attracted by the neodymium magnet. For the TEM observation, the Na-P1 zeolite, the magnetite, and amorphous phases were confirmed using the electronic diffraction of the center of the particle. The nano-sized and aggregated magnetite particles were observed in the bright-field image. Due to the slow formation of the zeolite crystals after formation of the nano-sized magnetite, the magnetite particles existed at the grain boundary between the polycrystalline zeolites.

We tested that the magnetic zeolite (200 g) and the soil (2 kg) obtained from the rice fields in Fukushima were mixed using a shaking apparatus with $NH_4{}^+$ ion containing solution. The magnetic zeolite with radioactive Cs collected using neodymium magnet (8000 gauss). We succeeded to decontaminate ca. 80 % radio active Cs from the soil using the magnetic zeolite.

The Mission of Human Geoscience in the Study of Disasters and Global Environmental Problems

HIMIYAMA, Yukio[1*]

[1]Hokkaido University of Education

The Human Geoscience Section of JpGU has been emphasizing the importance of studying increasing disasters and global environmental problems together in an integrative way, and has worked together with the Human Geoscience Committee of the Science Council of Japan to organize various meetings and issued proposals related with global environmental problems and hazards/disasters. The lecture reviews these activities and their achievements, the harsh reality of the still continuing Great East Japan Disaster, and the worsening global environmental problems and the efforts to combat them, and discusses the missions of human geoscience now and towards future.

A new research field after the 2011 Tohoku earthquake and tsunami

IMAMURA, Fumihiko[1*]

[1]International Research Institute of Disaster Science, Tohoku University

The Tohoku region in Japan was hit by a gigantic earthquake of M=9.0 subsequently followed by a huge tsunami which occurred off the Pacific ocean. Both of them have caused huge damage on the eastern coast of Japan, having a huge inundation area more than 500km2 with the attack of destructive wave forces. There are several issues why this tragedy occurred, and what unrecognized factors contributed to the high vulnerability of the area, and how the risk at each region in the future earthquake and tsunami.

The damage actual situation of the East Japan great earthquake disaster and the study base formation of practical disaster prevention studies based on the lesson are big problems and develop the situation of the damage, a future evaluation, prediction from elucidation of a giant earthquake and the outbreak mechanism of the tsunami and must record a then lesson to earthquake disaster archives. Furthermore, study such as the ways of the disaster prevention that stood on improvement of the trust of the risk evaluation, the construction of support studies, cooperation with the disaster medicine, the history culture will be necessary to prepare for domestic and foreign disasters.

In natural disaster scientific research, I arrest prior measures, the outbreak of the disaster, influence of the damage, urgent correspondence, restoration, revival, forehandedness with a series of disaster cycles and elucidate the phenomenon in each process, and it is necessary to make the lesson generalization, unification. Social incorporate result of the natural disaster scientific research that assumed knowledge and the world provided from the research in the East Japan great earthquake disaster, the action to reconstruction contracts a field and a human being, society is smart and copes for a disaster cycle to become complicated and systematizes study to build society system keeping a lesson alive through hardship as ”practical disaster prevention studies”, and a wound wants to form the scientific value.

How volcanology will manage environment and hazard?

FUJII, Toshitsugu[1*]

[1]Crisis & Environment Management Policy Institute (CeMI)

In order to mitigate volcanic disaster, it is necessary to understand the timing and magnitude of eruption before eruption, and to evaluate the transit of eruption properly, indicating the development of volcanology is essential. Therefore, the roles of volcanology and volcanologist are important to mitigate the volcanic disaster.

Japanese volcanologists have contributed to mitigate the volcanic disaster in case of volcanic unrest or eruption. A few examples will be reviewed during the session.

However, these contributions have not been made by the volcanological society, but by volcanologists personally. It is not clear how the academic society such as volcanological society should contribute to mitigate the natural disaster. Academic society could be an organ to contribute in risk evaluation through the scientific discussion within the society, but may not be an organ to engage in risk management.

Recent transformation of the snow and ice disaster and emerging issues

KAWASHIMA, Katsuhisa[1*] ; KAMIISHI, Isao[2]

[1]Research Institute for Natural Hazards and Disaster Recovery, Niigata University, [2]Snow and Ice Research Center, National Research Institute for Earth Science and Disaster Prevention

Recently, the natural environment and social environment surrounding Japan, such as the increased global warming and the acceleration of demographic aging, have changed greatly. A few decades ago, there was a view that snowfall will decrease sharply with the progress of global warming and the resultant snow disaster will be drastically alleviated. However, since heavy snowfall appears frequently after the 21st century, it is being accepted widely that the impact of global warming on variations in snow cover is not a simple problem. The heavy snowfall events which appeared in three consecutive years from 2010/11 winter to 2012/13 winter are good examples, and consequently more than 100 people were killed each year. Moreover, it is noteworthy that the aspect of snow disaster has greatly differed from the time of Showa. In relation to earthquakes and heavy rainfalls which occurred frequently in the heavy-snow region of Japan, new issues of the compound disaster events, hardly taken note until now, began to gain prominent attention recently. In this study, I am going to discuss about the research perspective towards mitigation of the snow disaster.

Space disasters and space weather studies

KIKUCHI, Takashi[1*]

[1]Solar-Terrestrial Environment Laboratory

When the solar flare occurs, the high energy particles hit the satellite and cause serious troubles in the communication and broadcasting systems. The geomagnetic storm causes induced currents giving damages to the power transmission system. To avoid the damages due to the solar flare and geomagnetic storms, we are doing research to achieve the prediction model of the solar flare and magnetospheric and ionospheric storms. This talk will present examples of the satellite failures and power outage and also the simulation studies which will enable us to predict the space weather.

Estimation of the paleotsunami size using tsunami deposits along the eastern Nankai Trough

FUJIWARA, Osamu[1*]

[1]Active Fault and Earthquake Research Center, AIST

Repeated great earthquakes (M8 class) and accompanying tsunamis occurred along the Nankai Trough have severely damaged the coastal areas along the trough. In response to the 2011 Tohoku-oki earthquake and tsunami, Cabinet office, Government of Japan came up with a new policy to the damage assumptions for the great earthquake and tsunami generated from this plate boundariy. That is, a doctrine that gives serious consideration to the greatest class of earthquake and tsunami, which take every possibility into account, was announced.

The announced ”greatest class of earthquake and tsunami” along the Nankai Trough by the Central Disaster Management Council of the Cabinet Office (2011, 2012) has a rupture zone covering the almost entirely of the Nankai Trough (Mw 9.1) and is much larger than formerly estimated one. As this great earthquake and tsunami would hit the area with clustered population and industries, disaster prevention measure for these catastrophes increasingly attracts public attention.

Japanese historical documents cover the past 1300 year records of the great tsunami-inducing earthquakes generated from the Nankai Trough, so called Nankai and Tokai/Tonankai earthquakes. However, M9-class mega earthquake as mentioned above has never reported in this area. In considering whether out-sized earthquake and tsunami announced for the Nankai Trough will do occur or not, it is necessary to verify whether unknown out-sized earthquake has occurred in the geological time scale. Paleo-seismological studies including the tsunami deposit researches are also needed to expand the time range of the earthquake and tsunami records beyond the historical documents and to make the reliable and realistic size estimation for the palate boundary earthquakes and tsunamis based on their recurrence history.

In reconstructing the paleotsunami size, it is needed to consider the influence of coastal geomorphic developments in centennial to millennium time-scale. Seaward expansion of alluvial lowland (migration of coast line) and coastal uplift are primary factors for these topographic changes, which can function as ”natural barrier” for the tsunami inundation. For this reason, the older tsunami deposits tend to distribute the deeper inland and higher altitude. If the effect of these natural barrier is not considered, there is a risk that will come into the over estimation for the size of palerotsunamis. In considering the effect of natural barrier, tsunami deposits suggesting the out-sized earthquake have not found from the sedimentary sequence formed along the Enshu-nada and Suruga Bay coast in the last 4000-5000 years.

Tsunami Sediment along the Nankai Trough and Nuclear Power Plants

OKAMURA, Makoto[1*]

[1]Science Research Center

We know well interplate megathrust earthquakes have been occurred repeatedly through several decades to centuries. Based on this common knowledge, huge earthquakes and tsunamis must be occured within a period of several thousand years. We research on tsunami sediment from lacustrine deposits along the Nankai Trough for prehistoric Nankai Trough Earthquake. As a result, large tsunami has been occurred 300 years interval through past 6,000 years. The Hoei Earthquake, AD1707 was the biggest tsunami through last millennium as mentioned after ancient manuscripts. Nevertheless, over the Hoei Earthquake tsunami sediments were found in several cores collected from lacustrine deposits.

However, we only have poor knowledge about these interplate earthquakes through millennium. Actually, the Fukushima Accident after the Kashiwazaki, we cannot evaluate even small-sized earthquake (Mw6.8), and 3.11 tsunami. We, seismologists and engineers, said ”out of image” just after 3.11 off Tohoku District Earthquake. Never say ”safe or safety” again about future earthquake and tsunami related nuclear power plants.

Change of giant tsunami study and the risk evaluation of the NPP before and after the 2011 Tohoku earthquake

OKAMURA, Yukinobu[1*]

[1]The National Institute of Advanced Industrial Science and Technology

When the 2011 Tohoku earthquake occurred, the study of the 869 Jogan earthquake by AIST has finished the first stage and the evaluation of the Jogan earthquake was almost concluded in the Headquarters for Earthquake Research Promotion, and also the back check of nuclear power plants seem to have been slowing down.

The study of Jogan earthquake by AIST started 2004 and was included in the project supported by MEXT from 2005 to 2009. The final report of the project submitted to MEXT in 2010, which concluded that a giant tsunami was generated during the AD869 Jogan earthquake which was larger than M 8.4 based on tsunami deposits survey in the Sendai and Ishinomaki plains, and that the recurrence interval of the giant tsunamis was 450 to 800 years. The AIST study team understands that the source area could extend to the north and south because the survey area of tsunami deposits was insufficient, and tsunami inundation was wider than the distribution of tsunami deposits. The survey of tsunami deposits of wider area had been started from 2010, but it was difficult to find coastal plains which preserve tsunami deposits.

The re-evaluation of all of the nuclear power plans started in 2007 based on new criteria of the safety assessment. The plants were evaluated by three sub-committees and the result was reported to the joint committee. Evaluation against strong motion by earthquake was preceded putting tsunami evaluation off later. In 2009, the middle reports of the Fukushima No.1 NPP was submitted to the joint committee which did not mentioned to the Jogan earthquake, and then only the minimum model of the Jogan earthquake was evaluated. The further discussion of its magnitude and tsunami has not been conducted before March 11, 2011.

The study of Jogan earthquake have been presented in meetings of earth science societies by AIST and medias reported several times since 2005, but the possibility of giant earthquake along the Japan trench was not discussed in the community of earthquake science. In addition, it is not easy to change the society that was not ready to giant earthquake. In these circumstances, nuclear power plants were working during the re-evaluatio, while many problems have been pointed out.

The situation has changed dramatically after the 2011 Tohoku earthquake. Society shares sense of crises against giant tsunami. The tsunami assessment has been made not based on known maximum earthquakes but unknown possible maximum. The safety of nuclear power plant were in doubt and the operation can be started after the safety of the plant was confirmed. Government dose not hesitated to assume maximum earthquake and tsunami, then possibility to point put unknown giant tsunami has been declined. But there is still unknown in earthquake, so it is necessary to continue study and to tell the society truce what we know and do not.

Strong motion characteristics of Mega-Thrust earthquake and the seismic response of NPP as a massive, stiff structure

KAWASE, Hiroshi[1*]

[1]DPRI, Kyoto University

The 2011 Tohoku earthquake generated a large number of strong motion records with high acceleration at many observation points, mainly in Miyagi and Ibaraki Prefectures. The distribution of seismic intensities observed or collected by JMA shows that intensity 7 was recorded only at K-NET Tsukidate (MYG004) in Kurihara City, but that intensity 6 upper were recorded at 40 points in four prefectures. When we compare the distribution of the peak ground acceleration (PGA) and velocity (PGV) of the strong motion records observed by K-NET and KiK-net of NIED with the empirical attenuation relation of Si and Midorikawa we can see that PGAs exceeded 500 Gals extensively along the coast from the Central Sanriku to Ibaraki Prefecture, but that PGVs in the area were lower than 80 cm/s. Because of the stochastic nature of the strong motion generation from the large-sized ruptured area there is no site with the coherent intermediate-period (around 1 s) velocity pulse with PGA larger than 800 Gals and PGV higher than 100 cm/s, which is the primary reason for not having severe seismic damage onto the ordinary low-rise buildings.

Prof. Sakai of Tukuba Universiy investigated the structural damage around the site with JMA intensity 6 upper to find that there are no site with heavy damage. We also found that, by using the nonlinear response models which can reproduce the damage ratios caused by the 1995 Hyogo-ken Nanbu (Kobe) earthquake, the structural damage potentials of the observed strong motions were relatively minor for most of the sites. These facts suggest that the current ordinary buildings in Japan, which is basically designed by using the rigid-structure concept, are capable to survive to the strong shakings from the mega-thrust earthquakes.

On the other hand the structural damage prediction by the Cabinet Office of the Japanese Government is made from the empirical relations with respect to seismic intensities of the predicted strong motions. Since such empirical relationship are all based on the damage observed during the 1995 Kobe earthquake, the relationship is good for the inland earthquake but not appropriate to the strong motions pervasively observed during the mega-thrust earthquakes with high PGAs but not so high PGVs. To prove this we independently predict strong motions and using the nonlinear response models we estimated structural damages and found heavily damaged sites only close to the shore line with soft ground conditions.

The same kind of smaller responses were predicted for the nuclear power plant (NPP) structures by using the strong motions predicted by the Cabinet Office in 2003 (Seckin et al., 2008, WCEE). The response of the NPP for predicted strong motions were about twice larger than the elastic limit of the structure, in terms of the relative shear deformation ratios. This is because on one hand the rigid body design concept makes structures sufficiently strong to the high PGA input and on the other hand the elastic limit used for the design is quite low compared to the ordinary buildings. Thus from the structural point of view strong motions during future mega-thrust earthquakes would not be a primary risk for NPPs despite of the spectral amplitude higher than the design input.

Safety regulations of nuclear power plant for tsunami after the 2011 great Tohoku-oki earthquake

TANIOKA, Yuichiro[1*]

[1]Institute of Seismology and Volcanology

Due to large tsunamis caused by the 2011 great Tohoku-oki earthquake, at First Fukushima Nuclear Power plant, cores were melted and explosions were occurred. Many inhabitants are still evacuated now because of radioactive contamination on land. About four months after this accident, the Nuclear Safety Commission of Japan made the committee for earthquake and tsunami related regulation guidance. In the committee, the revision of the earthquake-resistant design examination guidance was discussed. Before the accident, tsunami was treated as ”consideration for the earthquake accompanying phenomenon”. In the new guidance, ”the safe design policy for tsunami” became an item different from ”the earthquake-resistant safe design policy”. In March, 2012, a new examination guidance including the safe design policy for tsunami was made.

Then, in September, 2012, the Nuclear Regulation Authority was newly established in Japan. Under the Authority, ”the study team on the regulatory requirement for light water nuclear power plants - earthquake and tsunami ?” was established. The study team discussed about ”new safety design standard for earthquake and tsunami”. That was finalized in June, 2013.

In this new safety design standard, concept of the multiplex defense is adopted. 1) Tsunami should not get into a site. 2) When a tsunami get into a site with any reasons, the tsunami should be protected from a house or constructions. 3) When a tsunami get into a house, the power should be supplied from higher place near a site to prevent a severe accident. For tsunami should assume the largest tsunami source from the largest expected event. It is important to understand the concept of the multiplex defense. Some people may think that it is OK to have small inundation from small holes because the houses are protected from water. If such a thought comes out for the multiplex defense, a risk may increase ironically. I wish that the concept of the multiplex defense should be applied closely.

Seismic Safety Regulations and Earthquake Science

KOKETSU, Kazuki[1*]

[1]Earthq. Res. Inst., Univ. Tokyo

The first parts of seismic safety regulations for nuclear power plants consist of seismic and tsunami hazard evaluations as in the regulations for other structures. Although there are probabilistic and scenario assessments for the seismic hazard evaluation, the scenario assessment is mainly used and the probabilistic assessment is only in auxiliary use to evaluate remaining risk. Therefore, knowledge of earthquake science mostly contributes to making choices of scenario earthquakes in the scenario assessment.

This presentation mostly discusses the seismic hazard evaluation for nuclear power plants as the conveners requested, but also discusses the tsunami hazard evaluation as related to large subduction zone earthquakes. In addition, various phenomena occurring at nuclear power plants due to the 2011 Tohoku earthquake and their relation to these hazard evalutions and choices of scenario earthquakes are discussed.

We finally show from the above that the earthquake science cannot contribute to the real safety of a nuclear power plant unless unknown phenomena can be foreseen. We also discuss the danger of the idea that real safety can be reached if ”decision is made without prejudice only from the scientific and technical point of view.”

Collaboration beyond the difference between science and government

YAMAOKA, Koshun[1*]

[1]Graduate School of Environmental Studies, Nagoya University

Government and public take actions with decisions and judgments based on scientific knowledge. Science community widens and deepens human knowledge with continual research efforts. Therefore, any scientific conclusion, which is once regarded as true, can be denied by later researches. This is the origin of disagreement between science, which has essential uncertainties, and government and society, which require definite decisions. They need to acknowledge such differences that exist between science and government to improve the society.

In the volcano eruption prediction in Japan, the relationship between science community and government-public functions well. The reason is ”reasonable distance” between them. Japan Meteorological Agency (JMA) is responsible for issuing volcano information for evacuations. The information is justified in the discussion of the Coordinating Committee for the Prediction of Volcanic Eruption (CCPVE), where both scientists, geologists to geophysicists, and government personnel participate. Scientists often devoted themselves to the disaster reduction plan in local society near volcanoes, also contributing establishment of reasonable-distance between scientists and local government-public.

The Headquarters of Earthquake Research Promotion (HERP) is responsible for making use of the scientific knowledge of earthquakes in disaster reduction. In contrast to the volcano eruption prediction, it is rather difficult to keep reasonable distance between scientists and government-public for the following reason. The community of earthquake science is much bigger than that of volcano eruption prediction. Government personnel are changed in two years. Most of earthquake scientists live in Mega cities, and many prefectures have no earthquake scientists to ask for advices.

Volcanic Alert Levels were established following the requirement by the public. The level is designed so that each level corresponds to a definite evaluation action of the residents. Although, this is more than that volcano science can provide, the level functions so far with a conservative operations. For example, in the 2011 eruption of Kirishima nobody was insured or killed in spite of no precursors are observed. The alert level was kept level 2 after the small eruption of the previous year.

HERP issues long-term probability of earthquake occurrence in Japan, which was a strong requirement of the public after the 1995 Kobe earthquake. Characteristic earthquake model is used for the evaluation, because this the only usable model for the calculation of long-term probability of earthquake. To meet the responsibility for the public the government have to evaluate earthquake probability for all of major active faults and plate boundaries in Japan territory, in spite of large uncertainty. In the evaluation the off-Tohoku area are divided into several regions, each of which was assigned its own characteristic earthquake. Interaction of asperities, which represents the region division, was not taken into account. The off the coast of Tohoku earthquake is really a result of such interaction. After the earthquake the ”Off-the-coast-of-Tohoku-type” earthquake are introduced in the evaluation process, but still based on the characteristic earthquake hypothesis. The disaster reduction plan based on the long-term evaluation depends on the polity of the Cabinet Office or local governments.

The above examples are the results of interaction among social demands, governmental policy and state-of-the art of scientific knowledge. Though we have to admit that they are more than the present achievement of volcano and earthquake science, it is inevitable to issue some information for practical disaster reduction. We need to make continual efforts to improve the disaster reduction measure through effective communication between governmental personnel, public and scientists.

KAMIOKA, Norimasa[1*]

[1]Kochi prefectual board of education secretariat,School safety management division

In 2013, the Kochi prefectural Board of Education created teacher's instructional documents for disaster prevention education called "the Kochi Safety Education Program (for earthquakes)" and handed it out to all the teachers in Kochi. It explains the outline of the program and introduces some specific efforts to promote disaster prevention education in Kochi.

Advancing disaster preparedness in Okinawa Prefecture

MATSUMOTO, Takeshi[1*] ; FUJIWARA, Ayako[1]

[1]University of the Ryukyus

Okinawa Prefecture located in the south-westernmost part of Japanese Islands and in the subtropical area is often attacked by characteristic natural disasters which are different from the other areas in Japan, such as, destructive typhoons after passing the Western Pacific Warm Pool, high tide due to typhoons and warm water eddies, many earthquakes of both plate convergent type and due to active across-arc fault slip, most of them may induce tsunamis because their hypocentres are mostly sub-seafloor. Disaster preparedness, especially in Okinawa Prefecture is to be taught at the school education. Currently, 'Home Economics' is the only subject in which disaster preparedness is taught in junior and senior high schools in Japan. Therefore the articles on disaster preparedness in the current official textbooks on 'Home Economics' for junior and senior high school education were investigated in order to search if they contain descriptions enough to fulfil the disaster preparedness education in these schools. The results, however, show that the description in all the official textbooks was poor and that the volume of the description was half page in the minimum case and two pages even in the maximum case. The authors therefore started the following practice to fulfil the disaster preparedness education at schools.

A brochure to explain the nature of these natural disasters characteristic of Okinawa Prefecture and to teach how to prepare for the natural disasters was printed for auxiliary materials for school education. It includes the aspects of both natural science (earth science) and home economics, such as preparedness in the viewpoint of food clothing and shelter.

Japanese government established the system for renewing educational personnel certificates in 2007 and mandated the adoption of it in April 2009. The new system shows that only persons who have attended the certificate renewal courses over 30 hours and passed the examination before the expiration of the valid period can renew their certificate which is valid for next ten years. The purpose of this system is for teachers to acquire the latest knowledge and skills. Since 2012, the author has offered a 6-hour certificate renewal course titled by 'Disaster preparedness in Okinawa ? practicing development of teaching materials for school pupils'. This course was targeted mainly for science and home economics teachers of junior and senior high schools to tell the school pupils how to save their lives in case of devastated natural disasters.

Urban Disaster

KAWATA, Yoshiaki[1*]

[1]Faculty of safety Science

Disasters in urban area have evolved with urbanization such as urbanizing disaster, urbanized disaster, urban disaster and Super-urban disaster. These changes of the disasters are discontinuous due to phase tradition. The condition will be proposed by the worst damage scenario. The disaster vulnerability depends on several conditions such as rapid urbanization and inadequate land use management, over-population and its density, imbalance of natural environment, over-dependence on social infrastructure and public service. Disaster resilience was proposed in Hyogo Framework of Action (HFA), the 3rd United Nation Conference on Disaster Reduction in 2005. Japanese government will promote the disaster resilient policy, but it does not include community based projects which is also supported by people in any community. In the case of retrofit of houses, community based promotion is necessary because the cause of a fire is an earthquake vulnerable old house in the community.

Natural Disaster in The World

KAWATA, Yoshiaki[1]*

[1]Faculty of Safety Science

Natural disasters have two characteristics. The former is that disaster history repeats itself and the latter is locality. In Istanbul, Turkey, plate boundary earthquakes have occurred 27 times since 438. Mayon Volcano, Philippines had erupted 50 times in 400 years since 17th century, therefore average time interval is 8 years. In Asia, natural disasters hold a certain percent of the world such as number of occurrences : 36%, property damage : 47%, death toll : 62% and number of injured : 89%. The last two has increased due to rapid growth of population in urban area. The combination with gigantic earthquake and tsunami and volcano eruption had occurred in Japan as 1) 864 to 887 with Mt. Fuji eruption, Jougan earthquake and tsunami and Nankai-trough earthquake and 2) 1703 to 1707 with Genroku earthquake in Tokyo, Nankai-trough earthquake and Mt. Fuji eruption. We are now under clear effect of global warming. For example, in South Asia, the number of flooding has increased nearly twice in next ten years. Since 1995 in China, river flood disasters occurred five time with the victims of more than one hundred million. In 2005, hurricane Katrina with category 5 hit New Orleans and just three weeks after hurricane Rita also hit the damaged area. She was also category 5 and they made compound disaster. Finally, we proposed vicious cycle among population increase, disaster occurrence and poverty in rural area and urban area. The pair of two vortexes is very stable, therefore it is necessary to become economic growth to break the voltexes.

Keywords: Natural disaster, Global warming, Vicious cycle

Support by the health care providers in the reconstruction phase of disaster

TAKADA, Satosho[1*]

[1]Graduate School of Health Sciences, Kobe University

In the reconstruction phase, health care providers should pay particular attention to vulnerable groups which include the poor, women, children, elderly, handicapped and people with preexisting mental disorders.

Japanese people have experienced two severe natural disasters for the last two decades. The Hanshin-Awaji Earthquake occurred in the early morning of the January 17, 1995. Approximately 6,433 people perished and more than 43,792 people were injured. Homes of more than 300,000 people were totally or partially destroyed. Citizens not directly affected by the earthquake had to endure extreme disruption and confusion in their daily lives due to the long time disruption of daily activities resulting from the severely damaged infrastructure.

The Great East Japan Earthquake measuring a magnitude of 9.0 created a devastating tsunami that resulted in the destruction of a nuclear power station with the release of radioactive materials into the environment. The disaster occurred on March 11, 2011, and created one of the most severe humanitarian disasters in modern day Japan. According to the most recent estimates, 15,870 people perished during the disaster, with an additional 2,814 missing, and more than 329,777 being internally displaced. Some statistical models estimated that 727 of those who perished were children.

Three aspects were focused in this paper. The first is the data of psychological reactions in the small children and their mothers following the Hanshin-Awaji Disaster, and the second is the data obtained of children with intellectual or physical disabilities. Thirdly, I would like to introduce our activities in Indonesia and Tohoku based on our experiences gained after the Hanshin-Awaji Earthquake.

[1]Saitama prefectual Fukaya dai-ichi High School, [2]NPO corporation nature reproduction center toward ”the rich sea mingled with fresh water area clean, [3]Urawahigashi high school,Saitama, [4]Kaijo Junior and Senior High school, [5]Kanagawa Prefectual Sagamihara Seiryo High School, [6]Faculty of Education and Human Sciences, Yokohama National University, [7]Faculty of Education and Human Studies, Akita University, [8]Seibu Gakuen Bunri High School, [9]Kanto Gakuen University, [10]J.F.Oberlin University, [11]Saitama Municipal Sashiougi Jumior High school, [12]Seiko Gakuin High School, [13]Hot Springs Research Institute of Kanagawa Prefecture, [14]Tokyo Metropolitan Ryogoku Senior Hight School, [15]Tokyo Medical and Dentel University, [16]Saitama Prefecural Kumagaya Girls’ Upper Secondary School, [17]Miyamaedaira elementary school

From 2012, the new national curricula standards has been in effect according to Ministry of Education, Culture, Sports, Science and Technology guidelines.

Among most high school students three or more subjects are chosen from the following four subjects; Basic Physics, Basic Chemistry, Basic Biology and Basic Geoscience.

As a result, The number of students who choose Basic Geoscience in 2014 has increased by about 3.5 times compared with that of the number under the former national curriculum guidelines, and some improvement came to be seen in people’s geoscience literacy.

During this time, the Educational Affairs Committee of JpGU, in preparation for the next national curriculum revision, consider the way of desirable high school geoscience education through preliminary discussion in the study meeting (December 2012) and symposium (May 2013).

In order to raise geoscience literacy, it is necessary for the number of students studying geoscience to increase even more.

It is necessary to discern what is asked of high school geoscience education by society, and include the appropriate contents.

In order to allow students to learn the content effectively, we need to discuss what kind of subject setup is desirable.

In this session, based on the discussions so far, we present three drafts about the subject setting of a high school geoscience with different points of view. In addition, we plan to deepen discussion about the future direction of geoscience education taking into consideration the presentation about expectations for geoscience education from people who do not specialize in science.

Keywords: next national curriculum revision, high school geoscience education, subject setting

Suggestion of the modified selective subject based on the current Basic Earth Science

OBI, Yasushi[1*] ; KAWAGATA, Shungo[2] ; KOBAYASHI, Norihiko[3] ; TAKIGAMI, Yutaka[4] ; NOUMI, Fuminaga[5] ; MINAMISHIMA, Masashige[6] ; MIYAJIMA, Satoshi[7] ; YAJIMA, Michiko[8] ; WATANABE, Masato[9]

[1]Kanagawa Prefectual Sagamihara Seiryo High School, [2]Yokohama National University, [3]Seibu Gakuen Bunri High School, [4]Kanto Gakuen University, [5]Saitama Municipal Sashiougi Jumior High school, [6]Tokyo Metropolitan Ryogoku Hight School, [7]Saitama Prefectural Fukaya dai-ichi High School, [8]Tokyo Medical and Dentel University, [9]Kawasaki Municipal Miyamaedaira elementary school

Current basics subjects (2 credits) are subjects set based on mind of science for all, and the contents are veneer knowledge. However, it is thought that these basic subjects contribute to the improvement of good scientific literacy upbringing of the balance of the high school student's knowledge because a study rate of all subjects of four subjects of science rose because three subjects of science choice are required. In addition, it is realistic subject setting when based on the situation to teach the subject that does not match a specialty of a high school science teacher.

However, as contents of basics subjects are broad and veneer and have not the learning a principle and structure, the memorized tendency of the item is deeply concerned. Based on this reflection, we want to propose a new Basic Earth Science including contents learning a principle and structure by the selection of contents of the current basics subject carefully.

O02-03 Room:503 Time:April 29 15:05-15:30

Suggestion of the new high school general science with the contents necessary as earthian

YAMASHITA, Satoshi[1*] ; ABE, Kunihiro[2] ; IIDA, Kazuaki[3] ; UEMURA, Takeshi[4] ; KAWAMURA, Norihito[5] ; HATAKEYAMA, Masatsune[6]

[1]Saitama Prefectural Kumagaya Girls' Upper Secandary School, [2]NPO corporation nature reproduction center, [3]Urawahigashi high school,saitama, [4]Kaijo Junior and Senior High school, [5]Faculty of Education and Human Studies,Akita University, [6]Seiko Gakuin High Scool

Existing national curricula standards(N.C.S) in high school require 3 basic sciences of the 4 basic sciences, an improvement on the former N.C.S. But it is not enough for students to only study 3 basic subjects for coming to a deeper understanding of their place in earth's ecological system.

Therefore we would like to propose two new types of 'General Science' which need 4 credits or 6 credits in school classes.

One type integrates four science subjects into one compulsory subject with the aim of developing better understanding of the global environment and sustainable society,and is based on learning of the problem solution type with high regard for key competency. The other type is to divide 4 basic sciences into 2 subjects in order to understand science literacy, and consists of 'physics and chemistry' and 'biology and earth science' at this time, we want to suggest the former, which integrates four basic science subjects.

Keywords: general science, compulsory subject, problem solution type, understanding global environment scientifically

Proposal of novel compulsory subject which is mixed Geoscience, Geography, environment, and natural disaster prevention

NEMOTO, Hiroo[1*] ; MIYAJIMA, Satoshi[2] ; HATAKEYAMA, Masatsune[3]

[1]Division of Natural Sci., J. F. Oberlin Univ., ERI(Guest), [2]Saitama Prefectural Fukayadai-ichi Upper Secondary Sch., [3]Seikou Gakuin Secondary Sch.

The subcommittee of school curriculumme at the committee of school education at Japan Geoscience Union (JpGU) has investigated into the contents of Earth and Planetary Sciences and its related Sciences of next and future subjects of upper secondary schools based on the next and future national standard curricula in Japan. We would like to make 3 types of subjects and their contents. In this presentation, we will report novel compulsory subject of them.

This novel compulsory subject will be invented based on new concepts which break down long-established the framework of current subjects. The contents of this subject consist of geoscience, geography, environment, natural disaster prevention, and so forth. The educational purpose of this subject is to acquire the scientific literacy and the attainment ability of type of PISA, Programme for International Student Assessment, through the ability of natural and social sciences. As a result, students will be able to get ability to take action and thinking faculty for environmental problem and natural disaster prevention by themselves scientifically.

My Expectations to High School Subject ”Earth Science” under the New National Curriculum Standard in Japan

ABIKO, Tadahiko[1*]

[1]Kanagawa University

The new national courses of study in science education of high schools implemented formally in 2013 have asked high school students to choose 3 science subjects from 4 subjects such as physics, chemistry, biology and earth science. This revision has led to following changes; First, the number of students to choose earth science has drastically increased and most of them tend not to study earth science deeply, but to regard it as sort of general education. Second, and what counts most is, their interests in the most important problems of the global environmental issues are increasing. If these tendencies are continued to be seen, new earth science as a high school subject shall have a very serious and critical mission to enhance student’s general science literacy and their motivations for engagement or action in solving those real life problems, while they must be active to make effective conditions of the sustainable development in our human life as well as in all kinds of life on the earth.

Hunting mega-quakes -What we can and cannot find out from tsunami deposit-

SHISHIKURA, Masanobu[1*]

[1]Active Fault and Earthquake Research Center, AIST

The giant tsunami of 2011 Tohoku was inundated into further inland and transported sand and mud from the coast. Such sand and mud are called tsunami deposit. Researchers have surveyed past tsunami deposits before the 2011 tsunami, and have revealed that the 869 Jogan tsunami had very large inundation in the Tohoku area. Because the inundation area was eventually almost similar between the 2011 and 869, studying past earthquakes and tsunamis (paleoseismology) came to be recognized in its importance for forecasting magnitude of tsunami. However finding out past phenomena beyond several thousand years is not easy. In this talk, I would like to introduce how to reconstruct the past earthquake and tsunami from historical records, tsunami deposits and coastal topography, including episode of field survey and relationship with society.

Keywords: great earthquake, tsunami, tsunami deposit, paleoseismology

Recent eruptions in Japan (review): past and future

NAKADA, Setsuya[1*]

[1]ERI, Univ. of Tokyo

In late November of 2013, eruption started in Nishinoshima approximately 1,000km south of Tokyo, and the activity continued. Including this eruption characterized by gentle lava outflow, various types of eruptions occurred in Japan during recent decades. For instance, Shinmoe-dake (Kirishima) woke up with explosive pumice eruption in 2011 after a quiescent period of 300 years. Sakurajima repeats explosions every day. Miyakejima erupted with subsidence of the volcano peak area in 2000. Eruption at Unzen issued pyroclastic flows for several years in early 1990s. Except some people damaged directly by it, volcanic eruption itself fascinates people, and the resultant landforms, hot springs, and fertile plateaus bring blessings to people. Therefore, eruption activity is different from other natural hazards. In the volcanic belts surrounding the Pacific, such as Indonesia, Chile and so on, eruption activity in the Japanese Islands was very low in magnitude during these centuries. After the large earthquake on March 11, 2011 which caused a extensive crustal movement in the whole East Japan, seismic activity increased in several volcanoes in the East Japan including Mount Fuji. Volcanologists were worried about eruptions triggered. However, no volcanic eruptions were triggered during, at least, three years. Does an earthquake trigger volcanic eruption really?

In this lecture, I review recent major volcanic eruptions in and outside the Japanese Islands with their research results. In addition, I will mention on the possibility of large-scale eruptions near future, especially at Mount Fuji stopping eruption for these 300 years and at volcanoes that experienced caldera-forming eruptions in the past.

Keywords: volcanic eruption, Nishinoshima, natural hazards, triggering eruption, Mount Fuji, Caldera eruption

Career path of young scientists

NAKAMURA, Masato[1*]

[1]Institute of Space and Astronautical Science of Japan Aerospace Exploration Agency

For sustainable development of geosciences, it is necessary to consider supporting and training system of geoscientists, especially for young geoscientists who hardly get permanent academic positions under recent condition surrounding Japanese young scientists. They are worrying about their carrier paths, with considering their work-life balances in parallel. Due to anxious of invisible future, some of them quit trying to become scientists when they face to life events such as childbirth and care of their children or parents, If this situation will continue still more, our academic field, geosciences, will reduce gradually. Therefore, I will introduce to them mental attitude required for geoscientists and successful role models, i.e., active senior geoscientists by doing continuous efforts.

Effort for Diversity Promotion, University of Tsukuba

HABAZAKI, Makiko[1*]

[1]Office of Diversity, University of Tsukuba

The University of Tsukuba promotes the gender equality based on the 3rd Basic Act for Gender-Equal Society and the 4th Science and Technology Basic Plan in Japan, recognizing our social role and responsibility to form a gender equal society. In 2007, the Committee on Gender Equality and the Office of Gender Equality were established, and 'Basic Principles and Policies on Gender Equality' has been enacted in 2008. For the three years from 2009 to 2012, a project of 'University of Tsukuba Style: Sustainable Support for Women Researchers' program was adopted as a strategic fund of a model of support for women researchers for Promoting Science and Technology. Therefore we endeavor to develop its environment of the gender equality. In April 2012, 'the Office of Gender Equality' was reorganized to 'the Office of Diversity', and 'Basic Principals and Policies on Diversity' was designed to become a university where human potential and diversity are respected and all stakeholders can experience pride and joy in their work. In March 2013, 'Action Plan of Diversity, University of Tsukuba' was designed, and in August, new project was adopted as 'Fund for supporting activities for female researchers'. In response, we are going on amplification of environment for gender equality and diversity.

We are promoting various projects based on following five purposes in 'Action Plan of Diversity (from 2013 to 2018)'.

1. Promotion for diversification in university management
2. Offering of assistance in the balancing of education, research, and work with family life
3. Expansion of diversity in next generation
4. Pursuit of awareness-raising activities targeting faculties, staffs, and students
5. Pursuit of gender equality through partnerships with the local community and international society

Workers during a Childbirth, Child Care, and Family Care can employ for tenured faculty members and secure of substitute teachers. The University also opened Au Work-Life Balance Counselling Room for such workers. For educational activity, we have held some seminar of awareness of diversity for managerial staff, and class of 'Work-Life I and II' for university student. Then, we have been focused 'Expansion of lower' that educate young generation (especially women) wanted to be scientist. As a result of these efforts, the ratio of women researcher has increased year by year at University of Tsukuba.

Balance with caring for parents, caring for children, and studying-My experience in caring for my parents-

OHYA, Hiroyo[1*]

[1]Graduate School of Engineering, Chiba University

Suddenly one day, if your parents are given half a year to live and you become care for your parents-. The caring for parents suddenly comes to you and may continue for a long time. When I was caring for my little children, my father was given half a year to live due to cancer. I will talk about my experience for caring for my father, caring for children, and studying in this session. Shall we think about caring for parents from each point of view regardless that you experienced or not?

Now my children are university and high school students. I will also talk about the difference of life-work balance between the childhood and adolescence.

An Encouragement of doing *Ikumen* and taking *paternity leave*

YOSHIDA, Hiroki[1*]

[1]Fathering Japan, Nonprofit Organization

The author has a confident to contribute to all male scientists, who have an idea of taking a *paternity leave*. We can learn many things and grow up ourselves by taking care of children. However, the time as to be a current parent especially for a small child is too short. Thus, male scientists should do *Ikumen* right now and take *paternity leave* if necessary.

The term parental leave includes maternity, *paternity*, and adoption leave. The minimum benefits are stipulated by Japanese law. Although such valuable supports are provided by the government, there are few people experienced *paternity leave*. One of the reasons is too worry about eyes of surrounding people such as colleagues and neighbors. Even they take *paternity leave*, they may have a hard time to take care of children. Parenting is different from repeating same things as just for feeding, substituting diapers, etc. It is an important work to bring up and to educate children, precious talented people in the near future. Praising, encouraging and smiling are the most important for education not only for children but also for all people. *Ikumen* experience will be sure to help your private life as well as academic and scientific works.

Now and Future Thailand’s Family

TANGWATTANANUKUL, Ladda[1*]

[1]Graduate School of Engineering and Resource Science, Akita University

In Thailand, families reside with their family size either in cities or countryside. The family size in countryside is larger than one in cities. The marriage practice allows women to move into husband’s family.

Family member are delegated household each other. Women do household: cooking, cleaning and washing. Instead, men do heavy work in their house. When children reach about 8 years old, they need to assist their mother and father like cooking and taking care of younger siblings. Most men of Thailand can cook and taken care of kids. Recently, the family likes to pay money to housekeeper to clean house and wash clothes. Some family’s grandmother and grandfather are in house. They take care of kids when the parent goes to work out. Women worked in company or government ask maidservant to stay with her family. Maidservant will take care of baby and cooking for the host family. They get foods and salary about 20000 yen per month. Most of the maidservants are teenager and the maidservants are from Myanmar or Laos. However, recently women who graduate from colleges or universities become choosing to work for long period before marriage.

Geopark

OIKE, Kazuo[1*]

[1]Chairman, Japan Geopark Committee, Kyoto University of Art and Design

Looking at the landscape constructed by the activity of the earth, tasting vegetables and fruits produced by the blessing of nature, we learn the natural phenomena, regional history and culture of the geoparks.

The basic characteristics of nature of Japan islands are earthquake occurrence, volcanic eruption and tsunami. Japan’s geoparks are located along the deformation belt and are also the parks of the earth where the culture of the Japanese people who have lived in natural disasters is intoruduced.

On December 2013, thirty three geoparks has been certified by the Japan Geopark Committee. Six of them have been certified to join the Global Geopark Network. We will continue to learn from the beauty of nature of Japanese archipelago, and introduce it to people of the world.

Nature parks as a tool for local sustainable community

MATSUDA, Hiroyuki[1*]

[1]Yokohama National University

Abstract

Biosphere reserve (BR) of UNESCO's Man and the Biosphere (MAB) Programme seeks balance between sustainable use of natural capitals and biodiversity conservation, rather than protection of primeval nature. In the early stage of the MAB programme, BR encouraged academic research in the site and usually consisted of core area and buffer zone. Forest Ecosystem Reserve of Japan follows the concept of BR zoning.

Since 1995, BR consists of core, buffer and transition areas. Transition area supports sustainable use of natural capitals (Figure 1). Therefore, BR becomes a good arena of development of local economy. Also global trend of environmental movement shifts from protection of primeval nature to conservation of natural resources.

BR recommends involvement of all actors in management and decision-making processes. New forms of institutional cooperation and links between different levels of economic and political decision making. Aya BR, designated in 2013 as the 5th Japanese BR, is recognized as one of the best models of participatory approach for BRs in the world. Bokova (Director-General of UNESCO) said, "From the Luberon-Lure BR in France and the Aya BR in Japan to the Dana BR in Jordan, local communities are developing bio-products that meet both local and global needs, and in ways that contribute to a healthy environment and reduce waste."

Geopark from the viewpoint of residencial research

KIKUCHI, Naoki[1*]

[1]Research Institute for Humanity and Nature

Residential research is a new method being proposed for use in problem-solving research that corresponds to the actual local circumstances and from the stance of the scientist/researcher not only being a resident but also a member of the local society concerned. I participated in a project involving storks, an endangered species, being returned to the wild, which took place in the area around Toyooka City in Hyogo Prefecture, and in researching the environmental sociology of Hyogo Park of Oriental White Stork, and thus also gaining experience as a residential researcher. The Sanin Kaigan Global Geopark is also in the area, and hence the storks being returned to the wild and the activities of the geopark are correlated, with also having been involved in the geopark's activities to a certain extent. Based on this personal experience I discuss the potential of geoparks being a tool to use in solving local problems , from the point of view of residential research.

Keywords: residential research, integrated local environmental knowlede, re-introduce project of the oriental white stork, adaptive governance

Think about the Geopark - After landslides disaster from the eyes of the guide

NISHITANI, Kana[1*]

[1]Izu Oshima Geopark

Three and a half years have passed since I met the Geopark. I have continued to guide because I have been fascinated by the story of plants, animals and human beings and the earth involved each other. So everyone‘s sensitivity and eyes for wonder, knowledge and experience was always different that I felt every tour would be the only one story in the world.

October 16 of this year, 36 people died, three people were still missing in Izu-Oshima. Because of the landslide disaster caused by heavy rain of typhoon No. 26. We thought ” Water drainage is good in this islands because it is young volcano here.” We were scary the eruption and tsunami, but not worry about floods. We couldn’t imagine the landslide disaster.

”Why we could not notice the danger? Why we could not tell it to the person who become a victim? ”. I felt unbearable thought. If I could worn it, a life would not to be lose. Then, I realized that there is lots of sadness in the back of words ”We are living on the land that volcanoes made ”.

Now, We are starting the reconstruction in Izu-Oshima. There are various problems, which are always changing. I feel that facing the reconstruction and disaster is just a Geopark itself.

We had the seminar by volcanic expert, and inviting lecturers from Miyakejima, Unzen Geopark, and Sanriku Geopark, for residents.

Are there any changes to the residents by sharing the information with different Geoparks?

We consider the role of a network of Geoparks through various activities after the disaster.

Keywords: geopark, guide, Izu Oshima, net work, disaster, rule

Summary of the evaluation process of Japan Geopark Committee

WATANABE, Mahito[1*]

[1]Geological Museum, Geological Survey of Japan, AIST

Japan Geopark Committee (JGC) has started its evaluation of prospective geoparks in 2008. Geopark specialists from the geoparks of Japanese Geoparks Network (JGN) joined as on-site evaluators in 2012.

Dossiers are evaluated by the JGC member and they decide which candidate should be further evaluated on-site. JGC decides a on-site evaluator and a assistant evaluator for each candidate area from those who are well experienced person in one of Geopark. One JGC member and two evaluator conduct a on-site evaluation for 2-3 days. Detailed evaluation report based on the dossier and the on-site survey is written by them and submitted to the JGC. JGC that is composed of eleven member make a final decision on each application.

Check list for the evaluation are revised every year by JGC and on-site evaluation from the geoparks.

volcano gifts from the south Izu Peninsula Geopark

YOSHIKAWA, Kaoru[1*] ; HORINO, Yoshiaki[1] ; ISHII, Chiharu[1] ; TUKUDA, Hiromi[1] ; KOYAMA, Masato[2]

[1]Izu Peninsula Geopark Promotion Council, [2]Shizuoka University

The Izu Peninsula was situated to the south of the Japanese archipelago long time back. Due to the movement of the Philippine sea plate, it moved gradually to the North and collided with Honshu. In the Izu Peninsula, which was formed out of this mutual collision a great range of natural diversity can be seen, which makes it unique as a peninsula on the global scale. It is possible to observe the geological mechanisms that formed the peninsula in different locations. The peninsula is ideal to observe the geological processes ranging from submarine volcanism, land volcanism due to the collision of landmasses and ongoing volcanic activities. As a geopark, Izu Peninsula is attempting to collaborate with other geoparks and raise awareness on natural disasters as results of tectonic level processes, while preserving local nature, culture and history.

In March 2011, 13 cities and towns came together to form the core of the geopark. In September 2012 the geopark was accredited by the Japanese Geoparks Network. In December 2013 two more towns joined the geopark area. The geopark employed a new researcher on human geography in 2013 and published its newsletter.

Apart from these the geopark is working to assess the volcanic gas conditions in Teishi Kaikyu area with the Natural Disaster prevention unit of the Shizuoka University, giving guide programs, popularizing earth science for children, and participating in childrens summer school camps. In the Asia Pacific Geoparks Networks Conference (APGN 2013) the geopark put up its poster and introduced its activities.

Mt. Naeba foot geopark concept -The person from 30,000 years before to the present, and relation of the ground -

SATOU, Nobuyuki[1*] ; NAKAZAWA, Hidemasa[1]

[1]Tsunan town Board of Education

Here we present the outlines of the Mt. Naeba foothills geopark concept.The geopark is located in the northwest of Mt. Naeba, which area includes both Tsunan town of Niigata prefecture and Sakae village of Nagano prefecture. It is characterized by the facts that while the area has 3 to 4 meter of annual snowfall the population of over 10,000 is maintained, and that 30,000 years of history and cultures of people interacting with the earth can be learned.Numerous environmental changes have occurred on the earth, in the air, in the oceans and on the lands. Studies on the rocks, clays, volcanic ashes, plant and pollen remains in the peat layers, information from archaeological remains and various meteoric factors, enable us to know the influences of the environmental changes to the lives of the people.The Mt. Naeba foothills emerged about 3 million years ago and the base of the land was formed by the lava flow of the Mt. Naeba. Through the development of river terraces, snowfalls and waters from springs, a rich natural environment was formed. The present environment as the snowy country began about 8,000 years ago. Tendency towards the sedentary way of life increased in the prehistoric times with the development in the exploitations of resources. The land formation and the peoples lives are closely related.For example, during the Jomon period, 5000 years ago, people formed very unique flame-style pottery using indigenous clays, made stone tools using volcanic flows or sedimentary rocks and lived in the settlements constructed on the river terraces. There are plenty of archaeological data showing the relations of the land and the people.We began to think about our land seriously placing the Mt. Naeba foothills geopark as a keyword. This idea is to reflect our land which is a precious treasure with geo-eco-culture, to love, to learn, to protect and to pass on the region to the next generations. A group of local people called Geo-egg emerged recently, and many inhabitants began to have consciousness to learn more about the land they were born and bred visiting the local heritages.For us, the Mt. Naeba foothills geopark is one of the hopes for overcoming the disaster of the Northern Nagano earthquake.

Amakusa Geopark plan

KUNITAKE, Yuko[1*] ; KANAZAWA, Hiroyoshi[1] ; UGAI, Hiroaki[1] ; HASE, Yoshitaka[1]

[1]Amakusa Geopark planning promotion committee

The Amakusa Islands, consisting of about 120 islands are located in the southwest area of Kumamoto Prefecture: a beautiful archipelago with geologic and geographic characteristic landscapes and a 100 million year history, not to mention a treasure of ancient fossils offering its visitors a fantastic glimpse into times gone by. A unique culture has been carved out of life on these islands by its inhabitants adding to the many breath-taking sightseeing opportunities. The plan of the Amakusa Geopark is to show off the diversity of geology, geography, history, culture, industry and ecology in Amakusa with a mind of ecologic conservation and economic growth.

Residents and officials alike collaborate to preserve the geologic inheritance of Amakusa with an educational perspective. Exposing the unique beauty of this inheritance as a tourist attraction in conjunction with the history and culture of the area, an attractive geo-tourism will be founded aimed at the promotion of the Amakusa area.

Shimokita Peninsula Geopark Design;The glory of 4 oceans,one land 4 geological elements

ARAYA, Tomofumi[1*] ; MIYASHITA, Junichiro[1] ; UEDA, Hayato[1] ; ITO, Michio[1] ; MITSUNO, Yoshiatsu[1]

[1]shimokita peninsula geopark design promotion meeting

About Shimokita Peninsula

Shimokita Peninsula is located on the northeastern side of Aomori Prefecture, and the northernmost point of Honshu Island. It stretches across 1 city, 1 town and 3 villages surrounded by 4 bodies of water; the Pacific Ocean in the east, the Sea of Japan in the west, Mutsu Bay in the south, and the Tsugaru Straight in the north.

Shimokita Peninsula Geopark contains the 4 major geological elements that make up the island of Japan, including Osorezan ' s gold ore deposit and caldera, Hotokegaura ' s green-tuff series, the vast coastal exposure of quaternary strata in the Tanabu area, and Cape Shiriya ' s accretionary body. Shimokita also has a rich history and culture influenced by the Kitamaebune shipping trade, the Abeshiro kuroko mine, the northernmost distribution of monkeys in the world, the Tsugaru Straight ' s Blakiston ' s line, etc. Shimokita is blessed with amazing resources in a wide variety of fields.

Reason for applying to the JGN

The Shimokita Peninsula lacks universities and public museums so many people don ' t have a chance to study at a higher level, and realize how lucky we are to have many valuable natural treasures and learning resources.

Turning this area into a geopark will give people a chance at higher education and help create pride and love for Shimokita.

Through this geopark we hope to educate and explore Shimokita together with the next generation so that we can all learn of its value and importance.

Shimokita Peninsula Geaopark Desgin: Theme and Story

Japan is made up almost entirely of four basic geological elements; the non-volcanic Pacific coastal range consisting of the accretionary body, the axial volcanic chain, the sedimentary basin between the coastal and axial ranges, and the green-tuff mountains and hills which record the genesis of the Sea of Japan.

This geopark is the only one that touches both the Pacific Ocean and the Sea of Japan making it the only place where we can see all four basic elements in one place.

Also the peninsula is surrounded by four bodies of water and each body of water supports its own unique type of fishing. Fishing is the main industry that supports Shimokita.

Thus the theme of this project is [Shimokita Peninsula Geopark: The glory of 4 oceans, one land 4 elements.] The sub-themes are [East Coast Zone: Gift from the Pacific Ocean,] [Tanabu Plains Zone: Competition between land and sea,] [Osorezan and Mutsu Hiuchidake Volcanic Zone: Volcano and hot spring blessings,] [West Coast Zone: Split land.]

Contribution to JGN

As a place without universities or museums we hope to exchange ideas with other members of the JGN so that we may develop higher education and lifelong learning opportunities here in Shimokita. We hope to contribute to the JGN by demonstrating a system of higher education without the support of a university.

In Japan we believe that spirits live in mountains, trees and rocks. Osorezan and Hotokegaura are famous places for praying to the spirits. People come from all over Japan to talk to Itako, blind mediums who speak with the deceased at Osorezan.

With Osorezan at the center of the Shimokita Peninsula Geopark another contribution to the JGN is a geopark not only with amazing geology, but with the intangible resource of faith.

In Conclusion

The Shimokita Peninsula Geopark may not have anything that no other geoparks have or anything more amazing, but it is unique in that it is the only geopark in Japan which touches both the Pacific Ocean and the Sea of Japan.

The people of Shimokita want to protect, preserve and share the amazing natural resources of Shimokita with others. We hope that by taking pride in our home, our love for Shimokita will be carried on for generations and visitors will see it as a special place too.

Applying to join the JGN will allow the people of Shimokita to realize the value of our natural resources. It will also give us a new reason to love the peninsula and create a new type of tourism.

Keywords: Japanese national geopark, 4 oceans, 4 geological elements, Love for Shimokita(Love for one's home), Faith;Mt.Osorezan

The Promotion of Nanki Kumano Geopark Plan

HIGASHIKAWA, Tomoaki[1*] ; HASHIZUME, Masaki[1] ; TAWARA, Takaharu[1] ; TANIWAKI, Tomokazu[1]

[1]Nanki Kumano Geopark Promotion Council

The area of Nanki Kumano Geopark Plan is located in the southern part of the KiiPeninsula, the southernmost point of Honshu. It consists of a city, 7 towns and a village: Shingu City, Shirahama Town, Kamitonda Town, Susami Town, Nachikatsuura Town, Taiji Town, Kozagawa Town, Kushimoto Town and Kitayama Village.

The total area of Nanki Kumano Geopark Plan is approximately 1,356 km^2; the area stretches 60 km from east to west and 60 km from north to south. It includes various landforms ranging from steep mountains over 1,000 m to deeply-indented coastlines formed by the submerged coast.

The area of Nanki Kumano is blessed with mild and moist climate, but does not have many plain fields because it consists largely of steep mountains. Besides, roads were not built in earlier times. Therefore, the livelihoods of people have relied on forestry, fishery, and shipping industry since a long time ago. In addition, the geography, nature and culture of this area inspired a feeling of awe in city people away from the area. Historically, many people have visited this area and it has prospered as sacred sites of Kumano worship. In modern times, it has become a key area of forestry, fishery, and shipping and has also thrived on diggings of mineral resources, papermaking industry, hot springs and tourism.

However, in recent years, regional disparity between urban and rural areas has widened. We can see depopulation, aging and industry decline in rural areas, although pavements, railroads, ports and an airport have been developed and traffic has become more convenient than before.

In this situation, the progress of earth science gradually revealed the formation process of geological and geographical features peculiar to this area. Moreover, it has turned out that those features are quite unique. This area consists of three kinds of geological conditions formed by a series of plate movements. The central part is made up of accretionary prism formed by subduction of oceanic plate near the ocean trench. The eastern and western parts are respectively composed of forearc-basin sediments formed on accretionary prism. Additionally, igneous rocks are distributed in the eastern part. These three landforms exist in this area due to the encounter of plates. Thus, we can learn typical three geological formations showing the formation process of the land in addition to dynamic planet activity, namely, subduction of plate.

Culture, history, industry and people's life have been developed in this area by using geological and geographical features. People feel a sense of pride in each of them and gradually recognize that they are valuable assets that should be left to future generations.

The area of Nanki Kumano is the core of Sacred Sites and Pilgrimage Routes in the Kii Mountain Range registered as a World Heritage Site in 2004. Sacred Sites, Pilgrimage Routes, Cultural Landscapes are already regarded highly as worthwhile. However, we think not only they but also charm and value of this area can be enhanced by exploring dynamism of a land formation, the formation process of nature and contacts between people and nature in this area. We are working on the geopark project with the idea that charm and value of this area will give local people confidence and pride and will create new jobs and opportunities for human interaction. We believe it important for sustainable local development to advance this project in the area of Nanki Kumano. Therefore, we apply for membership in Japanese Geoparks Network.

We would like to contribute to Japan Geoparks Network by demonstrating a new model of geopark activities; we can enhance each value of the sites by connecting the geological heritage with the existing property: the UNESCO World Heritage Site, Kushimoto Coral Communities (a registered wetland under the Ramsar Convention) and Yoshino-Kumano National Park.

Geographic History of the Purple Mountain and Suigo and the Life Carried on to the Future

SHIBAHARA, Toshitsugu[1*]

[1]Mt.tsukuba Area Geopark promotion Council

Mount Tsukuba is located in the northeast of Kanto Plain. From the distance, the mountain looks like a single peaked mountain which is a rare view in Kanto area. The mountain is called ”Shiho”, meaning a purple mountain, since the color of the mountain surface looks purple in the evening reflected by the setting sunlight.

The crest has steep double peaks constructed of solid gabbros which were intruded and risen approximately 75 million years ago.

The mountainside (declive) and the base of the mountain (piedmont) are covered with debris of gabbro and weathered debris of granite.

The gentle curves of the mountain skirts make its mountain shape beautiful. Additionally, as the northeast tip of Kanto Plain, the surrounding regions centering the Kasumigaura Lake make the scenic beauties of ”Suigo” with broad platforms and lowlands formed by the 4th period of the sea level change.

Therefore, blessed with the ”geological inheritance”, the Mount Tsukuba is renowned as we have an expression, ”Mt.Fuji in the west, Mt.Tsukuba in the east.” So, the mountain has been regarded as the landmark of Kanto. Also, even competing with Mt.Fuji, which has just been approved as one of the World Heritages, the mountain worship and many Japanese traditional culture and art have originated in this area.

The activities typified by the water transport in Kasumigaura Lake, stone manufacturing and pottery, have had developed its own style independently even though the region was located near Edo(Tokyo). It is particularly worth noting that they supported the modernization of Japan. Inada granite was used for architectures such as the Diet Building, Bank of Japan and Nihon-bashi Bridge in the Meiji Era.

In the modern age, Tsukuba Science City is established on the platform at the base of Mount Tsukuba. The area is vitalized from both inside and outside Japan and has started to create the future.

Evaluating the features of this area-the nature, the history and people’s activities-from the geological and geographical points of view, each element may not seem to relate to each other. However, once you change your perspectives, you can find fascinating, charming and attractive aspects in them.

So, in Tsukuba Area Geopark, we view every geographical and geological feature of this area as a series of the eternal history and rediscover the value of the geological features of this area, share it with people inside and outside of the region and carry on to the future.

Concept for the Tateyama Kurobe geopark:Feel the tales of dynamic time-space, 3800Ma history and 4000m topography !

MASUBUCHI, Yoshiko[1*] ; OONO, Hiromi[1] ; TANBO, Toshiya[1] ; FUJITA, Masato[1] ; ISHIZU, Hidetomo[1] ; TAKEUCHI, Akira[1] ; NAKAO, Tetsuo[1] ; HORIUCHI, Yasuo[2]

[1]Tateyama Kurobe geopark Promotion Conference, [2]Tateyama Kurobe geopark Support Municipalities Conference

”4000 meters times 3.8 billion years”; this is how we could express the geological history and geography of the eastern part of Toyama Prefecture. Nature guides activities in each of 9 municipalities have made it a duty to transmit the scale of those numbers, protect the land and make good use of it. And this, in turn, has been the founding principle behind the Tateyama Kurobe geopark.

The region of the Tateyama Kurobe geopark is now located in the geologically very active region. The volcanic and tectonic activities that have been ongoing since the Mesozoic Era create the Toyama bay that is over 1000 meters deep, and the Tateyama Mountain Range that is over 3000 meters tall. Since they place in a very compact location, the eastern part of Toyama Prefecture has a dynamic and unique landscape and geology. Besides, the region has the youngest granite on Earth which is said to be around 800 thousand years old and it shows rapid tectonic activity. While the oldest mineral on Japan, Eoarchean?Paleoproterozoic zircon (over 3.8 billion years old), was also identified. This turns the region into a life-size ”encyclopedia of geology”. It encompasses various minerals and sings of the multiple events occurred during the long history of Earth, including rests of the collision that created the Asian continent during the Paleozoic. In the present time, large quantities of precipitation which comes from the Sea of Japan to the Tateyama Mountain Range return to the Sea of Japan through the mountain glaciers located in the southernmost in the Far East, rivers and numerous springs in the alluvial fans. This water circulation maintains unique natural environment in this region.

Since the earliest times, the people had come to understand the importance to protect the resources of the land and sea and the voluntary nature guides system was established in 1970s by Toyama prefecture. This is pioneer in nature guides system in our country. The nature guides activities become widespread throughout the northern Japanese Alps and the coastal plain by Toyama Bay. We cannot still say that many citizens and travelers in the region understand the whole story above. However, recently we have found that more people are aware of the importance of the land and began to grow a strong wish to know more about what makes their land special.

All of this above makes us think that ”that is on what our region and landscape is based”. We want to use the geopark activities as catalyzer to bring together all those actors in order to bring out the interest of the people about the region. However, we believe that we need an organization at the center of it all that is ”built by the people, for the people”. Therefore, instead of limiting ourselves to the various organizational forms in existence, we decided to pioneer an organization that would make this possible, having the local actors themselves create it, receiving support from both private and public sectors. This is because we believe that, in our region, the people and the governments should work as partners together for the management of the geopark.

JGN National Training meeting Summary - The current state and issue of Geoguide development -

SAKANOUE, Hiroyuki[1*] ; ISHIKAWA, Toru[1]

[1]The Council for the Promotion of the Kirishima Geopark

In the various geoparks around the country special features, required knowledge, and original curriculum has been established and geoguide training is progressing. However, in Kirishima, there are more than a few areas that have concerns over the content, length and so forth of the curriculum. Also, due to the differences in shape and environment of the features such as mountains, beaches, and islands the crisis management skills required of guides is substantial and various forms of support will be needed.

At the November 2013 JGN National Training Meeting held in Kirishima Geopark, geoguide development was the chosen theme. Local guides gave presentations and shared information on current conditions and issues and then participated in a lively group debate on the topic of risk management. With the information gleaned from this training meeting compiled with general information a report detailing the objectives of Kirishima Geopark guide development will follow.

Authorization System of San'in Kaigan Geopark Guide

FUKUHARA, Youichiro[1*] ; SAN'IN KAIGAN GEOPARKE, Promotion council[1]

[1]San'in Kaigan Geopark Promotion Council

San'in Kaigan Geopark Promotion Council established an authorization system which authorizes local guides who fulfill a certain criteria as "San'in Kaigan Geopark Guide", to improve the guide information for visitors and develop the skills of local guides.

San'in Kaigan Geopark includes three cities and three towns in three prefectures, and tour guides has been existed since before this area became one of geoparks. Various tour guide services were provided, showing visitors around the town and coastal area, for free or with charge. To add the geological elements to these guide services and fascinate visitors even more, the council and local guides in the San'in Kaigan Geopark spent a lot of time discussing about the training and requirements to set a uniform criteria in 2012-2013, aiming to promote geotourism.

There are two levels in the authorization system of San'in Kaigan Geopark Guide. Local guides must guide a specific geosite in the area and explain about the geopark system and overview to receive a level 1 certificate. To receive a level 2 certificate, in addition to the skill of level 1, local guides must help the council's events as representative guides of the San'in Kaigan Geopark.

The requirements of level 1 guide are 1) Taking training courses about basic knowledge of geopark, geosite, guide and risk management admitted by the council, 2) Being covered by general liability insurance, and 3) a person who belongs to tourism facilities registered in the council. This certificate is valid for three years.

In addition to active experiences as a level 1 guide, the requirement of level 2 guide is passing qualification test conducted by the council.

In the near future, by operating this authorization system, we aim to boost the skills of San'in Kaigan Geopark Guide and promote active geopark activities.

About the ideal Geopark guide in the Geopark

KONOMATSU, Masahiko[1*] ; ONISHI, Nao[1]

[1]Wakayama University

As of January, 2014, there is the Geopark of 33 areas in Japan. It is predicted that the numbers increase from local sightseeing promotion more. When a tourist observed the geo-site in the Geopark, they are impressed by mentioning a creature, the history, the culture of scenery and the topography, geological feature, and knowing the local splendor, and it become a repeater. However, the tourist cannot often understand the knowledge of the earth science including the origin of a geological feature, the topography only by watching merely scenery and the topography by oneself, and reading a guidance signboard. Therefore the guide can tell charm and an impression to a tourist to a tourist as a story concerning the geo-site because a Geopark guide exists. In addition, I can go to the attractive geo-site in usual times because a guide goes together at the place that I cannot go. Furthermore, as for the guide, a climate, a creature, culture are concluded based on a geological feature, the topography; remind you of it.

I am shown that even the guidelines on member standard to the Global Geopark Network (GGN) train a guide and perform the tour with the guide. Therefore, in the Geopark, a Geopark guide and the training become the important matter. The training lecture of the Japanese Geopark guide sets a curriculum while devising information sharing in what I do by Geopark meeting and JGN whole country workshop in Japan in each Geopark and is carried out.

Therefore, through an expert Geopark guide, there was what kind of skill and, in this study, examined a tourist what kind of response you gave. Furthermore, about the training system of the Geopark guide, I investigated nationwide tendencies and extracted the points that I weighed it, and were common. I compared it with the training system of a common ecotourism.

In addition, in Wakayama where the writer is, there is Nanki-Kumano Geopark design, and the training of the Geopark guide is carried out from 2013. What kind of person took lectures, and questionary survey did what kind of skill the body had there.

In consideration of the tendencies that were a common point and the whole country, I suggested it about a curriculum of the necessary geo-guide training based on real attendance true satisfaction to a minimum.

Keywords: Geopark, Geopark guide, The training of the Geopark guide, Nanki-Kumano Geopark design

Trainning of Geoguides by Nankikumano Geopark

YAMAMOTO, Toshio[1*] ; TANIWAKI, Tomokazu[2]

[1]Pacific Consultant, [2]Wakayama Prefecture

The Nanki Kumano geopark concept is an area of the southern part of Kii Peninsula used as the southernmost tip of the main island of Japan, and is an area which consists of1 city 7 town 1 village in Shingu-ctiy, Shirahama-cho, Kamitonda-cho, Susami-cho, Nachikatsuura-cho, Taiji-cho, Kozagawa-cho, Kitayama-village, and Kushimoto-cho.

East and west and the north and south of this area are about 60 km, and a gross area is as wide range as about 1400 km2, and it is an area which has complicated coastline by a drowned coast, and various geographical features from the steep mountain land over 1000m. About geology, it consists of three geology objects produced by the motion of a series of a plate. The central part consists of an accretionary prism made by subduction of an oceanic plate near the trench, and the eastern part and the western part consist of front arc basin deposition objects formed on the accretionary prism. Furthermore, the huge eruptive rock object is distributed over the eastern part.

On these grounds, a respectively characteristic geographical feature scene and ecosystem, and culture are cherished, and they are connected deeply mutually. With such a background in Nanki Kumano, various attractive ”encounter” between the ground, a living thing, and a person has always been produced.

From these things the Nanki Kumano geopark concept was born by the theme which meets with the nature and culture of Kumano cherished on the three grounds which the plate met and were produced.

In the Nanki Kumano geopark promotion conference, 100 or more persons’ geopark guide is scheduled to be trained between the fiscal 2013 and the fiscal 2015 . There is an application of attendance exceeding 70 persons and the geopark guide of the 1st term (about 60 persons) was born in the fiscal 2013 . It is carrying out the curriculum which thought local training, practice of geo-tour, etc. as important on the basis of acquisition of a guide technique or a safety control on the occasion of geopark guide cultivation, and trained the geopark guide with high quality which can guide for counter value.

Trial geo-tour to which a participant takes the lead and performs it in order to develop having learned by a lecture or local inspection training in geopark guide cultivation as practical skill is included in the curriculum. By this measure, in which it is difficult to attach to the body in the guide cultivation lecture of a lecture,the practice power about the importance of a safety control or time management was able to be trained, and the bottom raising effect of the whole geopark guide ,an improving point when performing the geopark guide in the evaluation meeting after enforcement can be clarified,was able to be acquired.

Moreover, it became an important opportunity to consider the composition of the tour for having a visitor enjoy oneself by planning and carrying out trial geo-tour and actually looking back upon it. In this trial geo-tour, the opportunity that it will perform making the tool of the area for greeting a visitor, and it will heap geopark activity that the guide cultivation lecture attendance student itself works on a local contractor for development of the Geo-bowl,is also growing.

About the geopark guide after cultivation, opportunities, such as a school and skull session, are prepared and continuous skill improvement is aimed at. Moreover, cultivation of an upper geopark guide is also scheduled to be tackled

Hakone Geopark -The activities by cooperation with various organizations

AOYAMA, Tomofumi[1*]

[1]Hakone Geopark Promotion Council

The Hakone Geopark Promotion Council, established in 2011, is consisting of 72 affiliates including educational institutions, volunteer groups, a wide variety of companies and NPOs in the area. They are not only working for Geopark's activities independently, but acting by cooperating with each organization.

We introduce some examples of the investigative commission by council members about development of goods and maintenance of signboards.

Concept behind the Tateyama Kurobe geopark: towards the cooperation of private and administrative organizations

MASUBUCHI, Yoshiko[1*] ; TANBO, Toshiya[1] ; FUJITA, Masato[1] ; TAKEUCHI, Akira[1] ; ISHIZU, Hidetomo[1] ; NAKAO, Tetsuo[1] ; KOSHIMIZU, Kazunori[2] ; HORIUCHI, Yasuo[2]

[1]Tateyama Kurobe Geopark Promotion Conference, [2]Tateyama Kurobe Geopark Support Municipalities Conference

The Toyama plain is divided roughly into two equal parts by the centrally located Kureha hills: the east side, called Gotou (East of Kureha), and the west side, called Gosai (West of Kureha). Each side has its own landscape and traditions. On the west side, in Gosai, you have a region where the influence of the Kaga clan is still felt strongly; on the east side, in Gotou, you have a region influenced by the unique shape of the land, with a steep mountain range over 3000 meters tall overlooking many coastal alluvial fans, where the many people live. The Tateyama Kurobe geopark is based in Gouto, this east side, with its landscape and traditions, and with its people's industriousness and thoughts that shaped the region.

A peculiarity in this region is that, in order to protect the land and understand its value, governments have supported many residents and organizations, which would then pursue various activities on their own.

With this in mind, various local regional study groups, field researchers, university and high school teachers, and other professionals gathered together and, on January 20th 2013, created the Kurobe Tateyama geopark Research Group. The Group has proposed to turn the whole region into a geopark, conducting various researches about the current amount of human activity and natural resources in the region, as well as about the future tasks and responsibilities that would come with the organization of a geopark. At the same time, they contacted the various local governments situated in the region to promote the idea of geopark, as well as to receive their support regarding its current and future activities. Also, and this is the peculiarity of this region's geopark, the group also made contact with the region's business community, where they not only promoted the geopark but also promoted their direct participation in its activities, making the local businesses, which are at the base the local industries and economy, have a strong role in all the geopark activities.

This is how, on December 9th 2013, the Kurobe Tateyama geopark Association was founded, upon what would become its predecessor, the aforementioned Kurobe Tateyama geopark Research Group. This Association, receiving support from both local businesses and local governments, was given the responsibility of all activities pertaining to the realization of the geopark in terms of human resources. The Association itself is privately run, their members linked to regional development and local business leaders. The organization currently consists of the following groups: activity planning group, research and education group, Geo-guide formation group, Geo-tourism group. While, at this moment, the geopark is supported by a volunteer staff, in the future, the organization seeks to have the geopark fully supported economically by local firms and touristic businesses.

Also, the Association seeks support from the local governments, mostly in three forms: support in the protection and usage of the designated geosites through bylaws and regulations, usage of the geopark in local and environmental education and disaster prevention by inclusion into the school curriculum, and making of the various public museum employees' currently volunteer work in the geopark organization into a part of their duties. At this moment, the Association is preparing the "Tateyama Kurobe geopark Support Municipalities Conference", in order to get a hold on their support to fully start the geopark's activities during 2014.

The association aims to have the geopark activities supported by the partnership of both private and public sectors, by having them be responsible for the maintenance of both activities and installations. This is how we are aiming for regional development through the Tateyama Kurobe geopark.

Activities and work for the future in the Hakusan Tedorigawa Geopark.

HIBINO, Tsuyoshi[1*]

[1]Hakusan Tedorigawa Geopark Promotion Council

We have advanced various activities since 2010 in the Hakusan Tedorigawa geopark. Hakusan Tedorigawa Geopark was certified as a Japanese geopark in 2011. We carried out various activities, such as the activities to promote the geopark, educational activities, training for guides, environmental maintenance for geopark and so on, after the cetrification.

In 2013, we had the domestic examination for application to the Global Geopark Network, but the result was not reached. Although we received some good evaluation about the activities of the geopark by this examination, and we were able to share it among various people who pushed forward the activities for the geopark. Furthermore, the work that should be solved became more clear and also became the index in pushing forward the future activities. We will promote various activities for solving these works in the Hakusan Tedorigawa Geopark.

Joint Management of Geopark and Biosphere Reserve - The Case Study in the Hakusan Tedorigawa National Geopark in Japan

AOKI, Tatsuto[1*]

[1]School of Regional Development Studies, Kanazawa University

Area of the Hakusan Tedorigawa National Geopark (GP) in Japan is partly overlapped with that of Hakusan Biosphere Reserve (BR). The organizing committee of the Hakusan Tedorigawa GP has started to manage Hakusan BR for making to coexist these two programs within the same region (see our poster presentation for in details).

As well known, both program is controlled by UNESCO, and the purposes of these programs are became almost the same after the Sevilla strategy of BR in 2002 as follows.
>Conservation the regional nature and natural heritage
>Encourage the scientific research and education for regional nature
>Encourage the local community and economy though the scientific based sustainable using the regional natural resource

The local ecological diversity can’t exist without local geodiversity. Furthermore, the local geo-diversity provides much of effect for the local people through the local ecosystem. Fundamentally, the general ideas of these two programs are inseparable. On the other hand, these two programs must be separate on the park system. The authors think that it is necessary to take care following points to for making to coexist these two programs.

For inside of the park
>promoting the scientific relationships between two programs
>making relationships between organizing committees of each program
>organizing the TPO for using each brand and trademark
>organizing budget and human resources

For outside of the park
>promoting the scientific relationships between two programs
>organizing the methods for advertises these two programs

Networking of geology, history and culture in the Izumo region

RITSUO, Nomura[1*] ; TAKASU, Akira[1] ; IRIZUKI, Toshiaki[1] ; HAYASHI, Masahisa[1] ; TASAKA, Ikuo[1] ; TSUJIMOTO, Akira[1]

[1]Kunibiki Geopark Project Center, Shimane University

The ground of Izumo, Shimane Prefecture, was formed in association with the creation of the Chugoku Mountains, the Sea of Japan and the largest brackish lakes, Shinjiko and Nakaumi, in Japan, all of which were episodic in the Earth history. A lot of geologists have investigated such characteristic features of Izumo area and have found its unique geological figures such as magnetite-rich granite of the late Mesozoic and early Cenozoic Era, severely deformed Neogene sediments, huge alluvial plane, and the Quaternary volcanoes. A varied nature of such geologic basements leads the birth of local industry, using diversified biological and mineral resources, and as a consequence led to the formation of so called " Izumo culture. " There was much folklore in a long human history, such as well known " Kunibiki legend. " Izumo is thus very famous as the place of mythical world. We enhance interdisciplinary research on the geological, geographical and biological nature linking to the history and culture of the Izumo region. Main goal of our project is to make a plan of national and international geo-park for the Izumo region

Our research project is based on the fruits resulted from the active investigation that mainly carried out by the geologists in the Department of Geoscience, Shimane University, as a plan to make a geopark for the San ' in and Shimane districts. The 38 geological places in the Izumo region were introduced in the publication, " 100 geosites selected in the San ' in and Shimane districts, " that was published in 2013. On our schedule, we will set up a social organization to promote our geopark project in coming April, 2014.

Device and the present conditions of ***Mine-Akiyoshidai Geopark Plan***

OBARA, Hokuto[1*] ; FUJIKAWA, Masayuki[1] ; YAMAGATA, Tomoko[1]

[1]Mine-city Geopark Promotion Council

The geopark activities in Mine area located in the middle western part of Yamaguchi Prefecture have been promoted from 2011. The geopark name and the theme are decided as follows; "***Mine-Akiyoshidai Geopark Plan***" and "**The history of the earth and the life to breathe on the karst plateau**". The contents of Geopark Plan and its present status will be presented.

The name and theme spotlight Akiyoshidai Karst Plateau in Mine area. The limestone which forms the karst plateau originated from coral reef of oceanic island. It has various information of natural history, so that contains academic value very much. Scientific and cultural values concerning the geology, geography, biology, ecology and human culture in Akiyoshidai are very high. Therefore, Akiyoshidai Karst Plateau is very precious worldwide.

In Mine area, as well as Akiyoshidai Karst Plateau, there are Omine Coalfield which is mined high quality anthracite (hard coal) and Naganobori Copper mine which is the oldest public copper mine in Japan. We aim to keep those geo-resources, use them for an instructional activity positively, and apply them in local promotion.

Creating new geo business and the role of key persons in the San'in Kaigan Geopark

IMAI, Hiroko[1] ; NIINA, Atsuko[2] ; MATSUBARA, Noritaka[3*]

[1]NPO Tajima Marine School, [2]Regional Innovation Research Center, Tottori University of Environmental Studies, [3]Division of Geo Environmental Sciences,University of Hyogo

The economical success is essential for the sustainable development of geoparks. Local business is the main actor to offer high quality products and service in a geopark. If they can satisfy of the demand of consumers and visitors, the geopark itself will become a higher quality one. This presentation reports on the case studies of geo business from the beginning to the present in the San'in Kaigan Geopark.

Effects and Issues of Resident Involvement in Walking Model Route Map

MATSUBARA, Noritaka[1*] ; SAKIYAMA, Tohru[1]

[1]Division of Geo Environmental Sciences,University of Hyogo

One of the important roles of geopark activities is resident understanding of the geopark concept, territory and its features. For this purpose, it is important that local residents participate in geopark activities positively. However, in Japan, where local development has been undertaken by governmental organizations, it is difficult for local residents to take part in geopark activities.

This time, we planned ”Geopark Walking Model Route Map” across the San’ in Kaigan Geopark in cooperation with local people, to promote better understanding and communication with local people, government and academia involved in geopark activities.

<San’ in Kaigan ”Geopark Walking Model Route Map”>

In a geopark, creating a tour route and map which allow visitors to explore the geosites easily is required. We have therefore prepared a ”Geopark Walking Model Route Map” for walking tours in half-day or one day, and for enjoying the feature of each area. Each map includes outlines of about twelve must-see geological spots, allowing visitors to enjoy sightseeing and learn about the San’ in Kaigan Geopark. 20 model courses extending to three prefectures (Kyoto, Hyogo and Tottori) were created until fiscal year 2012.

<The process for planning a ”Geopark Walking Model Route Map” >

1) San’in Kaigan Geopark Promotion Council Academic Group selects the candidate sites from the area where geopark activities are prosperous, and if requested to create a map by local residents.

2) Local guides, tourism facilities, local residents, geopark-related officials and academic members form a working group on creating a draft of map.

3) The working group surveys the field and checks the highlights, safety, estimated walking time, etc.

4) Academic Group creates a map.

5) The working group checks the content of the map.

Since Academic Group directly got involved in creating a map, the contents were thought to become difficult. To make it understandable to the general public, we posted images and descriptions on the map to Facebook and modified them to more simply by collecting public opinions through SNS during the process 5).

<Effects and issues of resident involvement in ”Geopark Walking Model Route Map”>

We were able to make ”Geopark Walking Model Route Map” useful for local residents, by involving experienced local guides and people in the area. It is important that geopark guides take part in map creation especially in the process 2) and 3). Firstly, geopark guide’s participation made the map more practical. Secondly, by working together by local residents and researchers, scientific information could be shared among local people.

As mentioned above, we think that resident involvement in planning ”Geopark Walking Model Route Map” was effective, however, some problems were found in its operation. The map is not used effectively in the area which has fewer visitors and no local guides. From now on, it is also necessary to accept visitor’s opinions and correct continuously so that the map may come to be more effective and useful for both visitors and local residents.

Shimonita geopark and regional construction

KANBE, Satoru[1*] ; OKAWARA, Junjiro[1] ; SEKIYA, Tomohiko[1]

[1]Shimonita geopark promoting office

Shimonita Geopark is a Geopark comprised of the farming and mountain village Shimonita town that assumed Shimonita-negi and konjac located in Southwest Gunma a special product.It is the farming and mountain village that is full of nature among the Mt. Myogi and Kanto mountains and is a town historical as a stage of the branch road of Nakasendo Road.

I am said to be the sacred place of the geological feature study from old days, and the geological feature phenomena that they hid a secret of the Japanese Islands birth. Those geological features bring about the unique life and culture of people of the land.

I introduce sightseeing, citizen-based town planning of Shimonita town utilized these area resources.

In a sightseeing side, we open a course in a guide training lecture so that a local guide guides you and begin the sightseeing taxi which I matched with a world heritage as tourlists who came by a train.

In an eduction side, because the teaching materials becoming the help of the science education of the elementary and junior high school are abundant, we perform an invitation from Tokyo and wrestle for activity to have local children know the charm of the hometown more, and to bring up regionalism

In addition, the symposium of the theme ”how protected local treasure” held a symposium last year and, as the place that thought about the sustainability of local resources, utilized the network of the Geopark and had you report the example of sustainable resources utilization from many aspects.

In Shimonita town, I wrestle as consistency of the local promotion that is sustainable by Geopark activity.

Total Design Strategy of Sakurajima-Kinkowan Geopark

ISHIMIYA, Satoshi[1*]

[1]Sakurajima-Kinkowan Geopark Promotion Council

The Geopark is thought of as a place where, across a long period of time, the local peoples' thoughts on community planning and improvement can be expressed as a single goal.

With that idea in mind, the Sakurajima-Kinkowan Geopark's information sharing and role as a geopark are based on a Total Design strategy.

The Total Design strategy, logo, character design, etc. are products of a team of local designers and illustrators who work both in and outside of Kagoshima.

The results of these design specialists' work are a friendly character and design, which draw interest from a wide age group, and allow them to enjoy the Geopark and its activities at their own pace.

The current poster uses this Total Design to introduce Sakurajima-Kinkowan Geopark.

Aso Geopark Infrastructure Development; International Students Monitoring Tour

KATAYAMA, Akira[1*] ; ISHIMATSU, Akinobu[1] ; YAMAUCHI, Mariko[1]

[1]Aso Geopark Promotion Council

Aso Geopark has been applied for joining the Global Geopark Network (GGN) in December 2013.The Promotion Council has been maintaining both the hard and soft elements of the park infrastructure for not only Japanese tourists but also visitors from abroad as we expect more visitors after becoming the GGN member. In November 2013, international university students in the Tokyo area, who are from Canada, UK, Czech Republic, Korea, China and Taiwan, are interested in Aso region, carried out 3days monitoring tours to evaluate Aso Geopark's foundations to meet visitor satisfaction. The group researched geological sites, public transport systems, the Geopark's base facilities, guiding leaflets and foreign language service at tourists' information and accommodations. During the tour, related people from municipalities, accommodation unions and the council staff gathered together with students and discuss about findings which students discover as native tourists.From the monitoring tour, overall performance includes guide's skill, numbers of signboards and omotenashi at accommodations are relatively highly satisfied. However, explanations in multilingual signboards at public transport stations and base facilities and also automatically translation service on the geopark official website were pointed out and need of immediate development.Even though there are many experiment activities in Aso Geoaprk, most of students suggested having more kindly information service from an entrance to a goal for main tourist's route to look around Aso region with stress free. Explanations for Japanese culture such as use of Ryokan and Onsen, hot spas are essential.This monitoring tour has been programed to have sustainable relationship between the council staff and students as an adviser for future infrastructure developments. Only long-term stay students were selected and asked to check the geopark's official website both before and after the monitoring tour.The promotion council will boost our infrastructures from this research and continue to have more monitoring activities.

The earth science learning tourism Let’s enjoy learning The Chichibu Geopark!

MIYAGI, Satoshi[1*] ; YOSHIDA, Ken-ichi[1]

[1]The Chichibu Geopark Promotion Council Japan

People avoid taking part in the Geo-tourism on focus the geology or topography due to its image as difficult and not-interesting.
However, once you go to Geo-tourism, you can enjoy learning the history, culture and the local life by talking with local guide.
The Chichibu Geopark held monitor tours The earth science learning tourism which set on the several themes, by bus and train this year.
People who participated in the monitor tour commented as follows:
-Hope many people to understand the importance of nature.
-Nice to hear the details by local people.
-Hope to conserve and restore the industrial heritage.
-Hope to continue the Geopark monitor tour.
Geo-tourism is the journey to make us enjoy by local guide as interpreter of the earth.
We continue to discover, to familiarize and also to conserve and utilize the goodness of Chichibu as the local treasure.

Private organization for lifelong learning in the Geopark -San-in Kaigan Geopark Saloon (tentative name)

SAKIYAMA, Tohru[1*] ; NIINA, Atsuko[2] ; MATSUBARA, Noritaka[1] ; IMAI, Hiroko[3] ; IMAI, Manabu[3]

[1]Graduate School of Regional Resource Management, University of Hyogo, [2]Regional Innovation Institute, Tottori University of Environmental Studies, [3]NPO Tajima Umino Gakko

Local branding is required in a geopark, and therefore the lifelong education is one of the important activities of the geopark. The staffs of many education and research organizations such as universities and museums are working in the San-in Kaigan Geopark. They do research activities and take part in the operation of the geopark as the member of the committee. Furthermore, they educate for geopark guides and general citizens. These educations are carried out by each organization in cooperation with municipalities individually. There are many small educational facilities and community center in the geopark and some of them provide some educational programs related to geopark. Furthermore, individual guide groups and nonprofit organizations related geopark activity also provide opportunity of learning of training for guides and improving their skill. Summarizing and provision of information by promotion council of San-in Kaigan Geopark are expected, but all programs cannot be grasped by following reasons.

(1)Most of events are not for full area but close to a municipality.

(2)Most of promoting offices of the geopark belong to industry and tourism division, but most of educational facilities belong to education board in the city or town.

(3)Some information on the private offices, NPO and university are not easily spread, because of operating system of the organization led by local government.

(4)Secretariat has very much work because of the wide geopark.

Then we started up a private group (San-in Kaigan Geopark Research Group) for the lifelong education. Members of San-in Kaigan Geopark Research Group belong to universities , NPO, corporations, guide groups and administrative officers.

The San-in Kaigan Geopark Research Group supports the San-in Kaigan Geopark through following educating programs.

(1)Holding regular meetings

(2)Coordination of seminars provided by many educational facilities

(3)Providing original seminars

(4)Planning and execution of out-reach program (geo-caravan)

(5)Providing lecturer

(6)Execution of continuous professional development for geopark guide (Geo-CPD)

The group is composed mainly of staffs of NPO, personal organization and university, and can provide the educational activities across the administrative division. Participation of staffs from various fields makes the geopark expect spreading cooperation in the San-in Kaigan Geopark.

A Five Senses Sensation in Oga City Geopark Study Center -Geological Geo-Cite and Human History&Culture Meeting Point-

IGARASHI, Yusuke[1*] ; KIKUCHI, Mitukazu[2] ; OYAMADA, Tomoko[2]

[1]Oga City Board of Education, [2]Oga City Geopark Study Center

The Oga City Geopark Study Center was officially opened on August in 2012. This opening followed on from the establishment of the Oga Peninsula-Ogata region as one of the Japanese Geopark sites on September in 2011. The creation of this center focused on the idea that by coming to visit, you would be able to learn everything that there is to know about the Oga Peninsula-Ogata Geopark and surrounding area.

Since the opening of this facility, more than half of the guests at the Geopark center have consisted of arranged educational institution visits - among these visits, Elementary School guests have been the most in number so far. Recently, we are seeing an increase in visits to the center when the weather is poor outside, as this is the biggest issue for people who are traveling to visit the area as part of a 'Geo-Tour'.

Depending upon the guest, we have aimed to provide a wide range of learning materials considering the age and the purpose of the visit. We have also given a high priority to hands-on, participatory ways of learning that will require the use of all five senses of the visitor.

For the lower grade Elementary School learners, we have also provided a range of picture-story style shows which are related to both the Geopark, as well as the legends and stories of Oga City. During the summer and winter vacation times, a workshop is held for Elementary School guests where rock specimen and stones from the Oga area are used to make replicas and models of various common fossils. We are very keen to promote these hands-on activities to the enjoyment of our guests.

Aside from the geological elements of our center, it is also felt that we should promote and educate visitors to the human history of the region in order to preserve our cultural and traditional assets. We aim to cover both of these points comprehensively and widely.

Going forward, it is our aim to promote the human and geological connection and to explore this intertwined relationship. We wish to further our success in this by cooperation with the Ogata Village Polder Museum of Reclaimed Agricultural Land, located only a few kilometers away from our Geopark's location.

It is with this announcement that we would like to introduce you to our facility and activities and express the wish for prospects which lead us to a bright and successful future.

How the precise geological model is utilized in education at schools

YOSHIKAWA, Hirosuke[1*] ; HATANAKA, Takenori[1] ; OTSUKA, Masahiro[2]

[1]Dinosaur Valley Fukui Katsuyama Geopark Promotion Council, [2]Arado elementary school

In 2013, a precise geological model of this region was created with the help of a scientist. This model has mainly been utilized in schools to develop various lessons about Geo-visualization.

The point of this project is not simply to reveal this regions geological features; rather, it aims to awaken the children spirit of inquiry and provide them with the educational opportunity to experience surprise and discovery. We will now present an example of how this geological model was utilized and explain how it may be applied in the future.

Geo-tour program for children during summer vacation in Choshi Geopark

YAMADA, Masahito[1*] ; IWAMOTO, Naoya[1] ; NAKAMURA, Kizuna[1]

[1]Geopark Promotion Office, Choshi City Hall

1.Purpose

Choshi Geopark Promotion Council organized geo-tour for children during summer vacation last year, which is in collaboration with the Association of Chiba Institute of Science (hereafter CIS), Choshi Ryokan union Choshi Inn union, Choshi GeoParty. The purpose of this geo-tour is to provide unique experiences for the children that can also be used as part of their summer homework, and to create a model of overnight package tour.

2.Schedule of geo-tour

The geo-tour was held four times. The first (Jul 24 to 25), the second (Jul 31 to Aug 1) and the fourth round (Aug 27 to 28) have activities such as ”biological observation at rocky shore, touch the nature fun”. The third round (Aug 8) was one day trip with ”observation of the stratum, that can also be submitted to the children’s school as their summer homework.

For the overnight program, we first gathered at Choshi Station at 9:30am, according to the arrival time of the JR limited express. After giving an orientation in CIS, the next event was biological observation at the rocky shore in Nagasaki coast. Then there was plant observation in Kimigahama followed by lunch break in the Culture Center for Youth and Children. In the afternoon, we made star plates and watched a planetarium show. Next, we explored at Inubosaki in the late afternoon. On the next day, there were observation of the landscape at the top of the Mt. Atago-yama, moved to climax forest and had summary of the experiences learned during the programs. The last event was a closing ceremony that all the children were given a participation certificate.

For the one day trip, after giving an orientation in CIS, there were interpretation of layers and sampling of tephra at Byobugaura, and lunch time at CIS. In the afternoon, we observed the sampling using stereoscopic microscope.

3.Advance preparation

Preparation of this geo-tour was started around late April. The events were organized primarily by exchanging information using e-mails. A Working Group meeting was carried out about once a month.

Application of this geo-tour was started from Jun 10 through the ”Jaran” internet version, that reservation was received at each accommodation.

We posted advertisement on the web site of the Choshi Tourism Association and the Choshi Geopark Promotion Council. In addition, we made flyers and sent to each museum and Secretariat of Geopark Promotion Council in Kanto region on July 9. Also, an article was published to the local newspaper on July 20.

The number of participants did not increase as expected. Thus, we changed the program to accept participants from the local people who do not need accommodation.

4.On geo-tour days

The numbers of children for round one to four were 6, 2, 2 and 21, respectively. Many of them were delighted to join the tour.

According to the questionnaire results, many children enjoyed playing at rocky shore. A mother of participants who is born and raised in Choshi commented that she can feel the enjoyable part of Choshi again and another mother would like to learn more about Geopark.

5.Evaluation meeting

Evaluation meeting was held on Sep 19 with a total of 16 participants. The discussion was held by dividing the participants into groups in a workshop format with sticky notes.

The positive comments raised in the meeting were ”The children have fun”, ”Various organizations have cooperate”, ”Various projects could be introduced”, ”Overall framework was constructed ”, ”Accident-free” and so on.

On the other hand, the problems are ”Difficult to understand how to apply”, ”Necessary to devise PR activities”, ”The program was too packed ”, ”Setting of dates”, ”Few participants”, ”Consideration for participants”, ”Difficult to understand the interpretation”.

In addition, the solutions suggested are ”Take action as soon as possible”, ”Separate geo-tour from accommodation”, ”Learn from other Geoparks”, ”Consider the situation of the day” and ”Have a better contact system and role-sharing”.

What's the meaning of sharing the thought and the experience? The report what we learned through symposium in Izu-Oshim

NISHITANI, Kana[1*] ; SHIRAI, Iwahito[1]

[1]IZU Oshima Geopark

What is sharing of a thought or experience?
The report what we learned through the symposium in Izu-Oshima

After the landslide disaster of the typhoon 26, we will take a symposium in order to learn how to faced the trouble after a disaster and how to live on this island. We will invite people from Miyake-island and the Sanriku Geopark where have experience of eruptions or tsunami, and we will exchange opinions.

Moreover, in order to send some information all of residents equally, we planed to make a booklet for shearing the experience of disaster.

We will consider about the role as a network of the Geopark from our measures.

Exhibition of ”Geohistory of Hachirogata” Established in Polder Museum of Ogata Village

SHINDO, Tomoya[1*] ; WATANABE, Akira[1] ; USUI, Noriyuki[1]

[1]Polder Museum of Ogata Village

Polder museum of Ogata village was opened in 2000. Main theme of the exhibition was Hachirogata reclamation project and history of Ogata village, such as the reclamation works, start of Ogata Village, settlement project as colonists and the lives of the settled people. In the preparation of the museum, Natural History in Ogata also was nominated for the exhibition theme, exhibition on ”Geography of Hachirogata” were also included in it. However, it was decided that the exhibition plan is excluded completely in the process of planning reduced for various reasons.

In 2011, Oga Peninsula-Ogata Geopark was certified by the Japan Geopark Committee for the first

The picture book about geo-stories of Toay-Usu global geopark

KAGAYA, Nire[1*] ; HATA, Yoshiaki[1] ; NAKAYA, Asami[1] ; ENDO, Kazuya[1] ; TAKEKAWA, Masato[1] ; HIROSE, Wataru[1] ; SASAKI, Hikaru[2] ; SASAKI, Mayuko[2]

[1]Toya-Usu Global Geopark Council, [2]SESENSITKA

Toya-Usu global geopark is a volcanic geopark located in Hokkaido in northern Japan. There are major farms producing vegetables and fruits in this area, and the lands the crops are grown on contain a moderate amount of alkaline ash and pumice from the Toya volcano and the Usu volcano. Therefore, the soil is well suited for cultivation, with a balanced pH and good runoff of water. Also, there are forests in various transition stages around Mt. Usu. This produces bio-diversity with each environmentally-accepted creature. This is due to frequent disturbance and restoration by the eruptions of Usu volcano in recent years. Because of this, we can find a lot of hidden tales ”Geo-Stories”, associated with the activity of the living Earth when we focus on the different aspects of local industry, people’s livelihood, and the natural habitats of living things.

In 2014, Toya-Usu global geopark produced the picture book Toya-Usu Global Geopark Storybook in order to comprehend the relationship between the worlds above and under the ground world. It is edited to include easy-to-understand text and illustrations to reach local people of all ages.

Keywords: Geopark, geo-story, Toya, Usu

Winter is the Time for Geo-tour!! : The Recommended Winter Trekking Course in Toya-Usu

KAGAYA, Nire[1*] ; HATA, Yoshiaki[1] ; NAKAYA, Asami[1] ; ENDO, Kazuya[1] ; TAKEKAWA, Masato[1]

[1]Toya-Usu Global Geopark Council

In Hokkaido, Japan the number of tourists in the period from April to September 2012 (34 million) was double that of the period from October 2012 to March 2013 (17 million). This gap between the number of tourists in summer and in winter is large when compared with any other region of Japan. This is because the low temperatures and snow in the winter months is standing in the way of winter tourism in Hokkaido, which is a high latitude location.

The downturn in the tourism industry during the winter is an old challenge. In our Geopark, it continues to disturb local employment and industrial growth, and marks it hard to have a stable income throughout the year. Creating new attractions in the region is a solution of vital importance for the promotion of our Geopark and the sustainable development of the local economy.

The winter is actually the best season for enjoying the outdoors of our Geopark, when you can easily see the steaming active lava domes and craters due to the low temperature, as well the beautiful landscape covered with snow. Snow-shoe trekking is becoming popular these days in Japan. There is a lot of potential for a successful tour in the winter months. Here I will present our recommended winter trekking course.

Selecting potential geosites in the eastern Kii Peninsula, SW Japan

KAPUSCIK, Dorota[1*]

[1]Waseda University

The geologic structure formed by plate subduction along trenches is well preserved in Southwest Japan. Formed from Jurassic to Paleogene eastward trending belts of accretionary complexes with metamorphic rocks characterize the geology of the Kii Peninsula.

The eastern Kii Peninsula presents varied geological features, such as rocks exposures and fossils, which displays the history of formation of the Japanese Islands. The aim of this work is to identify significant geological sites in the region and set the basis for establishing geosites in future. A geo-site, in the field of geo-tourism, is a geological attraction with the highest value rank, which identification would play the essential role in development of geo-tourism in this region.

Scientifically important geosites has been picked up together with the sites of unique history and culture within the study area including Ise, Toba and Shima City in eastern Kii Peninsula. The valorization of selected objects, from the aspect of geo-tourism development in the region, is based on field studies and detailed petrographic analyzes by using samples from rock exposures on the surface. The thin sections analyze provides information about more precise surface trace of the Median Tectonic Line (MTL) in the eastern Kii peninsula, which can be use as the most attractive point of geological trips in the region.

This work also focus on the lack of geo-touristic infrastructure that would make available all their advantages for educational and tourism purposes. Though several MTL outcrops are visible among local roads in relatively close distance to popular touristic spots, most visitors do not notice this fact. Sufficient information about geosites, as well as the access facility, is the most important for visitors. Establishing a tentative geo-touristic course in the study area would increase public awareness of geoscience education, protection and conservation important landscapes for future generation and help tourists with better understanding the geology of visited area.

Strata Observation Party Evolved into the Geo-Tour -The Oga Peninsula-Ogata Geopark's Trial-

WATANABE, Kosei[1*] ; TAKEUCHI, Hirokazu[1] ; SUGAWARA, Sinichi[1]

[1]Oga Peninsula-Ogata Geopark Promotion Council

The Oga Peninsula-Ogata Geopark is a suitable place for geological learning and research. We could examine the strata for 70 million year-long doramatic history. Every year, many students and researchers in the field of geology come to visit. At the beginning of Geopark's authorization period, due to desired efforts in education and research, this area was considered to be particularly "difficult" Geopark compared to other locations. However, more recently due to the interaction and exchange of ideas from various geological conventions and from within the community of Geopark inspectors, we are happy to announce this area is now more "fun" Geopark.

With this announcement, we would like to introduce our progress and the results, the bright future prospects.

The geopark which feels the sound which turns over the page of the history of the earth

SATO, Misao[1] ; SATO, Hidekazu[1*] ; MIURA, Go[1]

[1]miyagi kuriharacity

The causes for Kurihara to aim at a geopark were Heisei 20 Iwate and the Miyagi inland earthquake.

In this earthquake, very various types and destructive movement of the slope of a scale which exceed 3000 from the summit of the mountain of the volcano which constitutes the Ou mountain range to foot arose.

Inland epicentral earthquake.

This is business of the earth in the Ou mountain range repeated since ancient ancient times, the natural wonder itself can be felt here and it is thought that Nature is moving.

”The sound which turns over the page of the history of the earth is felt.”

In the Ou mountain range, this meaning has only the history for the 1 million ? 2 million years the history for earth 4,600 million years, and in it, and Iwate and the Miyagi inland earthquake in the meantime are new occurrences of five years ago.

We should make it the hit of a between, should feel it and must merely have felt the dreadfulness of the earth.

We have helped the moment which turns over rightly 1 page that the Ou mountain range will change greatly, in the history of It continues for a long time endlessly.

Since it seethes with the senses rather than explaining, it is expressing it in the word of ”feeling sound” by the Mt. Kurikoma foot geopark concept.

Locality exploration of archaeological relics and a theme of geopark - an example of the Yakumo geopark plan

OYA, Shigeyuki[1*] ; KATOH, Takayuki[2] ; THE ASSOCIATION OF GEOPARK PLAN, In yakumo[3]

[1]Yakumo education comittee, [2]Earth Science Co.Ltd, [3]Yakumo town

Yakumo-cho is a town that has the chief industries of the dairy farming and the fishery which owns the two seas of the Pacific Ocean and Sea of Japan, being in the narrowest part in Oshima Peninsula.

Since 2012, it is doing an activity while the geopark conception preparatory meeting of the private base gets the support from Yakumo town, too.

Oshima Peninsula is the peculiar place which was the corridor connect with Honshu , like a geological feature like landform and also for the people to come and go since the Old Stone Age.

Therefore, the one of archaeological relic which was carried from Honshu in the converse to the one from the inland in Hokkaido is jumbled up around Yakumo town. These relics are also beautiful for modern human beings.

Accordingly, the tour by which an use and an origin are explained about the stone and it observes relics and observes the geological feature of the source of supply and the candidate site can be organized. It thinks of that the case cooperates with some geoparks in each place, too.

The examples are as follows {The archaeology relic (the stone quality)-Locality-The way of visiting}.

1. Jadeite→Itoigawa City→ Visit to the Itoigawa geopark
2. Obsidian-→Akaigawa village and Shirataki area of Engaru town→Visit to the Shirataki geopark
3. Blue schist→Kamuikotan belt→Visit to the Asahikawa geopark (plan)
4. So-called ”Aotora” (Greenshist to blueshist facies metamorphosed bannded pyrocrastic rock brocks in a serpentinite mass) →Nukabira serpentinite mass, Kamuikotan belt→Visit to the Hidaka mountains museum (Hidaka town)
5. Rodingite metazomatized from serpentinite itself with Cr-spinel→Nukabira serpentinite mass, Kamuikotan belt→Visit to the Hidaka mountains museum (Hidaka town)
6. Welded tuff bearing hornblend (house-formed production) →Nigorikawa pyroclastic flow→Visit to around the Nigorikawa caldera
7. Silicified shale→The Yakumo formation with the contact zone of intrusive rocks→Visit to several localities around Yamumo town
8. Marlite→The nodule in Yakumo formation→Visit to Kami-Yakumo area, Yakumo town
9. Agate→The area of volcanic rocks of submarine such as Kunnui-, Yakumo-, Kuromatunai- formations→The Kuroiwa in Yakumo town, R. Kunnui-gawa in Oshamanbe town, and R.Shiribeshi-toshibetu-gawa in Imakane town
10. Talc→Era area in Matsumae town→Visit to Matsumae town
11 .Asphalt→Yamakoshi area in Yakumo town, Kuji city in Iwate prefecture→Visit to the oil showing of Yamakoshi, and the Sannriku geopark

Keywords: Yakumo geopark plan, archaeological relics

Mini Geotourism Centered on Itoigawa's Old Town

II, Toru[1*] ; WATANABE, Seigou[1] ; TAKENOUCHI, Ko[1]

[1]Itoigawa Geopark Council(Itoigawa City Geopark Promotion Office)

One of the main points of entry for the Itoigawa Geopark is Itoigawa Station,located in the middle of Itoigawa's Old Town.The north side of the station has since long ago been a shopping area.Once lively with activity, it now sees little foot traffic. This problem is shared with many rural cities,the causes include:loss of customers to large suburban box stores, the recent trend away from public transport,and declined enthusiasm among shop owners due to decreased sales and difficulty in finding successors.In 2009 came Global Geopark certification and plans were undertaken to further utilize and revitalize the Old Town in time for the new Hokuriku Shinkansen Line in March 2015.In this session,we will introduce how we are using Geotourism in order to increase foot traffic in the Old Town.The center of the old town district is an area called 'Ro-no-Ji' for its square shape resembling the Japanese character 'ro'. It is largely commercial and is often used for events such as festivals.Itoigawa Station lies at one corner of Ro-no-Ji alongside a tourism information center which includes geopark information.In the Old Town are a statue of Princess Nunakawa,a local deityp;and historical landmarks including the beginning of the old Salt Trail,Kaga-no-I Brewery,and a gangi-lined street.Gangi are traditional roofs built over streets Japan's snowy regions.This street preserves the image of Japan before modern shopping malls.A number of Geopark-related sights show ways in which the land has changed.These are all valuable tools in the development of the Old Town District.The Itoigawa Machinaka Collection is an event that has been held every year since 2006.Participation is increasing yearly and in 2013 a Town Walking Tour attracted many participants looking to enjoy the Old Town.The 'Increase Shop Charms Women's Club' was formed in 2010 by 50 women working in the Old Town to help revitalize the area in preparation for the new Shinkansen.They now help with the Machinaka Collection, sell limited edition sweets, and participate in events in the area,helping to reenergize the district.The Itoigawa Geopark Council promotes downtown walking through pedestrian maps. These maps include interesting sights around the station as well as specialty products available at downtown shops.The leaflet targeted toward women has been particularly well-received.Itoigawa Station is a hub which connects the Hokuriku Main Line with the Oito Line,and so travelers occasionally must wait for their connection. Wanting to capitalize on this,a Geopark Guide Walking Tour program was tested. Over 10 days in late October,8 people participated in these impromptu tours.All 8 were women who,having time to spend before their next train,enquired at the tourism desk about things to do. The guides primarily focused on the gangi street,Kaga-no-I Brewery,the seaside viewing platform, and downtown shops, from which some visitors bought gifts.Others declined the tour,but took leaflets to walk the town alone.To improve secondary transport from Itoigawa Station,a Town Loop Bus began operation in 2011.Running weekends and holidays, the bus starts at the station and makes a 40 min.loop through central Itoigawa's main tourist sites.Among these are the Fossa Magna Museum,Chojagahara Archaeological Museum,and the Itoigawa Folk History Museum.These are all indispensable facilities within the Geopark and the new bus line is important for visiting Geotourists.Since starting an all-day pass program in 2013, ridership has increased.The Old Town has many sites of interest,but they are being overlooked.Few people visit the Old Town outside of events.In order to help people understand the charms of this area, we must improve information transmission and hospitality.We mustn't miss the opportunity afforded to us by the opening of the new Hokuriku Shinkansen to increase visitors to this forgotten gem.

Investigation and preservation of old Coalmine in the Mikasa Geopark

NII, Tadahiro[1*] ; KURIHARA, Ken'ichi[2]

[1]Promotion Policy Division, Mikasa City Office, [2]Mikasa City Museum

Mikasa city is the area of Mikasa Geopark had many coalmines.
Therefore, Mikasa created prosperity by coalmine, which has many remains of them.

To consider using those remains, we investigated worth of them from point of architecture.
Then, based on the results, We tried to safety state of around the Nishiki headframe in 2013.The Nishiki headframe is believed to have completed in December 1920, and it is the oldest remaining headframe in Hokkaido.The headframe is approximately 10 meters high, and the shaft is approximately 197 meters deep.

So, we introduce you the action of preservation and reuse those remains in the Miasa Geopark.

Rice farming and culture in Yuzawa Geopark

KAWABE, Kenichiro[1*]

[1]Yuzawa Geopark Promotion Group

Yuzawa Geopark is a member of the Japan Geopark Network from 2012. In 2013, Yuzawa Geopark have created a catch copy and story. We are using the word ”Life and History”, in this copy.In this presentation, I will introduce the rice farming and culture in Yuzawa Geopark.

People have been praying for a good harvest. Also, a lot of the daily necessities and equipment used in religious ceremonies were made from rice straw. It was born from rice farming that praying for a good harvest and making daily necessities. And then, we are inheriting the culture from old generations. The inheriting is supported in rice farming that has been actively.

Diversity of ”freezing” and its application to activities in the Tokachi-Shikaoi Geopark

ONISHI, Jun[1*] ; SAWADA, Yuki[2]

[1]Tokachi shikaoi geopark Promotion conference, [2]Fukuyama city university

“ Freezing ” is one of the main themes of Tokachi-Shikaoi Geopark. It appears in many different features: periglacial phenomena and landform, ecology, and life-style of residents in this region. We show some examples of geomorphic features related to cold climate, and activities of residents adapting to the “ freezing ” winter and even using ice to build hot spa, ice bar and other activities on “ freezing ” Lake Shikaribetsu.Our poster will show introduction to the world of freezing.

Viewing the Earth's Climate from Space

FREILICH, Michael[1*]

[1]Director, Earth Science Div. NASA Headquarters

Earth is a complex, dynamic system we do not yet fully understand.
The Earth system, like the human body, comprises diverse components that interact in complex ways.
We need to understand the Earth's atmosphere, lithosphere, hydrosphere, cryosphere, and biosphere as a single connected system.
Our planet is changing on all spatial and temporal scales.
This presentation will highlight how satellite observations are revolutionizing our understanding of and its response to natural or human-induced changes, and to improve prediction of climate, weather, and natural hazards.

The Solar Power Sail for Round Trip Exploration to Jupiter Trojans and Deep Space Cruising Observation

YANO, Hajime[1*] ; NAKAMURA, Ryosuke[2] ; MATSUURA, Shuji[1] ; SEKINE, Yasuhito[3] ; TOYODA, Michisato[4] ; AOKI, Jun[4] ; YOSHIDA, Fumi[5] ; TAKATO, Naruhisa[5] ; KINOSHITA, Daisuke[6] ; YONETOKU, Daisuke[7] ; YOSHIKAWA, Makoto[1] ; MORI, Osamu[1] ; SOLAR SYSTEM SMALL BODY EXPLORATION WGT, .[1] ; SOLAR POWER SAIL WG, .[1]

[1]JAXA/ISAS, [2]AIST, [3]The University of Tokyo, [4]Osaka University, [5]NAOJ, [6]Taiwan Central University, [7]Kanazawa University

Since 2002, the Solar Power Sail WG has been studying a mission design of Japan's first outer planet region exploration, by demonstrating the solar power sail technology, and it is bound to Jupiter Trojan asteroids, which may hold fundamental clues of the Solar System formation and revolution discussed by two competing hypotheses between the classic model and the planetary migration model. The former suggests that Trojan asteroids are mainly survivors of building blocks of the Jupiter system, while the latter claims that they must be intruders from outer regions after the planetary migration of gas planets settled.

After Jupiter flyby, the spacecraft will reach to a candidate Trojan asteroid, hopefully being larger than a few 10's of km in size. Both global remote observation and deployment of an autonomous lander will be conducted. On the surface of the Trojan asteroid, sampling will be attempted for in-situ TOF mass spectrometry and passing the sample container to the mothership for a possible sample return option.

Also during the cruising operation, "dust free" astronomical platform beyond the cocoon of the zodiacal light formed by the main asteroid belt for the benefit of infrared astronomy searching for the first generation light of the Universe, let alone continuous observation of the zodiacal light structure of the Solar System. Extremely long baseline with the observation from the Earth, gamma-ray burst observation can identify their sources.

This presentation discusses major scientific objectives of an exploration mission to Jupiter Trojans for the first time in the history, its mission design and spacecraft system using solar power sail, a hybrid propulsion system of electric propulsion and photon sail, which inherited from the IKAROS deep space solar sail spacecraft, together with major engineering challenges, in-situ observation instruments and operational options including landing and sample return from the surface of a Trojan asteroid.

EUROPA CLIPPER MISSION CONCEPT OVERVIEW

PAPPALARDO, Robert[1] ; GOLDSTEIN, Barry[1] ; MAGNER, Thomas[2] ; PROCKTER, Louise[2] ; SENSKE, David[1] ; PACZKOWSKI, Brian[1] ; COOKE, Brian[1] ; VANCE, Steven[1*] ; PATTERSON, G. wesley[2]

[1]Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA 91109, [2]The Johns Hopkins University, Applied Physics Laboratory, Laurel, MD, 20723

A NASA-appointed Science Definition Team (SDT) recently considered options for a future strategic mission to Europa, with the stated science goal: Explore Europa to investigate its habitability. The team worked closely with a technical team from the Jet Propulsion Laboratory (JPL) and the Applied Physics Laboratory (APL). Together, the group considered several mission options, which were fully technically developed, then costed and reviewed by technical review boards and planetary science community groups. Study results strongly favored an architecture consisting of a spacecraft in Jupiter orbit, making many close flybys of Europa, and concentrating on remote sensing to explore the moon. The resulting nominal mission design is innovative for its use of gravitational perturbations of the spacecraft trajectory to permit flybys at a wide variety of latitudes and longitudes. The design enables globally distributed regional coverage of the moon's surface, nominally with 45 close flybys at altitudes from 25 to 100 km. We will present the science and reconnaissance goals and objectives, a mission design overview, and the notional spacecraft for this concept, which has become known as the Europa Clipper. The Europa Clipper concept provides a cost-efficient means to explore Europa and investigate its habitability, through understanding the satellite's ice and ocean, composition, and geology. The set of investigations derived from these science objectives traces to a notional payload for science, consisting of: Ice Penetrating Radar (for sounding of ice-water interfaces within and beneath the ice shell), Topographical Imager (for stereo imaging of the surface), ShortWave Infrared Spectrometer (for surface composition), Neutral Mass Spectrometer (for atmospheric composition), Magnetometer and Langmuir Probes (for inferring the satellite's induction field to characterize an ocean), and Gravity Science (to confirm an ocean). Among the many science investigations addressed, Europa Clipper could potentially characterize plumes linked to Europa's internal lakes or ocean. The mission would also include the capability to perform reconnaissance for a future lander, with the Reconnaissance goal: *Characterize safe and scientifically compelling sites for a future lander mission to Europa*. To accomplish these reconnaissance objectives and the investigations that flow from them, principally to address issues of landing site safety, two additional instruments would be included in the notional payload: a Reconnaissance Camera (for high-resolution imaging) and a Thermal Imager (to characterize the surface through its thermal properties). These instruments, in tandem with the notional payload for science, could assess the science value of potential landing sites. This notional payload serves as a proof-of-concept for the Europa Clipper during its formulation stage. The actual payload would be chosen through a NASA Announcement of Opportunity. If NASA were to proceed with the mission, it could be possible to launch early in the coming decade, on an Atlas V or the Space Launch System (SLS).

The icy moons of Jupiter ? Europa, Ganymede, and Callisto ? are believed to contain global subsurface water oceans underneath their icy crusts. The possibility is intriguing that these large liquid water oceans represent ”habitable” environments. Investigation of the latter is a major objective of ESA’s Jupiter Icy Moons Explorer (JUICE) mission. The Ganymede Laser Altimeter (GALA) is one of the instruments focusing on aspects related to the presence and characterization of subsurface water oceans by measuring Ganymede’s tidal deformation. GALA will further contribute (a) to the exploration of the surface morphology and physical properties of Ganymede, Europa and Callisto, (b) to determination of their interior structures from a combination of shape, topography and gravitational field data, and (c) to understanding the satellites formation and evolution especially with respect to subsurface water oceans. GALA will investigate the surface and topography of Ganymede in particular. Topography data is needed to account for the effects of topographic heights on the gravity field and to account for near surface mass distribution anomalies above the reference figure; to support geological studies, e.g. to identify and characterize tectonic and cryo-volcanic regions on the icy moons and to identify periodic variations of Ganymede’s shape due to tides.

Investigations by GALA will furthermore contribute to determine the orientation and rotational state of Ganymede and to study surface characteristics (roughness, slopes, and albedo) on Ganymede, Europa, and Callisto.

The instrument can be operated from ranges smaller than about 1000 to 1300 km (depending on the different albedo values and surface slopes of Europa, Ganymede and Callisto) during flybys and orbital pericenter passages. The main phases for acquiring data at Ganymede are the final circular orbit phases, where continuous operations are possible from altitudes around 500 km and 200 km, respectively.

Here, we will give an overview on the GALA experiment focusing on its scientific goals and performance.

Longevity of an internal ocean in Ganymede

KIMURA, Jun[1*] ; VANCE, Steven[2] ; HUSSMANN, Hauke[3] ; KURITA, Kei[4]

[1]Earth-Life Science Institute, Tokyo Institute of Technology, [2]Jet Propulsion Laboratory, [3]DLR Institute of Planetary Research, [4]Earthquakle Research Institute, The University of Tokyo

The outer solar system may provide a potential habitat of extra-terrestrial life. Most moons orbiting planets in the outer Solar System, at orbits beyond the snow line, such as Jupiter or Saturn, are covered with water ice and are referred to as ”icy moons”. Galileo’s detection of induced magnetic fields combined with imaged surface characteristics and thermal equilibrium modeling of the moons, support that the Jovian icy moons Europa and Ganymede, and possibly Callisto, may harbor liquid water oceans underneath the icy crusts. The presence of internal oceans in the icy moons means that a deep habitat different from Earth’s biosphere may exist, located beyond the ”habitable zone” of the Sun. Evidence for oceans is not definitive, however, and awaits confirmation measurements. Also, the depth and composition of the oceans remain unclear, as do their variability through time.

Here we focus on Ganymede, the largest moon in the Solar System and the primary target of a new mission to the Jupiter system, the Jupiter Icy Moons Explorer (JUICE), which is planned by the European Space Agency (ESA). The bulk density of Ganymede, 1.936 g/cc, indicates a composition of approximately equal amounts of rocky material and water. Previous measurements of Ganymede’s gravitational field and intrinsic magnetic field by the Galileo orbiter suggest that its interior is completely differentiated into three layers, a convecting metallic core at the center, a rocky mantle surrounding the core, and an outermost water-ice shell. The water-ice layer in total has a thickness of 800-1000 km. A layer of melted, salty water that lies beneath the icy crust would be the best way to explain the signal of magnetic induction.

To investigate the lifetime of an ocean (thickness change through time) assumed to be initially in an entirely liquid state, we performed numerical simulations for the internal thermal evolution using a spherically symmetric model for the convective and conductive heat transfer with radial dependence of viscosity, heat source distribution, and other material properties. Here we take into account the energy due to decay of long-lived radioactive elements and also evaluate the effect of tidal heating. If the ocean were composed of pure water, a primordial ocean would have disappeared (completely solidified) within 1 Gyr even if tidal heating for the current orbital state were included. Consistent with previous predictions , this result indicates that significant tidal heating in the past, or strong antifreeze components (e.g., salts or ammonia),

are needed if the presence of the internal ocean in Ganymede would be confirmed from future JUICE observations. We numerically investigate their effect on the lifetime of the ocean.

Impact basin relaxation on Pluto: Implications for the presence of a subsurface ocean

KAMATA, Shunichi[1*] ; NIMMO, Francis[2]

[1]Hokkaido University, [2]UC Santa Cruz

Large-scale topographies, such as impact basins, on solid planetary bodies deform in geologically long timescales. The degree of deformation depends mainly on the viscosity, and the viscosity is strongly controlled by temperature. Consequently, viscous relaxation of large impact basins has been studied to investigate the thermal evolution of terrestrial planets as well as that of icy satellites of giant planets [e.g., 1-4].

Pluto, an icy dwarf planet, is likely to possess large impact basins. In this study, we investigate long-term viscoelastic deformation of impact basins on Pluto which can be compared with forthcoming observational data from New Horizons, the first Pluto explorer.

Although little is known for Pluto, its interior is likely differentiated into a rocky core and an outer H_2O layer [e.g., 5]. The presence of a subsurface ocean, however, is highly uncertain. If the outer (solid) H_2O layer is convective, the radiogenic heat from the rocky core is efficiently transferred to the surface, and temperature of the H_2O layer can be lower than its melting temperature. On the other hand, if the outer H_2O layer is conductive, the heat from the core can melt the H_2O layer. The main controlling factor whether the H_2O layer is convective or conductive is the reference viscosity: the ice viscosity at its melting temperature [6]. In this study, we calculate viscoelastic deformation of impact basins assuming different viscosity profiles and examine the effect of the presence of a subsurface ocean on basin relaxation.

For the initial study, we use two time-independent viscosity profiles; one profile assumes a stiff top shell overlying a thick subsurface ocean, and the other assumes a completely solidified interior. The same viscosity profile in the shell is assumed.

Our results indicate that the instantaneous elastic response largely differ between the viscosity models. However, long-term relaxation does not differ much because it is controlled by the viscosity profile in the shell, which is identical in our calculations. Nevertheless, long-term relaxation strongly depends on the reference viscosity, the main controlling factor whether the shell is convective. Consequently, relaxation state of impact basins can be used to infer the reference viscosity as well as the presence of a subsurface ocean. This result would be applicable to icy satellites of Jupiter and Saturn.

Our next step is to use time-dependent viscosity profiles. To do so, we have modified our relaxation code to take into account the temporal change in the shell thickness. The results will be discussed.

Sub-millimeter observations of icy bodies toward understanding of planetary formation and cosmochemistry

SEKINE, Yasuhito[1*] ; KASAI, Yasuko[2] ; SAGAWA, Hideo[2] ; KURODA, Takeshi[3] ; KODAMA, Kenya[1] ; HORI, Yasunori[4] ; IKOMA, Masahiro[1] ; KURAMOTO, Kiyoshi[5] ; YURIMOTO, Hisayoshi[5]

[1]University of Tokyo, [2]NICT, [3]Tohoku University, [4]NAOJ, [5]Hokkaido University

The present-day composition of regular icy satellites consists of combinations of initial conditions and subsequent evolution. These icy satellites are considered to have been formed in a circumplanetary disk associated with giant planet formation. Thus, icy satellites that are not geologically active, such as Callisto, would serve as solar system fossils, which may preserve the information of the protoplanetary disk and planetary formation. On the other hand, geologically active satellites, such as Europa and Enceladus, would provide particular geological processes and consequent products of geochemical reaction. Sub-millimeter observations are capable of providing unique isotopic and chemical compositions of gas molecules in atmospheres and plumes of the icy satellites. In this paper, we discuss key observational targets and their importance for planetary formation theory and geo/cosmochemistry, especially focusing on sub-millimeter observations of Galilean satellites by the Jupiter Icy moons Explorer mission, JUICE.

Proto-atmospheres on giant icy satellites forming within gaseous circum-planetary disks

MIKAMI, Takashi[1*] ; KURAMOTO, Kiyoshi[1]

[1]Department of Cosmosciences, Graduate School of Science, Hokkaido University

In spite of the great similarity in size and mean density, the giant icy satellites Ganymede, Callisto, and Titan have very different surface environments. In particular, only Titan holds a thick atmosphere dominated by N_2. Recent data of the Cassini spacecraft indicated that atmospheric N_2 is probably originated from other nitrogen-bearing species like NH_3. However, it still remains an open question when and how N_2 was generated. This is partly because the physical states of giant icy satellites have been poorly understood.

According to a widely-accepted theory of regular satellites formation, the giant icy satellites were formed in subnebulae with low temperature and low pressure taking a long accretion time. Some models assert that their surfaces were kept too cold to induce significant differentiation during accretion. However, these satellites may capture a significant amount of subnebula gas, which possibly forms proto-atmospheres along with gases volatilized from icy components. Such a hybrid-type proto-atmosphere may have significant blanketing effect.

Here, we numerically analyze the structure and effect of a hybrid-type proto-atmosphere. Our model atmosphere is hydrostatically connected with subnebula at the satellite Hill radius. It contains H_2 and He as nebula gas components, H_2O and NH3 as volatilized ice components. The radiative-convective equilibrium structure is solved as a function of surface temperature. The subnebula conditions are given by Canup and Ward (2002), the temperatures are 150 K at Ganymede, 120 K at Callisto, and 50 K at Titan, and the corresponding subnebula pressures are varied over 0.1-10 Pa.

For all the boundary conditions, the proto-atmosphere is opaque due to water vapor, so that the outgoing thermal radiation (OTR) flux at top of the atmosphere is smaller than that of black body radiation without atmosphere when the surface temperature is higher than 273 K. When the surface temperature is lower, the OTR fluxes from the proto-atmospheres of Ganymede and Callisto are close to black-body radiation because these atmospheres have low surface pressure and are optically thin due to large scale height under high background temperature. On the other hand, the proto-atmosphere of Titan has another type of solution with the OTR fluxes significant lower than blackbody radiation under low surface temperature. This is due to the formation of optically thick atmosphere tightly bounded by gravity because of low background temperature.

These results imply that a warm proto-atmosphere near 200 K could be kept on Titan for a long time after the end of accretion. Our stability analysis suggests that the proto-atmospheres of Ganymede and Callisto were lost associated with the dissipation of the Jovian subnebula, but that of Titan survived after the dissipation of the Saturnian subnebula.

In the case, NH_3 vapor pressure would be kept high under the irradiation of the solar UV for a long time. The present atmospheric N_2 of Titan may be generated by photochemical reaction of NH_3 vapor in such a warm proto-atmosphere.

The difference of cloud formation process between Jupiter and Saturn.

TAKAHASHI, Yasuto[1*] ; HASHIMOTO, George[2] ; ISHIWATARI, Masaki[1] ; TAKAHASHI, Yoshiyuki[3] ; ONISHI, Masanori[3] ; KURAMOTO, Kiyoshi[1]

[1]Hokkaido Univ, [2]Okayama Univ, [3]Kobe Univ

Gas giant planets have hydrogen-rich, thick atmospheres, and their styles of cloud activities are thought to be closely related to the profile of radiative cooling rate in troposphere. For example, Recent studies indicate that it basically controls the intermittency of cumulonimbus clouds. In spite of its significance, however, no systematic estimate has been made for the radiative cooling profiles of gas giant planets.

Recently, we have developed a 1D radiative-convective equilibrium model for such hydrogen-rich atmospheres. The model atmosphere continues to a lower boundary where the optical depth from the top of atmosphere is sufficiently large and the thermal structure follows convective equilibrium. The atmospheric composition and potential temperature of each planet are given from observational constraints. The mixing ratios of H2O, CH4, NH3, H2S, PH3 and NH4SH follow their saturation vapor pressure in the altitudes where their condensation occurs. Collision induced absorption of H2-H2 and H2-He, and line absorption of H2O, CH4, NH3, H2S, PH3 are included while the extinction by condensates is neglected. Under these settings, our model can calculate a reasonable atmospheric vertical structure by the iteration of radiative transfer calculation and convective adjustment.

For the case of Jupiter, the peak of radiative cooling rate is 1.6e-7 K/sec at 0.7 bar level. Also, our model predicts the radiative-convective boundary i.e., tropopause to be located around 0.3-0.4 bar level, where is slightly higher than the uppermost NH3 condensation layer ˜0.5 bar. For the case of Saturn, the peak of radiative cooling rate is 3.5e-8 K/sec at 0.53 bar, and the separation of tropopause and NH3 cloud layer is larger than that of Jupiter. This implies that the Saturnian NH3 cloud formation is essentially confined in the troposphere, whereas the Jovian one is also affected by the stratospheric processes.

Figure description : Radiative heating rate profile (solid lines, bottom x axis, K/sec) and Volume mixing ratio of NH3 profile (dashed lines, top x axis, mole fraction). Y axis is pressure (bar). Shaded area represents between NH3 condensation level and tropopause level. Red means Jovian model, and blue means Saturnian model. Note that these results are calculated with the polytropic temperature profiles for preliminary calculation, not thermal equilibrium profiles.

The Galilean satellites (Io, Europa, Ganymede, and Callisto) are expected to be dark when eclipsed by the Jovian shadow. However, we have discovered that Ganymede and Callisto are still surprisingly bright at 1.5 μm even when not directly lit by sunlight, based on observations from the Hubble Space Telescope and the Subaru Telescope. Their eclipsed luminosity was one-millionth of their uneclipsed brightness (i.e. $\sim$50 μJy for Ganymede and $\sim$30 μJy for Callisto in eclipse), which is low enough that this phenomenon has been undiscovered until now. In contrast, Europa in eclipse was not detected ($<$5.5 μJy), a potential clue to the origin of the source of luminosity. Likewise, Ganymede was observed at 3.6 μm by the Spitzer Space Telescope but it was not detected either ($<$3.6 μJy), suggesting a significant wavelength dependence. Why are they luminous even when in the Jovian shadow? These facts may be consistent with sunlight scattered by dust in the Jovian upper atmosphere, and if this is the case, observations of Ganymede and Callisto while eclipsed by the Jovian shadow provide us with a new method to investigate Jupiter's atmospheric composition.

Simulated radiative forcing by molecules in Jupiter's stratosphere

KURODA, Takeshi[1*] ; MEDVEDEV, Alexander[2] ; HARTOGH, Paul[2]

[1]Tohoku Univ., [2]MPS

We present the radiative heating and cooling rates by molecules for Jupiter's upper troposphere and stratosphere (10^3 to 10^{-3} hPa) with a newly developed parameterization which is suitable for general circulation models. The scheme is a band model based on the correlated *k*-distribution approach, which accounts for the heating due to absorption of solar radiation by CH_4, and cooling in the infrared by C_2H_6, C_2H_2, CH_4 and collision-induced transitions of H_2-H_2 and H_2-He.

The band model achieved the accuracy of within 10% in comparison with the line-by-line calculations. We show the sensitivity of the heating/cooling rates due to variations of the mixing ratios of hydrocarbon molecules calculated with this scheme, in addition to the calculated radiative-convective equilibrium temperature which is in agreement with observations in the equatorial region. Our results suggest that the radiative forcing in the upper stratosphere is much stronger than it was thought before [Conrath et al., 1990]. In particular, the characteristic radiative relaxation time decreases exponentially with height from 10^8 s near the tropopause to 10^5 s in the upper stratosphere.

EXCEED EUV spectral images of Jupiter and Venus

YOSHIKAWA, Ichiro[1*] ; YOSHIOKA, Kazuo[2] ; MURAKAMI, Go[2] ; TSUCHIYA, Fuminori[3]

[1]University of Tokyo, [2]ISAS, [3]Tohoku University

An earth-orbiting Extreme Ultraviolet (EUV) spectroscopy is the first mission of the Small scientific satellite Platform for Rapid Investigation and Test -A (Sprint-A) conducted by ISAS/JAXA. A single science instrument (EXCEED) is boarded on Sprint-A. We have started to observe the solar planets in the EUV spectral range, and will extend to the identification of extrasolar planet atmosphere.

I will show the first light of the EXCEED and the next.

Occurrence characteristics of Saturn's short-term radio burst

MARUNO, Daichi[1] ; KASABA, Yasumasa[1*] ; KIMURA, Tomoki[2] ; MORIOKA, Akira[1] ; CECCONI, Baptiste[3]

[1]Tohoku Univ., [2]ISAS/JAXA, [3]Obs. Paris

Saturn kilometric radiation (SKR) is emitted from auroral electrons and suggested to be correlated with Saturn's auroral processes. We extracted northern SKR (N-SKR) and southern SKR (S-SKR) burst events, by newly defined selection criteria, with radio data observed by the Cassini Radio and Plasma Wave Science (RPWS) instrument in the period from day 250 of 2005 to day 200 of 2006. The data was separated into northern and southern components according to its circular polarization degree. As a result, 16 N-SKR burst events and 36 S-SKR burst events were identified in this period. Based on statistical studies of these events, we obtained the following results: (1) We derived typical frequency profiles of N- and S-SKR during SKR bursts to compare the intensity of N- and S-SKR bursts. The profiles show that the S-SKR burst was more intense than the N-SKR by 7 dB in the main frequency range. From the recent studies, the north-south asymmetry could be explained by the difference in solar illumination due to the tilted the magnetic and rotational axis. (2) By comparing onset timings of N- and S-SKR bursts, we found that 67 % of S-SKR burst events were accompanied by N-SKR bursts or burst-like enhancements. (3) To elucidate what determines the timing of SKR burst onsets, we compared the onset timing of N- and S-SKR bursts with each SKR phase of the periodic modulations. The result showed that the timing of SKR burst onsets generally depends on both the N- and S-SKR modulation phases. This suggests the existence of the internal control of SKR burst onsets. It is, however, noted that some SKR bursts occurred out of phases with SKR modulation phases. That indicates the timing of SKR bursts can also be determined by the external process, i.e., solar wind compressions. (4) We investigated the time evolutions of SKR intensities in the main frequency range and the low frequency range before and after SKR bursts. By comparing them with AKR intensity evolutions at AKR breakup, we found that they had two similarities: the enhancement of lower-altitude source regions prior to onsets and the formation of the distinct higher source regions. On the other hand, their timescales are quite different. In addition, this study pointed out that the two-step evolution scenario could not be directly applied to Saturn's case.

In conclusion, our study demonstrated the north-south asymmetry, the conjugacy and the dependence on the SKR periodic modulations of SKR bursts. These results would be helpful for understanding the auroral process at Saturn's magnetotail reconnections by elucidating the relationship between SKR bursts and reconnections. We consider the third result is particularly important because this suggests that both northern and southern periodicities would affect magnetotail reconnections.

Submillimeter-Wave Instrument (SWI) for JUICE: Current Status of the Instrumental Development

SAGAWA, Hideo[1*] ; KASAI, Yasuko[1] ; KIKUCHI, Kenichi[1] ; NISHIBORI, Toshiyuki[2] ; MANABE, Takeshi[3] ; OCHIAI, Satoshi[1] ; KURODA, Takeshi[4] ; SEKINE, Yasuhito[5] ; HARTOGH, Paul[6]

[1]National Institute of Information and Communications Technology (NICT), [2]Japan Aerospace Exploration Agency, [3]Osaka Prefecture University, [4]Tohoku University, [5]University of Tokyo, [6]Max Planck Institute for Solar System Research

The Submillimetre-Wave Instrument (SWI) is a passive submillimeter-wave heterodyne instrument proposed as one of the scientific payload instruments for the Jupiter Icy Moons Explorer (JUICE) mission. It measures the thermal emission from atmosphere of Jupiter and its moons at the frequency region of 500 - 600 GHz (with keeping 1200 GHz range as an optional concept). Thermal emission from the surface of moons will also be measured. JUICE/SWI provides unique observational data for characterization of the Jovian stratosphere such as thermal structure, dynamics, and distribution of minor species; and for exploration of tenuous-atmosphere and surface environment of the Jovian moons. By detecting hydrogen and oxygen isotopes in the water vapor of Jovian moons' atmosphere, SWI can also contribute to understanding the origin and distribution of water in our solar system.

This paper presents the current status of the development of SWI instrument, including the updates on the science targets and their feasibility studies. The SWI instrument is being developed through international cooperation. The Japanese team contributes to the development of the submillimeter reflector (mirror). The submillimeter reflector is one of the key components of SWI, and it determines the spatial resolution of observations. Currently a 30-cm aperture diameter reflector is considered, providing a spatial resolution of 2 mrad (FWHM) at 600 GHz. In order to fulfill the stringent requirement of weight reduction, we evaluated the material of the reflector and optimized its rib structure. The side lobe suppression is also an important factor to improve the quality of observations.

Development of JUICE/Ganymede Laser Altimeter (GALA)

NAMIKI, Noriyuki[1] ; KIMURA, Jun[2*] ; KOBAYASHI, Masanori[1] ; HUSSMANN, Hauke[3] ; LINGENAUBER, Kay[3] ; TEAM, Gala-japan[4]

[1]PERC/Chitech, [2]Earth-Life Science Institute, Tokyo institute of Technology, [3]DLR Institute of Planetary Research, [4]JUICE Japan Group

The overarching theme for JUICE is: The emergence of habitable worlds around gas giants, and the focus is to characterise the conditions that may have led to the emergence of habitable environments among the Jovian icy satellites, with special emphasis on the three oceanbearing worlds, Ganymede, Europa, and Callisto. JUICE will be launched in 2022, and will arrive at Jupiter in 2030. After several fly-bys to Europa and Callisto, JUICE will be inserted into an orbit around Ganymede in 2032 and will continue scientific observations for eight months until the end of nominal mission in 2033. Ganymede Laser Altimeter, GALA, measures distance between the spacecraft and the surface of the satellite from time of flight of a laser pulse. Together with positions of the spacecraft and mass center of the satellite, surface topography of the satellite is calculated from measured distances. The GALA data are particularly important for finding of internal ocean.

1) if the ocean exists beneath icy crust, tidal deformation of the satellite is so large that temporal variation of the topography as great as a few tens meter shall be detected.

2) small eccentricity of orbit of Ganymede causes libration that will be observed as lateral shifts of footprint of laser beam at the surface.

3) improved determination of spacecraft orbits by cross over analysis results in precise estimate of low degree harmonics of gravity field. Thus accurate Love number will be calculated to infer internal density structure of the satellite.

Global topographic data derived by GALA are also important for the study of tectonic history at the surface, elastic and viscous structure of ice crust, and thermal evolution of interior of the icy satellite. For example, linear structures such as ridges and grabens reveal extension stresses due to past variation of thermal states. As well, flat surface and thin crust may indicate partial melting of the crust and consequent internal lake. These observations on various geologic activities lead to understanding of transport of heat and materials from interior to the surface. Further, a comparison of styles of tectonics of ice crust and that of silicate lithosphere will likely shed a new light on the theory of plate tectonics of the Earth.

GALA is developed by international collaboration of scientists and engineers in Germany, Switzerland, and Japan. Its conceptual design is based on the laser altimeter on board of Mercury orbiter, BepiColombo, and consists of transceiver unit (TRU) with laser optics and appropriate electronics, electronic unit (ELU) with digital range finder module, digital processing module and power converter module, and laser electronic unit (LEU) with laser control electronics. Japanese team provides receiver telescope, backend optics, detector, and analogue electronics of TRU. The transmission optics of TRU and entire LEU are developed at DLR in Germany, and ELU is developed at Bern University in Switzerland. Assembly and integration are conducted at DLR under a supervision of the principal investigator of GALA. We therefore need to pay special caution on interfaces between analogue electronics and range finder, low-temperature environment, and radiation environment that Japanese space scientists have never experienced before.

Accretion of Solid Materials onto Circumplanetary Disks from Protoplanetary Disks

TANIGAWA, Takayuki[1*] ; MARUTA, Akito[2] ; MACHIDA, Masahiro[2]

[1]ILTS, Hokkaido University, [2]Kyushu University

We investigate accretion of solid materials onto circumplanetary disks from heliocentric orbits rotating in protoplanetary disks, which is a key process for the formation of regular satellite systems. In the late stage of gas-capturing phase of giant planet formation, the accreting gas from protoplanetary disks forms circumplanetary disks. Since the accretion flow toward the circumplanetary disks affects the particle motion through gas drag force, we use hydrodynamic simulation data for the gas drag term to calculate the motion of solid materials. We consider wide range of size for the solid particles (10^{-2}-10^{6}m), and find that the accretion efficiency of the solid particles peaks around 10m-sized particles because energy dissipation of drag with circumplanetary disk gas in this size regime is most effective. The efficiency for particles larger than 10m size becomes lower because gas drag becomes less effective. For particles smaller than 10m, the efficiency is lower because the particles are strongly coupled with the back-ground gas flow, which prevent particles from accretion. We also find that the distance from the planet where the particles are captured by the circumplanetary disks is in a narrow range and well described as a function of the particle size.

Hydrogen Isotope Ratio and Thickness of Martian Ground Ice: Implication from Multi-Water-Reservoir Model

KUROKAWA, Hiroyuki[1*] ; USUI, Tomohiro[2] ; DEMURA, Hirohide[3] ; SATO, Masahiko[4]

[1]Nagoya University, [2]Tokyo Institute of Technology, [3]University of Aizu, [4]Kyushu University

Martian surface ice is currently observed only as polar layered deposits (PLDs), whereas Mars Odyssey Gamma Ray Spectrometer (Boynton et al., 2002; Boynton et al., 2007) and Mars Express radar sounder observations (Mouginot et al., 2012) propose the presence of much larger amount of ground ice in the mid- to high-latitudes. The total volume of PLDs is 20-30 m in Global Equivalent Depth (Zuber et al., 1998; Plaut et al., 2007). Ground-ice region is expected to spread over a few tenths of percent of the total Martian surface, yet the thickness (i.e. volume) is poorly constrained (Mouginot et al., 2012).

The thickness of the ground ice is related to the evolution history of the Martian water reservoirs. After ancient oceans became extinct (˜4Ga), the oceanic water would become ”surface ice”, which currently occur as PLDs, and ”ground ice” which would extend from high latitude to mid- or low-latitude. Atmospheric escape of hydrogen and oxygen through the Martian history causes decrease of the amount of the ice. The signature of the evolution history is recorded by hydrogen isotope ratio (D/H). Martin atmosphere and soil have D/H ratio of ˜6 (relative to SMOW) (Owen et al., 1988; Webster et al., 2013), which is higher than the Martian primitive D/H ratio of ˜1.3 (Usui et al., 2012).

We constrain the hydrogen isotope ratio of surface ice and ground ice, and estimate the thickness of ground ice, using a multi-water-reservoir box model (see figure shown below). The model solves the evolution of water inventories and D/H ratio of atmosphere, surface ice, and ground ice during the ice age. Atmospheric escape and sublimation are considered as D/H fractionation processes. We adapt our model to the Matian ice age (4Ga to present). The initial D/H ratio is that of ancient ocean, which is informed by D/H data of the Martian meteorite ALH84001 formed at ˜4.1Ga (Lapen et al., 2010): D/H = 2.2-4.0 (relative to SMOW) (Boctor et al., 2003,Greenwood et al., 2008).

First, we show the results from two water-reservoir box model (ice and atmosphere). The ratio of atmospheric D/H and ice D/H is in a quasi-equilibrium state of the fractionation caused by atmospheric escape and sublimation. The ratio of the present Mars is mainly determined by the fractionation caused by sublimation.

Second, we show the results from four water-reservoir box model (surface ice, ground ice, high-latitude atmosphere, and mid- to high-latitude atmosphere). Assuming the atmospheric condition of the present Mars, the mixing of two atmospheric reservoir is inefficient in D/H exchange between surface ice and ground ice, which results in the independent growth of D/H ratio of the surface ice and the ground ice. To fractionate the D/H ratio of the surface ice and the ground ice into ˜6, the thickness of active ground ice which can exchange water with atmosphere is constrained. Thin active ice causes high deuterium concentration. The required thickness is a few hundred meters, which is distinctly large value compared to the thickness that HDO diffusion works (˜10 m in 1 Gyrs). Nature of this active ground ice might be partially melted ice suggested by recent observations of recurring slope lineae (McEwen et al., 2014), hydrated clathrates in underground cryosphere, or breathing porous permafrosts.

New evidence for plate tectonism on Mars: Accreted Terrains

DOHM, James[1*] ; MARUYAMA, Shigenori[1]

[1]Earth-Life Science Institute, Tokyo Institute of Technology

Reported evidence for plate tectonism has included spatial association among magnetic anomalies, large (thousands of kilometers long) structures, and highly degraded promontories interpreted to be andesitic domes, thrust faults, folds, structurally-controlled basins, large mountain ranges, and topographic and crustal-thickness-model signatures of structural control (including plate movement) within and along the margin of the northern plains. Significant evidence for an ancient phase of plate tectonism on Mars, newly identified, is accretionary complexes, informed through Earth analogs exquisitely detailed here in Japan. This finding represents a new frontier in the geologic investigation of Mars, bringing greater attention to pre-Tharsis (˜>4.0 Ga) terrains, which record Earth-like conditions. Pre-Tharsis, Earth-like conditions include an active dynamo and plate tectonism, as well as Habitable-Trinity conditions?an ocean, relatively thick atmosphere, and primordial crustal materials enriched in phosphorous, iron, among other elements important to life, all of which interact due to hydrological cycling driven by the Sun. Accreted terrains, which mark major crustal shortening through subduction of oceanic crustal materials and associated accumulation of andesites and granites, could comprise rock records on Mars dating back more than 4.2 Ga. Considering planetary evolution of Mars, largely informed through our understanding of the evolution of Earth, the accretionary complexes are likely to record environmental conditions during a time range of several hundred million years, which includes possible fossil life if initiated and evolved during the extremely ancient (>4.0 Ga) Habitable-Trinity conditions. A prime example of an extremely ancient accretionary complex is located to the west of Claritas rise, southwest margin of the Tharsis superplume. At the meeting we will present evidence of a Martian accretionary complex and discuss the implications of such a significant finding, including highlighting the next phase of geologic investigation of the evolution of Mars and its bearing on Astrobiology.

Environmental monitoring camera system for the Martian aerosols and water vapor for the Japanese Mars rover, MELOS

MANAGO, Naohiro[1*] ; NOGUCHI, Katsuyuki[2] ; OGOHARA, Kazunori[3] ; SUZUKI, Makoto[4] ; HASHIMOTO, George[5]

[1]Chiba University, [2]Nara Women's University, [3]University of Shiga Prefecture, [4]Japan Aerospace Exploration Agency, [5]Okayama University

We propose the environmental monitoring camera system of aerosols and water vapor in the Martian atmosphere for the Japanese Mars rover, MELOS. The meteorology and the climate of Mars are strongly controlled by the aerosols, which consists of dust and clouds in the Martian atmosphere, and the better understanding of the basic parameters such as optical depth, radius distribution and composition of the aerosols enables us to describe the effect on the Martian meteorology and climate quantitatively. The water vapor also affects the Martian meteorology and climate through the infrared radiation and the generation of clouds. The MELOS aims at the search for life, and it needs the basic knowledge of the meteorology and climate at the landing site for detailed discussion. Therefore we should conduct the measurements of aerosols and water vapor at the MELOS landing site simultaneously.

To satisfy the requirement of monitoring the aerosols and water vapor in the MELOS rover mission, we propose a three-CMOS-camera system, which consists of a direct sunlight camera, a scattering light camera and a high-resolution color camera. The direct sunlight camera has four wavelength band (340 or 450nm and 550nm for aerosols and 870 and 940nm for water vapor). The scattering light camera also has the same wavelength band, but it is directed at the neighborhood of the sun and at several points along the great circle including the sun and is utilized for aerosol measurements. The arrangement proposed here basically follows the previous Mars missions, e.g., Viking lander, Mars Pathfinder and Mars Exploration Rover. The high-resolution color camera obtains pseudo color pictures around the rover and is intended to support the navigation for the life search experiment.

[1]ISAS/JAXA, [2]STEL, Nagoya Univ., [3]Dept. Geophys., Grad. Sch. Sci., Tohoku Univ., [4]IRF, Sweden, [5]Toyama Pref. Univ., [6]Planet. Plasma Atmos. Res. Cent., Tohoku Univ., [7]Cosmosciences, Hokkaido Univ., [8]Rikkyo Univ., [9]Kanazawa Univ.

The atmospheric escape from Mars is considered to be closely associated with the evolution of the Martian atmosphere as well as the existence of the water on Mars. We are now investigating a project to study the global feature and the physical process of the atmospheric escape from Mars. It is expected to consist of at least two orbiters; one of the orbiters is aimed to make in-situ observation of plasma and thin atmosphere at about 100 km altitude, and the other is for the atmospheric imaging and solar-wind monitor. We are planning to make simultaneous observation of the atmospheric escape by the interaction with the solar wind by both of in-situ measurement orbiter and remote-sensing one. Now we are examining the quantitative measurement targets to fully understand the Martian atmospheric escape. At the same time, the sorts and performance of scientific instruments on these orbiters are examined. And furthermore, the preliminary spacecraft design, orbit design and mission plan to achieve the scientific goal are investigated.

Development of a dust imager for Mars landing mission

SATOH, Takehiko[1*] ; OGOHARA, Kazunori[2] ; HASHIMOTO, George[3] ; MIURA, Kazuhiko[4] ; MANO, Takaaki[5]

[1]Japan Aerospace Exploration Agency, [2]University of Shiga Prefecture, [3]Okayama University, [4]Tokyo University of Science, [5]National Institute for Materials Science

We report progress in developing a dust imager for future Mars landing missions. As Martian dust is a key element of its environment and a potential hazard for human exploration, it is essential to know what is Martian dust and how it works. However, little is known about the Martian dust due primarily to lack of measurements. Direct imaging would greatly increase our knowledge about the Martian dust (previously, an Atomic-Force Microscope onboard Phoenix acquired just one image).

The dust imager under development is not a microscope but a ”bare” imaging sensor of which pixels are fine pitched. After exposing the sensor to the air with dust for a while, we illuminate the sensor with a parallel beam so that shadows of particles on the sensor are directly imaged. In this way, the imager does not need a focusing mechanism and is expected to be very light-weighted and robust. Although the status is still the laboratory-experiment level, this small tool would greatly contribute to the Mars science and exploration.

Tech., [6]The University of Aizu, [7]Tokyo Institute of Technology, [8]JAXA, [9]Keio University, [10]Chiba Institute of Technology, [11]Osaka University, [12]The University of Tokyo

Past trial of direct detection of life on Mars by 1970's Viking mission reported a negative conclu-sion, whereas numbers of circumstances provided by recent Mars exploration missions in the last dec-ade indicate that there are good reasons to perform another life detection program.

Here we propose Life Detection Microscope that has much higher sensitivity than the instrument onboard Viking. Indeed Life Detection Microscope (LDM) that we propose here could detect less than 104 cells in 1 gram clay. Our life detecting instru-ment has the sensitivity that is three orders of mag-nitude higher than the one onboard Viking that issued the negative conclusion. LDM is capable of identifying what we think to be the most fundamen-tal features that a cell should possess to constitute life.

Our Investigation Goals are:

1: High-resolution characterization of regolith and dust particles.

2: Search for any type of organic compounds in Mars surface samples. The compounds include cells, other biological materials, and abiotic polycyclic aromatic hydrocarbon (PAH).

3: Identify cell-like structure in which organic compounds are enveloped by membrane, which may represent Martian life.

[1]University of Tokyo, [2]TiTech, [3]IRSPS, [4]National Institute of Polar Research, [5]ISAS, [6]Tokyo University of Pharmacy and Life Science

Mars explorations of past decades indicate that ancient Mars had environment somehow similar to that of Earth. Existence of large bodies of water, chemical building blocks of life, a wide range of oxidation states, and a magnetic field indicate that Mars would have been habitable. Recent studies of microbes in extreme environments show that some terrestrial microbes have possibilities for surviving and proliferating under the current martian environment, if these are placed in some specific conditions such as with sufficient shield from UV light (attained only at more than several centimeters below the surface) and with the existence of gradients of free energy. Such environmental conditions likely exist at some specific locations even the present Mars. For this reason, we are developing a new instrument called LDM (Life Detection Microscope), which is designed to detect less than 10^4 cells in 1 gram clay, orders of magnitude higher than previous attempts performed by Viking landers. To maximize the chances of the detection of organisms, the landing sites should be carefully selected in terms of the possibility of the existence of near-surface water, as well as recent geological activities and release of volatiles. Traces of possible liquid water flow have been reported at a number of locations including those recognized as the recurring slope lineae, seasonal flows on slopes of several craters, and anastomosing slope streaks. These are proposed to be the result of small and continuous seeps of subsurface brine water, which could persist for a longer period providing a habitable environment. In this talk, we examine the morphologic characteristics of these features and discuss their origins in the line of geological contexts for selecting appropriate landing sites for the LDM instrument.

Interannual analyses of the meridional distributions of Martian dust and clouds obtained by MRO-MCS

NOGUCHI, Katsuyuki[1*] ; IMAE, Kaori[1] ; KAWANISHI, Mai[1]

[1]Nara Women's University

We investigated the interannual variability of the meridional distributions of dust and clouds in the Martian atmosphere by using Mars Reconnaissance Orbiter Mars Climate Sounder (MRO-MCS) measurements. As the previous analyses did not consider measurement errors to depict the zonal averages, we took a criterion of 10% for the measurement error. Results show that Mars Year (MY) 29, which is regarded as a standard year in the previous analyses, had an enhancement of dust in the high altitudes (above 10 Pa) in the tropical region, and such an enhancement was not found in other MYs (28, 30 and 31). On the other hand, the distribution of ice clouds in MY 29 roughly agreed with other MYs' distribution.

Implementing Martian dust lifting scheme into DCPAM, and a diagnosis experiment of surface dust flux

OGIHARA, Hirotaka[1*] ; TAKAHASHI, Yoshiyuki O.[2] ; ISHIWATARI, Masaki[1] ; ODAKA, Masatsugu[1] ; HAYASHI, Yoshiyuki[3]

[1]Department of Cosmosciences, Graduate school of Science, Hokkaido University, [2]Graduate School of Science, Kobe University, [3]Department of Earth and Planetary Sciences, Graduate School of Science, Kobe University

The Martian dust cycle influences thermal states of its atmosphere, hence it plays an important role for determining states of the Martian atmosphere(Gierasch and Goody, 1968). Dust processes to be considered are dust lifting, turbulent mixing, advection, and gravitational sedimentation. Parameterizations of lifting by model resolved wind stress and by model unresolved vortices such as dust devils are considered. The Martian dust cycle has been simulated with general circulation models implemented above dust process schemes by some research groups. For example, Kahre et al.(2006) roughly simulated a seasonal variation of dust loading. The seasonal variation of dust loading has a peak in during northern autumn and winter. In contrast, DCPAM (Takahashi et al., 2012), which is a general circulation model developed by our group, has not been implemented above dust process schemes. Aims of this study are to implement dust process schemes into DCPAM, and to perform numerical experiments on the dust cycle with it. In the future, we will consider about interannual variability of the Martian dust distribution, which still has not been reproduced. In this work, we implement dust lifting scheme by model resolved wind stress into DCPAM. Addtionally, we perform an experiment with dust lifting to investigate behavior of this dust lifting scheme. And, we compare our model's results with thoses of Kahre et al.(2006).

The model utilized is DCPAM which is developed by GFD Dennou Club. DCPAM adopted three dimensions primitive equations. A radiative scheme by Takahashi et al.(2003, 2006) is used. This include the radiative effects of gaseous CO_2 and suspended dust. And, used suspended dust distribution is spatially and temporally fixed. A turbulent process is estimated by used vertical diffusivity based on Mellor and Yamada(1974). A surface process is estimated based on Louis et al.(1982). Each parameter are selected as Martian values. We use a surface distribution of thermal inertia, albedo and topography observed by Mars Grobal Surveyor. A horizontal discretization is the spectral method, and the trauncation wavenumber is 21. A vertical discretization is the finite difference method, and the number of layor is 32. We integrate 3 Mars year, and use the last 1 Mars year for analysis.

First, we implement a dust lifting scheme called by KMH scheme(Kahre et al., 2006) into DCPAM. Then, we perform a diagnosis experiment of surface dust flux with this. This result is similar to result by Kahre et al.(2006) as follows. In regions around latitude 50N degree and 30S degree, strongly dust lifting occurs during northern autumn and winter. At latitude 50N degree, it appears that eastward waves, which have zonal wavenumber 1 and period 6 Mars days, contribute to dust lifting. it is to be considered the baroclinic wave(Briggs et al., 1979). At latitude 30S degree, it appears that westward waves, which have zonal wavenumber 1 and period 1 Mars days, contribute to dust lifting. It is to be considered the diurnal thermal tidal wave(Joshi et al., 1979), and dust lifting tends to occur at 16 o'clock local time. These results qualitatively are consistent with these of Kahre et al. (2006), but are not quantitatively consistent with these of Kahre et al.(2006). For example, our model's surface dust flux is greater by a degree of magnitude then these of Kahre et al.(2006) in the northen polar cap. The reason is probably that the number of vertical levels and the method for estimating turbulent mixing are diffrent from those of Kahre et al.(2006). In this work, we implemented dust lifting scheme by model resolved wind into DCPAM. We are now implementing dust lifting scheme by dust devils into DCPAM. Then, we are going to implement advective scheme and gravitational sedimentation scheme into DCPAM in turn, and perform numerical experiments for their implementation test.

Assessment of Mars surface environment for MELOS1 lander using Planetary General circulation model DCPAM

ODAKA, Masatsugu[1*] ; SUGIYAMA, Ko-ichiro[2] ; TAKAHASHI, Yoshiyuki O.[3] ; NISHIZAWA, Seiya[4] ; HAYASHI, Yoshiyuki[5] ; HASHIMOTO, George[6]

[1]Department of Cosmosciences, Hokkaido University, [2]Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency, [3]Center for Planetary Science, [4]RIKEN Advanced Institute for Computational Science, [5]Department of Earth and Planetary Sciences, Graduate School of Science, Kobe University, [6]Department of Earth Sciences, Okayama University

1. Introduction

The Mars exploration program MELOS1, which is to mainly challenge life and surface environment exploration, is now planning by space engineering and planetary science community in Japan. To support designing the landing module and observation instruments and ensure safety experiments during entry, decent and landing phase, plausible range of meteorological conditions at MELOS1 landing site is required.

We try to assess the Mars surface environment from planetary to atmospheric boundary layer scale by using simulation results obtained by General Circulation Model (GCM), Regional Meteorological model, and Large Eddy Simulation (LES) model (LES). For mesoscale assessment, CReSS which is developed by HyArc Nagoya University will be used. For boundary layer scale, SCALE-LES which is developed by RIKEN AICS will be used as LES model. Both numerical model are now tuned to Mars and preliminary experiments are performed (Sugiyama et al. 2013; Nishizawa et al. 2013). For planetary scale assessment, we use a planetary atmospheric general circulation model DCPAM which is developed by GFD Dennou Club (Takahashi et al. 2012). In this study, we compare simulation results of DCPAM to observation results of Viking and Mars Path Finder (MPF) and investigate proper method for assessment of Mars surface environment by using DCPAM data. By using this method, we show some assessment results at proposed landing sites of MELOS1.

2. Data

DCPAM is a spectral GCM including physical processes appropriate for Martian atmosphere. The topography, surface albedo and thermal inertia in the model is based on observation results obtained by Mars Global Surveyor (MGS). The horizontal truncation wave number is 31, which corresponding horizontal resolution is about 200 km. The number of vertical layer is 16 and the height of lowest level is about 3 m. The seasonal variation of atmospheric dust distribution is given which is based on typical case of MGS observation. Numerical integration is performed for 7 Mars years with isothermal no motion initial condition. The data of last two years are used for analysis. The proposed landing sites are Newton Crater, Nili Fossae, and Isidis Planitia. The period of analysis is 90 sols from Ls = 331, 324, 14, and 135 which are corresponding to four mission window. In each period, diurnal variations every 15 sols are investigated.

3. Methods of analysis and results

In comparing the DCPAM results to observation results of Viking and MPF, the atmospheric temperature and wind velocity at observed altitude are estimated assuming the boundary layer similarity theory in neutral case is valid near the model surface. The surface pressure at actual altitude is estimated assuming hydrostatic balance with constant scale height which is calculated by the using model temperature. The comparison between estimated values from DCPAM results and observations show that the observed diurnal variation of atmospheric temperature is well reproduced by using 2nd level (about 12.5 m height) temperature of DCPAM, and seasonal variation of surface pressure is almost represented by using the scale hight corresponding to 10th level (about 1.35 km height) model temperature and subtracting offset value (60 Pa).

Based on above results, analysis of the DCPAM data at the three proposed landing site during four mission periods are performed. At Newton Crater, which is the first proposed site, during 90 sols from Ls = 331, the diurnal mean atmospheric temperature ranges from 190 to 220 K. The amplitude of diurnal change of atmospheric temperature is about 50 - 70 K. The air temperature is almost constant during this period and its value is about 140 K. The maximum values of direct and diffuse solar radiative flux are 480 Wm^{-2} and 40 Wm^{-2}, respectively. We will also estimate the extent of variation of meteorological variables, such as temperature and pressure, at the proposed landing sites by analyzing DCPAM data with different dust distribution.

Estimation of Martian atmospheric composition change caused by CO2 condensation and its application to radio occultation

IKEDA, Sayaka[1*] ; NOGUCHI, Katsuyuki[1] ; KURODA, Takeshi[2] ; PAETZOLD, Martin[3]

[1]Nara Women's University, [2]Tohoku University, [3]University of Cologne

We estimated the Martian atmospheric composition change caused by CO_2 condensation using the Ar measurements obtained by Gamma Ray Spectrometer (GRS) onboard the 2001 Mars Odyssey. We applied this estimation of the composition change to the rederivation of the radio occultation (RO) measurements of Mars Global Surveyor (MGS) obtained at polar latitudes of the winter hemisphere, because the MGS RO standard product which is available to the public did not consider the atmospheric composition change by CO_2 condensation. Using the rederived MGS RO measurements, we investigated the occurrence of CO_2 supersaturation in the Martian polar winter atmosphere and found that there were more supersaturation in the rederived data than in the original data.

Equation of state of $(Fe,Ni)_3S$ phase - Implications for Mars internal structure

AKAGI, Shunsuke[1] ; SAKAI, Takeshi[1*] ; HIRAO, Naohisa[2]

[1]Geodynamics Research Center, Ehime University, [2]Japan Synchrotron Radiation Research Institute

The existence of lower mantle ($MgSiO_3$-perovskite layer) has an important role on Mars thermal evolution. The layer thickness of Mars lower mantle depends on the depth of the core-mantle boundary (CMB). The depth of CMB is related to the Mars core density. Although the structure model of Mars core was discussed based on the equation of state of pure iron and FeS (e.g., Urakawa et al., 2004), Fe_3S phase and also the effect of nickel on the density should be considered.

We newly established the equation of state (EoS) of $(Fe_{0.89},Ni_{0.11})_3S$ up to about 40 GPa by high pressure experiment using diamond anvil cell. Considering EoSs of γ-Fe (Tsujino et al., 2013), γ-FeNi (Tsujino, 2012), Fe_3S (Seagle et al., 2006), and $(Fe_{0.89},Ni_{0.11})_3S$, the effects of nickel and sulfur on the density was determined. Then, we determined the Mars core density corresponding to the composition model based on SNC meteorites. Our new model shows relatively thin lower mantle compare to previous one. Moreover, if Mars core contains 16 wt.%S and 7 wt.%Ni (Sanloup et al., 1999) and if Mars has an entirely liquid core (Fei and Bertka, 2005), there is a possibility of disappearance of Mars lower mantle.

About drift, oscillations and steps of the center of mass of the Moon

BARKIN, Yury[1*] ; HANADA, Hideo[2]

[1]Sternberg Astronomical Institute, Moscow, Russia, [2]National Astronomical Observatory of Japan, Mizusawa, Japan

We have previously predicted and studied a step (abrupt) shift of the center of mass of the Earth in 1997 - 1998 years relatively to the mantle (Zotov, Barkin, Lubushin, 2009). In accordance with the basic provisions of the geodynamic model of excitation of planets and satellites shells (Barkin, 2002) we expected and we expect similar displacements of the centers of mass for other bodies in the solar system (for Mercury, Moon, Sun, Titan, Mars, etc.). Moreover, according to our hypothesis these abrupt geodynamic phenomena for solar system bodies are synchronous (Barkin, 2000) and, in particular, it should appear in 1997-1998. On the Earth, the similar jumps in 1997-1998 were observed in almost all planetary processes (Barkin, 2009). In the case of the Moon similar jump of center of mass obtains a confirmation in the data of laser observations and accounts for a specified period of time 1997-1998.

The jump (step) in the center of mass of the Moon in 1997 on data of laser ranging of reflectors on the lunar surface. On the basis of current laser measurements of distances to reflectors mounted on the Moon the preliminary estimates of the parameters of drift, oscillations and jump of the center of mass of the Moon were obtained. Their dynamic interpretation on the base of a geodynamic model of forced relative oscillations of the shells of planets and satellites has been done (Barkin, 2002). In the paper of G.A. Krasinskii (2003) from the analysis of lunar laser range measurements (or rather their residual differences compared with the theoretical celestial-mechanical design values of ranges) an abrupt (step) changes (in 1997 - 1998) in the coordinates of reflectors on the very substantial distances of about 15 -25 cm in selenographic coordinate system of the epoch have been discovered. Since jumps of coordinates for all four observed reflectors were quite close, it is natural to assume that the jump occurred in the position of the center of mass of the Moon by about 25-35 cm relatively to the lunar crust (in direction toward the Earth). Extremely important here is the fact that the jumps occurred in 1997-1998, as it was predicted by the theory of the unified geodynamic synchronous rhythms in variations of the activity of natural processes on the bodies of the solar system (Barkin, 2000). For the mean values of displacements of reflectors the following values were obtained (in meters): -0.15 +/- 0.04 m (offset along x coordnate - from the Earth), 0.23 +/- 0.07 m (offset on y - east), - 0.23 +/- 0.07 m (offset along z - to the north). Thus in 1997, the center of mass of the Moon abruptly shifted to a geographical point on the lunar surface with coordinates 40.0o N, 32.1o W approximately on distance in 0.36 +/- 0.11 m. According to the Krasinskii work (2003) we have identified trends in the changes of distances to reflectors and their abrupt changes before 1997 and after 1998, with rates of about 0.036 ns / year (before the jump) and at a rate of 0.128 ns / year (after the jump). If we consider only the drift relatively to the axis x, then estimates the drift velocities decrease: 0.98 cm / year - until 1997 and 1.47 cm / year - since 1998. It is expected to perform a spectral analysis of the residual differences of distances in order to identify their cyclic variations (with lunar months periods and with multiple periods).

Interpretation of unexplained secular changes of the lunar orbit

BARKIN, Yury[1*]

[1]Sternberg Astronomical Institute, Moscow, Russia

Unexplained secular effects in the orbital motion of the Moon are consequences of the observed phenomenon of remove of the center of mass of the Moon relatively to its mantle and crust toward the back-side. An explanation of anomalous part of secular variation in the longitude of the Moon and in the eccentricity of the lunar orbit has been obtained.

Unexplained secular variation of the eccentricity of the lunar orbit. In the works of James Williams and his colleagues showed that the observed rate of secular change of the eccentricity of the orbit of the Moon in 2.3x10 (-11) 1/year can not be explained within the framework of the classical model of the tides. Earth tides give only a fraction of the value specified in 1.3x10 (-11) 1/year and lunar tides result even effect with the opposite sign and give part of the acceleration in -0.6x10 (-11) 1/year. Remains unexplained an anomalous part of the secular change in the eccentricity (1.6 +/- 0.4) x10 (-11) 1/year. This value corresponds to abnormal changes in the distances to the perigee and apogee at 6 mm / year. ”Abnormal speed distances to the perigee and apogee of the lunar orbit is up to 6 mm / year and its cause is unknown” (Williams J.,2006).

Tidal acceleration and evolution of the Moon’s orbit. Laser ranging method proved to be very sensitive to the tidal acceleration of the Moon. Tides on the Earth dominate in the transfer of angular momentum, and energy in the orbital motion, in particular in the removal of the Moon from the Earth. Tidal effects on the Moon are separable from the effects of Earth tides in laser range measurements to the Moon (Chapront et al., 2002; Williams et al., 2009). Full tidal acceleration in the mean orbital longitude (due to the tides of the Earth and the Moon) is estimated at -25.85” 1/cy2, corresponding to the removal of the Moon from the Earth at a speed of 3.81 cm / year (Williams et al., 2009). The rate of secular variation of the eccentricity of the lunar orbit e = (9 +/- 3) x10 (-12) 1/year also detected on the basis of long laser observations over a period of 38.7 years (March 16, 1970 - November 22, 2008) (Williams, Boggs, 2009). The basis of dynamical studies makes a precision lunar ephemeris DE421, taking into account all of Newtonian and Einsteinian effects. The authors believe that the study of the evolution of the lunar orbit is an important and surprisingly difficult task. Lunar laser ranging provides the numerical values for the two sources of dissipation on the Earth and the Moon.

Possible secular drift of the center of mass of the Moon relative to its crust and mantle toward the back side and an explanation of the anomalies of the orbital motion. In this report we give some first estimations of the possible rate of the secular drift of the Moon center of mass with respect to its crust and mantle in the 10 - 15 mm / year toward the back-side of the satellite. This secular drift of the center of mass of the Moon should be considered by the studying of the orbital motion of the Moon on laser-based observations. Namely, to add to the value obtained by laser observations. The result will be an estimate of the secular increasing of semi-major axis is the center of mass of the Moon. It should be expected that this will obtain the interpretation and explanation of the unexplained part of the secular acceleration of the Moon orbit and the anomalous part of the secular variation of the eccentricity of the lunar orbit, identified according to the perennial laser observations of the Moon. An anomalous part of the orbital acceleration (unexplained) of the Moon is 0.7” / cy2, and the anomalous part of the secular variation of the eccentricity is characterized by rate in 1.23x10 (-11) 1/year (Williams et al., 2011). Found offset - drift of the center of mass of the Moon (12 - 15 mm / year) is explained by the mechanism of excitation and the relative displacements of the shells of the Moon (solid core, liquid core, mantle) (Barkin, 2002).

Deep interior structure of the Moon inferred from Apollo seismic data and the latest selenodetic data

MATSUMOTO, Koji[1*] ; YAMADA, Ryuhei[1] ; KIKUCHI, Fuyuhiko[1] ; KAMATA, Shunichi[2] ; IWATA, Takahiro[3] ; ISHIHARA, Yoshiaki[3] ; HANADA, Hideo[1] ; SASAKI, Sho[4]

[1]RISE Project Office, NAOJ, [2]University of California Santa Cruz, [3]JAXA, [4]Osaka University

Internal structure and composition of the Moon provide important clue and constraints on theories for how the Moon formed and evolved. The Apollo seismic network has contributed to the internal structure modeling. Efforts have been made to detect the lunar core from the noisy Apollo data (e.g., [1], [2]), but there is scant information about the structure below the deepest moonquakes at about 1000 km depth. On the other hand, there have been geodetic studies to infer the deep structure of the Moon. For example, LLR (Lunar Laser Ranging) data analyses detected a displacement of the lunar pole of rotation, indicating that dissipation is acting on the rotation arising from a fluid core [3]. Bayesian inversion using geodetic data weakly suggests a fluid core and partial melt in the lower mantle region [4]. Further improvements in determining the second-degree gravity coefficients and the Love numbers will help us to better constrain the lunar internal structure.

Recent analyses of GRAIL data have achieved the improved k_2 accuracy; JPL solution is 0.02405 ± 0.00018 [5], and GSFC solution is 0.02427 ± 0.00026 [6]. The two solutions are consistent with each other within their error bounds, and the accuracy of k_2 is now about 1 %. By introducing the improved gravity coefficients and k_2 from GRAIL mission, the updated LLR data analysis has also resulted in a better h_2 determination. Such accurately-determined Love numbers will contribute to constrain the structure of the lunar deep interior, such as the radius of the possible liquid core. It is difficult, however, to tightly constrain the internal structure from the geodetic data only because there are trade-offs among the structures of crust, mantle, and core. The combination of the Apollo seismic data and the geodetic data therefore afford the key to better determination of the lunar interior structure. We included geodetic data of the mass, the mean moment of inertia, the Love numbers h_2 and k_2, and 262 P and S travel time data in the analysis.

Markov Chain Monte Carlo (MCMC) method is used to infer the model parameters. When we used a five-layer model consisting of crust, upper-mantle, mid-mantle, lower-mantle, and core, the core radius is estimated to be 483 ± 22 km, and the core density values tend to be sampled around the assumed lower limit of 3600 kg/m^3. However, the inferred core radius is significantly larger than the magnetic constraint from SELENE data [7] which predicts the upper bound of the core radius to be 400 km. This discrepancy might be attributed to a possible low velocity layer above the core-mantle boundary which was not included in the five-layer model. We will discuss the results when such a low velocity layer is taken into account.

Observations of lunar rotation on the Moon: possibility and problems.

HANADA, Hideo[1*] ; TSURUTA, Seiitsu[1] ; ASARI, Kazuyoshi[1] ; CHIBA, Kouta[2] ; INABA, Kenta[2] ; FUNAZAKI, Ken-ichi[2] ; SATOH, Atsushi[2] ; TANIGUCHI, Hideo[2] ; KATO, Hiromasa[2] ; KIKUCHI, Mamoru[2] ; ARAKI, Hiroshi[1] ; NODA, Hirotomo[1] ; KASHIMA, Shingo[1]

[1]RISE Project, National Astronomical Observatory, [2]Faculty of Engineering, Iwate University

The lunar rotation is one of the essential and basic target of selenodetic observations for investigation of the interior of the Moon as well as those of gravity fields, and high accuracy of the observations have a potential to detect signals related to the structure of lunar deep interior including the core. We have developed a small telescope like a PZT (Photographic Zenith Tube) for observations of Lunar rotation with the target accuracy of 1 milli-seconds of arc (1 mas)[1]. Theoretical investigation shows that observations by the telescope in the polar area of the Moon will open great possibilities for determining the libration in inclination ρ and node Iσ with the accuracy much better than before, although the determination of the libration in longitude will not be very well. It also showed that the determination error in the libration angles will not exceed $\sqrt{2}\varepsilon$, where ε is the positioning error of stars and is regarded as 1 milli-seconds of arc [2].

There are several technical problems to be solved in the development of the telescope. Effect of large temperature change is one of the most serious problem for such a precise observation, and we can loosen thermal condition by about ten times by introducing a diffraction lens compared with the case not introducing it. It is possible, on the other hand, that the vibrations of the mercury surface caused by the ground vibrations lead to fluctuations of star positions on CCD as large as 1 second of arc judging from laboratory experiments. The amplitude of the fluctuations depend on the amplitude of the ground vibrations and the depth of mercury pool. We can reduce the effect of the vibrations by making the mercury pool shallow down to the minimum depth. In the case of the mercury pool of 64mm diameter, the depth of 0.5mm is the best according to our experience [3]. It is important to keep the proper period of the mercury pool away from the period of ground vibrations in order to avoid the resonance. It is also effective to lengthen the integration time, and it can improve the reliability of the mean value of the center of a star image by statistical procedure.

We have already made a bread board model (BBM) and we will observe the deflection of the vertical on the ground by using the BBM for the time being in order to evaluate the characteristics of the total system of the telescope.

THE EARTH ORIENTATION PARAMETERS AND THE VARIATION OF THE SECOND ZONAL HARMONIC OF THE GEOPOTENTIAL

BARKIN, Mikhail[1*] ; FILIPPOVA, Alexandra[1] ; NOVIKOVA, Daria[1] ; PEREPELKIN, Vadim[1]

[1]Moscow Aviation Institute, Moscow, Russia

The study of the time variations of the geopotential as a result of the rotary-oscillatory processes of the Earth motion is of a significant natural-sciences and practical interest. Oscillations of the Earth ′ s inertia tensor components depend on many factors, among them the mechanical and physical parameters of the planet, the motions of tide-forming bodies, and the observed large-scale phenomena in nature. Time-dependent variations of these and other factors (regular and irregular oscillations, stochastic fluctuations, secular variations) affect the Earth rotary-oscillatory processes and the rotational parameters of the planet. The dynamic processes of the Earth orientation parameters (EOP) in turn have an effect on its figure and lead to the fluctuations of the gravitation field. Observed variations of the EOP, the variations of the Earth ′ s gravitational field and oscillations in the large-scale geophysical events appear to be in a considerable correlation.

An amplitude-frequency analysis of the rotary-oscillatory Earth motion under the action of gravitational-tidal perturbing torques from the Sun and the Moon is carried out using the classical mechanics' methods. The simulation results of the oscillatory process in the motion of the Earth pole and the variations of the second zonal harmonic of the geopotential are studied. Based on the dynamic Euler-Liouville equations expressions for amplitude and phase of the Earth pole oscillations are obtained. A comparison of the spectral power densities of the time series between the Earth pole coordinates and the variations of the gepotential is carried out. A functional dependence of the aforementioned component of the geopotential from the amplitude and phase of the Earth ′ s pole oscillatory process is shown.

The free and forced librations of the Moon with liquid shell and solid core

BARKIN, Yury[1*] ; HANADA, Hideo[2] ; MATSUMOTO, Koji[2] ; BARKIN, Mikhail[3]

[1]Sternberg Astronomical Institute, Moscow, Russia, [2]National Astronomical Observatory of Japan, Mizusawa, Japan, [3]Moscow Aviation Institute, Moscow, Russia

In report we present our results of the study of lunar physical libration of the Moon on the base of its two and three layers models. On the base of analytical solution for two layers model (the Moon with liquid core) and empirical theory of the Moon ′ s rotation (Rambaux, Williams, 2011), we have identified period, amplitude, and the initial phase of the forth mode of free libration of the Moon, caused by liquid ellipsoidal core. Preliminary results of studies of three-layers model of physical librations of the Moon have been obtained on the base of some simplified approach for the problem of rotation of the Moon with liquid and rigid cores. The plans for future studies of the Moon rotation are discussed.

The modern view of internal structure of the Moon planet takes into account a complex two- or three-layer model. In our work the analytical theory of lunar physical libration based on its two-layer model consisting of a non- spherical solid mantle and of the ellipsoidal liquid core has been developed. The Moon moves on high-accurate perturbed orbit in the gravitational field of the Earth and other celestial bodies. On the base of two layers model of the Moon we have fulfilled systematic studies of the Moon physical librations. And in first we have presented a solution of the problem in components of vector of angular velocity of the Moon. An analytical presentation of LOD of the Moon with high accuracy in form of trigonometric series has here the progressive value. In first we have determined the fourth mode of free libration of the Moon caused by the influence of the liquid core oscillations of pole axis of rotation of the Moon (its mantle), with a long period in 205.7 yr, with an amplitude of 0 ″ 0395 and the initial phase of -134 ^{0} (for the initial epoch 2000.0). This oscillation reflects the so-called phenomenon of free oscillation of the liquid core. The estimates for the dynamic (meridional) oblatenesses of the ellipsoidal liquid core of the Moon: 0.000442 and 0.000283 have been obtained. These fundamental parameters of geodynamics of the Moon could be determined only on the base of data of observations. Earlier the attempts to determine the period of free core nutation undertaken. Our results were obtained by comparing of the developed analytical theory of lunar physical libration with empirical theory libration of the Moon, constructed on the basis of laser observations in last about 40 years (Rambaux, Williams, 2011).

Preliminary results of studies of three-layers model of physical librations of the Moon have been obtained on the base of some simplified approach for the problem of rotation of the Moon with liquid and rigid cores. We have analyzed the Cassini ′ s motion of the decoupled solid core and its librations in longitude to compare with the Moon motions. On the base of Getino, Ferrandiz et al. approach we give estimations of the periods of free librations of this system. We have constructed differential equations of rotational motion of three layers Moon from positions of the Hamiltonian formalism with application of Andoyer ′ s and Poincare ′ s variables. Now we construct analytical theory of rotation of the Moon system consisting from the non-spherical mantle, ellipsoidal liquid core and solid core.

Viscosity structure dependence of large-scale polar wander rate of the Earth: A potential impact of a low-viscosity zone

HARADA, Yuji[1*] ; XIAO, Long[1]

[1]China University of Geosciences

In this study, we make an attempt to quantitatively evaluate an effect of presence of a low-viscosity layer inside the mantle of the Earth on the timescale of its polar wander. In particular, we perform model calculation of the viscoelastic Love number which characterizes the mechanical response of the interior of the Earth, and then investigate how the timescales and strengths of some relaxation modes in the Love number depend on the viscosity structure. I compare the structure dependence of these relaxation modes with that of the polar wander speed. For the sake of convenience of this numerical calculation, we simplify the multilayered structure of the Earth and assume its incompressibility to compute the relaxation modes.

In this calculation, we apply the quasi-fluid approximation which makes it possible to integrate the polar motion equation as a non-linear one. Its reason is because the linear approximation is not allowed for the large-scale polar wander as dealt with in here. Following the applicable condition of the quasi-fluid approximation, we consider load history which timescale is slower than the characteristic one of the viscoelastic deformation of the asthenosphere.

As a result of the calculation mentioned above, we find that the timescale of the polar wander depends almost only on the longest relaxation mode. It is a remarkable point here that, in fact, the ratio of the strength of this relaxation mode governing the polar wander to the total viscoelastic Love number is not so large. In other words, this fact means that the other modes which amplitudes of tidal deformation are more dominant have almost no effect with respect to the timescale of the polar wander. Apparently, this might seem to be a peculiar result.

The reason for this dependence is because the timescale only of the above-mentioned longest mode is much longer by a few orders of magnitude compared to those of the other modes. A mode with a longer time constant of viscous relaxation has an effect which stabilizes rotation axis in a longer term even if its strength is smaller. Oppositely, a mode with a shorter time constant contributes less to the long-term rotational stability because of its faster relaxation even if its strength is larger.

In the light of this result, we can tell that the structure dependence of the true polar wander rate also basically reflects just that of the relaxation time of this longest mode. Actually, even assuming the internal structure without the low-viscosity layer inside the mantle, we still find the influence of this mode to be prominent. Once we take the existence of the low-viscosity layer into account, lower its viscosity is, shorter the timescale of the longest mode is. It can be less than forty percent at shortest. However, if this viscosity becomes lower than a certain value, the timescale of this mode is asymptotic to a constant value. Such a trend results from that this layer behaves as a fluid rather than a viscoelastic body in a sufficiently long timescale due to its too low viscosity.

Here we conclude from the calculation result shown above that the presence of the low-viscosity layer inside the Earth generally shortens the timescale of the large-scale polar wander, and also that this impact mainly stems from the variation in the timescale of the longest relaxation mode. Indeed, the preexisting works have already discussed the dependence of the timescale of the large-scale polar wander on the internal structure of the Earth as well. However, they have not examined the impact of the low-viscosity layer therein, considering a more simplified viscosity structure. Also, they have not clearly stated that the major controlling factor on the true polar wander speed. On the contrary, this work estimates the timescale of the polar wander with explicitly including the impact of this layer, and shows the non-negligible effect of the heterogeneous viscosity structure on the large-scale polar wander.

Effects of global geodynamics in a series of astrometry observations of latitude at Poltava

KHALYAVINA, Lydmila[1] ; BARKIN, Yury[2*]

[1]Gravimetry Observatory, Poltava, Ukraine, [2]Sternberg Astronomical Institute, Moscow, Russia

Diverse geodynamic phenomena observed in the modern era, received a convincing explanation in the framework of the northern drift of Earth's core. Model proposed and developed by Yuri Barkin relative to the set of ancient geodynamic processes: the secular drift of the Earth's pole, non-tidal acceleration of the Earth's rotation, secular change of gravity, the evolution of the earth's figure, plate tectonics, the formation of specific geological structures, etc.

The North drift of the core generates mass redistribution of the Earth and leads to changes in the gravitational field. Since astrometry instruments have as a reference axis direction of the local plumb line, then this process should be displayed in the slow position changes no polar zenith Observatory. It is shown that for locations in the northern hemisphere, the north drift of the core causes the displacement of local plumb in a southerly direction. Is the picture of long-term changes in the direction of gravity (NST) in the meridian of Poltava for the period 1962 - 2013 based on long-term observations of latitude prismatic astrolabe taking into account: 1) high-precision catalogs (HIPPARCOS, ARIHIP, Tycho-2), 2) improved model of the pole C01 IERS; 3) the theory of the precession-nutation IAU2000; 4) plate tectonics (NUVEL1A-NNR). The resulting long-period changes in NST can be represented as the sum of three components: a linear trend with velocity ~-0.0003 ″ /yr, the nonlinear part of the trend, consisting of two branches (descending - in 1962 to 1996. And rising - in 1998 and 2010.), which can be regarded as a fragment of a wave with period T~50 years and amplitude A~0.02 ″ ; quasi cyclic part with 11 - year period, close to the main period of index of solar activity period and amplitude <0.01 ″ .

The linear part of the translational displacement means the plumb line to the south of Poltava, which is consistent with the above Barkin ′ s model. The observed velocity of motion of zenith corresponds to moving the center of mass of the Earth in a northerly direction at the velocity in 1.4 cm/yr. Found that the nonlinear part of the trend and the 11-year cyclicity in the shifts of plummet quite clearly reproduce the form of low-frequency polar latitude variations at Poltava derived from model C01 (EOP IERS). Actually observed amplitude of long-period oscillations of latitude caused by pole motion, in 2 times higher than the calculated amplitude. The non-linear part of the trend is the projection on the Poltava meridian of the Markowitz wave.

It is shown that both low-frequency cycles are negatively correlated with the corresponding components of the index of solar activity. The most probable mechanism of solar activity influence on the motion of the pole is the North Atlantic Oscillation. An increase in the amplitude of low-frequency polar displacements of Poltava zenith in astrometric observations requires a special study. One from possible explanations - the influence of the features of the geological structure in the vicinity of Poltava, which is located in the center of the so-called rift Poltava site.

Minerals detection on Mars from Mars Reconnaissance Orbiter (MRO) CRISM data

JIN, Shuanggen[1] ; BARKIN, Yury[2*]

[1]Shanghai Astronomical Observatory, Chinese Academy of Science, [2]Sternberg Astronomical Institute, Moscow State Uniersity

Martian mineral detection and mapping can provide important information and constraints on Martian aqueous history, which can be used to assess the potential habitability of Mars. Degrees of addressing the key question for Martian aqueous alteration are dictated by the depth and extent of grasping the Martian hydrous mineral. Therefore, it is important to know detailed minerals and chemical induction of the existence of water on the Martian surface at past or present. In-situ observations of the Martian rovers, such as Spirit, Opportunity and Curiosity have provided the mineralogical analysis of Martian surface, but restricting in a limited areas. Compact Reconnaissance Imaging Spectrometer for Mars (CRISM) aboard the Mars Reconnaissance Orbiter (MRO) with enhanced spectral resolution can provide more information at spatial and time scale. In this paper, CRISM near-infrared spectral data are used to identify mineral classes and distribution at Martian Gale region, including kaolinite, chlorites, smectite, jarosite, northupite and salts. The detection of northupite that is indicative of evaporation in Gale region suggests that the Gale region has experienced the climate change from moist condition with mineral dissolution to dryer climate with water evaporation.

The solidification of a magma ocean of Vesta

KAWABATA, Yusuke[1*] ; NAGAHARA, Hiroko[1]

[1]Earth and Planetary Science, The University of Tokyo

Asteroid 4 Vesta is the only preserved intact example of a large, differentiated protoplanet. Observations of surface spectra of Vesta provide convincing evidence for a differentiated interior. Vesta is considered as the parent body of HED meteorites.

Whether growing mineral grains remain suspended in the magma ocean or settled out is crucial for the primary interior structure of a planet.

The purpose of this study is to understand the role of grain size of crystals on solidification of a magma ocean under a turbulent flow. We select asteroid 4 Vesta as a subject of this study due to the presence of HED chondrites as a reference. In this study, we consider the solidification before the rheological transition occurs.

We assume that the interior structure of Vesta had already differentiated to form a core. We use the bulk silicate Vesta composition proposed by Righter and Drake (1998), which is a mixture of L and CV chondrites with the ratio of 7 to 3 adjusted for core separation. We calculate liquidus, solidus and solid fractions using the MELTs program (Ghiorso and Sack 1995; Asimow and Ghiorso 1998).In vigorously convective systems such as magma oceans, the temperature distribution is nearly adiabatic and isentropic (Solomatov, 2000).

The heat flux can be calculated with the help of the blackbody radiation. This heat flux must match the heat flux transported to the surface by convection. Convection changes to a regime sometimes called hard turbulence at very high Rayleigh number such as those in the magma ocean, of which heat flux is shown by Siggia (1994).

To describe the rate at which particles settle out of a turbulently convective fluid, we use the model by Martin & Nokes (1989).The particle number is calculated by

$dN/dt=N(-g\triangle\rho a^2)/(18\rho\nu h)$

where N is the particle number, g is the acceleration due to gravity, a is the diameter of the particle, $\triangle\rho$ is the density difference between the crystal and the magma, ν is the kinematic viscosity, and h is the depth of the fluid layer (Martin & Nokes, 1989).

The adiabat, liquidus and solidus of the magma ocean of Vesta are very steep, that is, they have negligibly small dependence on pressure.

Thermodynamic calculations with the MELTs program showed that olivine is the first liquidus phase at ˜1900K, followed by orthopyroxene and spinel. At the very late stage, clinopyroxene appears consuming orthopyroxene if chemical equilibrium is maintained.

The fluid dynamic evaluation shows that a very small fraction of crystals are separated from the magma ocean until the rheological transition which varied from 100um to 1cm in the current work. The thickness increases with time, which is shown in Figure.

Evaluation of fluid dynamic regime shows that the magma ocean on Vesta was at the hard turbulence regime, suggesting near equilibrium crystallization until the rheological transition takes place at the crystal fraction of 60% at 1649K.

The role of grain size on fluid dynamics is very small, but the amount of crystals settled down to the bottom of the magma ocean has small dependence on the grain size. If the crystal size is 1cm, 1km thickness bottom layer is formed.

The fluid dynamic regime changes into soft turbulence in 100 years in the order in the magma ocean of Vesta.

The summary of our conclusion is as follows.

(1)The pressure effect in the interior of Vesta is negligibly small.
(2)The solidification of a magma ocean of Vesta before the rheological transition follows batch solidification.
(3)The size of crystallizing grains has a minor effect on the evolution of magma ocean until the rheological transition.
(4)The mantle would be harzburgite if the interstitial melt was effectively extracted at the later soft turbulence stage.

Thermal evolution simulation of Vesta including convection and melt migration

NOGAMI, Tatsuhiko[1*] ; SIRONO, Sin-iti[2]

[1]Division of Earth and Planetary Sciences, Graduate School of Science, Nagoya University, [2]Division of Earth and Planetary Sciences, Graduate School of Science, Nagoya University

Vesta has been regarded as the parent body of the HED meteorites. From the observation of DAWN spacecraft, the uppermost layer of Vesta is composed of howardite and its thickness ranges from 50km to 80km (Jutzi et al. 2013). It is known that the ratio of the number of eucrites to diogenites is around two. Based on these facts, rapidly cooled magma layer on Vesta should be more than 10km in thickness.

In this work, I studied the evolution of internal thermal evolution of Vesta due to heating of decay of 26Al. I calculated the temperature distribution by solving numerically heat conduction equation. According to Formisano et al.(2013), if Vesta completed its formation within 1.4Ma from the injections of 26Al into the solar nebula, the degree of silicate melting inside Vesta exceeds 50 vol%. But in that work, convection and melt migration were not taken into account. These two mechanisms contribute to cool down Vesta. It is expected that the formation of Vesta should be completed earlier if these effects are taken into account. On the other hand, it is known that it takes about a few million years for Vesta-size planet to complete its formation according to the standard model of planetary formation.

As a convection model, I adopted the model of Kaula (1979). It was assumed that generated melt migrates to the surface instantaneously, and the migrating melt to the surface was accounted as the rapidly cooled magma. There are two parameters in this study, including a (the percentage of melt migration) and t0 (formation time of Vesta), and perform simulation taking into account the convection and melt migration.

As a result, convection and melt migration substantially change the evolution of internal thermal structure, and total volume of magma considerably depends on a and t0. The magma volume increases as a increases. On the other hand, the magma volume decreases as t0 increases.

When t0=0, corresponding to no decay of 26Al at the beginning, and if $a>0.3$, the erupting magma layer of 10km in thickness is formed. When a=1, corresponding to total melt migration, the magma layer of 10km is formed if $t0<0.9$Ma. According to these results, Vesta should be completed its formation within 0.9Ma after CAI formation, and more than 30% of generated melt should migrate the surface. But total generated melt migration is not reasonable . If $a<1$, Vesta has to be formed earlier than a=1.

Therefore, it is suggested that the formation time of Vesta should be earlier than the estimate by Formisano et al.(2013), and rapid formation mechanism of 100km sized objects is needed.

Thermal conductivity measurements of sintered glass beads and application to planetesimal thermal evolution

TSUDA, Shoko[1] ; SAKATANI, Naoya[2*] ; OGAWA, Kazunori[3] ; TANAKA, Satoshi[3] ; ARAKAWA, Masahiko[4] ; HONDA, Rie[5]

[1]University of Tokyo, [2]The Graduate University for Advanced Studies, [3]Institute of Space and Astronautical Science, [4]Kobe University, [5]Kochi University

In the planetary formation process, dusts in the early solar nebula would have formed into planetesimals. Planets and asteroids have been formed by collisions of planetesimals. To constrain planetesimal ' s formation process and internal structure is an important issue. Especially, thermal evolution of planetesimal is key phenomenon for this purpose, and thermal conductivity of the planetesimal constituents is an essential parameter for understanding the thermal evolution.

As planetesimals are treated as dust aggregates, they would experience sintering when their temperature increases as a result of thermal evolution. The sintering makes neighbor particles bonded. The thermal conductivity of powered materials before sintering has been researched recently. However, thermal conductivity of sintered dust has not been measured under vacuum. Once dusts undergo the sintering, contact faces, so-called neck, are formed between dusts. The sintering causes growth of the neck and decrease of the porosity. It is thought that these changes make thermal conductivity higher than not-sintered dusts.

Based on our previous measurements of the thermal conductivity of glass beads, a positive correlation between thermal conductivity and compressional stress (thus, the inter-particle contact area) was observed with sample porosity remaining constant. Therefore, the thermal conductivity should be expressed as a function of not only porosity but also contact area between the particles.

This study aims at investigating thermal conductivity of the sintered materials under vacuum condition, in order to estimate effect of the sintering on thermal evolution of planetesimals. Especially, we focus on the dependence of neck size on the thermal conductivity.

We used three sizes of glass beads (250, 500, and 1000 μm) as analogous samples of dusts. For respective glass beads, we made three sintered samples with different degrees of sintering, or different neck size, in order to investigate the neck size dependence of the thermal conductivity. To measure the neck size, the sintered particles were separated and the neck crack size was observed using optical microscope. The thermal conductivity was measured by line heat source method under vacuum.

As a result of these experiments, we confirmed that the neck sizes of the nine samples had different ratio of neck size to beads radius, whose average values were ranged from 0.075 to 0.30. The thermal conductivity was ranged from 0.036 to 0.25 W/mK. These values were more than 10 times higher than that of not-sintered glass beads. Combining the results of neck size and thermal conductivity measurements, it was found that the thermal conductivity is proportionally related to the neck size ratio independent of the particle size. In these experiments, the porosity was constant about 40%. Therefore, when we calculate thermal evolution of planetesimals under sintering, the thermal conductivity should be estimated from the neck size at least until the neck size ratio grows up to 0.3 (initial stage of sintering).

Finally, we calculated the thermal evolution of the planetesimal using the relation of the thermal conductivity and the neck ratio we found in this experiment. Hypothesized planetesimals have radius between 100 m and 1000 m, formation age between 1 Myr and 3 Myr after CAI formation, and dust diameter of 1 and 1000 μm. As a result of the calculation, it was found that the sintering and resulting increase of the thermal conductivity make internal peak temperature more than 1000 K lower than the case when the sintering effect is not included in the calculation. In addition, internal temperature structure and neck size (or material strength) distribution in the planetesimals vary widely depending on the size and formation age of the planetesimals and particle size of dust.

The effect of melt on frictional behavior and the implication for deep moonquake

AZUMA, Shintaro[1*] ; KATAYAMA, Ikuo[1]

[1]Department of Earth and Planetary Systems Science, Hiroshima University

Apollo program (Passive Seismic Experiment) investigated a number of seismic events in moon (e.g., Nakamura 2003). These seismic events (moonquakes) are classified to four categories; thermal moonquake, shallow moonquake, impact moonquake and deep moonquake (Latham et al., 1969). In kinds of moonquake, deep moonquake is especially interesting because the occurrence depth of deep moonquake (700?1200 km) is obviously in plastic deformation region where frictional behavior and fracture does not occur. Analysis of PSE (Passive Seismic Experiment) data and modelling in previous studies suggest that the partial melt layer underlies near the occurrence depth of deep moonquake (Weber et al., 2011). Therefore partial melt possibly is one of important factor on the deep moonquake. Here we show the results of frictional experiments using a borneol?diphenylamine which can be adjusted in melt fraction and dihedral angle (Takei 2000). When dihedral angle is 30o, frictional coefficient becomes small with decrease of melt fraction. Although frictional coefficient is significantly decreased when dihedral angle is 0o, frictional coefficient does not depend on melt fraction. When dihedral angle of partial melt is 0o, frictional behavior is fully dominated by partial melt. Partial melt is considered to have the three effects on the shear strength. First, our frictional experiments found that partial melt decrease frictional coefficient. Second, partial melt behave as the pore pressure. Third, partial melt extracts the water from the surrounded rocks, and induces the shear localization (the stress concentration). Considering these effects of partial melt on frictional behavior, partial melt might be one of important factors on deep moonquake.

Velocity scaling of granular convection and its application to timescale of regolith migration

YAMADA, Tomoya[1*] ; KATSURAGI, Hiroaki[1]

[1]Graduate School of Environmental Studies, Nagoya University

On the basis of accurate surface observation of asteroid Itokawa, it has been thought that regolith migration and sorting could occur [1]. Besides, Nagao et al. revealed that cosmic-ray exposure age of Itokawa's surface grains is less than 8 Myr [2]. As a possible explanation for such active and young surface of Itokawa, regolith convection caused by impact-induced seismic shaking has been considered [1]. Indeed, granular convection can be readily observed in the laboratory experiment of vertically vibrated granular matter (e.g. [3]). However, the quantitative feasibility of granular convection under the microgravity environment has not been studied well so far. Although the direct control of gravity is quite difficult, we instead employ the scaling approach to figure out the gravity dependence of granular convective velocity. Specifically, we measure the granular convective velocity under various experimental conditions. Then, using the systematically obtained data, we find a scaling relation among the convective velocity, gravitational acceleration, and other control parameters such as vibration frequency, grain size, and so on. We also estimate the timescale of regolith migration due to the granular convection by using the obtained scaling.

The grains used in this experiment are glass beads of diameter d = 0.4, 0.8, or 2 mm (AS-ONE corp. BZ04, BZ08, BZ2). The experimental setup consists of a cylinder made by plexiglass of its height 150 mm and inner radius R = 16.5, 37.5, or 75 mm. The cylindrical cell is filled by glass beads to make a granular bed of the height H = 20, 50, 80, or 110 mm. The system is mounted on an electromechanical vibrator (EMIC 513-B/A) and shaken vertically. The vibration frequency f is varied from 100 to 300 Hz and the maximum dimensionless acceleration is varied from 2 to 6. Motions of glass beads on the sidewall of the container are captured by a high-speed camera (Photoron SA-5) with a macro lens. PIV (Particle imaging velocimetry) method is used to compute the vertical component of the convective velocity, v_z. The maximum value of the velocity is nondimensionalized as $v_{zmax}/(gd)^{1/2}$, where g is the gravitational acceleration. Using the obtained experimental data, we scale $v_{zmax}/(gd)^{1/2}$ by the shaking parameter S [4] and the dimensionless system size L. S represents the energy balance between vibration and gravity, $S=(2\pi Af)^2/gd$, where A is shaking amplitude. L is the scaled system size defined by $L=(RH)^{1/2}/d$.

As a result of systematic dimensional analysis, we obtain a scaling form, $v_{zmax}/(gd)^{1/2} \sim S^{0.47}L^{0.82}$. From this scaling form, we find that the granular convective velocity v_{zmax} depends on the gravitational acceleration g as $v_{zmax} \propto g^{0.97}$ when the maximum dimensionless acceleration is fixed. This means that the granular convective velocity is almost proportional to the gravitational acceleration. We also find that the timescale of regolith migration due to the granular convection is almost independent of its roll size, by assuming that L is the dimensionless convective roll size. In the presentation, we are going to discuss the consistency between the regolith migration timescale and cosmic-ray exposure age of Itokawa's surface grains.

Experimental study on impact-induced seismic wave propagating in granular materials

MATSUMOTO, Eri[1] ; YASUI, Minami[2*] ; ARAKAWA, Masahiko[1]

[1]Graduate school of Science, Kobe University, [2]Organization of Advanced Science and Technology, Kobe University

Introduction:

A seismic wave survey is a direct method to investigate the sub-surface structures of solid bodies, so we measured and analyzed these seismic waves propagated through these interiors. Earthquake and Moonquake are the only two phenomena that have been observed to explore these interiors until now, while the future surveys on the other bodies, (solid planets and/or asteroids) are now planned. To complete the seismic wave survey during the mission period, the artificial method that activates the seismic wave is necessary and the one candidate for the artificial one is a projectile collision on the target body. However, to utilize the artificial seismic wave generated on the target body, the relationship between the impact energy and the amplitude and the decay process of the seismic wave should be examined. If these relationships are clarified, we can estimate the required sensitivity of seismometers installed on the target body and the distance from the seismic origin measurable for the seismometer. Furthermore, if we can estimate the impact energy from the observed seismic wave, it is expected to estimate the impact flux of impactors collided on the target body. In this study, we carried out impact experiments in the laboratory, observed the seismic waves by accelerometers, and examined the effects of projectile properties on the amplitude and the decay process of the seismic wave.

Experimental methods:

We did impact experiments by using the one-stage gas gun at Kobe University. The projectile was a polycarbonate cylinder with the diameter of 10 mm and the height of 10 mm, and a stainless and an alumina ball with the diameter of 3 mm. The stainless and the alumina balls was accelerated with the sabot made by polyethylene. The impact velocity was $\sim$100 m/s. The target was prepared by putting 200 μm glass beads into the container with the diameter of 300 mm and the height of 100 mm, up to 80 mm depth. Three accelerometers (response frequency $<$10 kHz) were set on the target surface at different distances from the impact point. The observed seismic waves were recorded as voltage on the data logger (A/D conversion efficiency 100 kHz).

Experimental results:

We calculated the propagation velocity of seismic wave by using the traveling time from the impact point to the site of accelerometer and the impact velocity, and obtained 105 $\pm$ 15 m/s. Additionally, the relationship between the maximum acceleration, g_{max}, and the normalized distance, x/R (x: distance from impact point, R: crater radius), was determined as g_{max} =268$(x/R)^{-2.8}$. From these results, it is found that the seismic wave attenuates with similar waveform on the same target, irrespective of projectile type. The duration keeping the maximum acceleration was estimated to be $\sim$0.3 ms, and this value was almost consistent with the penetration time of projectile estimated by using the model proposed by Niimi *et al.* (2011). McGarr *et al.* (1969) studied the energy conversion efficiency from impact energy to seismic momentum and obtained the ratio of the impulse of projectile during the penetration, I, to the kinetic energy of projectile, E_k. As a result of this study, the I/E_k was obtained to be $1.6 \times 10^{-2} \pm 1.0 \times 10^{-2}$. On the other hand, McGarr *et al.* (1969), which the lexan projectile collided on the sand target with the impact velocity of 2-8 km/s, was obtained to be $6 \times 10^{-6} \pm 4 \times 10^{-6}$. This difference might be caused by the dependence of impact velocity on the energy conversion efficiency.

Velocity measurements of impact jetting during oblique impacts

KUROSAWA, Kosuke[1*] ; NAGAOKA, Yoichi[1] ; HASEGAWA, Sunao[2] ; SUGITA, Seiji[3] ; MATSUI, Takafumi[1]

[1]PERC, Chitech, [2]ISAS, JAXA, [3]Dept. of Complexity Sci. & Eng., The Univ. of Tokyo

Impact jetting is a widely-known phenomenon in both hypervelocity impact experiments and hydrocode calculations. There are two important features in impact jetting, which are (1) extremely high velocity greater than the impact velocity and (2) the high degree of shock heating. Jetting has been considered as a mechanism for the origin of chondrules, tektites and impact glasses, Pluto, and the Moon. Jetting during a symmetric collision between two thin plates has been well studied. However, the understanding of jetting for spherical impactors is essential for planetary applications and it has not been obtained. One of the reasons for this is the lack of the experimental data of hypervelocity jetting of obliquely-impacted spherical projectiles. Although the temperature of jetted vapor has been investigated under a wide range of experimental conditions, only 3 data points, including unpublished data, have been reported as the jet velocity, which is one of the important anchors for developing a jetting model.

In this study, we conducted a series of oblique impact experiments using spherical projectiles and 3 different targets and investigated the jet velocity as a function of impact velocity and target materials. The frame rate of a high-speed imaging was 100 ns/frame to resolve the jetting initiation during projectile penetration. We found that the velocity ratio of the jet velocity to the impact velocity increases as the shock impedance of target increases at a given impact velocity and decreases with as impact velocity increases.

We obtained the first systematic data set for the jet velocity of spherical projectiles during oblique impacts. Using the data set, we constructed a physical model to explain the observed jet velocities. We found that (1) a classical phenomenological model constructed by Ang (1990) predicts well observed jet velocities if we use the vertical component of impact velocity instead of impact velocity in his model and that (2) observed jet velocities can be obtained by the sum of the horizontal component, the deformation velocity of the shocked projectile, and the particle velocity after isentropic release. The latter model may provide a physical basis of the jet formation

Both the standard and our physical model predict the jet velocity during oblique impacts reaches 2.5 times than the impact velocity. Although the mass of jetted materials must be small for energy conservation, the aerodynamic interaction between such hypervelocity jet and an ambient atmosphere may be significant because the heating rate of aerodynamic ablation is proportional to the cube of the velocity. In the case for an oblique impact on Titan, the jet velocity may reach 30 km/s in the case of typical cometary impacts and may generate strong EUV radiation from produced high-temperature plasma in the N2CH4 atmosphere via aerodynamic interaction near the surface of Titan. Active chemical reactions of C-bearing species may be driven by the produced EUV. The available energy source near the current Titan surface is only cosmic rays. Thus, hypervelocity jetting may be a new energy source for atmospheric chemistry on Titan.

The stability of amino acids in early ocean by meteorite impacts: Implication for chemical evolution of biomolecules

UMEDA, Yuhei[1*] ; SEKINE, Toshimori[1] ; FURUKAWA, Yoshihiro[2] ; KAKEGAWA, Takeshi[2] ; KOBAYASHI, Takamichi[3]

[1]Graduate School of Science, Hiroshima University, [2]Graduate School of Science, Tohoku University, [3]National Institute for Materials Science

Prebiotic oceans may have contained abundant amino acids, and were subject to meteorite impacts, especially during the late heavy bombardment. It has been unknown how meteorite impacts affected such dissolved amino acids in the early oceans. Experiments in the present study were performed using aqueous solutions containing olivine or hematite powders and ^{13}C-labeled glycine and alanine. In particular, the reaction products from ^{13}C-labeled amino acids are expected to compose ^{13}C, distinguishing if they are contaminants or not. Two powders of olivine and hematite help to keep the oxygen fugacity low and high during experiments, respectively in order to investigate the effect of oxygen fugacity on chemical reaction of amino acids. The run product of selected amino acids and amines in samples were analyzed with liquid chromatography-mass spectrometry (LC/MS). Some experiments were carried out in the presence of ammonia and/or benzene. The results revealed that amino acids survived partially or reacted out in early ocean through meteorite impacts. It was found that glycine changes into alanine and large amounts of methylamine and ethylamine are formed. Amine formation from alanine was increased considerably in the presence of Fe_2O_3 rather than olivine under similar impact conditions. XRD for the recovered hematite powders indicated the presence of a small amount of magnetite, suggesting that the oxygen fugacity was kept high enough to be close to the Fe_2O_3-Fe_3O_4 buffer. The formation of n-butylamine, detected as the largest number of carbon species in the recovered samples from the solutions with ammonia and benzene, suggests that chemical reactions to form new biomolecules can proceed through marine impacts. These results suggest that amino acids in early oceans can proceed further by impact-induced reactions, implying that impact energy plays a role in the prebiotic formation of various biomolecules, although the reactions depend upon the chemical environments as well.

Organic aerosol experiments for CH_4/CO_2 atmospheres using a hydrogen/helium UV lamp

HONG, Peng[1*] ; SEKINE, Yasuhito[1] ; SUGITA, Seiji[1]

[1]Complexity Sci. & Eng., Univ. of Tokyo

Organic aerosols are photochemically produced in CH_4-rich reducing atmospheres, but their production mechanisms are not well constrained. Organic aerosol layers are believed to influence the surface temperature of early Earth, through its anti-greenhouse (Pavlov et al., 2001) and/or indirect greenhouse effects (Wolf and Toon, 2010), however, because of the uncertainty of the aerosol production mechanism, there are large uncertainties inherent in previous estimates of the aerosol production rate and optical depth of aerosol layers (Trainer et al., 2006). In order to put a constraint to the production mechanism and obtain aerosol production rate applicable to CH_4/CO_2 atmospheres, we conducted laboratory experiments to form organic aerosol analogues using a hydrogen/helium lamp that simulates solar far UV (FUV) with wavelengths longer than 110 nm. We measured the aerosol production rate as functions of UV flux and of CH_4/CO_2 ratio in the reactant gas. The aerosol production rates were determined by ellipsometrically measuring the growth rates of thin organic films deposited on a substrate. The UV fluxes from the hydrogen/helium lamp were measured by N_2O/CO_2 actinometry. Our experimental results show that the aerosol production rate is not a second-order function but a linear function of UV flux. This leads to a lower estimate for aerosol production rate due to FUV irradiation, when extrapolating the production rate in Titan's atmosphere to early Earth and exoplanets. We also found that the aerosol production exhibits a steep decrease when the CH_4/CO_2 ratio becomes less than unity. In order to interpret the dependence of aerosol production rate on the CH_4/CO_2 ratio, we also performed one-box photochemical calculations, including 791 reactions and 134 species up to C_8 hydrocarbons. The one-box photochemical model was validated against some basic carbon species (CH_4, C_2H_2, C_2H_4, C_2H_6, CO, CO_2), in which the abundances of those species calculated with the model and observed with a quadruple mass spectrometer (QMS) show a good agreement. We found that the observed production rate is in a good agreement with polymerization reaction rates involving aromatic hydrocarbons (i.e., benzene), suggesting benzene is the key parent molecule controlling the aerosol production. On the other hand, polymerization reactions involving polyynes do not account for the experimental data, suggesting that they are not the limiting molecules. This implies that aerosol production rate in an early Earth atmosphere due to solar FUV would become significantly lower than a previous estimate which includes polymerizations of polyynes as formation reactions of aerosols (Pavlov et al., 2001), resulting in an optically thinner aerosol layer by a factor of 100. Thus the optical depth of organic aerosol layers produced by solar FUV in an early Earth atmosphere would not have had efficient anti-greenhouse effect or indirect greenhouse effect, which makes other greenhouse effect important for the Archean climate, such as greenhouse effect of ethane. We will also discuss the possibility of aerosol formation through nitrile reactions driven by high-energy particle irradiation, which could be more efficient than the aerosol production due to solar FUV.

Proto-atmosphere on giant icy satellites forming within gaseous circum-planetary disks

MIKAMI, Takashi[1*] ; KURAMOTO, Kiyoshi[1]

[1]Department of Cosmosciences, Graduate School of Science, Hokkaido University

In spite of the great similarity in size and mean density, the giant icy satellites Ganymede, Callisto, and Titan have very different surface environments. In particular, only Titan holds a thick atmosphere dominated by N_2. Recent data of the Cassini spacecraft indicated that atmospheric N_2 is probably originated from other nitrogen-bearing species like NH_3. However, it still remains an open question when and how N_2 was generated. This is partly because the physical states of giant icy satellites have been poorly understood.

According to a widely-accepted theory of regular satellites formation, the giant icy satellites were formed in subnebulae with low temperature and low pressure taking a long accretion time. Some models assert that their surfaces were kept too cold to induce significant differentiation during accretion. However, these satellites may capture a significant amount of subnebula gas, which possibly forms proto-atmospheres along with gases volatilized from icy components. Such a hybrid-type proto-atmosphere may have significant blanketing effect.

Here, we numerically analyze the structure and effect of a hybrid-type proto-atmosphere. Our model atmosphere is hydrostatically connected with subnebula at the satellite Hill radius. It contains H_2 and He as nebula gas components, H_2O and NH_3 as volatilized ice components. The radiative-convective equilibrium structure is solved as a function of surface temperature. The subnebula conditions are given by Canup and Ward (2002), the temperatures are 150 K at Ganymede, 120 K at Callisto, and 50 K at Titan, and the corresponding subnebula pressures are varied over 0.1-10 Pa.

For all the boundary conditions, the proto-atmosphere is opaque due to water vapor, so that the outgoing thermal radiation (OTR) flux at top of the atmosphere is smaller than that of black body radiation without atmosphere when the surface temperature is higher than 273 K. When the surface temperature is lower, the OTR fluxes from the proto-atmospheres of Ganymede and Callisto are close to black-body radiation because these atmospheres have low surface pressure and are optically thin due to large scale height under high background temperature. On the other hand, the proto-atmosphere of Titan has another type of solution with the OTR fluxes significant lower than blackbody radiation under low surface temperature. This is due to the formation of optically thick atmosphere tightly bounded by gravity because of low background temperature.

These results imply that a warm proto-atmosphere near 200 K could be kept on Titan for a long time after the end of accretion. Our stability analysis suggests that the proto-atmospheres of Ganymede and Callisto were lost associated with the dissipation of the Jovian subnebula, but that of Titan survived after the dissipation of the Saturnian subnebula.

In the case, NH_3 vapor pressure would be kept high under the irradiation of the solar UV for a long time. The present atmospheric N_2 of Titan may be generated by photochemical reaction of NH_3 vapor in such a warm proto-atmosphere.

Atmospheric formation and thermal evolution of a proto-Mars growing in the solar nebula

SAITO, Hiroaki[1*] ; KURAMOTO, Kiyoshi[1]

[1]Cosmo Sci., Hokkaido Univ

It is widely accepted that Mars is a survivor of proto-planets formed by oligarchic growth i.e., the runaway accretion of planetesimals. Numerous planetesimals impacts onto the growing proto-Mars likely cause shock-melting, resulting into the early core formation as constrained by the chronology of Martian meteorites. Such impacts should also induce the degassing of H_2O and other molecular species from accreting materials, which contributes to atmosphere formation. Since the oligarchic growth proceeds within the solar nebula, a growing Mars probably acquired a proto-atmosphere consisting of the mixture of nebula gas component and degassed component. Such a hybrid-type proto-atmosphere may play important role in thermal balance and volatile partitioning between the planetary surface and interior. However, the structure and behavior of such atmosphere has been poorly investigated so far.

In this study, we build a one-dimensional radiative-convective (RT) equilibrium model for a hybrid-type proto-atmosphere assuming a compositional double layer structure. Here the upper layer is dominated by H_2-He continuing from the solar nebula and the lower one is dominated by degassed components enriched in H_2O. Radiative transfer is modeled, taking into account the absorptions by H_2, He and H_2O. RT equilibrium structures are obtained as a function of thermal luminosity that would be balanced with accretional heating rate and the amount of degassed component. The degassed component consists of H_2O and H_2 with molar ratio 1:5 in equilibrium with metal and silicate. The accretion time is taken 10^6-10^7 years.

For the pure H_2-He atmosphere, the surface temperature is kept lower than 700 K. Supply of degassed component increases the surface temperature that can exceed 1500 K given the mass of degassed component more than 1% of the Mars mass. If planetesimals contain enough proportions of H_2O and other heavy volatiles, growing Mars would have global magma ocean sustained by the blanketing effect of proto-atmosphere. This would promote core formation and transport of dissolved volatiles.

Line-by-line calculations of radiation properties for exoplanets with steam atmosphere

ONISHI, Masanori[1*] ; HASHIMOTO, George[2] ; KURAMOTO, Kiyoshi[3] ; TAKAHASHI, Yoshiyuki O.[1] ; TAKAHASHI, Yasuto[3] ; ISHIWATARI, Masaki[3] ; HAYASHI, Yoshi-yuki[1]

[1]Department of Earth and Planetary Sciences, Kobe University, [2]Department of Earth Sciecnes, Okayama University, [3]Department of Cosmosciences, Graduate School of Science, Hokkaido University

For a hot water rich atmosphere, there is an upper limit on the thermal emission that is unrelated to surface temperature (Simpson, 1927, Nakajima et al., 1992). The radiation limit is deeply related to evolution of planetary atmosphere. Hamano et al., 2013 showed that terrestrial planets can be divided into two distinct types on the basis of their evolutionary history during solidification from the initially hot molten state depending on whether incoming flux from a host star is larger or less than the radiation limit. On the other hand, the first direct image of an exoplanet has finally occurred in 2004 (Chauvin et al., 2004), it is expected to observe radiation spectrum from terrestrial planets near future. If we can observe the spectrum, we have potential to clarify the atmospheric and surface environment and history of the planets. In order to estimate the planetary environment from the observation, numerical simulation of radiative transfer is needed. The most reliable calculation method of the radiation is line-by-line treatment. Goldblatt et al., 2013 calculates the radiative transfer of a pure water atmosphere by line-by-line treatment. Goldblatt et al., 2013 investigates only one case of surface water amount, one current ocean mass case. In this study, we calculate the radiative transfer in steam atmosphere by line-by-line treatment in several surface water amount cases.

Absorption cross section of water vapor was calculated from HITEMP2010 (Rothman et al., 2010) and MT_CKD continuum model (Mlawer et al., 2012). We used a 1D convective model in pure water atmosphere. The surface temperature was varied from 250 to 2000 K. The total water amount of water was varied from 0.01 to 5 current Earth ocean mass (270 bar). For rapid calculation, we prepared absorption cross section table and calculated required absorption cross section by cubic spline interpolation. A two-stream approximation (Toon et al., 1989) was used to calculate radiative transfer by line-by-line treatment with resolution of 0.01 cm^{-1} wavelength.

A radiation limit of our study is 282 W m^{-2}. The value is good agreement with that of Goldblatt et al., 2013. When the total water amount is lesser, increasing of outgoing thermal flux over radiation limit occurs in lower surface temperature conditions. In 0.01 current ocean mass condition, increasing of flux occurs in lower than 1000 K. In this case, most of flux radiate from 10 micron and 4 micron window region. Results of optical depth calculation indicate that we can't detect NIR and IR radiation from the surface of planets with surface temperature higher than 1500 K, even if the planet has 0.01 water amount.

Dependence of the runaway threshold on water distributions on the surface of Earth-like planets

NITTA, Akira[1*] ; ABE, Yutaka[1] ; O'ISHI, Ryouta[2] ; ABE-OUCHI, Ayako[2]

[1]Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo, [2]Atmosphere and Ocean Research Institute, University of Tokyo

Liquid water is one of the most important material not only for its large effect on planetary climate but also as a controlling factor of the habitability [e.g. Kasting et al., 1993]. Water planets, which are planets with liquid water on their surface, can be divided in 3 types: 'ocean planets', 'partial-ocean planets', and 'land planets'. Ocean planets have enough water to cover their surface entirely. Partial-ocean planets, which are like the Earth, have an interconnected ocean and lands. Land planets have little water in scattered lakes around both Poles [Abe et al., 2013, Hawaii, Kona]. The type of the water planet is determined by the balance between the surface water transport, which depends on the amount of water and topography, and the atmospheric water transport, which depends on the global circulation.

Surface water on each water planet is unstable and entirely vaporized when the planet receives insolation above a certain critical value. It is because of the positive feedback of the greenhouse effect of water vapor. This phenomenon is called the runaway greenhouse. In the following, the critical insolation is called 'runaway threshold' [e.g. Abe and Kasting 1988; Nakajima et al, 1992; Kopparapu et al., 2011].

Abe et al. [2011] discussed the difference of the runaway threshold between Earth-sized ocean planets and land planets using a 3-D model for the first time. They found that the surface water of land planet is significantly stable than that of ocean planet against the large insolation. While an ocean planet gets unstable and the runaway greenhouse occurs when the insolation reaches about 130% of that on the present Earth, a land planet remains stable until the insolation reaches 170%. However, a land planet that they represented is only one of the various situations of land planets, and they didn't mention the effect of variety of surface water distributions on the planetary climate.

Takao [2013] showed the dependence of the runaway threshold on latitudinal surface water distribution using the combination of meridional energy balance model (EBM) and the vertical radiative-convective equilibrium model. He suggested that runaway threshold of the Earth-sized water planet varies with the degree of latitudinal localization of surface water. Nevertheless, his 1-D EBM was so simple that he could neither discuss about the effects of longitudinal distribution of surface water, nor include dynamical global circulation.

In this study, we perform numerical experiments to clarify the effects of the surface water distribution on runaway threshold of Earth-sized planets with a 3-D model, GCM.

We use CCSR/NIES AGCM 5.4g [Numaguchi, 1999], which includes dynamical atmospheric circulation, radiative transfer, formation of clouds, and so on. While this model is adapted to the present Earth, it cannot calculate the change of surface water distribution determined by the water amount and topography. Therefore, we assumed the surface water distribution, which is determined as a result of the balance between the surface and atmospheric water transport in reality, and used it as the boundary condition. Then, we raised the insolation gradually until the surface water got unstable for each surface distribution, and evaluated the runaway threshold.

We found that the degree of localization of surface water significantly affects the runaway threshold, and it varies from 180% (extremely localized land planet) to 130% (ocean planet) continuously. Even if no surface water is given low latitudes area initially, because the Hadley circulation transports water to such area, when the initial surface water area reaches adequately low latitudes, the runaway threshold is almost the same as that of ocean planets, that is, 130%. We also investigated the dependence on the longitudinal water distribution. As a result, even if the total area of surface water is the same, there are about 10% of differences in the runaway threshold depending on its distribution.

Dead zones by electric heating in protoplanetary disks

MORI, Shoji[1*] ; OKUZUMI, Satoshi[1]

[1]Tokyo Institute of Technology

Turbulence driven by magnetorotational instability (MRI) is a viable mechanism of angular momentum transport in accretion disks. In protoplanetary disks, however, there is a region where the ionization degree is too low for MRI to be active (e.g., Gammie 1996; Sano et al. 2000). Whether turbulence is present or not strongly affects the growth of dust particles to planetesimals. Therefore, a good knowledge of the size of dead zones is essential to understanding planet formation.

In this study, we focus on the heating of electrons by turbulent electric fields and its effect on the ionization state of protoplanetary disks. Previous studies have assumed that electrons in the disks have the same temperature as the neutral gas. However, this is not necessarily the case in MRI-driven turbulence, in which turbulent electric fields can significantly heat up electrons (Inutsuka & Sano 2005). Heated electrons efficiently adsorb onto dust grains, and therefore electron heating leads to a reduction of the ionization degree (Okuzumi & Inutsuka, in prep.). This could effectively increase the dead zone size by reducing the saturation level of MRI turbulence outside the conventional dead zone.

The aim of this study is to show where in protoplanetary disks the effect mentioned above becomes important. We calculate the ionization degree of disks assuming that MRI operates outside the dead zone. For a minimum-mass solar nebula with the dust grain radius of 0.1um and dust-to-gas mass ratio of 0.01, we find that the effect becomes significant in a region extending from the outer edge of the dead zone (at ˜20 AU from the central star) out to 70 AU. Furthermore, our analytic estimate suggests that the saturation level of turbulence in this region is significantly low.

Collisional disruption of sintered dust aggregates

SIRONO, Sin-iti[1*] ; UENO, Haruta[1]

[1]Graduate School of Environmental Sciences, Nagoya University

Planets are formed in a protoplanetary nebula consisting of gas and dust grains. The first step of planetary formation is coagulation of dust grains, leading to the formation of dust aggregates. Further growth of the dust aggregates is promoted by mutual collisions between them. The motion of dust aggregates gradually decouples from that of the gas as aggregates grow. Dust aggregates drift inward due to gas drag. If the inward drift is faster than aggregate growth, solid components in a protoplanetary nebula disappears and planets cannot be formed. To prevent infalling, many mechanisms have been proposed (Kretke & Lin 2007, Lyla et al.2009, Sandor et al.2011). Fast collisional growth during the infalling of icy dust aggregates (Okuzumi et al. 2012) is another possibility. These studies are based on the assumption that the motion of aggregates decouples from gas. The infalling velocity is on the order of 1m/s when substantial decoupling is attained. Aggregates should grow to the sizes corresponding to the infalling velocity. Is it possible?

Experimentally, collisional breakup velocity of micron-sized SiO2 dust aggregates is on the order of 1m/s(Blum 2010). Breakup velocity for H_2O ice aggregates is also on the same order(Shimaki & Arakawa 2012). However, it is difficult to produce highly porous dust aggregates experimentally due to the Earth's gravity. I conducted two-dimensional numerical simulation of sintered dust aggregates in this study. It has been pointed out that sintering of H_2O ice proceeds in wide region of a protoplanetary nebula (Sirono 2013). As sintering proceeds, a neck between adjacent grains grows and mechanical interactions between grains greatly change. The effects of sintering are taken into account by changing breaking forces of a contact. The interactions between non-sintered contacts (Dominik & Tielens 1997) are adopted for newly formed contacts.

If sinterng proceeds sufficiently such that a neck is disappeared, catastrophic disruption was observed at low collision velocities (˜10cm/s). This is because a contact is broken by rolling of a grain. On the other hand, catastrophic disruption at low collision velocities was not realized for less-sintered aggregates. This is due to immediate reconnection between grains with a non-sintered mode. These results depends on the tensile strength of H_2O ice. The breakup velocity increases as the strength increases. From the results obtained in this study, the evolution of icy dust aggregates is various, depending on the location in a protoplanetary nebula.

Planetesimal size and protoplanetary disk turbulence

KOBAYASHI, Hiroshi[1*] ; TANAKA, Hidekazu[2] ; OKUZUMI, Satoshi[3]

[1]Nagoya University, [2]Institute of Low Temperature Science, Hokkaido University, [3]Tokyo Institute of Technology

When the random velocities of bodies are greater than their surface escape velocities, the runaway growth of bodies occurs, which produces a single large bodies surrounded by leftover bodies in each annual of a protoplanetary disk. The slope of the size distribution of bodies becomes steeper through runaway growth. The slope of runaway growth is seen in the size distribution of 100km sized or larger bodies in the main belt. Since the random velocities rises by turbulent stirring in the disk, the planetesimal size above which runaway growth occurs is determined by the strength of turbulence. We discuss turbulence strength in the solar nebula.

The formation of gas planets from cores in type I migration

MAESHIMA, Naohiko[1*] ; WATANABE, Sei-ichiro[1]

[1]Division of Earth and Planetary Sciences, Graduate School of Science, Nagoya University

Many gas planets have been discovered. The formation of the gas planets requires that solid planets, which correspond to cores of gas planets, must achieve the critical core mass M_{crit} before the disk gas have entirely diffused. The cores moves radialy by torques caused by interaction with disk gas (type I migration). It was long thought that the cores fall into the star with very short timescale before achieveing M_{crit} by strong negative torque (Ward 1997, Tanaka et al. 2002). Recent study have showed that the region where positive torque operates is formed on the disk by corotation torque if we consider the non-isothermal process of the gas (Baruteau & Masset 2008,Paardekooper & Papaloizou 2008). As a result, equilibrium radii, where torque is zero, are created. The cores may accrete gas without falling into the star if they are trapped by equilibrium radius because the timescale of radial migration slows down to that of disk evolution. However, positive torque only operates for cores in limited mass range ($M_{p,min}<M_p<M_{p,max}$). If it takes long time for achieving $M_{p,min}$, the cores moves inward largely by negative torque. In this study, we examine how the orbit and mass of cores evolve depending on the disk model, and find the condition the disk must have for the gas planet formation.

The distribution of the gas surface density evolves by viscous diffusion and photoevaporation. The temperature distribution is determined by viscous heating and stellar irradiation. In the disk, an equilibrium radius is formed on the region where the main heating source shifts from the viscous heating to stellar irradiation. In this study, we investigate the possibility of the formation of gas planets at the equilibrium raidus. Cores grow by accreting planetesimals in their gravitational radius, and capture the disk gas if they achieve M_{crit}.

We find that the condition of gas planet formation is determined as follows. In diks evolving fast (α parameter of viscosity = 0.005), cores born in the middle region ($\sim$ 10AU) is captured by the equilibrium radius and capture the disk gas by achieving M_{crit} if core growth stars at the time when disk mass is still large (initial mass accretion rate $\sim 10^{-7} M\odot yr^{-1}$) and the ingredient of the cores is abundant (ratio of the solid material to gas is large $>$0.03). On the other hand, in the disks evolving slowly (α = 0.001), gas planets can be formed even if core growth stars at the stage when disk mass has been decreased (initial mass accretion rate $\sim 10^{-8} M\odot yr^{-1}$). In this case, the dependence on the ratio of the solid to gas is very weak.

Protoplanet Spin by Planetesimal Accretion

SHIBATA, Takashi[1*] ; KOKUBO, Eiichiro[2]

[1]University of Tokyo, [2]National Astronomical Observatory of Japan

In the standard scenario of planet formation, protoplanets or planetary embryos are formed through runaway and oligarchic growth of planetesimals. We investigate the spin parameters of protoplanets using N-body simulations. By N-body simulations we can calculate consistently the orbital, accretionary, and spin evolution of planetesimals. The spin of protoplanets are important for terrestrial planet formation since it affects the accretion condition of protoplanets and determines the spin of terrestrial planets. For the standard model of a planetesimal disk, a Mars-sized protoplanet forms in 0.5 million years around 1 AU. We find that the spin angular velocity of planetesimals decreases as their mass increases. Planetesimals obtain their spin angular momentum on the early stage of accretion where their mass ratio is not so large. Once a runaway-growing planetesimal (protoplanet) becomes large enough, it mainly accretes smaller planetesimals whose collisional angular momentum tends to cancel out since they collide from random directions. Thus the protoplanet increases its mass but not the spin angular momentum, which leads to smaller angler velocity for larger protoplanets. When a protoplanet reaches the isolation mass, its typical spin angular velocity is as high as 10% of the critical angular velocity for rotational instability under the assumption of perfect accretion in collisions. We find that the obliquity of planetesimals is well expressed by an isotropic distribution. During the protoplanet growth, the scale height of the planetesimal system is much larger than the size of planetesimals. Thus, collisions are three-dimensional and isotropic, which leads to the isotropic obliquity distribution. We show the dependence of the spin parameters on the initial planetesimal system parameters. The spin angular velocity increases with the bulk density of planetesimals. The dependence of the spin angular velocity on the planetesimal mass becomes weaker as the initial mass of planetesimals increases. However, these system parameters do not affect the obliquity distribution.

Gravitational accretion of particles onto moonlets embedded in Saturn's rings

YASUI, Yuki[1*] ; OHTSUKI, Keiji[1] ; DAISAKA, Hiroshi[2]

[1]Department of Earth and Planetary Sciences, Kobe University, [2]Graduate School of Commerce and Management, Hitotsubashi University

Collision and gravitational accretion of particles is an important issue related to the origin of ring-satellite systems of giant planets in the solar system. The Hill radii of Pan, Daphnis, Atlas, and Prometheus are found to be within 15 % of the observed long axes of these satellites given by the best-fit model ellipsoids. Also, the densities of these satellites (0.4 - 0.6 g cmˆ-3) are very low compared to the density of water ice and all approximately equal to the critical density at that distance, which is defined as the density of a body that entirely fills its Hill sphere. From these results, the small satellites within the orbit of Pandora are thought to be formed by accretion of small porous ring particles onto large dense cores, and further accretion seems to have been suppressed when the density of the satellite reaches the critical density at that distance. Local N-body simulations also demonstrated that a Hill sphere-filling body is produced by accretion of small porous particles onto a large dense core. However, it has not been studied how the degree of particle accretion onto moonlets in the inner parts of Saturn's rings depends on the distance from Saturn.

The shapes of these small ringmoons would also provide clues to the dynamical evolution of Saturn's rings. The fact that the shapes of these ringmoons approximately match those of their associated Hill sphere suggests that the moonlet cores were surrounded by a number of particles when they were formed. On the other hand, Pan and Atlas have the characteristic shapes with equatorial ridges, and are thought to be formed by two stages. First, their precursors whose shapes are similar to their Hill sphere without equatorial ridges were formed when the rings were thick. Then, equatorial ridges were formed through particle accretion onto the equatorial planes of the above formed objects after the rings became sufficiently thin and also before ring particles diffused. However, effects of dynamical properties of the rings on the shaping of moonlets formed by particle accretion have not been examined in detail.

Propeller-shaped structures have also been found in Cassini images of Saturn's rings. These propeller-shaped features are explained by gravitational interaction between ring particles and unseen embedded moonlets. From these observations, the sizes and orbital distributions of these unseen embedded moonlets are obtained, and such information provide us with clues to the evolution of the ring-satellite system. The propeller-shaped structures are mainly observed in the A ring. Recently, observations of similar structures have also been reported for the Cassini Division, and the B and C rings. Although some of these moonlets either may be collisional shards resulting from the breakup of a bigger icy progenitor ring body or may have formed by accretion of small low-density ring particles onto larger dense fragments, the origin of these moonlets is not clear.

Using local N-body simulation, we examine gravitational accretion of ring particles onto moonlets in Saturn's rings. We find that gravitational accretion of ring particles onto moonlets is unlikely to occur at radial locations interior to the outer edge of the C ring, unless the density of the moonlets is much larger than that of water ice or non-gravitational cohesive forces play a major role. Detailed analysis of accretion process of individual particles onto moonlets shows that particle accretion onto high-latitude regions of the moonlet surface occurs even if the rings' vertical thickness is much smaller than the moonlet's radius. The degree of particle accretion in outer rings is found to depend significantly on rings' vertical thickness and optical depth. Our results suggest that large boulders recently inferred from observations of transparent holes in the C ring are likely to be collisional shards, while propeller moonlets in the A ring would be gravitational aggregates formed by particle accretion.

Mass-Loss Evolution of Super-Earths: Constraints on Their Compositions and Origins

KUROKAWA, Hiroyuki[1*] ; KALTENEGGER, Lisa[2] ; NAKAMOTO, Taishi[3]

[1]Nagoya University, [2]Max Planck Institute for Astronomy, [3]Tokyo Institute of Technology

Recent progress of he search for exoplanets, for example the transit observations with Kepler space telescope, has pushed toward small planets. Especially, ”Super-Earths”, that are planets having sizes from Earth to Neptune, are revealed as quite common: ˜30% of solar-type stars have super-Earths (Howard et al., 2012). Therefore, an understanding of their compositions, which is related to their origins, is important for planet formation and evolution.

We can speculate the compositions of super-Earths both whose masses and radii are known by using theoretical mass-radius relations for different compositions. Some fraction of super-Earths have low density, which suggests the presence of H/He envelopes formed by protoplanetary-disk gas capture. There exist. on the other hand. high-density super-Earths possibly having rocky- or water-rich compositions. The origin of this dichotomy is one problem that we address in this study, which possibly arises from the difference of the amount of captured disk gas due to different masses and disk temperature in their formation stages, or from XUV (X-ray and EUV)-driven atmospheric escape in later evolution stages (e.g., Lopez et al., 2012). Another problem that we address in this study is ”the degeneracy of composition”: The compositions of super-Earths can be fitted by various ratios of H/He envelope, rock, and water. Their atmospheric compositions have been speculated by measuring their transmission spectra, but recent observations using Hubble Space Telescope suggested that cloudy atmospheres of super-Earths (Kreidberg et al., 2014; Knutson et al., 2014). If clouds are common in atmospheres of Super-Earths, direct measurements of their compositions are difficult because clouds obscure any features of atmospheric species.

In this study, we show constraints on these problems of compositions and origins of super-Earths by calculating their mass-loss evolution due to XUV-driven atmospheric escape considering the differences of host-stellar types. The ratio of XUV luminosity and bolometric luminosity differs among stellar types, which enables us to distinguish formation origin and mass-loss origin of the dichotomy of super-Earths with or without H/He envelopes. Also, the degeneracy of compositions can be solved by considering stability criteria to lose H/He envelopes.

We calculated the critical orbital radii to lose H/He envelopes for different stellar types, that corresponds to different equilibrium temperature depending on stellar types. The obtained critical separations are consistent with the distribution of the observed super-Earths with or without H/He envelopes, suggesting that the observed dichotomy has a mass-loss origin.In this case, we expect that super-Earths having moderate density and orbiting inside the critical separation are water-rich super-Earths without H/He envelope.

We also evaluated uncertainty caused by mass-loss model and XUV luminosity and discuss the validity of our results.

Exoplanet exploration for brown dwarfs with infrared astrometry

YAMAGUCHI, Masaki[1*] ; YANO, Taihei[1] ; GOUDA, Naoteru[1]

[1]National Astronomical Observatory of Japan

The astrometry is one of the oldest method for the exoplanet exploration. However, only one exoplanet has been found with the method. This is because the planet mass is sufficiently smaller than the mass of the central star, so that it is hard to observe the fluctuation of the central star by the planet. Therefore, we investigate the orbital period and mass of planets which we can discover by the future astrometric satellites for brown dwarfs with the mass less than a tenth of the solar mass.

So far five planetary systems have been found, whose mass ratios are larger than a tenth. For example, for the system whose distance, orbital period and mass ratio are 10 pc, 1 year and a tenth, respectively, the apparent semi-major axis reaches 3 milli-arcsecond, which can be well detected with the future astrometric satellites such as Small-JASMINE and Gaia. With these satellite, we can discover even super-Earth for the above system.

We further investigate where in the period-mass plane we can explore the planet for individual brown dwarf with Small-JASMINE and Gaia. As a result, we find that we can explore a wide region where period and mass are within 5 years and larger than 3 earth mass. In addition, we can explore the region around 0.1 day and 10 jovian mass, where planets have never found for any central star, and where we can explore only with Small-JASMINE for most target brown dwarfs.

Experimental study on organic aerosol formation in super-Earths' atmosphere: Implications for transit observations

KOBAYASHI, Jumpei[1*] ; SEKINE, Yasuhito[2] ; HONG, Peng[2]

[1]Dept. Earth & Planet. Sci., Univ. Tokyo, [2]Dept. Complexity Sci. & Engr., Univ. Tokyo

A super-Earth is an extrasolar planet with a mass greater than Earth and below Neptune. Although there is no super-Earth in our solar system, astronomical observations demonstrate that it is one of the major categories of planets beyond the solar system. Recent transit observations of super-Earths, including GJ 1214b, indicate that their atmospheres contain opaque clouds or haze at high altitudes. One candidate for the opaque materials is metallic or salt dusts, such as KCl and ZnS, which would condense in the upper atmospheres of super-Earths. Another candidate is organic haze, such as those observed in the atmosphere of Saturn's moon Titan, which would be composed of high-molecular-weight hydrocarbon aerosols produced through photochemical reactions involving CH_4. Given the proposed formation mechanisms of nearby super-Earths, e.g., planetary migration, they would have a wide variety in chemical composition of atmosphere. However, previous laboratory experiments have mainly focused on organic aerosol formation in Titan's and early Earth's atmospheres. Thus, both the formation rate and optical property of organic haze for various atmospheric compositions have been poorly constrained by laboratory experiments.

In this study, we investigate the formation rate and optical property of organic aerosols formed by laboratory experiments simulating super-Earths' atmospheres with a wide variety in chemical composition. We used initial gas mixtures of H_2 and CH_4 or CO_2 and CH_4, and varied the H_2/CH_4 or CO_2/CH_4 ratios. The experiments were conducted at a total pressure of 1 Torr in a flow system. Cold plasma irradiation was used to initiate aerosol formation. We measured the aerosol formation rate, chemical compositions of intermediate gas molecules, and optical property of aerosol using a spectroscopic ellipsometer, a quadrupole mass spectrometer, and a UV/VIS spectrometer, respectively.

Our experimental results show that the aerosol formation rate decreases with increasing the H_2/CH_4 ratio, suggesting that recycling of high-molecular-weight hydrocarbons to CH_4 occurs through reactions with H and H_2 under H_2-rich conditions. We also show that organic aerosols are produced less efficiently at higher CO_2/CH_4 ratios. The results of gas analyses also show that formation of high-molecular-weight hydrocarbons are inhibited at higher CO_2/CH_4 ratios. These results indicate that oxygen-bearing molecules and radicals formed by CO_2 dissociation oxidizes hydrocarbons produced from CH_4, which results in a lower aerosol formation rate at higher CO_2/CH_4 ratios. Optical constant of the aerosols formed under the conditions simulating super-Earths' atmospheres is significantly lower than those of Titan aerosol analogs.

Based on the experimental results, we discuss the chemical composition and formation process of transiting super-Earths, such as GJ 1214b, by comparing the observed transmittance spectra with the model spectrum. We suggest that organic aerosol production in a H_2-rich or CO_2-rich atmosphere is inefficient so that organic haze would not be capable of explaining the observed transit spectra of super-Earths, even if they contains gaseous CH_4 in the atmospheres.

Transmission spectrum models of low-mass exoplanet atmospheres with haze: Application to GJ 3470b

KAWASHIMA, Yui[1*] ; IKOMA, Masahiro[1] ; FUKUI, Akihiko[2] ; NARITA, Norio[2]

[1]The University of Tokyo, [2]National Astronomical Observatory of Japan

Since the first exoplanet was discovered in 1995, detection of more than 1000 exoplanets has been reported. Recently, transit observations of an exoplanet have been done at multiple wavelengths. From a decline in apparent stellar brightness due to a planetary transit, we can measure the plantary radius. In addition, observed dependence of the planetary radius on wavelength (which is often called the transimission spectrum) provides the information of absorption and scattering by molecules and small particles such as haze and clouds in the planetary atmosphere. Thus, the composition of the planetary atmosphere can be constrained by comparison between the observational and theoretical transmission spectra. The constraint on atmospheric composition gives an important clue to the origin of the planet.

Our observational group has recently observed transits of two low-mass exoplanets, GJ 3470b and GJ 1214b, at multiple wavelengths. For both planets, the observed transit radii in the optical wavelength region are greater than those in the near-infrared region, inferring the existence of haze in the atmosphere. While the observed transmission spectrum was already analysed theoretically in detail as for GJ 1214b, there are few researches discussing the theoretical spectrum models incorporating the effect of haze systematically for GJ 3470b. In this study, we have modeled theoretical transmission spectra of low-mass exoplanets orbiting close to their host stars. Then, applying the calculated spectrum models to GJ 3470b and GJ 1214b, we discuss the property of the atmospheres of both planets.

In calculating theoretical spectrum models, we have taken into account the vertical distribution of molecular abundances from the chemical equilibrium calculations, in addition to absorption and scattering of the incident radiation from the host star by molecules and haze particles in the planetary atmosphere. We explore the dependences of the atmosphere's metallicity, C/O ratio and water vapor abundances on the transmission spectrum. We also probe the dependences of haze's height, particle sizes and number density. In comparing the observed and theoretical transmission spectra, we have performed the chi-squared analysis to quantify the validity of each atmospheric model.

The SEEDS Exoplanet and Circumstellar Diks Survey

KUZUHARA, Masayuki[1*] ; TAMURA, Motohide[2] ; KUDO, Tomoyuki[3] ; HASHIMOTO, Jun[4] ; KUSAKABE, Nobuhiko[5] ; MATSUO, Taro[6] ; MCELWAIN, Michael[7] ; JANSON, Markus[8] ; TAKAHASI, Yasuhiro[2]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [2]Department of Astronomy, The University of Tokyo, [3]Subaru Telescope, [4]H. L. Dodge Department of Physics and Astronomy, University of Oklahoma, [5]National Astronomical Observatory of Japan, [6]Department of Astronomy, Kyoto University, [7]NASA Goddard Space Flight Center, [8]Astrophysics Research Centre, Queen's University Belfas

About 1,000 extrasolar planets (or exoplanets) have been discovered by now. Furthermore, Kepler survey has reported the presences of more than 3,000 exoplanet candidates (Huber et al. 2013). Thus, the planetary systems are common in our Galaxy, but it has known that those exoplanets have a variety of properties. Meanwhile, studies for circumstellar disks, which are the birth-places of planets, have also progressed. In particular, the radio telescope ALMA, whose operations have recently started, have provided intriguing data for the structure properties of protoplanetary disks (e.g., van der Marel et al. 2013; Casassus 2013). ALMA should provide a deep insight to the studies of circumstellar disks.

Direct imaging observations enable the discovery and study of exoplanets orbiting their host stars at wide orbital separations comparable to a few tens of AU, but the detections of those are impractical with indirect techniques such as radial velocity or transit method. Direct imaging is also useful to characterize circumstellar disks. The high-resolution observations of scattered light from protoplanetary disks or debris-disks have provided many important clues to reveal the physical disk-planet connections. We have progressed the SEEDS project, which aims at detecting and characterizing giant exoplanets and circumstellar disks with the Subaru 8-m ground-based telescope, state-or-the-art adaptive optics AO188, and a high-sensitivity infrared camera HiCIAO that we have newly developed. The total SEEDS sample will reach 500 targets, and this target sample adequately covers stellar ages ranging from 1 to 1000 Myr for solar-type stars. Also, intermediate-mass or low-mass stars are included in our SEEDS sample. The survey is currently in its fifth year, and to date, it has identified intriguing structures, such as gaps or spirals, in more than 10 transitional or debris disks (e.g., Hashimoto et al. 2012; Grady et al. 2013). Furthermore, SEEDS has discovered a massive giant planet candidate orbiting the B-type star Kappa Andromedae (Carson et al. 2013) and a Jovian planet in orbit with a size of about 44 AU (GJ 504b) around the G0-type Sun-like star GJ 504. GJ 504b has an estimated mass of about 4 Jupiter masses and effective temperature of 500 K. Among such the wide-orbit exoplanets directly imaged so far, GJ 504b represents the lowest-mass Jovian planet, and the inferred effective temperature is the coldest. The follow-up observations for GJ 504b have revealed the presences of methane in its atmosphere (Janson et al. 2013), allowing us to report the first methane detection in an atmospheres of directly imaged exoplanet. Thus, SEEDS has successfully identified and studied the exoplanets with the previously unknown properties. After the end of SEEDS survey, the comprehensive and statistical analysis of entire survey sample will be carried out. This analysis leads to improve our understanding about exoplanets and circumstellar disks. In addition, it should become a promising clue that connects to future exoplanet/disk studies, such as a survey of extrasolar Earths.

Here, we report the latest achievements of SEEDS project, such as the detection of GJ 504b. Moreover, its whole survey status and progress are also reported, as well as the future plan of SEEDS project.

Sonic Boom Analysis of Meteorite at Hypersonic Speeds in Earth Atmosphere

YAMASHITA, Rei[1*] ; SUZUKI, Kojiro[1]

[1]Graduate School of Frontier Sciences, The University of Tokyo

The sonic boom followed by the passage of shock waves may cause serious damage on the ground, when a meteorite falls at hypersonic speeds as experienced at the Chelyabinsk meteorite event in February 2013. Therefore, it is important to evaluate the sonic boom generated by the meteorite. In this study, the prediction method of the sonic boom developed in the aeronautical engineering is applied to the case of the meteorite. The nature of the sonic boom propagation in the earth atmosphere is evaluated by the whole-domain simulation technique, which is based on the computational fluid dynamics in the domain bounded by the flying object and the ground (R. Yamashita and K. Suzuki, APISAT2013, No. 02-05-3). The flowfield around the sphere with 20 m diameter is numerically obtained by solving the three dimensional Navier-Stokes equations with the gravity term. The earth ' s atmospheric model is based on the international standard atmosphere (ISO 2533:1975). The flight Mach number is 10 (about 3 km/s), the flight altitude is 10 km and the flight condition is the steady level flight. The computational grid is constructed by rotating the two dimensional grid about the body axis and the number of the grid points is about 5.5 million. After the numerical calculation is conducted by using the initial grid, the calculation is performed again with the adaptive grid reconstructed to align the bow shock wave to avoid the artificial smearing of the shock wave. For computational efficiency, the domain is divided into several sectors from the body to the ground. The shape of the meteorite is approximated as a sphere and the axi-symmetric flowfield is assumed in the sector near the body. The numerical fluxes are evaluated by SHUS scheme (E. Shima and T. Jounouchi, NAL SP, pp.7-12, 1997) with the third order accuracy by MUSCL interpolation technique. The time integration is conducted by MFGS (E. Shima, proceedings of 29th Fluid Dynamic Conference, pp.325-328, 1997) method. The gravity term is added to the governing equations as a source term.

The flowfield around the sphere is composed of the bow shock wave in front of the body and the trailing shock wave in the wake. Both the waves propagating downward are merged into a single wave at 8 km altitude. In such case, the sonic boom sounds only once, while the sonic boom generated by a supersonic airplane creates explosive sounds twice without merging of the shock waves. It is reported that Chelyabinsk meteorite has been broken into three big pieces and the sonic boom sounds three times at the ground (NHK COSMIC FRONT, June 2013). Hence, the number of the pieces is equal to that of the sound of explosion. This fact seems consistent with the present simulation result. The pressure rise across the shock wave decreases with the distance from the body because of the geometric spreading. In the actual earth's atmosphere, however, the rate of decrease becomes smaller near the ground, because the atmospheric pressure and temperature increase toward the ground. Assuming the pressure augmentation factor of 1.9 at the reflection of the shock wave at the ground, the peak pressure rise is estimated at about 1.5 kPa, which is 63 times as large as the maximum allowable pressure rise (24 Pa) determined in the environmental regulation for the supersonic airplane. In the case of the Chelyabinsk meteorite, the pressure rise is estimated at 3.2±0.6 kPa (Nature 12741) from the observation of the damage of the glass windows there. Although the numerical condition is not the same as the actual flight condition of the meteorite, the pressure rise due to the passage of a meteorite at hypersonic speeds is expected to be in the order of 1 kPa or higher.

As mentioned above, the prediction method developed in the aeronautical engineering has a great potential to predict the flight condition, say, the size, altitude and Mach number, from the magnitude of the sonic boom measured on the ground by conducting the parametrical study.

The brightness and the color temperature of the Chelyabinsk bolide

YANAGISAWA, Masahisa[1*]

[1]Univ. Electro-Communications

The bolide explosion on Feb. 15, 2013 over Chelyabinsk, Russia was the next most violent to the probable bolide explosion in Tunguska, Siberia in 1908. It was recorded by many dashboard movie cameras in a wide area around the city, and the movies are released on the Internet. We analyzed one of them and obtained the lightcurves of the bolide for three colors (see the figure for the temporal variations of the brightness). More than 95% of the radiant energy in the visible wavelengths was released in its flare-up for about 2 seconds. The luminosity ratios among the R (red), G (green), and B (blue) color bands are consistent with the 3500 K black-body radiation during the flare, while the pre-flare bolide was greenish-blue in color and the ratios do not agree to the black-body spectra. The maximum luminosity was 1.0 x 10^{15} W. The impact energy is estimated to be 1.9 x 10^{15} J or 450 kton in TNT equivalent (1 kton = 4.185 x 10^{12} J), based on an empirical formula for the radiant efficiency of bolides. The lightcurves and the impact energy almost agree to the results reported thus far.

Figure caption: Temporal variations of the source luminosities of the bolide in logarithmic scales. The thick (red), dotted (green), and thin (blue) lines correspond to the RGB color bands. The calculated intensities are negative in the periods without plot. The vertical scale on the right side shows the luminosity integrated over the wavelengths assuming 3500 K black body radiation. Seconds of 3:20 on Feb. 15, 2013 (UT) are shown in abscissa.

Statistical distribution of the solar system dusts by meteor head echo observations with the large-aperture radar

ABE, Shinsuke[1*] ; KERO, Johan[2] ; NAKAMURA, Takuji[3] ; FUJIWARA, Yasunori[4] ; WATANABE, Jun-ichi[5]

[1]Department of Aerospace Engineering, College of Science and Technology, Nihon University, [2]Swedish Institute of Space Physics (IRF), [3]National Institute of Polar Research (NIPR), [4]Nippon Meteor Society, [5]National Astronomical Observatory of Japan

A meteor head echoes is caused by radio waves scattered from the intense region of the plasma surrounding and co-moving with a meteoroid during atmospheric entry at about 70-130 km altitude. Meteor head echo observations were carried out using the high-power large-aperture (HPLA) Kyoto university Shigaraki middle and upper atmosphere (MU) radar in Japan (34.85deg N, 136.10deg E). Since 2009 the atmospheric trajectories and interplanetary orbital elements have been derived by the MU radar meteor head echoes (e.g.; Kero et al. (2012); Kero et al. (2011)). Approximately 120,000 orbital elements of meteors with excellent accuracy were obtained until January 2014. Typical error for velocity and semi-major axis are 0.3 km/s and 0.1 AU, respectively. Such a huge number of meteoroid orbits with the precise orbital accuracy has not been observed before. Here we report some results obtained by the statistical analysis of the database, such as orbital distributions and associations of comets and asteroids.

Laboratory experiment simulating Martian surface observation with submillimeter-wave polarimetric radiometry

ARIMURA, Taketo[1*] ; OCHIAI, Satoshi[2] ; KIKUCHI, Kenichi[2] ; KITA, Kazuyuki[3] ; KASAI, Yasuko[2]

[1]Graduate School of Science and Engineering, Ibaraki University, [2]National Institute of Information and Communications Technology, [3]Faculty of Science, Ibaraki University

Energies and materials exchange between the ground and atmosphere on Mars play important roles in the Martian general circulation. It is necessary to observe the spatial and temporal variability of the Martian surface from orbiter. However, it has been quite difficult to continually monitor the Mars surface in optical observation due to opaqueness of the Martian dust. Millimeter/submillimeter radiometers enable to observe the Martian surface through dust, though such measurement has never been conducted in planetary exploration. We assess the effectiveness of this observation method by laboratory experiment.

By observing millimeter/submillimeter emission from the Martian surface in several emission angles and two polarizations, we can derive physical temperatures, permittivity and roughness of the surface from brightness temperatures. In order to estimate each property from polarized brightness temperatures, we need to know relationship between emissivity or/and reflectivity in millimeter/submillimeter wave region and the parameters of surface.

We developed an experiment system to examine millimeter/submillimeter scattering and emission characteristics of the simulated Martian surface in a chamber. Measurement samples in the chamber are coolable at Martian surface temperature. The chamber is designed to measure emission of samples using a receiver and reflection of samples using a transmitter and a receiver. We can also obtain arbitrary-polarized emission with arbitrary incident angle by controlling mirrors in our system.

To discuss relationship between emission and surface parameters on the Martian surface, it is necessary to know influences of permittivity and surface roughness on the reflectivity. Therefore, we measured reflectance of Acrylic plate and Alumina grain at millimeter/submillimeter waves region. We discuss effects of permittivity and roughness on measured reflectivity of measurement samples in known polarization and incident angle. Moreover, we retrieve the permittivity and the roughness of sample from measured reflectivity. Using this measurement results, we expect a step closer to explanation of relationship between emission and surface parameters in the Martian surface at millimeter/submillimeter waves region.

Saturn's icy moon, Enceladus, exhibits ongoing geological activities, including eruption of water-rich plumes from warm fractures near the south-pole region. These geological activities together with the findings of Na-rich salts in the plumes suggest the presence of an interior liquid ocean beneath the icy crust. This demonstrates that Enceladus' plumes provide a unique opportunity to investigate the chemical composition of oceanic water, possible geochemical reactions, and habitability of the icy moon. However, due to limitations of in-situ measurements of the plumes by the Cassini spacecraft, it is not able to identify or quantify some key molecules, which could probe physical and chemical conditions of the ocean.

Here we discuss scientific importance and possibility of detection of HCN in the plumes by large ground-based, sub-millimeter telescope, ALMA. Because HCN is one of the fundamental materials contained in icy planetasimals in the outer solar system, and because it readily hydrolyzes in warm water($>$50 ℃), a lack of HCN suggests that Enceladus' interior would have experienced relatively high temperatures, i.e., a presence of hydrothermal activity. On the other hand, if HCN were presence in the plumes, this in turn means that Enceladus would have been cold throughout its history. Given the results of thermal evolution model, the latter case suggests late formation of the Saturnian system($>$5Myr) after CAI formation, which would result in a depletion of short-lived radiogenic heat source in Enceladus.

To evaluate the possibility to detect HCN in the plumes by ALMA, we first estimate a special distribution of H_2O gas density based on results from Cassini's observations and plume eruption modeling. Then, we calculate radiactive temperatures of HCN in the field of view of ALMA as a function of HCN concentration. Finally, the upper limit of HCN as a function of observation time will be obtained. For instance, if HCN were not detected within 4-6 hours of observation time, an upper limit of the HCN concentration in the plumes becomes 0.2% relative to water, which is comparable to a typical concentration of HCN in comets. Thus, the ALMA telescope is capable of detecting HCN in Enceladus' plumes within a reasonable observation time, if it were present in an amount comparable to that of comets. In either case whether HCN were presence or not, we would be able to constrain geochemical reactions and thermal history of Enceladus as well as the timing of formation of Saturnian system.

Development of SPH: Toward Understanding of Disk-planet Interaction Near the Disk Inner Edge

FUJII, Yuri[1*] ; IWASAKI, Kazunari[1] ; TSUKAMOTO, Yusuke[1] ; INUTSUKA, Shu-ichiro[1]

[1]Nagoya University

Recent observations of exoplanets reveal the existence of close-in planets. These planets are thought to form in outer disks and migrate inward because of the disk-planet interaction. If there are disk inner cavities, planets can stop migrating and stay in close-in orbit. Disk evolution is highly affected by these planets. Thus, the understanding of the interaction between disks and close-in planets is crucial. In this study, we develop a numerical scheme to investigate the interaction between disks and planets. Although the grid-based schemes are widely used in this context, there are difficulties in calculating with a disk inner cavity or eccentric planets. These difficulties can be removed by smoothed particle hydrodynamics (SPH) with high accuracy. In this presentation, we will talk about the development of code and the performance evaluation.

Evolution of a protoplanetary disk and chemical composition of planetesimals

NAGAHARA, Hiroko[1*] ; OZAWA, Kazuhito[1]

[1]Dept. Earth Planet. Sci., The Univ. Tokyo

We investigate physico-chemical evolution of the proto-solar disk at the early stage by developing a new model that combines physics and chemistry with special interest to temporal and spatial evolution of the disk. Then, we discuss how the composition of planetesimals varies depending on the time and space for their formation including refractory or volatile rich ones.

The basic of the model is a radial advection-diffusion equation, which includes drift and dispersion by turbulence with stochastic diffusion term calculated by the Monte Carlo method and which shows the diffusivity by the viscosity of the disk. The difference from conventional disk models is that the present method stands on the Lagrangean differentiation, and it is able to trace the movement of individ- ual particles.

A considerable amount of materials in the inner regions are transported outward at the early stage (t <10^5 yrs), which is because the surface density is much larger in the inner region at the early stage of the disk evolution. Although the outward flux is large at the early stage, there comes a larger amount of materials from the outer region even within ~10^5 yrs. The mixing ratio of materials from the inner regions to outer regions is almost unity within several AU all through the disk evolution, suggesting that thermally processed materials and unprocessed materials were mixed in the inner region of the disk. It is important that the relative abundance of materials from outer regions becomes larger with time, which implies that planetesimals formed within several AU at the early stage of the disk evolution consists partly of materials initially located at the inner regions and partly from outer regions, but those formed at the later stage contain more abundant law materials transported from the outer regions.

The mixing ratio of materials from the inner and outer regions is almost unity at the early stage but the fraction of materials from the outer regions increases with time. Combining the information about the maximum temperature that the particles experienced, we can constrain that early differentiated planetesimals such as the parent body of angrites and planetesimals with refractory-rich compositions such as CV chondrites were formed at the inner region of the disk in ~10^5 yrs. On the other hand, planetesimals for other carbonaceous chondrites or ordinary chondrites that are depleted in sulfur were formed later, possibly at ~10^6 yrs.

Simulating global dust coagulation with grain charging

OKUZUMI, Satoshi[1*] ; TANAKA, Hidekazu[2]

[1]Graduate School of Science and Engineering, Tokyo Institute of Technology, [2]Institute of Low Temperature Science, Hokkaido University

Growth of dust particles by collisions is the initial step of planet formation. Conventionally, the theory of dust coagulation in protoplanetary disks assumed electrically neutral dust particles, but in reality dust in the disks is likely to be charged given that the disks are ionized by cosmic rays and stellar X-rays. In our previous work (Okuzumi 2009; Okuzumi et al. 2011a,b), we extensively studied the role of grain charging in protoplanetary dust growth, and concluded that dust growth stalls at its early stage because of the excessively large (negative) charges carried by small dust aggregates. We also predicted that this ”charge barrier” could be overcome (albeit on a very long timescale) if dust in the disks is globally transported by radial drift and turbulent diffusion.

The purpose of the present work is to demonstrate the breakthrough of the charge barrier in a global setup. In order to do this, we have developed a new simulation code for global dust coagulation including the effect of grain charging. The new code is based on a previous code for planetesimal formation (Brauer et al. 2008; Okuzumi et al. 2012) but now calculates charging and Coulomb repulsion of dust particles at each location in a disk consistently with the particle size distribution at the same location. To verify the code, we perform some test simulations and compare them with the prediction from our previous theory.

N-body simulations of Rubble pile Collisions in Tidal fields

HYODO, Ryuki[1*] ; OHTSUKI, Keiji[1]

[1]Kobe University, Graduate School of Science

We examine collisional disruption of gravitational aggregates in the tidal environment by using local N-body simulations. We find that outcomes of such collision largely depend on impact velocity, direction of impact, and radial distance from the planet. In the case of a strong tidal field corresponding to Saturn's F ring, collisions in the azimuthal direction is much more destructive than those in the radial direction. Numerical results of collisions sensitively depend on impact velocity, and complete disruption of aggregates can occur even in impacts with velocity much lower than their escape velocity. In such low-velocity collisions, deformation of colliding aggregates plays an essential role in determining collision outcomes, because the physical size of the aggregate is comparable to its Hill radius. On the other hand, the dependence of collision outcomes on impact velocity becomes similar to the case in free space when the distance from the planet is sufficiently large. We submitted the results to the Astrophysical Journal.

An improved fragmentation model on outcome of planetesimal collisions

FUJITA, Tomoaki[1] ; GENDA, Hidenori[2*] ; KOBAYASHI, Hiroshi[3] ; TANAKA, Hidekazu[4] ; ABE, Yutaka[1]

[1]Department of Earth and Planetary Science, University of Tokyo, [2]Earth-Life Sicence Institute, Tokyo Institute of Technology, [3]Department of Physics, Nagoya University, [4]Institute of Low Temperature Science, Hokkaido University

Collisions between planetesimals or a planetesimal and a protoplanet are thought to occur frequently in the stage of planet formation, and these planetary bodies grow up through these collisions. However, if destructive collisions between them occur frequently, these bodies break up into fragments rather than promote the growth of them. Therefore, in order to understand the process of the growth for planetesimals and protoplanets, it is important to know the impact conditions under which a collision is destructive. The critical specific impact energy for catastrophic disruption $Q_D{}^*$, where the largest remnant has half the target mass, has been well investigated under various conditions so far (Holsapple et al., 2002; Benz & Asphaug, 1999; Leinhardt & Stewart, 2009). Such catastrophic impacts have been regarded as important process for planet formation. The values of $Q_D{}^*$ which has been referred and used most frequently were calculated by Benz and Asphaug (1999). Although they performed many impact simulations to determine $Q_D{}^*$, the resolution of their numerical simulation were quite low and they did not check the resolution convergence of $Q_D{}^*$. In addition, recent studies (Kobayashi & Tanaka, 2010; Kobayashi et al., 2010) have suggested that non-disruptive small-scaled impacts were also important to the growth of protoplanets, because these small-scaled impacts are much more frequent than disruptive impacts.

In order to discuss more correctly the growth of planets, a correct value of $Q_D{}^*$ and the relation between ejecta mass and impact energy for small-scaled impacts should be required. In this thesis, I investigate the resolution dependence of $Q_D{}^*$ and obtain a correct value of $Q_D{}^*$ for planetesimal collisions by numerical impact simulations with sufficient resolution. I also investigate small-scaled impacts, and formulate the relation between the ejecta mass and impact energy.

Using the smoothed particle hydrodynamics method (SPH) with self-gravity and without strength, I systematically perform the hydrodynamic simulations of collisions between rocky planetesimals. I consider collisions of 10 km and 100 km rocky targets and various sized impactors under various conditions such as impact velocity, impact angle and resolution.

I found that the value of $Q_D{}^*$ depended on resolution. This is because distribution ratio of initial impact energy to kinetic and internal energy of a target differs depending on resolution due to shear flows which appears during propagation of shock wave and rarefaction wave and ejection process. This energy distribution ratio, probably also $Q_D{}^*$, converges in using 7.5×10^7 particles. The resolution in Benz & Asphaug (1999), where they performed impact simulations with 5×10^4 particles, was insufficient. The $Q_D{}^*$ obtained by higher-resolution simulations is about a half order of magnitude smaller than that of Benz and Asphaug (1999). This means collisions between planetesimals or a planetesimal and a protoplanet are more destructive than previously thought. I applied improved $Q_D{}^*$ to the growth of protoplanets using analytical method proposed by Kobayashi et al. (2010). As a result, the mass of the finally formed protoplanet is a half smaller than the case for previous $Q_D{}^*$. In addition, I derived the formulation of scaling law representing the relation between ejecta mass and impact energy from small-scaled impacts to destructive impacts. I found that this relation can be scaled by target size, impact energy normalized by $Q_D{}^*$, and impact velocity, but it depend on impact angle. With $Q_D{}^*$ and the scaling law obtained in this study, the final grown mass of a protoplanet is 0.058 M_{earth} at 1AU and 0.17M_{earth} at 5 AU, where M_{earth} represents the Earth mass.

iSALE (impact-SALE) is a shock physics code based on the SALE hydrocode (Simplified Arbitrary Lagrangian Eulerian), which is an open code for planetary scientist. iSALE contains a number of option to model impact phenomena of geological materials. The calculation results can be easily visualized and analyzed using included software. A number of ANEOS tables and strength models of geological materials, including water ice, silicate rocks, and iron are also included. We have formed a user community called " iSALE users group in Japan " to introduce iSALE to the Japanese society for planetary science and to share information on the usage of iSALE. The URL of our wiki page and the mailing list are as follows.

The URL of the wiki page of iSALE users group in Japan

Study on fundamental characteristics of penetration dynamics into icy target

NAMBA, Kazuya[1*] ; SUZUKI, Kojiro[2]

[1]Grad. Sch. Eng., The University of Tokyo, [2]GSFS, The University of Tokyo

A penetrator, which penetrates the surface of a planet, a satellite and so on to investigate the interior by high-speed hard landing, is expected to play an important role in the solar system exploration of the future. Comparing to soft lander, penetrator has advantages of consuming less fuels, enabling us to launch multiple probes at a time because of its low mass, and so on. However, probe must survive hard impact in collision, thus no penetrator missions have been successfully achieved so far. The icy object, such as 24 Themis and Europa, is expected to contain organics which serve as the precursor of life in their subsurface. Therefore, the cryo-penetrator, which penetrates the icy object and investigate specimens of subsurface which have not been contaminated by cosmic rays, should have a high importance. For a penetrator into regolith, a fully-developed flyable penetrator has been successfully developed for the Lunar-A mission, though the mission itself has been cancelled. For icy target, however, the number of studies from the engineering viewpoint is quite limited, for example, the conceptual study on CRAF mission to a comet nucleus (Adams et al., NASA CR-177393, 1986). In this study, we investigated the fundamental properties of the penetration dynamics of the cryo-penetrator, by conducting penetration experiments into the target made from H_2O ice.

Penetration experiments were conducted by using a ballistic range in our laboratory. The projectile is accelerated by the compressed air, launched horizontally and crashed into a target body. Impact speed is set from 100 m/s to 300 m/s. Two types of projectile, a needle-like one (iron, size: ϕ2.45x15mm, mass: 1.71g) and a blunt cone-like one (brass, ϕ8.4x15mm, 2.33g) are used. Three types of target, pure H_2O ice (size: 270x175x130mm, mass: 5.5kg, density: 0.90g/cm^3, porosity: 3%), low purity H_2O ice (150x120x100mm, 1.5kg, 0.75g/cm^3, 19%) and an oil clay (155x120x70mm, 2.2kg, 1.7g/cm^3) are used. A high-speed camera (frame rate: 2200-8800fps, exposure time: 15μs) is used to observe a sequence of events: the free-flight of the projectile, impact, crater formation, penetration, and so on.

We found that the penetration into H_2O ice produces ejecta of icy fragments, which erupt conically immediately after collision, and then produces the jet-like ejecta in the almost perpendicular direction to the surface that continues more than 100 msec. On the other hand, the penetration into clay target produces ejecta outward-conically for duration of a few msec. Moreover, we found that the penetrator tends to be pushed back from the target by the ejecta, since the ice around the projectile has been almost broken into pieces erupting as the ejecta and the penetrator cannot be fixed inside the target without receiving the gripping force from the ice. We also found that eruption was continued even after the projectile has completely bounced from the target. This phenomena is frequently observed when the projectile with a less slender body. In the case of a slender penetrator, however, it is hardly subject to bounce-back. Consequently, a slender shape seems more suitable to the penetrator for icy target. The shape of crater consists of the pit region on the center, the spall region which is a shallow depression on the periphery of the pit, and cracks spread a wide range of target. It is qualitatively consistent with previous researches using bullet shape (e.g. Kato et al., Icarus 113(2) 423-441, 1995., Arakawa, Low Temperature Science 66 113-121, 2008). The pressure at a point of impact is estimated by using the one-dimensional planar impact approximation (Wada, JSIAM 16(4) 19-31, 2006): the result shows that it is beyond the Hugoniot elastic limit (HEL), thus the H_2O ice is expected to behave like fluid in the vicinity of the impact point.

Experimental study of compaction process of powder bed by centrifuge experiment

OMURA, Tomomi[1*] ; KIUCHI, Masato[1] ; GUETTLER, Carsten[2] ; NAKAMURA, Akiko[1]

[1]Graduate School of Science, Kobe University, [2]Max-Planck-Institute for Solar System Research

Dust aggregates in protoplanetary disk are compacted by dust-dust collisions, ram pressure of the disk gas and self-gravity (Kataoka et al., 2013). At reaccumulation phase of asteroids, porosity of rubble pile and regolith would be determined by collisional pressure and self-gravity.

Relationship of porosity of powder layer and particle's radius is given by (Yu et al., 2003; Kiuchi and Nakamura, 2014)

$p=p_0+(1-p_0)\exp\{-mR_F^{-n}\}$ (1)

where R_F is the ratio between the magnitudes of the van der Waals force between two particles and gravity force on particles, therefore a function of particle radius. p_0, m, and n are constants. p_0 should be understood as the porosity without any interparticle force.

It is not clear if Eq.1 can be applied for powder layer under different gravity from 1 G. Eq.1 was originally derived for particles at surface, and we don't know to what extent this equation is able to be applied for the interior of planetary bodies, i.e., it has not examined for the porosity evolution of bodies due to the accumulation of new grains and blocks onto the surface. If Eq.1 is applicable to such case, porosity given by Eq.1 should be consistent with the result of the case in which R_F is reduced by increasing the gravity. In this study we perform experiments, under different gravitational accelerations, and we compare the results with Eq.1.

We use silica sand, 60 wt% of grains have sizes ranging from 7.5 μm and 80 μm and fly ash, 60 wt% of grains have sizes ranging from 1 μm and 8 μm. They were sieved into a cylindrical container of diameter 5.8 cm and depth 3 cm. After that, the top part of the bed over the height of the container was leveled off. Porosity of each granular bed is approximately 60 % and 70 %. The experiments were performed at elevated acceleration on a centrifuge to provide 1-18 G and observed with a video camera. In contrast with unidirectional compressive compaction using a piston, centrifugal compaction is capable of applying uniform compressive force at any place of the container without causing any local disturbance (Mizuno et al., 1991). After the materials were compressed, bed height was measured with a laser displacement meter and the difference between the initial bed height and the average bed height after acceleration was calculated.

As a result, it is shown that Eq.1 is consistent with experimental result within 6 % (silica sand) and 5% (fly ash) in porosity when assuming the grain diameter=24 μm and 4.5 μm, respectively. This diameter corresponds to the median of cumulative weight distribution of the grains. Also, the diameter of the small silica sand grains sticked with large grains is close to 24 μm.

High velocity impact cratering experiments on ice-sand mixture simulating the surface of icy satellites

TAKANO, Shota[1*] ; ARAKAWA, Masahiko[1] ; YASUI, Minami[2]

[1]Graduate School of Science, Kobe University, [2]Organization of Advanced Science and Technology, Kobe University

It is well known that ice-rock mixtures could be a main component of icy satellites, the surface crust of asteroid Ceres. Ceres' icy crust could be impacted by various asteroids with different components and physical properties will affect the crater morphology. Therefore, we would obtain various information from the investigation of the observed craters such as material properties of impacted asteroids and the internal structures of the icy crust and so on. To conduct these investigation, the laboratory experiments would be necessary to derive such information from the observed crater. Then, we should carry out the cratering experiments on ice, ice-rock mixtures and the layered target.

Impact experiments on ice has been conducted systematically under various conditions. However, the cratering experiments on ice-rock mixture were limited in the impact velocity range and the rock contents. It is necessary to experiment at the velocity higher than 4km/s to apply to craters on Ceres, but it is not done now. Therefore, we made cratering experiments on ice?rock mixtures at the impact velocity higher than 1km/s using the several types of the projectile, and compared them with the pure ice to clarify the effects of rock inclusion on the crater morphology and crater scaling law.

We installed and used a new two-stage light gas gun at Kobe University in 2013. We prepared ice-rock mixture targets simulating Ceres crust which consisted of water ice and quartz sand having a particle size of about 500μm, and the quartz content was regulated to be 81$\pm$2wt%. The ice-sand mixture was made in a cylindrical metal container with the height of 5$\sim$10cm and the diameter of 15cm. The water-sand mixture was frozen in a freezer with the temperature from -23 ℃ to -15 ℃. Used spherical projectiles were made of aluminum (2.7g/cm3), titanium (5g/cm3), and zirconium (5.7g/cm3), respectively. We lunched projectiles at 1.6$\sim$5.1km/s with nylon sabots to use various types of projectiles. To prevent targets from melting, the vacuum chamber was evacuated for insulation. The chamber pressure during the experiments was from 200 to 230Pa. A crater formation process was taken by an image-converter camera every 5μs, and 18 successive images were obtained for each shot. From these images, we examined the characteristics of impact eject such as the growth rate, and the shape, and it was compared with that of pure ice. We measured the crater shapes by a caliper.

We found that the spallation was difficult to occur on the ice-rock mixture targets compared to pure ice targets. So, the depth-diameter ratio of the crater for ice-rock mixtures, these dependencies on the velocities, and the projectile densities was different from that of pure ice targets. We found that the crater diameter on the ice-rock mixture is about a half of that on pure ice at the same impact energy. Hiraoka et al. (2004) made the cratering experiments on ice-rock mixture with the rock contents from 0 to 50 wt% at the constant impact energy. We compared their results with our results obtained for 80 wt% and found that our result is almost consistent with their results of 50 wt% content. This means that the crater size stop decreasing at 50 wt%, then it becomes almost constant until 80 wt%. We speculate that the crater size might drastically change to be small between 80 to 100 wt% corresponding to rock itself. It might be possible that the crater size could be controlled by the ice strength from 0 to 80wt% and by the rock strength at the range of content near 100 wt%. The crater scaling law proposed by Housen and Holsapple (2012) was applied, and the scaled crater radius π_R and the scaled strengthπ_Y were investigated in our results. Our results were compared with that of pure ice and the ice-rock mixture's dynamic tensile strength was supposed to be 100MPa if the ice-rock mixture was scaled by the same parameter as that of pure ice.

Experimental study on the decay process of impact-induced stress propagating through granular materials

MATSUE, Kazuma[1*] ; ARAKAWA, Masahiko[1] ; YASUI, Minami[2]

[1]Graduate School of Science, Kobe University, [2]Organization of Advanced Science and Technology, Kobe University

Introduction: Impact process is one of the most important physical processes in the solar nebula. In order to understand the impact histories related to planetary formation process, it is important to study the impact cratering process and the scaling law. Impact cratering experiments have been performed on granular material, and the crater size is found to be different depending on the target material. So, it is necessary to study how physical properties affect the cratering process, especially for excavation stage. Excavation flow is a main process that controls the crater size, so we should examine the effects of material properties. However, it is difficult to observe the flow inside the target, so we used the in-material sensor to measure the pressure. The pressure distribution in the granular target would show the flow and we can compare the crater size and the pressure distribution to clarify the effect of target materials on the crater formation process.

Experimental method: We prepared a target container with a pressure sensor to measure the stress generated by impact. It is made of aluminum with the size of 10cm×10cm×10cm, and we changed the depth of the granular target from 1 to 10cm. The pressure sensor (20kPa, ≤2kHz)was attached on the bottom of the container just below the impact point, and impact experiments were conducted by a free-fall or by a one-stage vertical He-gas gun in Kobe University. We studied the effects of projectile size and impact velocity on the crater size and the stress wave. We used glass beads and quartz sand with the diameter of 100 and 500μm as granular target, and glass balls (ϕ=7.75, 10, 15mm) in free-fall, nylon and alumina (ϕ= 3mm) in vertical gun experiments as projectile. Impact velocity is 2-5.5m/s in free-fall and 60-70m/s in vertical gun experiments. We observed crater size and pressure wave in each experiment.

Results: We found that the size of the impact crater strongly depends on the granular materials, that is, the crater formed on the quartz sand was systematically smaller than that formed on the glass beads. Then, we found that the pressure wave increased suddenly and decreased with a relaxation time depending on target materials. The relaxation time is small for quartz sand and long for glass beads, and the relaxation time of 100μm quartz sand was not measured because of normal mode oscillation of the pressure sensor: it means that the time is less than 0.5ms.

Although the normal mode oscillation of the sensor was observed in the high velocity impact and the shallow depth impact in the case of gas gun experiments, we analyzed the peak of measure pressure waves (P_{max}) and obtained the relaxation time (τ) by fitting them with the following function: $P(t)$-$P(\infty)$=$A\exp(-t/\tau)$, where t is time after the impact. As a result, τ is obtained to be 1ms for glass beads target irrespective of the bead size, and 0.1ms for 500μm quartz sand. The relationship between the pressure and the propagation distance was described by $P(r)=P_0(r/L)^{-b}$, where L is a projectile radius, r is distance, P_0 is an initial impact pressure, and b is a decay constant. The decay constant was found to change with the impact velocity and the target materials: it was derived to be 0.79,0.94 in a low velocity range, 1.61,1.71 in a high velocity range for glass beads, quartz sand.

We found that the relationship between the crater size and P_{max} at 4cm depth was different in each granular material. The crater size of the glass beads target was larger than that of the quartz sand at the same P_{max} . Then, we introduce a new parameter expressed by τ times P_{max}, so called impulse, I. We renewed the relationship using I instead of P_{max} and found that all data set were merged on one line. This means that I could be a suitable parameter to describe the material dependence of the cratering efficiency. We would like to clarify what material properties determine the τ and how it changed with the physical condition in the future.

Effects of impact angles on the impact strength of icy and rocky planetesimals for the collision among equal size bodies

KOMOTO, Yasunari[1] ; ARAKAWA, Masahiko[1] ; YASUI, Minami[2*]

[1]Graduate School of Science, Kobe University, [2]Organization of Advanced Science and Technology, Kobe University

Introduction: There are a lot of impact experiments to simulate planetesimals collisions, and most of them had a large mass difference between a projectile and a target. The impact strength is well known that they are described by the energy density: the ratio of the projectile kinetic energy to the mass of the target and the projectile. So, when the projectile is rather smaller than the target (this is an usual situation in the lab. experiments), the very high speed more than 1 km/s is necessary to disrupt the target. This is an analogy of the present asteroid collisions, but it might be far from the simulation expected in planetesimals collisions. Because we speculate the collisions among the similar size small bodies in the solar nebula, and the relative collisional velocity among them could be several 10 m/s. Therefore, it should be important that the planetesimals were disrupted or not at the impact speed around several 10m/s for the collisions among similar size small bodies, then we must conduct the collisional experiments to derive the impact strength of planetesimals in the similar size collisions. In this study, we carried out the impact experiments using the equal size ball made of ice, gypsum, and gypsum-glass beads mixture. These samples simulate icy planetesimals, planetesimlas for chondrite parent bodies. We also conducted not only head-on collision but also oblique collision and studied the effects of impact angles on the impact disruption.

Experimental methods: We prepared three types of ball sample with the size of 25 mm and 30 mm made of ice, gypsum-glass beads mixture, and gypsum. They were made by putting each solution in a round mold to form spherical sample. The impact experiments were made by using three types of accelerators: they are a spring gun for low velocity collision, a vertical gas gun for ice and a horizontal gas gun for gypsum, and the achieved velocity is from 4 to 160m/s. The oblique impact was also conducted by shifting the impact point from the geometrical center of the target. The impact angle was changed from 0 deg. (normal impact) to 80 deg. (nearly passing away impact). Impact experiments were observed by a high-speed camera and all of the impact fragments were collected to measure the weight and establish the size distribution. We looked for the recovered fragments to identify the same fragment found in the video image, and tried to construct the velocity-mass distribution of the impact fragments.

Results: We used the reduce mass to calculate the impact energy in the center-of-mass system, so the energy density Q_g was defined by the ratio of the kinetic energy of two bodies in the center-of-mass system to the mass of the two equal balls. The impact strength was obtained for the similar size collisions by using this Q_g. As a result, the impact strength ${Q_g}^*$ of ice and gypsum was derived to be almost similar to that obtained for the impact experiments with the mass difference more than 10. However, the ${Q_g}^*$ of glass beads-gypsum mixture was derived to be rather smaller than that obtained in the previous experiments. In the oblique impacts, the mass of the maximum impact fragment was found to decrease with the increase of the impact angle. So, we modify the energy density by using the velocity component normal to the impact surface which effectively work for the disruption, then this modified energy density enabled us to fit all of the data on one line for each target. Finally, we estimated the re-accumulation condition of planetesimals according to the velocity distribution of the impact fragments that obtained in this study. As a result, it is speculated that icy planetesimals could re-accumulate for the bodies larger than 20 km in the diameter, and this threshold size for the planetesimals of ordinary chondrite parent bodies is 5.2km and that for the planetesimals of carbonaceous chondtite parent bodies is 6.7km.

Dynamic compaction experiments of porous materials: Implications for impact compaction of pre-planetesimals

YASUI, Minami[1*] ; YOKOTA, Mizuki[2] ; SAKAMOTO, Kana[2] ; ARAKAWA, Masahiko[3]

[1]Organization of Advanced Science and Technology, Kobe University, [2]Faculty of Science, Kobe University, [3]Graduate School of Science, Kobe University

Introduction: Two theories are proposed for the growth mechanism of bodies with the diameter from cm to several hundreds meters (pre-planetesimals). One is that planetesimals could form by a gravitational instability in the dust layer of a protoplanetary disk. The other is that planetesimals could form by a repeating impact coagulation of dust aggregates. In this study, we focus on the latter theory. There are some problems that planetesimals could not grow because of rebound and catastrophic disruption among pre-planetesimals caused by the increase of average density. Sakamoto (2013) did free-fall impact experiments of porous snow simulating icy pre-planetesimals by using the stainless cylinder to examine the compaction conditions, and clarified the relationship between the impact stress and the final density profile and the size of compaction area. However, the impact velocities in her study were 0.7 to 3.5 m/s, relatively lower compared to the average impact speed of pre-planetesimals. In this study, we conducted impact experiments of porous materials at $>$5 m/s to examine the compaction mechanism, impact stress, and density profile.

Experimental methods: The target was high porous snow with the initial porosities of 70 and 80% and perlite particles with the density of 85 kg/m^3 simulating the icy and rocky pre-planetesimals. We did impact experiments of snow in the cold room (-10 ℃) at ILTS, Hokkaido University, and perlite at Kobe University, by using the one-stage vertical and horizontal light gas guns. The vertical gun was used for only snow targets. The target was prepared by packing ice grains or perlite particles into the acrylic tube, up to 120 mm depth, and the blue ice grains or the red perlite particles were put into the target every 20 mm from the bottom due to measure the density changing with depth. The piston was set on the target surface in the acrylic tube, and accelerated by the projectile to compress the target. The projectiles were an elastic ball with the diameter of 25 mm for horizontal gun and same ball installed on the cylindrical sabot with the diameter of 30 mm for vertical gun. The pistons were a polycarbonate, an aluminum, and a polyacetal cylinders with the diameter of 30 mm and the height of 10-30 mm to examine the effects of piston type. The impact velocities were 2-118 m/s. The impact compaction of the target was observed by a high-speed digital camera. The shutter speed was set to be 20 to 100 μs, and the frame rate was set to be 6000 to 10000 fps.

Results: First, we measured the impact stress from the motion of piston, σ_p, and compared σ_p with the strength calculated by Kinoshita method, Y. As a result, the σ_p was almost same with the Y for both perlite and snow targets.

Next, we measured the final density of target, ρ_f, and obtained the relationship between the ρ_f and the kinetic energy or the momentum of projectile. As a result, we found that the ρ_f for perlite was determined by the kinetic energy while that for snow was determined by the momentum. Furthermore, we proposed the model of ρ_f for perlite and snow by assuming these compaction mechanisms: the perlite compressed due to the fracture of perlite particles while the snow compressed due to the decrease of area among ice grains. We compared these models with our experimental results and found that they were almost consistent with each other.

Finally, we examined the relationship between the σ_p and the final density of top layer in the target, ρ_{f1}. As a result, we obtained as ρ_{f1}=3.0${\sigma_p}^{0.8}$ for perlite and ρ_{f1}=127${\sigma_p}^{0.3}$ for snow in kPa. The data for snow at σ_p $>$100 kPa was scattered because the compaction mechanism was changed at σ_p $>$100 kPa.

Effect of particle size distribution on thermal conductivity of powdered materials

SAKATANI, Naoya[1*] ; OGAWA, Kazunori[2] ; HONDA, Rie[3] ; ARAKAWA, Masahiko[4] ; TANAKA, Satoshi[2]

[1]The Graduate University for Advanced Studies, [2]Institute of Space and Astronautical Science, [3]Kochi University, [4]Kobe University

Understanding about heat transport mechanism of powdered materials, such as lunar surface regolith, is important issue in order to estimate planetary thermal evolution and present thermal state. Thermal conductivity of powdered materials depends on various parameters (particle size and its distribution, temperature, compressional stress, etc.). Depending on these parameters, thermal conductivity can vary by one order of magnitude. Due to insufficiency of the experimental studies, heat transfer mechanism is not understood enough, and it is difficult to constrain in-situ thermal conductivity on planetary surface.

Our purpose is to understand the heat transfer mechanism of powdered materials under vacuum conditions by means of systematic survey of parameter dependences of the thermal conductivity. This will enable us to model the thermal conductivity, which can apply the estimation of thermal conductivity structure on planetary surface. Most of previous studies focus on the powdered samples with uniform particle size. However, actual planetary regolith has wide range of particle size from sub-μm to mm. Moreover, parent bodies of chondritic meteorites would be composed of mixture of meteoritic matrix and chondrule. In this presentation, we will report the effect of particle size distribution on the thermal conductivity under vacuum.

Glass beads mixtures of 100 μm and 200 μm in diameters were used. Prepared samples had volume mixing ratio of 1:0, 2:1, 1:1, 1:2, and 0:1. Porosity of each sample was 0.38, 0.35, 0.32, 0.35, and 0.38, respectively. The thermal conductivity of these samples was measured by line heat source method.

As a result, 100 and 200 μm glass beads of uniform sizes had 0.0023 and 0.0035 W/mK, respectively. This difference in the conductivity would be caused by the difference of radiative heat transfer. On the other hand, mixing samples had thermal conductivity of 0.0039, 0.0029, and 0.0039 W/mK for mixing ratio of 2:1, 1:1, and 1:2, respectively. These conductivities related well to porosity. There were no linear relation between thermal conductivity and mixing ratio. We found M-shaped correlation between them.

The measured thermal conductivity can be represented by the sum of solid conductivity, which is conductive contribution through contact area between the particles, and radiative conductivity, which is radiative contribution through the pore between the particle surfaces. Our results will be explained by the variation of these conductivities with particle size distribution. Therefore, it is necessary to separate the measured values into solid and radiative conductivities for explanation of our experimental results. This can be accomplished by investigation of temperature dependence of the conductivity. In this presentation, we will report dependence of solid and radiative conductivities on the particle size distribution.

Measurement experiments of thermal conductivity and sound velocity in sintered glass beads

TSUDA, Shoko[1] ; OGAWA, Kazunori[1*] ; SAKATANI, Naoya[2] ; ARAKAWA, Masahiko[3] ; YASUI, Minami[3]

[1]The University of Tokyo, [2]The Graduate University for Advanced Studies, [3]Kobe University

The thermal conductivity and sound velocity of sintered particle materials (glass beads) were experimentally measured, and a correlation between them was investigated. Particles have often played important roles in the solar system history. Especially dust particles condensed in the early solar nebula formed planetesimals, and they remained as the main structure material of the bodies. The particles were then gradually sintered as temperature increased by disintegrations of radioactive isotopes. Finally, a part of planetesimals might be completely sintered and began to melt. Currently the sintered materials may also exist on the lunar and asteroid subsurface for example. Mechanical and thermal properties of such sintered materials are essential information for investigating the history of these bodies.

In the thermal issues, particles are known as a strong thermal insulator in vacuum. Although the thermal conductivity of sintered materials has never been measured, it is considered to be a value between the unsintered and a continuous rock, depending on degree of the sintering process. Concerning the sound velocity, characteristic feature depending on the sintering degree is expected to be similar to the thermal conductivity, because basically the phonon conduction is a common mechanism for both the thermal and sound phenomena in electrical insulation materials.

In this presentation, we report results of the first experiments of the thermal conductivity and sound velocity measurements in sintered particle materials. For measurement samples, 9 different blocks of sintered soda-lime glass beads were prepared: three bead diameters of 180-255, 355-500, and 710-1000 μm, and three degrees of sintering that have nearly the same porosity 40%. The cross section of sintering contact sites (neck) was evaluated for each sample. The thermal conductivity was measured by the line heat source method by a line heater and temperature sensors given in the sample in advance. The sound velocity was directly measured by a transmitter and receiver put at both ends of the block samples.

As results of the experiments, both the thermal conductivity and the sound velocity had an apparent correlation with each other, and with degree of sintering. They appeared almost in proportion to the neck diameter, which feature obviously indicates that the neck or contact size controls the bulk thermal and sound conductions, in weakly-sintered particle systems at least. These results can be directly applied to estimation of thermal and mechanical property of the ancient planetesimals. These results also suggest that the thermal conductivity of sintered materials, and also of unsintered particles probably, can be evaluated by measurements of the sound velocity.

Experiment to know the power to pull mutually between things that are axisymmetric for the Saturn's-like magnetic axis

MASE, Hirofumi[1*]

[1]none

The magnetic axis of magnetic field in the Saturn is corresponding to the rotation axis(1). And, Saturn's rings revolve on the equatorial plane of the Saturn(2). I want to think that the reason why beautiful rings exist miraculously is related to these miraculous features. The power to pull against each other between things that are axisymmetric for the magnetic axis is generated on the plane that passes center of the axial dipole field and intersects vertically for the magnetic axis. Because the material that composes the ring is tied to the material on the 180-degree other side by the surcharge-gravitation, Saturn's rings are generated and maintained. I am making the experiment that proves the truth of this hypothesis. I introduce the result of it.

∗∗∗∗Composition of experiment (Please refer to the drawing)∗∗

"A","C":the one(34L∗25W∗25H) that natural whetstone(sandstone) was cut

"B":the one(40L∗40W∗40-80H) that 4-8 pieces of permanent magnet(anisotropic ferrite,40L∗40W∗10H,B=79mT,F=2.746kgf)s were piled up

Device box:I used "two step box" on the market and remodeled it. The front side of the left cell of this box is glazed. The front side of the right cell of this box is opening. Plywood in which "B" is set is put on the medium plate of this box to close the hole in the plate. The left cell is airtight exclusive of the top of the vinyl chloride pipe. "A" is hung from the ceiling by two strings(1,700L) and can swing freely in the left cell. The space of "B" and "A" in geostationary point is about 20mm. "C" is hung from the top board in the right cell by the string. The edge of another string is bonded on the right side of "C". (State:"C1")"C" can be separated from "B" by pulling this string from the right side of this box. (State:"C2")"C" can approach "B" by loosening this string.

∗∗∗∗Condition of experiment∗∗I experimented on the following three kinds of by changing the composition and direction of "B". Condition 1:pile 8 pieces vertically(magnetic axis is perpendicular) Condition 2:pile 4 pieces vertically(axis, perpendicular) Condition 3:pile 4 pieces horizontally(axis, horizontal right and left)

∗∗∗∗Procedure of one experiment∗∗1.I wait as much as possible until the swing of "A" stops(now"C1"). 2.I begin taking a picture of the animation of "A" with the video camera(now"C1"). 3.After 2 minutes pass, I change State from "C1" into "C2"(now"C2"). 4.After 4 minutes pass, from "C2" into "C1"(now"C1"). 5.After 6 minutes pass, from "C1" into "C2"(now"C2"). 6.After 8 minutes pass, I end taking a picture.

∗∗∗∗Result of experiment∗∗"A" swung faintly when taking a picture was begun. 1.In case of Condition 1 and 2, the swing was controlled at time zone in State "C2" of the first times, and was amplified at time zone in State "C2" of the second times. 2.In case of Condition 3, I could not confirm special change of "A" during all time.

∗∗∗∗Consideration∗∗I seem I can conclude that static electricity and magnetism don't influence the result by the comparison between Condition 2 and 3. There is a possibility that the power that I had expected was detected.

Compositional and textural inhomogeneity of Chelyabinsk meteorites

ARAI, Tomoko[1*] ; ABE, Shinsuke[2] ; OHTSUKA, Katsuhito[3] ; HIROI, Takahiro[4] ; KOMATSU, Mutsumi[5] ; FAGAN, Tim[5]

[1]Chiba Inst. of Technology, Planetary Exploration Research Center, [2]Nihon University, [3]Tokyo Meteor Network, [4]Brown University, [5]Waseda University

Meteorites are important sources of information on composition and age of the solar system materials. However, collected meteorites are likely biased and unrepresentative of the near-Earth meteoroid population. Mineralogy and reflectance spectra of meteorites are used to link specific classes of meteorites and asteroids, but are not definitive enough. Meteorites of which fall were witnessed are rare and substantial case when meteorites and their parent bodies are directly linked, and both orbital and material data of the near-Earth bodies are known. The fireball was eye-witnessed near Chelyabinsk city of Russia in 15 February 2013, and associated meteorites of total mass of 4-6 ton, were subsequently recovered. Survey of physical and chemical nature of small bodies with an Earth-crossing orbit is crucial in understanding the origin and evolution of the near-Earth materials and in planetary defense. While near-Earth objects (NEO) >1 km dia. have been largely identified by NEO survey programs, most NEOs <?100 m dia. remain unknown. Thus, it is important to study the Chelyabinsk-sized objects. We present mineralogy and reflectance spectra of several chips of Chelyabinsk meteorites, which indicate chemical and spectral inhomogeneity, suggesting the complex history of the parent body.

Classification and petrologic features of chondrites of petrologic type 7

KIMURA, Makoto[1*] ; YAMAGUCHI, Akira[2] ; FRIEDRICH, Jon[3]

[1]Ibaraki University / National Institute of Polar Research, [2]National Institute of Polar Research, [3]Fordham University / American Museum of Natural History

Chondrites are classified into petrologic types 1-6, which distinguish the degrees of aqueous alteration (types 1-2), and thermal metamorphism (types 4-6). In addition, a petrographic type 7 has also been proposed to indicate an even higher degree of thermal metamorphism [1]. Such chondrites contain only relict chondrules, and plagioclase is commonly coarse-grained. Low-Ca pyroxene contains >1% CaO. However, most of these chondrites may actually be melt rocks or melt breccias [2], and the occurrence of a type 7 is controversial problem. However, LEW 88663 seems to be a genuine type 7 chondrite [3], not a melt rock.

Here we report the preliminary results of our petrographic study on ordinary chondrites classified as type 7, to explore their thermal history, classification, and genetic relationships to melt breccia and others.

Many chondrites are classified as type 7 in NIPR and other collections (77 chondrites at present). However, the detailed petrography has been rarely reported for these chondrites. Here we studied 4 H7, 4 L7, and 4 LL7 in NIPR collections. We also examined Uden (LL7).

All of the chondrites studied here show a well recrystallized texture. Triple junctions among olivine and pyroxene is commonly observed. However, Y-790124 and -790446 include many chondrules, indicative of type 6. A-880844 and -880993 contain clasts of various petrologic types, and are genomict breccias (H5-6 and LL4-6, respectively). Although Y-790144 does not seemto contain any chondrules, it is shock-darkened chondrite, and has lost its original texture.

Y-74160 has been extensively studied [e.g., 4]. This chondrite, Y-791067, and Uden consist of clasts among fine-grained matrix. The clasts comprise coarse-grained olivine, low-Ca pyroxene, and plagioclase. Olivine is typically included as chadacryst in pyroxene. The matrix is also highly recrystallized. Friedrich et al. [5] suggested that Y-74160 and Uden were subjected to Fe-FeS mobilization. These chondrites experienced partial melting, recrystallization, and brecciation, and may be classified as recrystallized breccias.

On the other hand, five chondrites, Y-75008, -790120, and -790960 (H7s), Y-82088 (L7), and Y-82067 (LL7), contain no or only a few relic chondrule in each section. They show highly recrystallized texture, and are not subjected to brecciation and melting. Y-82067 has composition identical to equilibrated LL chondrites [5]. These five chondrites are temporarily classified as type 7, if type 7 chondrite is defined to have experienced only a high degree of thermal metamorphism.

We are now examining modal mineral abundances and conducting mineral analyses, which will shed light on the classification criteria for type 7 chondrites.

Origin of eclogitic clasts in a CR2 chondrite: Evidence of frequent collisions and disruptions of large planetesimals?

HIYAGON, Hajime[1*] ; SUGIURA, Naoji[1] ; KITA, Noriko T.[2] ; KIMURA, Makoto[3] ; MORISHITA, Yuichi[4] ; TAKEHANA, Yoshie[1]

[1]Graduate School of Science, The University of Tokyo, [2]Department of Geoscience, University of Wisconsin -Madison, USA, [3]Faculty of Science, Ibaraki University, [4]Department of Geosciences, Shizuoka University

Achondritic clasts found in the Northwest Africa 801 (NWA801) CR2 chondrite have significant importance in planetary science (Sugiura et al., 2008; Kimura et al., 2010, 2013): (i) it provides strong evidence that achondrites formed earlier than chondrites, (ii) the clasts contain eclogitic high mineral assemblages (garnet and omphacite), suggesting formation at a high pressure (˜3 GPa and ˜1000 C; Kimura et al., 2013), and (iii) the clasts contain two lithologies, graphite-bearing (GBL) and graphite-free (GFL), and the presence of graphite in GBL implies some relations to ureilite.

We performed ion microprobe studies of oxygen isotopes and rare earth element (REE) abundances for selected minerals in the clasts (Hiyagon et al., 2014). Based on the newly obtained data and diffusion calculations, we discuss possible origin of the clasts, esp., whether they formed under a static high pressure in a large planetesimal or formed under a shock high pressure.

Key observations are as follows. (1) Olivine (ol) grains in the clasts (˜20 micrometers in size) are chemically homogeneous with Mg# 66-68. (2) Most of orthopyroxene (opx) grains (˜20 micrometers in size) are homogeneous with Mg# 70-75, but a few large opx grains (50-80 micrometers in size) have Mg-rich cores with Mg# 78-87. (3) Various geothermobarometers (7 equations for mineral pairs of opx-cpx, garnet-cpx, garnet-opx and garnet-olivine) consistently give a high P-T condition of 940-1080 C and 2.8-4.2 GPa. (4) All the oxygen isotopic data of ol and opx fall on a correlation line with a slope of ˜0.6. Data for GFL (ol) are homogeneous with delta18O ˜+5 permil, located close to the CCAM line and the ureilite field, but data for GBL (ol +opx) are variable with delta18O from +2.4 to +4.3 permil. (5) Major host minerals of REEs are chlorapatite (both LREEs and HREEs) and garnet (for HREEs). The estimated bulk REE patterns for GBL and GFL are almost flat (unfractionated) with ˜1.2 x CI and ˜1.8 x CI, respectively.

We consider that the presence/absence of graphite in the two lithologies may be due to absence/presence of smelting reactions, FeO (in silicates) + C (graphite) = Fe (metal) + CO (gas). This means that GBL might form at a deeper portion and GFL might form at a shallower portion, respectively, of a planetesimal.

We consider two different models: a shock high-P model and a static high-P model. Based on careful diffusion calculations, we argue that (1) almost homogeneous Fe/Mg ratios in ol and opx (with some Mg-rich cores) can be explained by heating at 1000 C for 120-800 years, (2) oxygen isotopic variations in GBL must have established before homogenization of Fe/Mg ratios in olivine, (3) consistency of different geothermobarometers requires equilibration of different elements among different mineral pairs, strongly suggesting a static high-P model, (4) in a static high-P model, ˜3 GPa corresponds to the pressure at the center of a large planetesimal with a radius of ˜1500 km, almost the size of the Moon, (5) consistency of different geothermobarometers also suggests a rapid cooling after heating several hundreds of years at ˜1000 C at ˜3 GPa, suggesting possibe disruption of the parent body.

In conclusion, the present results suggest frequent collisions and disruptions of a large planetesimals at a certain stage of the solar system evolution.

Estimation of the size of the angrite parent body

SUZUKI, Hiroko[1*] ; OZAWA, Kazuhito[1] ; NAGAHARA, Hiroko[1] ; MIKOUCHI, Takashi[1]

[1]Department of Earth and Planetary Science, University of Tokyo

Angrites has very old crystallization age yielding 4557 - 4564Ma (Brennecka and Wadhwa, 2012; Kleine et al., 2012) and are igneous rocks come from differentiated planetesimal or protoplanet (e.g. Prinz and Weisberg 1995; Baker et al., 2005; Weiss et al., 2008). Angrites preserve information on such differentiated planets, and are one of the best targets for studying processed operated in the early stages of planetary evolution of the solar system. However, the angrite parent body has not been found, and we have scarce knowledge on its planet size, which is one of the most important information in planetary science. The radius of angrite parent body is believed to be larger than 100 ? 200km because of the operation of dynamo, which requires prolonged high temperature of the planet interior due to heat production of ^{26}Al decay to achieve its core formation (Weiss et al., 2008; Elkins-Tanton et al., 2011). The upper limit of radius is not constrained at all, although 2440km is proposed based on ambiguous evidence for Mercury as the angrite parent body (Papike et al., 2003; Kuehner et al., 2006). The radius of the angrite parent body, particularly its upper limit, needs to be further constrained. In this study, we try to constrain the upper limit of the planet size from the presence of spherical voids as large as 25mm in D'Orbigny angrite.

D'Orbigny has many spherical voids suggesting that they formed in 100% molten magma before crystallization. The vesicles are deformed while ascending in the melt depending on several physical parameters such as, melt viscosity and the size of vesicles. There are two dimensionless numbers that determine the shape, Reynolds number and Eotvos (or Bond) number. Reynolds number is a ratio of inertia force and viscous force and Eotvos number is a ratio of buoyancy force and surface tension. These two numbers depends on gravity of the parental body, and the gravity depends on the radius of the parental body. Therefore, spherical shape of the largest void enables us to estimate the upper limit of the radius of the angrite parent body. The boundary conditions for spherical and nonspherical regimes have been determined by Bhaga and Weber (1981) based on fluid dynamic experiments and by Hua and Lou (2007) based on numerical simulations.

Spherical voids in D'Orbigny are armored by fine-grained olivine and plagioclase crystals, where are the first liquidus phases, suggesting that the spherical shape was frozen by heterogeneous nucleation and growth of these phases on the bubble wall. In order to know relationship between Reynolds and Eotvos numbers for D'Orbigny, accurate estimation of density and viscosity is very important, which are strongly dependent on temperature of shape freezing. The temperature was estimated by MELTS (Ghiorso and Sack, 1995) as metastable olivine liquidus for the D'Obigny bulk composition to be ˜1100 ℃, from which the density and viscosity of D'Obigny magma are estimated to be ˜3000 kg/m^3 and ˜1.0 Pa s, respectively. Surface tension of the melt is 0.35N/m according to Walker and Mullins (1981), which is corrected by 50% occupation of olivine and plagioclase on the bubble-melt interface. We assume the average density of the parent body as 4000kg/m^3 for the planet having core, such as asteroid 4 Vesta (Zuber et al., 2011). By using these parameters, we estimated the upper limit of radius to be 700±100 km, which is clearly much smaller than that of Mercury.

Crystallization experiment of alpha-Fe, gamma-Fe and iron compounds found in the Almahata Sitta and Antarctic ureilites

AOYAGI, Yuya[1*] ; MIKOUCHI, Takashi[1] ; SUGIYAMA, Kazumasa[2] ; YOKOYAMA, Yoshihiko[2] ; GOODRICH, Cyrena A.[3] ; ZOLENSKY, Michael E.[4]

[1]Dept. of Earth & Planet. Sci., Univ. of Tokyo, [2]Inst. for Materials Research, Tohoku Univ., [3]Planet. Sci. Inst., [4]NASA-JSC

Ureilites are ultramafic achondrites whose origin and petrogenesis are still controversial. The cooling rate of ureilites estimated from silicates is approximately a few degrees per hour, and it was considered to reflect catastrophic disruption of the ureilite parent body. Ureilites were broken into meter-sized fragments and then formed daughter body(ies) by re-accumulation.

Fe-Ni metal is one of the major components of all types of ureilites. Almahata Sitta, having fallen on the earth in October 2008, was classified as a polymict ureilite and ureilitic fragments from the Almahata Sitta contain abundant Fe-Ni metal. In previous studies, some grain boundary metals in Almahata Sitta ureilites show unique textures, not found in main group ureilites. These textures show characteristic assemblages with various combinations of α-iron (bcc), γ-iron (fcc), cohenite ($[Fe,Ni]_3C$) and schreibersite ($[Fe,Ni]_3P$).

Those metal textures resemble the product by steelmaking process in the earth, for example martensite (α-iron and γ-iron). Generally, these textures require rapid cooling equivalent to quenching by water ($>$100 ℃/s). However, the cooling rate estimated from silicates (ca. several ℃/h) is much slower than that in producing the martensite. Thus, these metal textures may record the event separated from the event that recorded in the silicates, that is, disruption of parent body. Therefore, studying these complicated metal textures will contribute to a better understanding of the formation and origin of metal in ureilites with the information about their thermal histories.

Those metal textures were only found in Almahata Sitta fragment #44, in previous studies, but we found similar assemblages composed of iron metal and its compounds in other fragments of Almahata Sitta and Antarctic ureilites. Forms and abundances are variable depending on samples, but it is suggested that those mineral assemblages in Fe-Ni metal are commonly found in ureilites.

To estimate the cooling rate which can form these iron and iron compounds textures, we performed cooling experiments by the electric furnace to heat and quench metal whose compositions correspond to metals showing complex metal phase assemblages in Almahata Sitta ureilite. The results suggest that those metal textures can be achieved in the cooling rate faster than the lowest limit between 10 ℃/s and 0.83 ℃/s, whose chemical composition is $Fe_{79.2}Ni_{3.4}P_{2.5}Si_{2.7}C_{12.2}$. At lower cooling rate (0.83 or 0.04 ℃/s) and 10 ℃/s of other starting material ($Fe_{86.4}Ni_{2.8}P_{0.7}Si_{4.1}C_{6.0}$), interstitial schreibersite among rounded iron was detected and neither cohenite nor γ-iron has been formed. In the carbon-free composition ($Fe_{91.2}Ni_{3.9}P_{0.5}Si_{4.4}$), similar textures were not generated at all cooling rates. This cooling rate, forming metal textures, is much faster than that estimated from silicates, and thus it is concluded that the event recorded by the silicates and the event formed the metal textures were truly separated.

Before disruption of ureilite parent body, primary metals probably melted and mixed with surrounding materials (graphite, phosphide and other iron compounds) to various extents at high temperature. The iron phase was considered to be uniformly γ-iron. Then, the ureilite parent body was destroyed and silicate minerals obtained cooling rate by quenching. Later, daughter body(ies) formed by accumulation of meter-size fragments. If daughter body(ies) was either shocked while still hot or heated by shock and then disrupted into smaller fragments (cm-size), the formation of iron textures may be achieved by super rapid cooling exceeding 1 ℃/s. The metal grains without γ-iron would experience relatively slow cooling due to larger fragment size. Consequently, it is considered that the complex coexistences of iron and iron compounds found in ureilites have recorded temperature change and fragmentation process due to the impacts on the parent body and daughter body(ies).

Early impact events on differentiated protoplanets: Evidence from basaltic achondrites

YAMAGUCHI, Akira[1*]

[1]National Institute of Polar Research

Impact events are a ubiquitous geological process on planetesimals and protoplanets, evidenced by the presence of shock and brecciated textures in asteroidal meteorites. However, evidence for early impact events were obliterated by overprints of later thermal events such as volcanism and thermal metamorphism. We investigated early impact events in these meteorites on the basis of mineralogical and geochemical data.

At present, there are ˜5 eucrites which were derived from distinct protoplanets. An anomalous eucrite, Ibitira, is a strongly recrystallized rock. Low-Ca pyroxene shows homogeneous compositions, indicating that these rocks experienced prolonged thermal metamorphism (˜900-1000 C), as did most basaltic eucrites. The presence of unequilibrated pyroxenes related to oxide grains can be explained by short reheating event (and partial melting) and rapid cooling. Normal eucrites, EET 90020 and Y 86763, and a cumulate eucrite Moore County seem to have experienced a similar history. Most likely explanation for this thermal history is that they were excavated by impact from hot interior.

Anomalous cumulate eucrites Dho 700 and EET 92023 are medium-grained granular rocks similar to cumulate eucrites. Anomalous basaltic eucrite, NWA 011 shows a recrystallized texture. These rocks are crystalline (unbrecciated) but contain significant amounts of impactor materials. Dho 700 and EET 92023 contain taenite which is not common in pristine eucrites. The high abundances of siderophile elements are explained by addition of ˜1% iron meteorites. Thus, these rocks experienced impact event before or during crystallization and thermal metamorphism.

All anomalous eucrites studied here show crystalline textures, but have evidence for impact melting or brecciation before thermal events. These meteorites record early collisional history possibly during the stage of runaway growth.

Shock features in a Martian meteorite, Tissint

MIYAHARA, Masaaki[1*] ; OHTANI, Eiji[2] ; EL GORESY, Ahmed[3] ; GILLET, Philippe[4]

[1]DEPSS, Graduate School of Science, Hiroshima Univ., [2]Institute of Mineralogy, Petrology and Economic Geology, Graduate School of Science, Tohoku Uni., [3]BGI, [4]EPFL

Tissint is the fifth fall Martian meteorite collected in Morocco on 2011 [1]. The nomination of a fall Martian meteorite is since 1962. Tissint will bring new clues for Martian evolution because it is less contaminated with terrestrial materials. Tissint is a member of shergottite. Many shergottites experienced a heavy shock event on Mars [e.g., Ref. 2]. We expected that Tissint should be also heavily shocked. A high-pressure polymorph is one of clear evidences for such a dynamic event. Accordingly, we described shock features, especially a high-pressure polymorph by FEG-SEM, EMPA, Raman spectroscopy and FIB-TEM techniques to clarify shock history recorded in Tissint.

We prepared several petrographic thin sections of Tissint for this study. EMPA analysis show that Tissint studied here consists mainly of olivine (Fa_{18-66}), pigeonite or augite ($En_{43-62}Fs_{23-37}Wo_{10-34}$) and labradoritic feldspar ($An_{62-66}Ab_{34-37}Or_{0-1}$). There are many melt-pockets, which is suggestive of a heavy shock event. FEG-SEM and FIB-TEM observations show that olivine grains entrained in the melt-pockets dissociated into silicate-perovskite (now almost amorphous or poorly-crystallized) and magnesiowustite, which is found in a Martian meteorite DaG 735 for the first time [3]. Silicate-perovskite and magnesiowustite show equigranular texture and less than ˜100 nm in dimension. We also identified ringwoodite lamella in some olivine grains adjacent to the melt-pockets. TEM images show that ringwoodite has a dimension of less than ˜500 nm. Raman spectroscopy analysis indicates that most feldspar now transforms into maskelynite. Jadeite-like crystals appear in some feldspar grain adjacent to the melt-pockets.

Considering the dissociation reaction of olivine into silicate-perovskite and magnesiowustite, shock pressure condition recorded in Tissint is beyond ˜23 GPa based on phase diagram deduced from static synthetic experiments [4]. Phase transformation from olivine to ringwoodite also occurs besides the olivine dissociation reaction. Phase transformation from olivine to ringwoodite occurs instead of olivine dissociation reaction with decreasing temperature but under same pressure condition [5], which is due to thermal gradient in the olivine grains adjacent to the melt-pockets although pressure condition should be almost homogeneous. The nucleation and grain growth of a high-pressure polymorph is kinetically controlled. Baziotis et al. (2013)[6] propose that Tissint experienced the largest impact event among known Martian meteorites because ringwoodite appear to be a huge single crystal based on their SEM observations. However, our TEM images clearly depict that ringwoodite is a fine-grained grain assemblage, suggesting that it is unlikely that Tissint experienced the largest impact event.

Estimation of bulk major element composition for Centimeter-Sized Impact Melt Clasts in Lunar Rocks using EPMA

NIIHARA, Takafumi[1*] ; KRING, David A.[2]

[1]NIPR / LPI / SSERVI, [2]LPI / SSERVI

Most of lunar surface rocks are brecciated and mixed with various types of rock fragments and impact melt clasts during multiple impact events. We are testing the Late Stage Heavy Bombardment on the Moon surface [1-3] using Apollo 16 centimeter-sized impact melt clasts in ancient regolith breccias. Bulk composition is a key to understand original (pre-impact) lithologies where the clasts come from [4, 5]. Large-sized impact melt rocks (>5 cm) have been classified into 4 major group (Group 1 to 4) according to Sm and Sc compositions [6]. We compiled major element compositions of the previously classified impact melt rocks [6] and found that we can classify major impact melt groups even when we use major element compositions. However, our samples, centimeter-sized impact melt clasts, are highly restricted on their masses and makes us difficult to obtain bulk composition using conventional techniques (e.g. INAA and XRF). Defocused beam analyses (DBA) with EPMA is used to estimate the bulk compositions for limited mass samples using petrological sections, however, nobody tested accuracy of DBA techniques using certified geochemical standard.

We use a thin section of BCR-2 (fine-grained basalt supplied from USGS) and tested accuracy of DBA method using an EPMA (CAMECA SX-100) at NASA Johnson Space Center. We measured 12 elements (Na, Mg, Si, Al, P, K, Ca, Ti, Fe, Mn, Cr, and Ni) at >250 points with 20 micrometer beam diameter. We corrected density effect following the Warren (1997) method [7]. Averaged SiO_2 and FeO have larger difference from USGS values (+4.4 wt.% for SiO_2, -4.68 Wt.% for FeO) relative to other elements (up to +/- 2.4 wt.%). Although there are major changes in SiO_2 and FeO values after correct the density effect (difference from USGS values are up to -4.1 Wt.% for SiO_2 and up to +4.6 Wt.% for FeO), we suggest the DBA compositions can useable for the fine-grained materials to estimate the bulk major element composition for Apollo 16 impact melt clasts.

We estimated the bulk composition by averaged DBA method for two impact melt clasts in an Apollo 16 ancient regolith breccia 61135 which have optically different 5 regions (Clast1 R1, R2, and R3; and Clast 2 R1 and R2) to reveal the original lithology of the impact melt clasts. Five regions from the two impact melt clasts can be divided into three chemical groups of high-K, low-K and intermediate compositions. Clast 1 R3 has high K (K_2O=0.72 wt.%) and P (P_2O_5=0.35 wt.%), and low Al (Al_2O_3=20.7 wt.%) and Ca (CaO=12.0 wt.%). On the other hand, Clast 1 R1 and R2 have low K (K_2O=0.31-0.27 wt.%) and P (P_2O_5=0.08-0.07 wt.%) with high Al (Al_2O_3=26.1-25.2 wt.%) and Ca (CaO=14.5-14.0 wt.%). Clast 2, in both dark and bright regions, has an intermediate composition between high-K and low-K melts (e.g. K_2O=˜0.46, P_2O_5=˜0.16 wt.%, Al_2O_3=˜22.9 wt.%, CaO=˜12.8 wt.%). The bulk Mg# of the 5 regions are similar (Mg#=80-78).

If the melts in the two clasts are related, there are two possible origins: (1) A single impact event hit a complex lithological target and incompletely mixed the melts, to produce high-K, intermediate-K, and low-K melt fractions. (2) An impact produced either a high- or low-K melt. A second impact produced a melt at the other end of the K spectrum. The melts in Clast 1 represent those two end member melts. If the second impact melt digested older fragments of the first impact melt, then that may have produced the intermediate compositions of Clast 2. Alternatively, the melts are not related and require three or more impact events.

Formation processes of silica polymorphs in lunar meteorites

KAYAMA, Masahiro[1*] ; TOMIOKA, Naotaka[2] ; SEKINE, Toshimori[1] ; GöTZE, Jens[3] ; NISHIDO, Hirotsugu[5] ; OHTANI, Eiji[4] ; MIYAHARA, Masaaki[1] ; OZAWA, Shin[4]

[1]Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University, [2]Institute for Study of the Earth's Interior, Okayama University, [3]Department of Mineralogy, TU Bergakademie Freiberg, [4]Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University, [5]Depertment of Biosphere-Geosphere Science, Okayama University of Science

Asteroid and meteorite collisions lead to formation of impact craters and thick regoliths on the Moon and also contribute to revolution of the Earth, e.g. Giant impact, the late heavy bombardments and the origin of life. Although lunar meteorites and Apollo samples have experienced such impact events during the ejection from the lunar surface or formation of immense basin, they were believed to contain few high-pressure mineral because of the volatilization during collision in the high vacuum (Papike 1998; Lucey et al., 2006). Recently, Ohtani et al. (2011) and Miyahara et al. (2013) discovered high-pressure silica polymorphs (coesite, stishovite and seifertite) in lunar meteorites, Asuka-881757 and NWA4734. Their existences provide constraints on the shock condition and give us valuable information on impact history on the Moon and the Earth.

The shock condition of meteorites has been estimated based on the pressure-temperature phase diagram obtained from high-pressure experiments using shock gun, multi-anvil press and diamond anvil cell (DAC) for various types of minerals including in silica polymorphs. There have been many investigations of the high-pressure experiments for quartz and amorphous silica glass, but not for the other polymorphs, regardless of dominant occurrence of cristobalite and tridymite in lunar meteorites. Since the transition pressure to high-pressure phase depends on a type of starting material (Kubo et al. 2012; Bläβ, 2013), it is necessary for understanding the detailed impact history of the Moon to conduct the high-pressure experiments for various types of silica polymorphs.

In this study, silica polymorphs in various types of lunar meteorites (anorthositic breccia, basalt, and gabbro and basalt clast-dominated breccia) were described using Raman spectroscopy, Scanning and Transmission Electron Microscope and X-ray diffraction analysis and the obtained results were compared with the data of high-pressure experiments for various types of silica polymorphs to clarify the phase transition process, interpret the formation process on the Moon and constrain shock pressure and temperature that the lunar meteorites have experienced.

Discovery of stishovite in an Apollo 15 sample and impact record on the Moon

KANEKO, Shohei[1] ; OHTANI, Eiji[1*] ; MIYAHARA, Masaaki[2] ; OZAWA, Shin[1] ; ARAI, Tomoko[3]

[1]Tohoku University, [2]Hiroshima University, [3]Chiba Institute of Technology

Thick regolith layers and many craters on the Moon indicate that the Moon has been heavily bombarded after the lunar formation. Short time intervals of high-pressure and high-temperature occurred on the lunar surface during the collision of asteroids on the Moon, and the constituent minerals of the Moon and asteroids transformed into high-pressure polymorphs during the high-pressure and high-temperature conditions. Although many brecciated lunar rocks have been recovered by the Apollo missions, any high-pressure polymorph has not been observed in Apollo samples so far. Silica is one of constituent minerals of terrestrial planets and asteroid. We investigated a lunar regolith collected by the Apollo 15 mission with a special interest on silica, because high-pressure polymorphs of silica are recently reported from shocked lunar meteorites (Ohtani et al., 2011; Miyahara et al., 2013). Here, we show stark evidence for stishovite from a sample collected by the Apollo 15 mission. X-ray diffraction analysis and transmission electron microscopic observations clearly confirmed the existence of a high-pressure polymorph of silica, stishovite, in the Apollo sample, which suggests that the lunar legolith preserves records of early shock events. Considering radio-isotope ages, lithologies, and shock features, stishovite was formed by an impact event in the near side Moon ca. 3.8-4.1 Ga ago.

Experimental constrains on shock conditions of meteorites based on non-equilibrium behaviors of silica and plagioclase

KUBO, Tomoaki[1*] ; KONO, Mari[1] ; KATO, Takumi[1]

[1]Dept. Earth Plant. Sci., Kyushu Univ.

Recent studies on shocked meteorites have revealed non-equilibrium behaviors of silica and plagioclase at high pressures. We focus on the following three points observed in meteorites to deduce the P-T-t shock conditions from high-pressure kinetic experiments. 1) The formation of seifertite as a high-pressure polymorph of silica, 2) The occurrence of jadeite from plagioclase that does not contain stishovite, 3) The formation of lingunite as a high-pressure polymorph of albite-rich plagioclase.

Seifertite is a polymorph of silica with alpha-PbO2 type structure that was found in shocked Martian and lunar meteorites (e.g., Sharp et al., Science1999; Miyahara et al., PNAS2013). Although this phase is thermodynamically stable at more than 90 GPa corresponding to the base of the lower mantle (Murakami et al., GRL2003), it has also been known that it metastably appears from cristobalite at around more than 40 GPa and room temperature (Dubrovinsky et al., CPL2001). We have carried out high-pressure and high-temperature in-situ XRD experiments of cristobalite using a Kawai-type multi-anvil (KMA) apparatus, and determined the formation kinetics of metastable seifertite and the following stable phase of stishovite. Because the activation energy for the seifertite formation is very low (˜10 kJ/mol), which is consistent with the recently proposed formation mechanism (Blab, PCM2013), it can metastably appear at low T conditions beyond the negative PT boundary from ˜10 GPa and 400C to ˜30 GPa and room T. We found the clear difference in the formation kinetics between seifertite and stishovite, which enables to estimate the P-T-t shock conditions from the coexistence of these phases in various ratios in meteorites.

The occurrence of jadeite from plagioclase that does not contain stishovite has been often reported in shocked meteorites (e.g., Kimura et al., MAPS2000). In-situ XRD study using KMA apparatus have revealed that jadeite forms first from (amorphous) plagioclase, whereas the nucleation of other minerals such as stishovite or garnet is significantly delayed (Kubo et al., NGEO2010). The missing stishovite problem can be explained owing to the differences in crystallization kinetics of high-pressure phases from plagioclase. The hybrid shock indicator combining these non-equilibrium behaviors of silica and plagioclase mentioned above consistently and strongly constrains the P-T-t shock conditions of Martian meteorites.

The formation of lingunite (albite-rich hollandite) in shocked meteorites (e.g., Gillet et al., Science2000; Tomioka et al., GRL2000) has remained unsolved. This phase appears in lase-heated diamond anvil cell (LHDAC) experiments as a minor phase at around ˜20-24 GPa and ˜1000C (Liu, PEPI1978) and ˜2000C (Tutti, PEPI07). However, KMA experiments indicate that the maximum solubility of NaAlSi3O8 component in hollandite structure is limited to ?50 mol% (Yagi et al., 1994, Liu, 2006). This clear contradiction may be due to the non-equilibrium origin. It has been suggested that the rapid T quenching in LHDAC experiments is important for the survival of lingunite metastably to the ambient condition. Our previous in-situ XRD study using KMA apparatus have indicated that lingunite is not formed at least ˜1200C at these pressure conditions (Kubo et al., NGEO2010). We are also preliminarily conducting some LHDAC experiments, however we have not observed lingunite at least ˜1400C. Further studies on the formation process of lingunite are needed to solve this problem, which may lead to construct another P-T-t shock indicator.

Laboratory impact experiments of rock projectiles onto simulated asteroid regolith: Impactor fragmentation and capture

NAGAOKA, Hiroki[1] ; NAKAMURA, Akiko[1*] ; SUZUKI, Ayako[2] ; HASEGAWA, Sunao[2]

[1]Graduate School of Science, Kobe University, [2]Institute of Space and Astronautical Science

We conducted laboratory impact experiments of rock projectiles onto target consist of silica sand used as simulated regolith surface. We investigate the relationship between degree of projectile fragmentation and impact velocity and particle size of silica sand.

Laboratory impact experiments have been performed to study the degree of target fragmentation, however, much less attention has been paid to the fate of the impactors. Experiments with impact velocity lower than 1 km/s were conducted using a powder gun and a gas gun at Kobe University, while experiments with higher impact velocity up to 5 km/s were conducted using a two-stage light-gas gun at Institute of Space and Astronautical Science. We collected the projectile fragments in the sand and weighed the mass of the largest fragments.

Destruction of rock projectiles is found to occur when the peak pressure is about equal to the dynamic tensile strength of the rock in the low velocity impact experiments (Nagaoka et al., 2014, MAPS). The largest fragment mass fractions in the high velocity impact experiments are higher than the expected from the result of low velocity impact experiments. The discrepancy is larger for the target with smaller silica sand particles. The larger fragments consist of multiple fragments and silica sand particles which were consolidated into larger particles by compression and the heating due to compaction of silica sand.

Secondary Ion Mass Spectrometry (SHRIMP) U-Pb dating of Chelyabinsk meteorite

KAMIOKA, Moe[1*] ; TERADA, Kentaro[1] ; HIDAKA, Hiroshi[2] ; KIMURA, Kosuke[2] ; SKUBLOV, Sergey[3]

[1]Osaka University, Department of Earth and Space Science, [2]Guraduate school of Science, Hiroshima University, [3]Institute of Precambrian Geology and Geochronology,

On Feburuary 15,2013, a meteorite fell into the area of Chelyabinsk in Russia .The petrographic and chemical analysis of the Chelyabinsk meteorite unambiguously classifies it as an LL5 ordinary chondrite (Galimov et al.2013). The reported Sm-Nd age of 3.7 Ga and Rb-Sr age of 0.29 Ga suggest that the Chelyabinsk meteorites could have suffered from the secondary event possibly due to shock metamorphism.For further understanding of the thermal history of Chelyabinsk meteorite, we carried out an in-situ U-Pb dating of phosphates of which closure temperatures is high (~600 ℃), using Hiroshima-SHRIMP.(Sensitive High-Resolution Ion MicroProbe).

Crystallization and subsolidus processes of the NWA 6704 ungrouped achondrite

TAKAGI, Yasunari[1] ; NOGUCHI, Takaaki[1*] ; KIMURA, Makoto[1] ; YAMAGUCHI, Akira[2]

[1]Ibaraki University, [2]National Institute of Polar Research

Introduction: NWA 6704 is an unique ungrouped achondrite. It consists of low-Ca pyroxene, less abundant olivine and plagioclase, minor chromite and merrilite, and trace awaruite, heazlewoodite, and pentlandite (1, 2). Although its bulk oxygen isotopic ratio is within the ranges of the acapulucoite-lodranite and CR chondrites, its petrography and mineralogy are evidently different from both of them (1). The U-Pb dating of this meteorite gives a $^{207}Pb/^{206}Pb$ date of 4563.75 +/- 0.41 Ma (3). To deduce its formation processes is important to understand formation of its parent body that may have predated the formation of chondrite parent bodies.

Methods: Polished thin sections were investigated by optical microscopes, electron microprobe analyzer (EPMA), field-emission scanning electron microscope (FE-SEM), Raman spectroscopy, and electron backscattered diffraction (EBSD).

Results: The most abundant mineral in NWA 6704 is orthopyroxene containing blobs of augite. Both Raman spectroscopy and EBSD data indicate that this pyroxene is orthopyroxene. The texture of the blob-bearing orthopyroxene is very similar to Kintokisan-type orthopyroxene (inverted pigeonite) (4). We call it early formed (ef-) pigeonite. There are another less abundant low-Ca pyroxenes: augite blob-free orthopyroxene, and pigeonite containing sub-micrometer-size augite exsolution lamellae. Here we call them primary orthopyroxene and later formed (lf-) pigeonite. Lf-pigeonite occurs as coherent overgrowth of the primary orthopyroxene and discrete grains in the interstices of large ef-pigeonite. Lf-pigeonite also occur as inclusions in olivine. Based on the EBSD data, modal abundances of ef-pigeonite, olivine, lf-pigeonite, primary orthopyroxene, feldspar, chromite, awaruite are 67.2, 16.8, 3.4, 0.6, 10.9, 0.4, and 0.4 vol.%, respectively. Crystallization sequence estimated based on the petrography is following: primary orthopyroxene =>awaruite =>ef-pigeonite =>chromite =>lf-pigeonite =>olivine =>augite (quite rare crystallized from melt) =>heazlewoodite =>pentlandite =>merrilite =>feldspar. Early formed pigeonite (blob-bearing orthopyroxene) shows a LPO of the [010] axis. Lf-pigeonite contains complex exsolution lamellae of augite. The thickest lamellae have ˜0.2 micrometer in width and 1-2 micrometer wavelength. Finest lamellae have <0.1 micrometer thick and ˜0.2 micrometer wavelength.

Discussion: Because [010] lattice preferred orientation of pyroxene in terrestrial rocks has been interpreted as settling of tabular pyroxene crystals in a stagnant magma chamber (5), ef-pigeonite could have settled in a stagnant magma chamber. Presence of Fe^{3+} in chromite and high NiO concentration in olivine (0.89 wt.% on average) suggest that this meteorite crystallized under an oxidized condition. About 1100 ^{o}C equilibrium temperature was estimated by using two pyroxene geothermometry and ˜950 ^{o}C by using olivine-spinel geothermometry. These high temperatures suggest that the meteorite cooled rapidly in this range of temperature. Multiple exsolution lamellae with thickness and wavelength similar to this meteorite were observed in Zagami martian meteorite. Its cooling rate between 1100 ^{o}C to 950 ^{o}C was estimated to be ˜0.02 ^{o}C/hr (6). This meteorite could be cooled as slow as Zagami did. Further studies are needed to clarify if a monotonous cooling can accomplish both high equilibrium temperatures estimated by geothermometers and sub-micrometer-size exsolution lamellae in lf-pigeonite. NWA 6704 has petrography similar to that of NWA 6693. However, there is a stark difference between these two meteorites. Blob-bearing orthopyroxene is the most abundant pyroxene in the former. On the other hand, low-Ca pigeonite is the most abundant in the latter. Therefore, it is possible that NWA 6704 is not mere a pair of NWA 6693.

Petrologic type from plagioclase size distribution

KAWASAKI, Takehiro[1] ; KIMURA, Makoto[1*] ; NOGUCHI, Takaaki[1]

[1]Faculty of Science, Ibaraki University

Ordinary chondrites are classified into petrologic types 3-6, reflecting thermal metamorphism. One of the criteria to classify types 5 and 6 is the size distribution of plagioclase. The size, 50 microns, has been commonly used to classify types 5 and 6. However, no any statistic study for plagioclase size has been conducted. Here we measured the size distribution, and discuss the classification of types 5 and 6. We studied 26 thin sections of types 5 and 6 from the H, L, and LL chondrite groups. Our study indicates that plagioclase of 50 microns are commonly encountered both in types 5 and 6. However, plagioclase of 80-100 microns is more abundant in type 6 than type 5. We also noticed that the size distribution of plagioclase in H6 is similar to that in type H5. The different criteria to classify H from L and LL are necessary.

Systematic isotopic studies of REE, Sr and Ba in eucrites

SERA, Kohei[1*] ; HIDAKA, Hiroshi[1] ; YONEDA, Shigekazu[2]

[1]Department of Earth and Planetary Systems Science, Hiroshima University, [2]National Museum of Nature and Sci.

The eucrites is meteorites that probably originate from the crust of asteroid 4-Vesta. Cosmochemical and chronological information of eucrites puts important constraints of on the evolutional history of the eucrite parent body (EPB). In this study, systematic istopic isotopic studies of Sr, Ba, Ce, Nd, Sm and Gd were performed on eight eucrites for better understanding of differentiation on the EPB. ^{138}Ce, ^{142}Nd, and ^{143}Nd include radiogenic components, and their isotopic variations correlate with La/Ce and Sm/Nd elemental ratios, respectively. The results were consistent with the isochron from previous studies (Makishima and Masuda, 1991; Boyet and Carlson, 2005; Andreasen and Sharma, 2007). The Rb-Sr chronometer consisting of ^{87}Sr/^{86}Sr and Rb/Sr for these eucrites is now in progress. Sm and Gd isotopic compositions of the eucrites showed the isotopic shifts caused by neutron caputure reactions due to cosmic rays irradiation. These isotopic shifts correspond to the neutron fluences ranging from 0.28 to 4.05 $\times$ 10^{15} n cm^{-2}, but these are almost consistent with their cosmic-ray exposure ages, suggesting no strong evidence of initial cosmic-ray irradiation on the surface of EPB. Most previous Ba isotopic studies of meteorites focused on the variation of r- and s-process nucleosynthetic components due to additional inputs in the early solar system. ^{135}Ba and ^{137}Ba isotopes are sensitive to s- and r-process variations, and often have deficits and/or excesses in chemical separates in carbonaceous chondrites due to the existence of presolar grains. In case of eucrites, there are no isotopic variations of all Ba isotopes, but some samples showed the slight excess of radiogenic ^{135}Ba probably from ^{135}Cs decay. Systematic isotopic data obtained in this study provide a hint to understand the evolution processes of differentiated meteorites. We are now applying this technique for the analyses of cumulate eucrites and diogenites.

Preliminary experiments on the formation process of lingunite in shocked meteorites

KONO, Mari[1*] ; KUBO, Tomoaki[1] ; KATO, Takumi[1] ; KONDO, Tadashi[2]

[1]Kyushu Univ., [2]Osaka Univ.

Albite-rich hollandite (lingunite) has been frequently found in shocked meteorites with other high-pressure minerals (Gillet et al., 2000; Tomioka et al., 2000). According to the laser-heated diamond anvil cell (LHDAC) experiments by Liu (1978), following the decomposition of albite ($NaAlSi_3O_8$) into jadeite ($NaAlSi_2O_6$) plus quartz (SiO_2) at 2-3 GPa, these phases recombine to form lingunite in the range of pressure between 21 and 24 GPa at about 1000 ℃, and then it decomposes again into calcium ferrite-type NaAlSiO4 plus stishovite at pressures above 24 GPa. Similarly, Tutti (2007) observed $NaAlSi_3O_8$ lingunite at 21-23 GPa and 2000 ℃ using LHDAC. In contrast to these LHDAC studies, high-pressure experiments using multi-anvil type (MA) apparatus revealed that the maximum solubility of $NaAlSi_3O_8$ component in hollandite structure is limited to ˜50 mol% at 14-25 GPa and 800-2400 ℃ (Yagi et al., 1994, Liu, 2006). This contradiction has not been solved yet, which makes it difficult to understand the shock conditions for the presence of lingunite in shocked meteorites. Tutti (2007) suggested that the stability of lingunite might be sensitive to temperature and could transform back when quenching rate is slow like MA experiments. However, the formation conditions of lingunite has not been well constrained even by LHDAC experiments.

To investigate the formation process of lingunite, we preliminarily carried out LHDAC experiments using a powder of natural albite as a starting material. The samples were compressed at room temperature, and then heated by the double-sided laser heating method using a Nd:YAG laser. The emission spectra were measured on both side of the heated sample, and used to estimate temperature. Heating duration at the maximum temperature was several minutes. Recovered samples were analyzed by X-ray diffraction method at BL-ARNE7 and BL-ARNE1 of photon factory, KEK. The results obtained suggest that jadeite and stishovite are present at 22 GPa and 1230 ℃. The assemblage changed into calcium ferrite-type structure and stishovite at 25 GPa and 1400 ℃. Hydrous aluminum silicate (phase egg) was also present in both samples probably due to the effect of absorbed water in the powdered stating material. We measured X-ray diffraction patterns at several points in the sample, which showed changes of the ratio of the constituent minerals due to the presence of pressure and temperature gradients, however we did not observe lingunite in any measured points. Although experimental conditions are still rather limited, our preliminary results suggest that the formation condition of lingunite is more than 1400 ℃ at these pressure ranges.

Surface roughness effect on KAGUYA LRS surface echo observation and its calibration

KOBAYASHI, Takao[1*] ; LEE, Seung ryeol[1]

[1]Korea Institute of Geoscience and Mineral Resources

KAGUYA Lunar Radar Sounder (LRS) was an HF (5MHz) radar whose primary mission was to explore subsurface of the Moon. Its footprint covered whole surface of the Moon in its operation period. All the data was processed by applying Synthetic Aperture Radar (SAR) algorithm so that the signal-to-noise ratio of target echoes as well as the spatial resolution was improved.

The data was further processed to extract nadir surface echoes so that the surface property of the Moon was studied in a spectral range of the HF band. The physical property that can be known directly from the data was the apparent reflectivity of the lunar surface in the frequency range of the HF band: The data contains scattering effect of surface roughness due to the surface terrain. We need to separate this scattering effect from the data so that we can make quantitative evaluation of the surface reflectivity. In order to meet this requirement, we carried out simulation of KAGUYA LRS observation to evaluate the surface scattering effect due to the lunar surface terrain.

The simulation was based on Kirchhoff approximation method. The Lunar Imager/SpectroMeter (LISM) Digital Elevation Model (DEM) data was utilized to simulate actual lunar surface terrain. Flat surface observation was simulated as the reference case before the simulation of actual LRS observation was carried out. We assumed that the dielectric constant of the lunar surface material was 4.0.

Our simulation revealed that even a mare surface where the surface is often regarded to be flat certainly behaved as a rough surface which gave a rise to decrease of the nadir echo intensities for a few decibels in comparison to the flat surface reflection. This effect gives a significant influence on estimation of regolith thickness in maria. Newly estimated regolith thickness was approximately a meter smaller than previously estimated value: it turned out to be 6 - 7 m in Mare Imbrium.

Determination of the dielectric constant of the lunar surface based on the radar echo intensity observed by the Kaguya

KUMAMOTO, Atsushi[1*] ; ISHIYAMA, Ken[1] ; KOBAYASHI, Takao[2] ; OSHIGAMI, Shoko[3] ; HARUYAMA, Junichi[4]

In the planetary radar observation, echo power and delay time depend on the effective dielectric constant, or equivalent dielectric constant including the voids in the planetary uppermost media. As for the Moon, because there is almost no material whose dielectric constant is far from the basalt rocks, the effective dielectric constant of the lunar uppermost media is considered to depend mainly on their porosity. So if we can determine the effective dielectric constant of the lunar uppermost media, we can derive their bulk density, or density including the voids based on the empirical relation between the dielectric constant and bulk density of the Apollo samples [Carrier et al., 1991].

If we are going to use echo power for determination of the permittivity, we should note that the radar echo intensity depends not only on the dielectric constant but also on the roughness of the surface. Therefore, we have determined the permittivity of the lunar surface with considering the surface roughness. In the analysis, the dielectric constant is determined by using the radar echo intensity obtained by Kaguya Lunar Radar Sounder (LRS) [Ono et al, 2000; 2008; 2010], and the surface roughness parameters derived from Digital Terrain Model (DTM) based on Kaguya Terrain Camera (TC) observation [Haruyama et al., 2008]. The global distributions of the echo powers in a frequency range of 4-6 MHz were derived from the Kaguya/LRS dataset. We have used the intensity of off-nadir echoes in an incident angle from 5 to 15 degree. The reason why nadir echoes are not used in the analysis is because the echo intensity changes drastically in small incident angle range due to the poor range resolution from the spacecraft to the off-nadir reflection point. The echoes arrived after the arrival of the nadir surface echo were identified as off-nadir echoes in this study. In addition, we have also derived the global distribution of the surface roughness parameters. The RMS height of the surface can be obtained by <(z(x+L)-z(x))ˆ2>, where z(x) is height of the surface derived from the Kaguya TC/DTM, L is baseline length, and <>denotes the average. If we assume the self-affine surface model, the roughness parameters H and s can be obtained by the least square fitting of the RMS heights to s LˆH. The off-nadir surface echo power can be calculated based on the radar equation. Assuming Kirchhoff Approximation (KA), the backscattering coefficient in the radar equation can be obtained from the roughness parameters H and s, and assumed dielectric constant [cf. Bruzzone et al., 2011]. Using the backscattering coefficient, we can calculate the expected off-nadir surface echo powers. By performing the comparison between calculated and observed echo powers, we can determine most plausible dielectric constant. In the calculation of the echo powers, the transmitting loss of LRS have to be determined, which are however difficult to measure in the ground tests. So we estimated the transmitting loss to be 5.8 dB by assuming that the average dielectric constant is to be 5.3, which are derived from bulk density of 2.55 g/cm3 in the highlands reported based on GRAIL observations[Wieczorek et al., 2013].

The obtained Hurst exponent H is less than 0.5 in the maria, and about 0.9 in the highland. The parameter s is about 1 in the maria, and about 0.3 in the highland. By applying the analysis method mentioned above, we could obtain the observed and calculated surface echo powers in the regions where H˜0.5, and H˜0.9. Based on them, we could estimate the average dielectric constant in the maria (H?0.5) to be 7, and that in the highland (H?0.9) to be 4. The bulk densities are therefore estimated to be 3.0g/cm3 in the maria (H˜5), and 2.1g/cm3 in the highland. It suggests that there are more voids in the highland than in the maria due to longer exposure to the meteorite impacts.

Tectonic evolution of Sinus Iridum and northwestern Imbrium regions

DAKE, Yuko[1*] ; YAMAJI, Atsushi[1] ; SATO, Katsushi[1] ; HARUYAMA, Junichi[2] ; MOROTA, Tomokatsu[3] ; OHTAKE, Makiko[2] ; MATSUNAGA, Tsuneo[4]

[1]Graduate School of Science, Kyoto University, [2]Japan Aerospace Exploration Agency / Institute of Space and Astronautical Science, [3]Graduate School of Environmental Studies, Nagoya University, [4]National Institute for Environmental Studies

Tectonic features, including mare ridges and lobate scarps, visualize the permanent strains of the lunar crust, and show ancient stress field in the shallow part of the crust, which can further places constraint on global thermal history [1], orbital evolution [2] or basin-scale mascon loading [3, 4]. Their formation ages are clues to understand the origin of tectonic movements. The subsidence of mare basalts began to affect the lithosphere as soon as they were deposited, but global tectonics can affect it long after their deposition. Some of the lobate scarps were recently estimated to be younger than 0.1 Ga [5]. It was pointed out there are some mare ridges even on the youngest mare basalts. These young tectonic structures suggest their origins other than the mascon loading. However, the amount of contraction induced by mascon loading have not yet been elucidated. The formation age of each mare ridge is not well understood. In this study, we estimated the ages of mare ridges in northwestern Imbrium and Sinus Iridum regions.

By means of optical data taken by the cameras onboard SELENE, we estimated the depositional ages of mare units and constrained the formation ages of ridges. Mare basalt lavas were so inviscid that the lava field initially made level surfaces. Therefore, the ages of deformed and dammed mare units by tectonic structures help us to determine the upper and lower bound of formation ages of the structures. We defined geological units by spectral features. The absolute ages of the units were estimated by crater-size frequency distribution measurements, applicable to craters with diameters ranging from 0.25 to 1 km, where the production and chronology functions of Neukum and Ivanov [6, 7].

The prominent mare ridges in the study area are ENE-WSW trending ridge system, hereafter Ridge System A, and NE-SW trending ridge system, Ridge System B. They are located at just to the south of Promontorium Laplace. They are parts of the concentric ridge system of Mare Imbrium, suggesting that the ridges are results of mascon loading. The eastern part of Ridge System A branches into three relatively small ridges. There is a unit boundary runs along the southern foot of Ridge System A. Relatively Ti-poor basalt [8] makes up the ridge, and relatively Ti-rich one [8] lies on the plain at the foot of the ridge. This indicates that the unit was dammed by the ridge. Therefore, the upper and lower limits of ridge formation are determined by the ages of the deformed and dammed basalt units. As a result, we estimated the ages of nine units and constrained the ages of tectonic structures as follows. Western part of Ridge System A and northern part of Ridge System B were formed between 3.0 to 2.1 Ga and 3.3 to 2.1 Ga, respectively. However, Ridge System A partially reactivated and become higher after 2.1 Ga. The middle part of Ridge System B also partially reactivated after 2.1 Ga. The southern part of Ridge System B deforms the youngest basalt indicating it was formed after 2.1 Ga.

Most of mare ridges in the study area can not be explained by mascon loading, because the major subsidence by mare basalt was occurred before 3.0 Ga in Mare Imbrium. Accordingly, this area was tectonically active after the deposition of mare basalts.

We also report other young tectonic features, such as lobate scarps and arcuate rilles in the study area.

The topography of tectonic features in northwestern Imbrium and Sinus Iridum were studied in detail using SELENE-LISM data to estimate the horizontal shortening achieved by the formation of the features. As a result, it was found that the shortening by the formation of mare ridges was smaller than previous estimations by two orders of magnitudes except for a ridge, along which shortening was as large as ~500 m at maximum.

Volcanic activity of lunar maria: Verification of super hot plume event at 2.0 Ga ago

KATO, Shinsuke[1*] ; MOROTA, Tomokatsu[1] ; WATANABE, Sei-ichiro[1] ; YAMAGUCHI, Yasushi[1] ; OTAKE, Hisashi[2] ; OHTAKE, Makiko[2]

Because the Moon is an endmember of terrestrial planetary bodies, to understand the thermal evolution of the Moon is necessary for understanding that of terrestrial planetary bodies. However, the process of magma ocean solidification and the thermal and structural evolution of the lunar mantle are still unknown.

Lunar mare basalts provide insights into compositions and thermal history of lunar mantle. Using image data from orbital satellites, a considerable number of maria have been dated by various techniques such as crater degradation measurement, crater size?frequency measurement, and stratigraphic relationship. Mare basalt ages indicate that eruptive activity has a second peak at the end of lunar volcanism (∼2 Ga), and the latest eruptions were limited in the Oceanus Procellarum and Mare Imbrium regions.

Using multiband images data obtained by SELENE/Kaguya, we have reinvestigated the relationship between titanium contents and eruption ages of mare basalts. Although the systematic relationship is not observed globally, an obvious increase in mean titanium content occurred at 2.3 Ga in the Oceanus Procellarum and Mare Imbrium regions, suggesting that the magma source changed at that time (hereafter, we call the volcanism before 2.3 Ga as Phase 1 volcanism, the volcanism after 2.3 Ga as Phase 2 volcanism.) The high-titanium basaltic eruption, which occurred at the late stage of mare volcanism, can be correlated with the second peak of volcanic activity at ∼2 Ga. The latest volcanic activity can be explained by the occurrence of a super hot plume originated from the core-mantle boundary.

To verify the super hot plume hypothesis, we calculate the difference between topography and selenoid in the mare region. We found a plateau structure around the center of the PKT region, whose the diameter is 1,000 km from southwest to northeast and 1,200 km from northwest to southeast and the altitude is 700 m. This plateau structure may be formed with ascending of super hot plume. Then, Phase 2 basaltic lava flows formed. If the ascending of super hot plume occurred ∼2.0 Ga ago, most mare formation had finished at that time and some transitional structures may have been left. In this presentation, we will discuss the relationship between Phase 2 high-titanium volcanisms and the super hot plume.

Numerical models of mantle evolution in the moon

OGAWA, Masaki[1*]

[1]Graduate School of Arts and Sciences, Univ. of Tokyo

Numerical models of magmatism in convecting mantle are presented to understand the lunar magmatism that was active for the first 1 Gyr but rapidly declined after that. In the model, the characteristic time of magmatism is on the order of several hundred million years, much longer than that of the model of magmatism on larger planets like Mars, because a positive feedback between magmatism and mantle convection does not work: Upwelling flow of mantle convection induces magma by decompression melting. The buoyancy of the magma enhances the upwelling flow itself, and hence makes magmatism vigorous in a large planet. This positive feedback, however, does not work in the moon because of its low Rayleigh number. The long characteristic time of magmatism in the model is consistent with observations. The suggested mild magmatism implies that the heat extraction by magmatism is inefficient in the moon. Since the convective heat extraction is also inefficient in the moon because of its low Rayleigh number, this inefficient heat extraction by magmatism suggests that the most important mechanism of mantle cooling in the moon is thermal diffusion. Indeed, the thickening of the lithosphere with time by thermal diffusion makes the activity of magmatism decline within the first 1 Gyr of its history regardless of the initial content of heat producing elements in the mantle and other parameters that controls magmatism and mantle convection in the models. It may be necessary to carry out further numerical studies that include the early chemical differentiation of the mantle by magma-ocean to understand the magmatism that remained active till 2 Ga locally in some areas of the moon.

Identification of secondary craters based on the Voronoi diagram of the lunar craters

KINOSHITA, Tatsuo[1] ; HONDA, Chikatoshi[1*] ; HIRATA, Naru[1] ; MOROTA, Tomokatsu[2]

[1]The University of Aizu, [2]Graduate School of Environmental Studies, Nagoya University

We developed an automatic method for detecting crater clusters with crater spatial distribution based on the Area Voronoi tessellation technique. In the method based on the hierarchical cluster analysis, the evaluation of crater strongly depends on the closest one crater (or one cluster). In the method based on Voronoi tessellation on the other hand, it depends on the adjacent all craters. Since, this approach does not misjudge the pair craters evaluated cluster by the method based on the hierarchical cluster analysis. When a small crater is close adjacent a large crater, a boundary line of Voronoi tessellation is in the rim of the crater. This is different from the line a person pulls by intuition. So, we select Area Voronoi tessellation. For estimate an area of Voronoi, we adopted the wave front method (Watanabe and Murashima, 2006). We applied the Area Voronoi tessellation to observed crater spatial distribution. If the area of Voronoi cell is small, the crater becomes the candidate of the crater cluster. As a result, for the evaluation of crater spatial distribution, we propose that the Area Voronoi diagram is suitable to identify candidates of secondary crater.

Keywords: secondary crater, Voronoi diagram

Kaguya is a Japanese lunar orbiter launched on September 14, 2007 and observed the moon for about 2 years. The Spectral Profiler (SP) on board Kaguya was a spectrometer which provided global data set of visible-near infrared continuous reflectance spectra of the Moon. GEKKO is a web-application used to visualize the data observed by SP. GEKKO displays the graph of SP spectra and tables of ancillary data with thumbnail images simultaneously taken by Kaguya imager/camera. The current version of GEKKO is very useful for viewing SP spectra, but does not include analysis functions.

The goal of this study is to develop a framework for implementing analysis functions of the SP data. For transferring the data from the client, the original GEKKO connects to the server using MapServer. However, in case of MapServer, the client-researchers can only analyze in a predetermined manner. Therefore, we prepared CGI scripts and incorporated them into GEKKO.

By using the new GEKKO system, the clients-researchers will be able to dynamically analyze the SP data. The clients can select, coordinate and add the functions according to their objectives. We prepared the basic functions commonly used for the spectral analysis, such as running average, normalization and also similarity measurement.

South Pole-Aitken (SPA) basin is one of the largest basin (2500 km in diameter [1]) on the lunar farside. In pre-vious studies, it has been suggested that most of the crustal material was excavated and that the mantle materials have been exposed [e.g., 1]. Particularly, because this excavation was the biggest at the central area of the basin, mantle materials exposed. Mantle material of this area is melted by the basin impact and produced impact melt [e.g., 2], therefore we suggest that investigation within this impact melt area lead up to understand mantle material conpo-sition. However, because SPA is very old and large, we cannot identify the impact melt area. In our study, we pro-duce a new mineralogical map of SPA basin interior, based on data derived from SELENE Multiband Imager (MI). In particular, we investigated mineralogy within the central depression of SPA by iron and titanium concentration and altitude data derived from SELENE. Using these method, we identified the impact melt area of SPA.

We prodused a mineralogical map within the central depression of SPA. As a result, we classified into three mineral type layers on this map ; low-Ca pyroxene layer, high-Ca pyroxene layer and very high-Ca pyroxene layer. From correlations of these layers and occurrences, we created the column diagrams of respective areas. Then, we suggested origins of these mineral type layers : The high-Ca pyroxene layer is impact melt area of the basin. The low-Ca pyroxene layer and the very high-Ca pyroxene layer is the ejecta of SPA basin and mare erupted after SPA basin formation, respectively. In fact, the area of the high-Ca pyroxene layer is impact melt area of SPA. In the fu-ture work, we will analyze mineral and chemical compositions within this area.

The studies using the spectral data obtained by Spectral Profiler (SP) and Multiband Imager (MI) onboard the Japanese lunar explorer SELENE/Kaguya revealed the global distributions of the purest anorthosite (PAN), olivine-rich materials, orthopyroxene-rich, and spinel-rich materials over the entire Moon. However, the global distribution of high-Ca pyroxene (HCP)-rich sites has been unclear so far. In addition to mare region, which is dominated by HCP, it has been reported that several ray craters on highland regions show HCP-dominant spectra. Thus, the global distribution of HCP-rich sites, especially for the lunar highland regions, would provide important information for the structure and evolution of the lunar crust and mantle. Thus, using the global data set of the SP, we conducted the global survey to find HCP-rich sites on the Moon, especially for the lunar highland regions. Here, we report the global distribution trend of the HCP-rich sites based on this survey.

Introduction: Previously we reported that highland materials with higher Mg# (Mg/[Mg+Fe] in mole percent in mafic minerals) (up to 80) than those on the lunar nearside were found on the lunar farside [1]. The observed higher Mg# on the lunar farside indicates that the farside crust consists of rocks that crystallized from less-evolved magma than the nearside crust. One of the other key parameters for evaluating solidification of the lunar magma ocean is Th abundance. Th is an incompatible element and concentrates in the liquidus phase when magma cools, therefore highland material that solidified earlier must have lower Th abundance than the highland material that solidified later. Th abundance distribution and its dichotomic nature were found to be lower on the farside than on the nearside [2].

If the dichotomic distribution of lunar highland Mg# and the Th abundance were formed by lunar magma ocean solidification, as the solidification proceeds, Mg# will decrease while Th abundance will increase, giving the two parameters a negative correlation. This study investigated the correlation of the two observed parameters of the lunar highland to validate the magma ocean origin of Mg# and Th abundance distribution on the lunar surface. We also tried to estimate the chemical composition of the lunar magma ocean by combining two remote-sensing data sets.

Method: Using Kaguya gamma-ray data, we derived the relative Th abundance (count of the observed gamma-ray data) map of the Moon as gridded data. We then derived the Mg# map of the lunar highland so that it had the same grid as the Th abundance map. For comparison with the derived Mg# and Th abundance correlation trend, we calculated the Mg# of the lunar magma ocean starting with different bulk chemical compositions by using the MELTS program [3]. The calculated starting magmatic compositions were bulk silicate Earth and bulk lunar magma ocean.

Results: The derived Mg# and Th concentration ratio of the same location indicates a negative correlation of the two parameters. In addition to the negative correlation, another interesting feature is that there seems to be two separate trends with lower and higher Th concentration ratios. Comparison of the observed Mg# and Th concentration ratio trend with that of the model calculation suggests that the observed data of the lower Th concentration ratio group matches the bulk silicate Earth composition better than the lunar magma ocean.

Discussion: The negative correlation of observed Mg# and Th concentration ratio suggests that current values of these parameters on the lunar surface are likely due to cooling of the lunar magma ocean as each location crystallized at a different solidification stage though the origin of the two apparent sets of the observed trends is not clear. The fact that the observed data of the lower Th concentration ratio group matches the bulk silicate Earth model better may imply that the chemical composition of the lunar magma ocean needs to re-evaluated and that the Mg# of the actual bulk lunar magma ocean may be higher than previously estimated although we need to further evaluate the effect of calculation conditions. The possibly higher Mg# of the bulk lunar magma ocean agrees with the reported higher Mg# (up to 80) in the farside highland than previously estimated based on the nearside sampled FAN compositions.

Some lunar meteorites contain clasts of nearly pure calcic plagioclase with high An values and low FeO (1). We proposed that these meteorites are derived from the lunar farside on the basis of estimated low concentrations of Th and FeO by the remote sensing data on the farside of the Moon (2). The Lunar Magma Ocean (LMO) model deduced from the Apollo samples is not able to explain such dichotmy of the Moon. Nyquist et al. (3) performed Sm-Nd and Ar-Ar studies of pristine ferroan anorthosites (FANs) of the returned Apollo samples and showed that a whole rock Sm-Nd isochron for selected FANs yields an isochron age of 4.47 Ga . Mineralogical studies of lunar meteorites of the Dhofar 489 group (2) and Yamato 86032 , all possibly from the farside highlands, showed some aspects of the farside crust. Nagaoka et al. (1) reported that many fragments in such meteorites contain clasts of nearly pure calcic plagioclase with high An values.

Mineralogy of magnesian anorthosite clasts in Dhofar 489, 309 and 307 (2) was used to deduce the ejection site of the Dhofar 489 group. Presence of fine-grained magnesian granulitic clast, and many crystalline clasts with rapid growth features were interpreted in terms of a large impact basin associated with small cratering. Among a few large basins of the farside, the Dirichlet-Jackson (DJ) basin has a few large craters on the floor, and the formation age by Morota et al. (4) is 4.25 Ga, which agrees with the Ar-Ar age (4.23 Ga) of Dhofar 489 (2). Based on the Th map made by KGRS, Kobayashi et al. (5) showed that the lowest Th regions in the lunar farside occurs near the equatorial region and noted that the regions well correspond to the high Mg number region (DJ) measured by SP, of the farside crust (6). These rocks with low Th may be crystallized from less-evolved magma than the nearside crust. Anorthosites composed of nearly pure anorthite (PAN) with low Th at many locations in the farside highlands and a map of the Mg numbers (6) also showed that the region around the DJ basin is consistent with the Mg numbers (70 to 76) of the magnesian anorthositic clast in Dhofar 489 (2). A large impact, which excavated a basin of the farside might have produced granulites in deep ejecta of a smaller impact.

We investigated a process of decomposition of Ca-rich plagioclase with fulvic acid, which is a complex natural organic acid produced in humified soils (7). The Ca ion released from plagioclase can be used to fix carbon dioxide as calcite as in oolites, and is useful for reducing carbon dioxide from the atmosphere on the Earth.

Volatile accretion on the Moon - A clue for the emergence of a habitable Earth.

HASHIZUME, Ko[1*] ; HARUYAMA, Junichi[2]

[1]Osaka University, Graduate School of Science, [2]Japan Aerospace Exploration Agency / Institute of Space and Astronautical Science

I would like to introduce the recent advancement in deciphering the information on accretion of planetary volatile compounds to the moon using lunar regolith samples. I will also make a brief comment on the future lunar explorations, toward a better understanding of volatile accretion to the early Earth-Moon system that possibly lead to the emergence of the habitable Earth.

Extraterrestrial solidified materials with multi-mixture on the Moon

MIURA, Yasunori[1*]

[1]In & Out Universities

The results of the present study are summarized as follows:

1) Study of the Moon provides largely valuable information on formation processes of primordial Earth and extraterrestrial celestial-bodies.

2) Identification of crystalline solids are almost similar between the Moon and Earth, though the Moon rocks might be formed by similar formation processes of terrestrial (Earth) rocks based on the crystalline parts. However, extraterrestrial solids are mixtures of multiple states shown as amorphous solids.

3) Formation of quasi-spherical Moon body formed mainly by impact-related melting process is found as heterogeneous and irregular distribution of lunar rocks with impact craters.

4) Fluid-bearing depositions irregularly distributed on the surface and interior of the Moon are largely based on storages on the interior formed by solidified mixtures of multiple states triggered by impact process on the Moon.

5) Different processes of solids between the Moon and Earth can be observed silica Si-O frameworks which can be obtained by the ion bombardment experiments. Crystalline rocks with hard silicate structures show higher ion-peaks of alkali ions (Na, K and Ca etc.), whereas solid-aggregates of the Moon rocks show higher ion-peaks of Si and Al ions which are easily destroyed by ion bombardment relatively.

6) Ion-peaks by the sputtering of Earth impact-breccias are clearly higher than those of the Moon breccias, which main differences are not rock textures but atomic bonding.

7) The air- and water-less Moon with solidified materials with multi-states is formed from nano-grains to macroscopic rocks by impact-related evolution process.

8) The primordial planet Earth with remained heterogeneous surface by impact-related process is considered to be different cyclic system of three states (air, liquid and solid) with macro-life activity which is formed by huge production from the interior triggered by huge collision process of the giant impact.

Re-examination of Excavation Cavity of the Impact Basins of the Moon based on GRAIL based Crustal Thickness Model

ISHIHARA, Yoshiaki[1*] ; NAKAMURA, Ryosuke[2]

[1]JAXA, [2]AIST

Large impact features, whose diameters are more than hundreds of kilometers, are called impact basins. Large impact basins can provide comparatively clear information of the cratering process and/or constrain the lunar thermal history. The internal or subsurface structures of basins can be assessed through an analysis of their associated gravitational and topographic signatures. The recently Kaguya/SELENE mission has improved the crustal thickness model not only for the nearside but also for the farside based on the first direct farside gravity and global topography mapping. Moreover most recent GRAIL mission vastry improved spatial resolution and overall accuracy of the lunar gravity models and lunar crustal thickness models. The GRAIL crustal thickness model gives us the opportunity to re-analyse excavation depth and diameter of basin forming impact processes anywhere on the Moon with improved accuracy. This study uses the GRAIL crustal thickness model, to reconstruct the excavation cavity geometry of large impact basins on the Moon.

Our method of reconstructing the excavation cavity of large impact basins is fairly simple. We assume that the thinned crust and uplifted Moho beneath features is a direct consequence of (1) the amount of crustal material excavated during the cratering process and (2) the subsequent rebound of the crater (basin) floor. We first construct azimuthally averaged profiles for the surface topography, mare thickness and subsurface structure of the Moho for each basin. Next, we restored the uplifted Moho and overlying crust to its pre-impact position. Estimating procedures of pre-impact position is almost the same as previous analysis. After removing mare fill, this process resulted in a roughly parabolic surface depression, that we interpret as being the first-order representation of the basin's excavation cavity.

One of the most important values of understanding the large impact basin is the depth-to-diameter ratio of the excavation cavity. We examine the depth versus the diameter of our reconstructed excavation cavities (excluding the Imbrium Basin and the South Pole-Aitken Basin). It seems that up to 400 km cavity diameter, the depth (hex) and diameter (Dex) are linearly related. Further more, the linear relationship (hex/Dex=0.079+/-0.006) is almost consistent with, though slightly smaller than, the value for craters orders of magnitude smaller in size (hex/Dex=0.1), suggesting that proportional scaling is valid for basin scale impact structures except the largest impact structures on the Moon. One of the reasons of smaller depth-to-diameter ratio are probably effects due to the post impact modifications. Impact basins which has excavation cavity diameter larger than 400 km show the different state. The average crustal thickness of GRAIL lunar crustal thickness model is 34 to 43 km. So excavation cavity diameter of 400 km is located the ragime boundary between the excavation/melting cavity within crust ragime and the excavation/melting cavity exeed the Moho interface ragime.

Lunar gravity anomaly recovery with the GRAIL level-1b and level-2 data

HASHIMOTO, Mina[1*] ; HEKI, Kosuke[1]

[1]Department of Natural History Sciences, Faculty of Science, Hokkaido University

First, we will talk about the lunar gravity anomaly recovery with the GRAIL level-1b data. Among several global lunar gravity field models available now, GRAIL offers the highest resolution. The Doppler tracking between Earth-based stations and lunar satellites can directly observe gravity field of the lunar nearside. SELENE could measure the farside, for the first time, by inter-satellite tracking using the high-altitude relay satellite. GRAIL employs the low-low inter-satellite tracking method, often called as ″ Tom and Jerry ″ . This is similar to GRACE, the twin satellites for the gravimetry of the earth. It observes the gravity field by ranging between the satellites using microwave. In this way, GRAIL got the global lunar gravity anomaly map. In our study, we use the GRAIL level-1b and level-2 data. Both data have become open to public at the PDS Geoscience Node at the Washington University, Saint Lewis. The level-1b data include satellite position data compiled as the GNV1b files, and inter-satellite ranging data (ranges, range rates, and range accelerations every five seconds) are compiled in the KBR1b files. In this study, we used these two data sets and estimated the mass distribution on the moon. We remodeled the moon ' s gravity anomaly program of the Lunar Prospector developed by Sugano and Heki (EPS 2004; GRL 2005). Using this program, we estimated the gravity anomaly of the specific parts of the lunar surface. We found the Level-1b data are able to recover them clearly. Then, we will introduce the next-stage study by using the GRAIL level-2 data set, and explain the scientific targets of our study. Recent study (Miljkovi?, K. et al., 2013) suggested that the size and depth of the crater depends on the mantle temperature as well as the size and speed of the projectile. We here study the gravity signatures of small to medium sized craters, and will find systematic difference between the lunar near and far sides.

Consideration of the seismic moment distribution of deep moonquake and the lunar deep structure

YAMADA, Ryuhei[1*] ; NODA, Hirotomo[1] ; ARAKI, Hiroshi[1]

[1]National Astronomical Observatory of Japan / RISE Project

The Apollo seismic network consists of 4 seismic stations (Apollo12, 14, 15 and 16) have observed deep moonquakes which occur repeatedly from specific source regions at depth of 700-1200 km in the lunar deep region. The deep moonquake occurs periodically related with positions of the Earth, the Moon and the Sun; that is tidal forces (e.g., Lammlein, 1977, Bulow et al., 2007). The 106 deep moonquake sources are currently located (Nakamura, 2005), the activity and largeness of the deep event and maybe occurrence mechanism are different among the sources (Araki, 2001).

Yamada et al., (2013) have investigated seismic moment of each deep event occurred from active and well-located 15 deep sources from analysis of data obtained in Apollo 12 station. To derive the seismic moment, we have to correct for characteristics of the Apollo seismometers, elastic and attenuation parameters of the lunar interior where the seismic phase passes, geometrical spreading and radiation pattern of the fault at source region from amplitude of the seismic event (Goins et al., 1981). In Yamada et al., (2013), recent lunar interior model VPREMOON (Garcia et al., 2013) are used, and the results have shown that the values of seismic moments are different among active 15 sources and far deep sources occur the events which have larger seismic moment than near sources.

In this study, we have derived the seismic moments of identical deep events observed in Apollo 15 and 16 stations to verify the previous results derived from analysis of Apollo 12 data. This analysis indicates that the values of seismic moments derived from each station data are respectively different from even if the events are identical. We found a tendency which deep moonquakes occur from far sources indicates larger differences in seismic moments derived from each station data than near source events. This may mean that the recent lunar interior model applied in this study has some problems. Especially, seismic quality factor in the mantle mainly affects on amplitudes of the seismic events. Previous studies (e.g., Nakamura and Koyama, 1982) have described that values of seismic quality factor had large uncertainty in lunar deep region. We, therefore, derived appropriate seismic quality factor so as to minimize differences of the seismic moments derived from each station data. In this analysis, we considered effects of possible radiation patterns because these values also have large uncertainty and effect on derivation of the seismic moments. We will report and discuss our new seismic moment distribution of deep moonquakes and new values of seismic quality factor in this presentation.

Variation of the ionized lunar sodium and potassium exosphere

YOKOTA, Shoichiro[1*] ; SAITO, Yoshifumi[1] ; ASAMURA, Kazushi[1] ; NISHINO, Masaki n[2] ; TSUNAKAWA, Hideo[3]

[1]ISAS/JAXA, [2]STE Lab., [3]Tokyo Institute of Tech.

Lunar exosphere has been observed and studied on many occasions by ground-based telescopes since the discovery of surface-bounded alkali exosphere. The observed exospheric components were alkali atoms such as Na and K because the emission lines are much brighter than for other conceivable components. The structure, source, and the transport mechanisms of the lunar exosphere have been discussed based on these ground-based observations of the alkali atoms. As for the source mechanism of the thin lunar alkali exosphere, five processes were proposed as follows: thermal desorption, electron-stimulated desorption (ESD), photon-stimulated desorption (PSD), ion-induced desorption (sputtering), and vaporization by micrometeoroid impacts. Structure of the lunar exosphere gives us the key parameters to investigate the source mechanism. The observed Na exosphere distribution suggested that PSD and/or sputtering do not simply release the exospheric particles. Since PSD is capable of releasing alkali atoms only out of very shallow region in the lunar soils, PSD has relatively limited store of the exospheric particles in the lunar surface. If there was no replenishing process, PSD would deplete surface alkalis. We present latitude and longitude distributions of Na+ and K+ fluxes from the Moon derived from the Kaguya low-energy ion data. Although the latitude distribution agrees with the previous ground-based telescope observations, dawn-dusk asymmetry has been found in the longitude distribution. Our model of the lunar surface abundance and yield of Na and K demonstrates that the abundance decreases to around 50%, at dusk compared to that at dawn due to the emission of the exospheric particles. It is also implicated that the surface abundance of Na and K need to be supplied during the night in order to explain the observed lunar exosphere with the dawn-dusk asymmetry.

Various appearances of whistler-mode waves observed near the Moon in the solar wind

TSUGAWA, Yasunori[1*] ; KATOH, Yuto[1] ; TERADA, Naoki[1] ; TSUNAKAWA, Hideo[2] ; TAKAHASHI, Futoshi[2] ; SHIBUYA, Hidetoshi[3] ; SHIMIZU, Hisayoshi[4] ; MATSUSHIMA, Masaki[2]

[1]Department of Geophysics, Tohoku University, [2]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [3]Department of Earth and Environmental Sciences, Kumamoto University, [4]Earthquake Research Institute, University of Tokyo

Narrowband whistler-mode waves whose frequencies close to 1 Hz have been observed near the Moon [Farrell et al., 1996; Nakagawa et al., 2003; Halekas et al., 2006; Tsugawa et al., 2011]. Broadband whistler-mode waves in the frequencies up to about 10 Hz with no preferred polarity have also been observed near the Moon [Halekas et al., 2008; Nakagawa et al., 2011, Tsugawa et al., 2012]. In addition, the lunar magnetometer (LMAG) aboard Kaguya detected right-hand polarized broadband waves, which is relatively weak and appears in the frequency range of several Hz. Since the angle between the wave vector and the sunward direction is large, the waves are not significantly Doppler shifted, indicating that they are whistler-mode waves. We also reveal the existence of harmonic waves whose fundamental waves appear in the frequencies near 1-2 Hz. The fundamental waves resemble the narrowband whistler-mode waves.

We construct criteria to select these waves and perform statistical analyses. Based on the statistical properties, we suggest possible scenarios of the generation and propagation of the four types of waves around the Moon. Whistler-mode waves in the frequency near the lower hybrid frequency generated through the reflection of ions by the Moon would be observed as (1) the narrowband waves in the spacecraft frame when the group velocity vector points to the sunward and is cancelled by the solar wind velocity, as (2) the broadband waves in the interaction region with various wave components, as (3) the right-hand polarized broadband waves when the wave vector points perpendicular to the sunward, and as (4) the harmonic waves in the same condition with NR with a large compressional component enough to be steepened.

JAXA is currently planning the lunar lander SELENE-2 project, a follow-up mission of SELENE. This project involves the dispatch of a lunar rover to investigate the lunar surface and rocks. We propose Laser-Induced Breakdown Spectroscopy (LIBS) as an instrument for mounting rovers. The LIBS conducts in-situ analysis of elemental composition.

The LIBS instrument uses a high intensity laser pulse and induced plasma. The plasma emits energy in the form of photons. The spectroscopic analysis of the plasma enables the determination of the elemental composition.

K-Ar dating is a radiometric method used in geochronology. It is based on the measurement of the product of the radioactive decay of ^{40}K into ^{40}Ar with a half-life of 1.25 Gyr. K is found in many rocks. Therefore, we can determine the solidification age of rocks by measuring the ratio of ^{40}K to ^{40}Ar in the rock. In the existing K-Ar dating method, K is measured using LIBS and Ar is measured using quadrupole mass spectrometry (QMS); thus, the method needs two measuring instruments. Our method can be applied to measure both K and Ar using only LIBS. Therefore, the instrument weight will be reduced if our method is applied successfully. The Curiosity rover, a part of NASA's Mars Science Laboratory mission, used LIBS to obtain the spectra of rocks present on the surface of Mars. The Curiosity rover's LIBS instrument detected K in the rocks. However, Ar has not been detected using LIBS. We conducted experiments to detect the Ar emission lines using LIBS.

Commonly, the temperature of plasma induced using LIBS is approximately 1eV (11600K) in the atmosphere. When temperature of plasma was 1eV, we expected that it is possible to detect the Ar emission lines at the wavelengths of 104.8nm and 106.7nm in the vacuum ultraviolet spectral range because no emission lines of neutrals and singly-charged ions of major elements exist in the range. However, as a result, we found that the plasma temperature might be several tens of eV in vacuum. We found that relative intensity of multiply-charged ions (e.g. Si(Ⅳ), Fe(Ⅱ)) emission lines is much stronger than the Ar emission lines. Therefore, we decreased the temperature of plasma in vacuum by decreasing the pulse laser intensity and conducted experiments. In addition, we conducted experiments to investigate the Ar emission lines, which we might be able to detect when the plasma temperature is higher than 1eV, in the vacuum ultraviolet (VUV)-near infrared (NIR) range in vacuum.

Japanese lunar explorer SELENE (Kaguya) discovered gigantic vertical holes of 100 m in diameters and depths in the Marius Hills, Mare Tranquillitatis, and Mare Ingenii of the Moon. These holes are possibly skylights of underground large caverns such as lava tubes, magma chambers, or faults. There are lots of scientific interests on the holes and associating caverns. In addition, these holes and underground structures are the best candidate locations for future lunar base. Similar holes have been also found on the Mars. The caverns connecting to the Martian holes may be the best place for Martian lives to emerge, evolve and survive because of their safer conditions than the Martian surface. We are now planning to establish a project working group to explore the lunar holes and caverns associating to the holes. We call the project as UZUME (Unprecedented Zipangu Underworld of the Moon Exploration).

We have a plan to install the corner cube mirror which has about 20cm aperture on the moon as part of a next SELENE project. The purpose is to explain the internal structure and the origin of the moon by measuring and analysing the distance between the moon and the earth with cm order accuracy. In order to actualize such a precise measurement, we have to manufacture the CCM with 0.1 sec angular precision and less the lambda/10 flatness for the mirror surface. In this presentation, we show the optical response analysis for deriving these degree of precision.

Lunar Laser Ranging (LLR) data are important for the investigations of the lunar rotation, tide, and lunar deep interior structure. The range accuracy of LLR has been less than 2 cm for the last 20 years due to the progress of laser transmit/receive system on the ground stations and the atmospheric signal delay model, however, one order or more accurate ranging than 2cm is needed for better understanding of the lunar deep interior. We are developing 'single aperture and hollow' retroreflector (Corner Cube Mirror; CCM) to be aboard future lunar landing missions. The aperture of CCM is 20cm because the reflection efficiency of that size is found to be higher than that of Apollo 11 array CCP (Corner Cube Prism). For the CCM ultra low expansion glass-ceramic (ClearCeramRZ-EX, OHARA Inc.; hereafter CCZ-EX)' or 'single crystal Si' is selected for candidate material of CCM taking into account small |CTE|/K (Thermal expansion coefficient over thermal diffusivity) and large specific Young modulus. The optical performance of CCM deformed by lunar gravity or solar illumination in the holder model is presented for some cases.

Lunar Laser Ranging Trial at Koganei SLR station

NODA, Hirotomo[1*] ; KUNIMORI, Hiroo[2] ; ARAKI, Hiroshi[1]

[1]National Astronomical Observatory of Japan, [2]National Institute of Information and Communications Technology

Introduction: The Lunar Laser Ranging (LLR) is a technique to measure the distance between laser stations on the Earth and retroreflectors on the Moon, by detecting the time of flight of high-powered laser emitted from the ground station. Since the Earth-Moon distance contains information of lunar orbit, lunar solid tides, and lunar orientation and rotation, observation data of LLR have contributed to the lunar science, especially for the estimation of the inner structure of the Moon through orientation, rotation and tide. There are five refroreflectors on the Moon, Apollo 11, 14, 15 (U. S. A.), Lunokhod 1 and 2 (french-made, carried by former U. S. S. R.). The Apollo 15 has largest aperture among them, and almost 75 % of the total LLR data are from Apollo 15 site.

System Description: Since there is no Japanese station which can range the Moon so far, a precursor ranging experiment by using the Satellite Laser Ranging (SLR) facility in the NICT Koganei campus in Tokyo is ongoing. The SLR station has a 1.5 m Cassegrain telescope with Coude focus. Normally it is equipped with a laser with 20mJ, 20Hz repetition rate, and 35 picoseconds pulse width for satellite ranging. In addition to it, a wide-pulse width laser (3 nanoseconds, which corresponds to 45 cm in 2-way range) with energy of about 350 mJ per shot, repetition rate of 10Hz, wavelength of 532 nm is introduced to detect photons from the lunar retroreflectors for demonstration. As the pulse width is broad, the high accuracy ranging is not expected, therefore it is solely used for the confirmation of the optical link budget between the ground station and retroreflectors on the Moon. As the photon detector, we use a SPAD (Single Photon Avalanche Diode) and also an MCP (Micro Channel Plate) photo multiplier whose quantum efficiency is twice as much as that of the SPAD in use. For the pointing, a CCD imager is also available in the same detector box. They can be switched by reflecting mirrors. To suppress the background noise, a bandpass filter (0.3 nm FWHM, 50 % transparency) and spatial filter (pinhole) with diameter of 400 microns are installed and checked. For better link budget, the contamination of optical elements of the telescope and on the optical bench was checked. The alignment of the laser emission path with respect to the laser receiving path and laser beam divergence has been adjusted to maximize the efficiency of the laser emission.

Pointing: Because the retroreflectors are small and they are not visible from ground telescopes, we point the telescope to known small-sized craters (˜10 km in diameter) whose positions are known in selenographic coordinate and thus in topocentric coordinate at the observation site. Then the offset angles in azimuth and elevation direction from the predicted pointing direction are determined so that the center of the crater comes to the center of the CCD images which are coalligned with the SPAD and the MCP. This procedure confirms the pointing of the telescope.

Observations: Trials for the lunar return have been conducted since autumn 2013. As of the date of submission, the ranging to the Moon is not successful. Therefore we need to detect the return from the Apollo 15 site by using the nanosecond laser pulse for the first step. As the next step, we need to know the condition on which lunar ranging is successful in Koganei, for example, lunar phase, distance to the retroreflectors, libration angles, and atmospheric conditions.

Understanding of lunar origin and evolution can be advanced through investigation of the lunar interior structure. The present thermal state of the Moon can be clues to the Moon's thermal history. In the SELENE-2 mission, we propose a lunar electromagnetic sounder (LEMS) to estimate the electrical conductivity structure of the Moon, which can be used to deduce the thermal structure of the Moon.

Temporal variations in the magnetic field of lunar external origin induce eddy currents in the lunar interior depending on the electrical conductivity structure and frequencies of the temporal variations. The eddy currents, in turn, generate temporal variations in the magnetic field of lunar internal origin. Therefore electromagnetic response of the Moon is obtained from magnetic field measurements by magnetometers onboard a lunar orbiter and a lunar lander. The response function is then used to estimate the electrical conductivity structure by solving an inverse problem. Here we assume a one-dimensional structure for electrical conductivity distribution. We show some results for a test of inversion.

Moonquake observation and lunar interior exploration by one penetrator station

YAMADA, Ryuhei[1*] ; ISHIHARA, Yoshiaki[2] ; KOBAYASHI, Naoki[2] ; MURAKAMI, Hideki[3] ; SHIRAISHI, Hiroaki[2] ; HAYAKAWA, Masahiko[2] ; TANAKA, Satoshi[2]

[1]National Astronomical Observatory of Japan / RISE Project, [2]Japan Aerospace Exploration Agency, [3]Kochi University

The penetrator developed through Japanese lunar explorer 'LUNAR-A' mission is system to deploy on-board sensors on the planetary surface by free-fall from an orbiter. The penetrator is smaller and lighter than typical soft-landers because it does not require complicated landing system and thermal control system, and it has an advantage to construct geophysical network on the planetary surface. However, on-board sensors require high shock durability to survive a penetrating impact. Through previous studies, we have already shown that seismometers for the penetrator can maintain the performance to detect moonquakes even after a shock over the impact to the lunar surface (Yamada et al., 2009) and the communication instrument on the penetrator properly operate for data transmission (Tanaka et al., 2010).

Although high shock durability of the penetrator was established, deployment of the penetrator has not been executed due to cancel of the LUNAR-A mission. We, therefore, have a plan to load the penetrator on a small satellite launched by the Epsilon Launch Vehicle. In the plan, we can carry only one penetrator due to strict weight limitation of the vehicle. For the reason, we currently study the expected scientific results obtained from the observation by one penetrator station.

The seismometers deployed through the NASA Apollo missions have detected some types of moonquakes; deep moonquake, shallow moonquake and meteoroid impacts. The seismometer for the penetrator has performance capable of observing these moonquakes, and verification of activities of these lunar seismic events through comparison with results from the Apollo mission will be one of important topics. Then, we can expect to obtain information about the lunar crustal thickness and structure if we can locate meteoroid impacts by their impact flashes from ground observation. In this presentation, we report that expected detection numbers of the lunar seismic events can be observed by the penetrator and the scientific results, and appropriate installation locations of the one penetrator to obtain good scientific results be described. Then, we also discuss the prospects for future network observation using the penetrator after the small satellite exploration.

On the attenuation of reflected echoes of Lunar Radar Sounder onboard Kaguya

TOH, Hiroaki[1*] ; KUMAMOTO, Atsushi[2]

[1]Graduate School of Science, Kyoto University, [2]Graduate School of Science, Tohoku University

The successful Japanese Moon probe, KAGUYA, was equipped with a variety of state-of-the-art scientific instruments including the Lunar Radar Sounder (LRS; Ono et al., 2010). LRS is a frequency modulated continuous wave (FMCW) radar with carrier frequencies from 4 to 6 MHz, and succeeded in observing distribution of reflectors beneath almost all the Moon's surface (Ono et al., 2009). Pommerol et al. (2010) further pointed out that the presence of the reflectors in lunar maria is negatively correlated with abundance of TiO2 because of its high electrical conductivity.

Loss tangent is defined as a ratio of the conduction to displacement current within an electric medium and hence an indicator of high electrical conductivity. If loss tangent is small enough, the permittivity and the electrical conductivity of the Moon's surface can be determined at the same time by comparing the reflected echo of LRS with its source pulse. Namely, by estimating the complex ratio of the received signal to the transmitted pulse, the dielectric constant can be known from the phase difference while the electrical conductivity can be derived by the observed amplitude attenuation and the permittivity obtained from the phase difference.

However, determination of the complex ratios is not straightforward because the reflected echoes are the product of a pulse compression technique and thus needs deconvolution to restore the true amplitude and phase of the echoes. Preliminary analysis of the LRS waveform data collected at the end of the fast down-link (21.3 Gbpd) mode [Jun. - Sep. 2008] showed that quality of the data is sufficient enough to perform necessary deconvolution. This implies that LRS can also be used as a ground penetrating radar.

In this presentation, the principle and the method for estimating the permittivity and electrical conductivity are first described in addition to the data used. Interpretation of the derived complex ratios and its spatial distribution on the Moon's surface is finally discussed and summarized.

The accmulation ages of subsurface layer in Mare Imbrium based on the SELENE observation data

ISHIYAMA, Ken[1*] ; KUMAMOTO, Atsushi[1] ; NAKAMURA, Norihiro[1]

[1]Graduate School of Science, Tohoku University

Lunar Radar Sounder (LRS) onboard SELENE succeeded in detecting the electromagnetic wave reflected at subsurface layer in low-titanium regions [Ono et al., 2009; Pommerol et al., 2010]. Multiband Imager (MI) and Terrain Camera (TC) onboard SELENE respectively investigated the lunar surface composition [e.g., Otake et al., 2012] and the eruption ages of lunar lava flows [e.g., Morota et al., 2011]. Besides, the studies combined the LRS, MI, and TC data revealed the subsurface structure around the impact crater [Oshigami et al., 2012], and suggests the brittle subsurface layer with a high-porosity [Ishiyama et al., 2013]. This study investigates the accumulated age of subsurface layer in lava flow units (Unit 12 and 8 [Bugiolacchi and Guest, 2008]) in the north Mare Imbrium. This investigation is significant for discussing lunar volcanic activity because we can estimate a eruption rate of lunar lava flow.

We identified three subsurface echoes under Unit 8 from the LRS data, and revealed that the margin of the deepest subsurface echo was consistent with the surface boundary between Unit 12 and Unit 8; Unit 8 is accumulated on Unit 12. These ages of the units were estimated to be 3.31±0.19 Ga [Bugiolacchi and Guest, 2008]. However, the previous study estimated these ages by using a lunar map data with a low spatial resolution (60 – 150 m/pixel). This low spatial resolution data causes a large error for estimating the age. Thus, this study used the lunar high-resolution ortho map data obtained from TC, which has 10 m/pixel. The age of Unit 12 was estimated to be ∼3.6 Ga, which was older than the age of Unit 8. This result is consistent with the order of the stratification identified from the LRS data.

In addition, we identified that Unit 8 can be divided into several units by using the plagioclase, FeO, and TiO2 Map data, produced from the MI data. We investigate the correspondence relationship between the subsurface echoes and the identified units, and then the history of lunar volcanic activity will be discussed in the presentation.

Experimental evidence for the deep high-Ti basalt magma in the lunar mantle

IGARASHI, Mako[1*] ; SUZUKI, Akio[1] ; OHTANI, Eiji[1] ; ASAHARA, Yuki[1] ; SAKAMAKI, Tatsuya[1]

[1]Division of Earth and Planetary Materials Science, School of Science, Tohoku University

The existence of high seismic attenuation zone at the depths greater than about 800 km implies that the lower mantle of the Moon could be partially molten (Nakamura et al., 1973; 1974). There is a longstanding hypothesis that the last fraction of the lunar magma ocean crystallized into a layer of dense Ti-rich cumulates at the shallow depths (˜100 km) early in the lunar history. It has been suggested that the cumulates subsequently sank into the deep interior of the moon because of its gravitational instability (e.g., Ringwood and Kesson, 1976). It is necessary to investigate the melting relations of the high-Ti basalt that may be erupted from the depths at high pressure (>4 GPa).In this study, melting relations of Apollo 14 black glass (Delano, 1986), the most Ti-rich lunar ultramafic glasses, were experimentally determined at the pressure of 4 GPa and the temperature range from 1300 C to 1450 C.

The high-pressure and high-temperature experiments were performed by using 3000 ton Kawai-type multi-anvil apparatus of Tohoku University. The samples were packed into graphite capsules and the experimental temperatures were measured by using W-Re thermocouples. The compositions of run products were analyzed by using FE-SEM (Field Emission Scanning Electron Microscopy). Our experiments depicted that the liquidus and solidus temperatures were determined to be 1450 C and 1325 C respectively at 4 GPa.

The liquidus phase is garnet, and the first consuming phase is ilmenite. Estimated temperature profile of the Moon at depths of 700 km -1200 km are between 1100 C and 1400 C (e.g., Gagnepain-Beyneix et al., 2006). The densities of partial melts and total melt were calculated by using the partial molar volume of the oxide components at one atmosphere (Lange and Carmichael, 1987) and the Birch-Murnaghan equation of state (Sakamaki et al., 2010). The densities of the melts formed by partial and total melting of the Apollo 14 black glass were heavier than those of the lunar deep mantle. Crystal-liquid density crossover is inevitable at the depth around 800 km, the pressure corresponding to 4 GPa. Therefore, the high-Ti basalt magma can exist stably if the lunar temperature profile is close to the upper bound of the estimated lunar temperature profile, suggesting existence of the low-velocity and low attenuation anomalies caused by chemical heterogeneities in the lunar deep mantle.

History of heavenly bodies collision of the solar system inside of the past one billion years studing from a lunar crate

KATO, Mami[1*] ; MOROTA, Tomokatsu[1]

[1]Nagoya University Graduate School of Environmental Studies

The moon preserve the record of the bodies impact history of the past 4.0 Ga as a crater, it is important the information to solution impact and orbit evolution of the bodies of the solar system.

Standard lunar cratering chronologies have been based on combining Luna and Apollo sample radiometric ages and impact crater densities. However, the bombardment history cannot be resolved in the past 3.0Ga because of the absence of samples with radiometric age ranging from 3.0 to 1.0 Ga. On the other hand, from crater density of lunar rayed craters, radiometric ages of lunar glass spherules, and statistics of terrestrial craters it has been suggested the hypothesis that the production function has increased in recent.

In this study, we determine formation ages of rayed craters using SELENE image data. Based on the finding, we will discuss a temporal variation of the cratering rate in the past 1.0 Ga.

Formation process of linear gravity anomalies and thermal evolution of the Moon

SAWADA, Natsuki[1*] ; MOROTA, Tomokatsu[1] ; ISHIHARA, Yoshiaki[2] ; HIRAMATSU, Yoshihiro[3]

[1]Graduate School of the Enviromental studies, Nagoya University, [2]JAXA, [3]Graduate School of Natural Science and Technology, Kanazawa University

The investigation of the subsurface structure in the Moon through a gravity distribution is one of means to understand the early evolution history of the Moon. Andrew-Hanna et al. (2013) analyzed gravity data, obtained by GRAIL (The Gravity Recovery and Interior Laboratory) and identified linear gravity anomalies (LGAs). They suggested that the LGAs resulted from ancient intrusions formed by magmatism with globally expansion. We can expect that such intrusions leave other evidences on the surface. In this study, we analyze topography data and FeO concentration distribution to find some characters corresponding to the LGAs and magma intrusion, and, together with the thermal history of the Moon, discuss the formation process of the LGAs on the Moon.

In this study, we focus 20 of LGAs reported by Andrew-Hanna et al. (2013) that show clear gravity anomaly. We use the 1/1024-degree gridded lunar topographic data from LOLA and the 10pixel/degree lunar FeO concentration distribution map from Clementina.

For topography data analysis, we set a study area that ranges 300km in orthogonal direction from a LGA. We apply a filter to remove topographical perturbation due to small craters. On a vertical profile to a LGA, the average, the standard deviation, and the average gradient of relative altitude are calculated with a reference altitude on a LGA. We define a vicinity area as an area within 50km from a LGA and a surrounding area as an area farther than 100km from a LGA on a vertical profile. Based on topographical features of both a vicinity area and a surrounding area, we categorize the topographic feature of LGAs into three types: mountain type, valley type, and unclassified type.

For FeO concentration data analysis, we calculate the average and the standard deviation of FeO concentration in vicinity areas of a LGA from the FeO concentration map.

The topographical data analysis reveals that most of the LGAs regions are categorized as the valley type. This result suggests that the LGAs regions are distributed over trough regions formed by tensile stress in the early history of the Moon. The FeO concentration distribution analysis reveals that the average FeO concentration of the vicinity areas in highland is 6.72 ± 1.62 wt%. This value is higher than that in the highland (<6 wt%) of the Moon, suggesting that an ancient intrusion is possibly exposed by later crater gardening.

We propose a following hypothesis on the formation process of the linear structures as a cause of LGAs from these results and the thermal history of Head and Wilson (1992). The stress state in the early period of the Moon is tensile stress for thermal expansion process. After crack formation due to the tensile stress before 4.0 Ga, the linear structures are formed by magma intrusion. The linear structures are covered by magmatism that forms mare during 4.0-3.0Ga. Ridges are formed in mare during 3.8-3.0Ga because of the compressive stress with the cooling of the Moon or in the impact basin. The formation of the ridges occurs in association with cracks near the linear structures.

Source of the lunar magnetic anomalies estimated with the prism model

YOKOYAMA, Takashi[1*] ; TAKAHASHI, Futoshi[1] ; TSUNAKAWA, Hideo[1]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology

Many magnetic anomalies have been observed on the Moon since the Apollo project, although the Moon has no global intrinsic magnetic field at present. The lunar magnetic anomalies are considered to be caused by remanent magnetization of the lunar crust. Several models of the lunar magnetic anomalies have been proposed (e.g. Hood et al., 2001, 2013; Richmond et al., 2008; Purucker et al., 2012; Nicholas et al., 2007; Hemingway and Garrick-Bethell, 2012; Wieczorek et al., 2012). However, the magnetized material and its magnetizing process have been still controversial. In the present study, we have analyzed several magnetic anomalies with the prism model, in which three dimensional position, size, horizontal direction and magnetization are parameterized. The observation data by Lunar Prospector and Kaguya at the low altitude were used in the analysis. We adapt a forward modeling approach, in which the source parameters are changed iteratively till the minimum RMS (Root-Mean-Squares) misfit between the model and data is achieved. The optimal number of the prisms for modeling is objectively determined using Akaike's Information Criterion.We will discuss possible source materials on the basis of the modeling results.

Lunar Electromagnetic responses to the stepwise changes in the IMF

HIGA, Tetsuya[1*] ; YOSHIMURA, Ryokei[2] ; OSHIMAN, Naoto[2] ; SHIMIZU, Hisayoshi[3] ; MATSUSHIMA, Masaki[4] ; TAKAHASHI, Futoshi[4] ; SHIBUYA, Hidetoshi[5] ; TSUNAKAWA, Hideo[4]

[1]Graduate School of Science, Kyoto University, [2]Disaster Prevention Reseach Institute, [3]Earthquake Research Institute, University of Tokyo, [4]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [5]Department of Earth and Environmental Sciences, Kumamoto University

The electrical conductivity structure of the lunar interior provides us very important information for investigation of the lunar origin and evolution. We attempted to estimate on the lunar electrical conductivity from magnetic field measurements by LMAG on board KAGUYA (SELENE) during the period from 21 December 2007 to 31 October 2008, when KAGUYA was in the orbit of 100-km altitude.

Magnetic fields are induced in the moon by changes in the interplanetary magnetic field (IMF). In order to confirm whether the lunar electromagnetic induction signals are observed in KAGUYA data, we compared KAGUYA data and data of ACE and WIND satellites, which locate around the Lagrange point (Sun-Earth L1), when the stepwise changes are shown in each data. LMAG measured the sum of the inducing and the induced fields, while ACE and WIND measured only the inducing field. It was found that LMAG recorded the lunar electromagnetic responses to the stepwise changes in the IMF.

Dyal and Parkin (1971) gave the homogeneous moon model and estimated lunar conductivity. Their estimation was carried out using the data measured by Apollo 12 magnetometer fixed on the lunar surface. In this study, we applied their method to the data of the orbiting satellite, KAGUYA. The homogeneous moon model was able to explain the electromagnetic response against the stepwise changes in the IMF well, and the estimated homogeneous lunar conductivity was 1×10^{-4} - 4×10^{-4} S/m. On the other hand, we found that LMAG data also recorded the anomalous signals in the minor components, not predicted from the above model. In order to confirm whether such signals are unique to KAGUYA data, we scrutinized the data obtained by Apollo and Lunar Prospector. As a result, we concluded that such signals are common when the stepwise changes penetrate the moon.

In this presentation, we will report the new analysis results of KAGUYA, Apollo, and Lunar Prospector data, and discuss the anomalous signals in the minor component of the responses to the stepwise changes in the IMF.

Plasma observations above strong lunar crustal fields in the solar-wind wake

NISHINO, Masaki n[1*] ; SAITO, Yoshifumi[2] ; TSUNAKAWA, Hideo[3] ; TAKAHASHI, Futoshi[3] ; YOKOTA, Shoichiro[2] ; MATSUSHIMA, Masaki[3] ; SHIBUYA, Hidetoshi[4] ; SHIMIZU, Hisayoshi[5] ; FUJIMOTO, Masaki[2]

[1]Nagoya University, [2]ISAS/JAXA, [3]Tokyo TECH, [4]Kumamoto University, [5]Earthquake Research Institute, The University of Tokyo

Plasma signature around crustal magnetic fields is one of the most important topics of the lunar plasma sciences. Although recent spacecraft measurements are revealing solar-wind interaction with the lunar crustal fields on the dayside, plasma signatures around crustal fields on the night side have not been fully studied yet. Here we show evidence of plasma trapping on the closed field lines of the lunar crustal fields in the solar-wind wake, using SELENE (KAGUYA) plasma and magnetic field data at 15 km altitude. In contrast to expectation on plasma cavity formation at the strong crustal fields, electron flux is enhanced above one of the strongest crustal fields, Crisium Antipode (CA), where the magnetic field along the spacecraft orbit is as strong as 80 nT. The enhanced electron fluxes above CA are characterized by bidirectional beams in the lower energy range (typically lower than 100 eV), which shows that these electrons are trapped on the closed field lines of the crustal magnetic fields, although a possibility of opened field configuration with cusps is not totally excluded. The observed electrons on the closed field lines may come from the lunar night side surface, while the mechanism of electron supply onto the closed field line remains to be solved.

A long-term all-sky imager observation of lunar sodium tail

NISHINO, Masaki n[1*] ; SHIOKAWA, Kazuo[1] ; OTSUKA, Yuichi[1]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

The Moon possesses long tail of neutral sodium atoms that are emitted from the lunar surface and transported anti-sunward by the solar radiation pressure. Since the earth crosses the lunar sodium tail for a few days around the new moon, the resonant light emission from sodium atoms can be detected from the ground. Although it has been reported that bright emissions from sodium atoms of the tail is observed during the Leonids meteor shower, only few events without meteor shower have been investigated so far. Here we show a long-term (over 15 years) observation of the lunar sodium tail using all-sky imager at Shigaraki Observatory (35N, 136E), Japan. We have surveyed our database of all-sky sodium images at a wavelength of 589.3 nm to find that a bright spot emerges around the anti-lunar point for a few days around the new moon. Although the sodium spot is the brightest during the Leonids meteor shower, a weaker sodium spot is detected in the period without meteor shower as well. The sodium spot gradually moves eastward (roughly, 0.2 hours a day), which shows that the sodium tail is strongly affected by the earth's gravity. We will present the latest results of our data analysis to discuss signatures of the lunar sodium tail as well as the origin of the lunar sodium exosphere.

Crystal structure, morphology, and isotopic compositions of presolar alumina grains in unequibrated ordinary chondrites

TAKIGAWA, Aki[1*] ; STROUD, Rhonda M.[2] ; NITTLER, Larry, R.[3] ; VICENZI, Edward, P.[4]

[1]Department of Geology and Mineralogy, Kyoto University, [2]The U.S. Naval Research Laboratory, [3]Carnegie Institution of Washington, [4]Smithsonian Institution, [5]National Institute of Standards and Technology

Corundum, the thermodynamically stable phase of Al_2O_3, is predicted to be the most abundant refractory dust species condensed in envelopes around oxygen-rich asymptotic giant branch (AGB) stars. Many presolar Al_2O_3 grains, which are the survival circumstellar dust grains, have been identified from acid-residues of chondrites. The grain morphology and crystal structure of presolar grains may reflect condensation conditions in circumstellar envelopes of AGB stars and processing in the interstellar medium (ISM) and protosolar disk.

Using scanning electron microscopy (SEM) we obtained detailed secondary electron images, energy dispersive X-ray spectroscopy (EDS), electron backscattered diffraction (EBSD) patterns, and cathodoluminescence (CL) spectra of each Al_2O_3 grain prior to isotopic measurements. Focused ion beam (FIB) lift-out sections were made from the identified presolar grains and the interior structures were observed with a transmission electron microscope (TEM).

The Al_2O_3 grains were identified from acid residues of QUE97008 (LL3.05) by EDS and observed in detail by field emission (FE) SEM at the Carnegie Institution of Washington (CIW). Previously identified alumina grains from Semarkona (LL3.0), Roosevelt County 075 (H3.1), and Bishunpur (LL3.15) were also used in this study. CL spectra were obtained with a FE-SEM equipped with a Gatan Mono CL4 system at NIST. EBSD analysis was performed with an FEI Nova 600 FIB-SEM equipped with an HKL EBSD system at the Naval Research Laboratory (NRL). Isotope measurements were performed with the Cameca NanoSIMS 50L ion-microprobe at CIW. Oxygen isotopes of 163 grains were measured using ~100 nm Cs^+ beam rastered over each of the grains. An O^- beam was used to measure the Mg-Al isotopic compositions of the presolar and some solar Al_2O_3 grains. Ultra-thin sections of presolar grains QUE053, 060, and 067 were prepared with the NRL FIB-SEM. TEM studies were carried out at NRL with a JEOL 2200FS field-emission scanning transmission electron microscope (STEM).

Eight presolar grains from QUE97008 and one from RC 075 were newly found. Grain QUE060 is classified into Group 2 and has a subhedral shape with clear flat facets. The surface is smooth except for a face with a cavity. TEM diffraction patterns of the FIB section indicated that the grain consists of multiple corundum crystallites. Dark-field TEM image showed large (>100 nm) and small (<30 nm) scale orientation variation. The large-scale misorientation observed on the right side of the grain seems to relate to the cavity. Small-scale distortions occur uniformly within the grain. EDS spectra showed that the Mg/Al ratio of QUE060 is ~0.01, and the NanoSIMS measurement revealed this high Mg content to be essentially pure radiogenic ^{26}Mg, with inferred initial $^{26}Al/^{27}Al$~0.01, similar to other Group 2 grains.

QUE067 is a thin Group 4 grain with very irregular morphology. Its $^{27}Al/^{24}Mg$ ratio was three times lower than in QUE060, but its inferred $^{26}Al/^{27}Al$ ratio was similar. No EBSD patterns of crystals were obtained from the grain surface but TEM observation on the FIB section showed that the interior of QUE067 was corundum, not amorphous.

The subhedral shape and smooth surface of QUE060 suggest that this grain was likely single crystalline corundum when it condensed in a circumstellar envelope of a low-mass AGB star, and that the polycrystalline nature, voids and distorted crystal structure inside the grain are secondary features.

A possible process to form large-scale misorientation and the cavity is grain-grain collisions in a SN shock in the ISM. A high velocity collision creates a shockwave propagating inside the grain, finally forming a crater. Small-scaled distortions may have also formed by collisions with small particles in the ISM. Such collisions are less destructive than with larger grains, but their probability is high. Ion bombardment in the ISM may also contribute to the small-scale distortions.

3-D observation of GEMS by electron tomography

MATSUNO, Junya[1*] ; MIYAKE, Akira[1] ; TSUCHIYAMA, Akira[1] ; NAKAMURA-MESSENGER, Keiko[2] ; MESSENGER, Scott[2]

[1]Dep. of Geology and Mineralogy, Kyoto Univ., [2]NASA Johnson Space Center

Amorphous silicates in chondritic porous interplanetary dust particles (CP-IDPs) coming from comets are dominated by glass with embedded metal and sulfides (GEMS). GEMS grains are submicron-sized rounded objects (typically 100-500 nm in diameter) with nanometer-sized (10-50 nm) Fe-Ni metal and sulfide grains embedded in an amorphous silicate matrix. Several formation processes for GEMS grains have been proposed so far, but these models are still being debated [2-5].

Bradley et al. proposed that GEMS grains are interstellar silicate dust that survived various metamorphism or alteration processes in the protoplanetary disk and that they are amorphization products of crystalline silicates in the interstellar medium by sputter?deposition of cosmic ray irradiation, similar to space weathering [2,4]. This consideration is based on the observation of nano-sized crystals (~10 nm) called relict grains in GEMS grains and their shapes are pseudomorphs to the host GEMS grains.

On the other hand, Keller and Messenger proposed that most GEMS grains formed in the protoplanetary disk as condensates from high temperature gas [3,5]. This model is based on the fact that most GEMS grains have solar isotopic compositions and have extremely heterogeneous and non-solar elemental compositions. Keller & Messenger (2011) also reported that amorphous silicates in GEMS grains are surrounded by sulfide grains, which formed as sulfidization of metallic iron grains located on the GEMS surface.

The previous studies were performed with 2D observation by using transmission electron microscopy (TEM) or scanning TEM (STEM). In order to understand the structure of GEMS grains described above more clearly, we observed 3D structure of GEMS grains by electron tomography using a TEM/STEM (JEM-2100F, JEOL) at Kyoto University. Electron tomography gives not only 3D structures but also gives higher spatial resolution (~a few nm) than that in conventional 2D image, which is restricted by the sample thickness (~>50 nm). Three cluster IDPs (L2036AA5 cluster4, L2009O8 cluster13 and W7262A2) were used for the observations. IDP W7262A2 was collected without silicon oil, which is ordinary used to collect IDPs, so this sample has no possibility of contaminations caused by silicon oil or solvent to rinse it [6].

The samples were embedded in epoxy resin and sliced into ultrathin sections (50-300 nm) using an ultramicrotome. The sections were observed by BF-TEM (bright field-TEM) and HAADF-STEM (high angle annular dark field-scanning TEM) modes. Images were obtained by rotating the sample tilt angle over a range of $\pm$65 degree in 1 degree steps. The obtained images were reconstructed to slice images. Mineral phases in the slice images were estimated by comparing with a 2D elemental map obtained by an EDS (energy dispersive X-ray spectroscopy) system equipped in the TEM/STEM.

Careful examination of the slice images confirmed that iron grains are embedded in the amorphous silicate matrix of the GEMS grains, but sulfide grains were mainly present on the surface of the amorphous silicate. These results are consistent with the model that GEMS grains formed as condensates [3,5], although more data are needed to conclude the origin of GEMS grains. The present study is the first successful example adapting the electron tomography to the IDPs. This type of analysis will be important for planetary material sciences in the future.

Condensation experiments of Si-rich gas into the chondrule melt for rapid low-Ca pyroxene formation using a new furnace

IMAE, Naoya[1*] ; ISOBE, Hiroshi[2]

[1]National Institute of Polar Research, [2]Kumamoto University

Introduction

Low-Ca pyroxenes (mainly enstatites) and the high-pressure polymorphs are the most major phases constituting rocks in the solar system. The formation mechanism of low-Ca pyroxenes in the solar nebula is problematic. It has been thermodynamically predicted that enstatite forms from forsterite by the reaction with Si-rich gas since enstatite and the preceding condensate Mg-silicate, forsterite, are in reaction relation (Grossman, 1972). However, the rate of the reaction is sluggish because of the solid diffusion-controlled in the enstatite layer, and the reaction is nearly treated as maximum fractional condensation (Imae et al., 1993). Also, the amount of enstatite condensed directly from the residual gas is very small. Tissandier et al. (2002) experimentally showed that pigeonite (CaO˜5-7 wt%) crystallized from chondrule melt by the interaction with Si-rich gas. In the present study, a new technique to simulate the solar nebula was developed and massive low-Ca pyroxenes (CaO˜1 wt%) were produced using the furnace.

Experiments

The total pressure was mainly controlled to be 100Pa under the hydrogen gas flow, using a butterfly valve indicated from the diaphragm-seal type pressure gauge. The maximum temperature for each run was 1200-1450^{o}C, in which pyroxene is in stable region and the cooling rate was mainly 100^{o}C/h. A tiny fragment of the Allende meteorite (˜30-50 mg for each run) was used as a starting material of the experiments. The staring material and silica powder were put avoiding the direct contact into the alumina cruicible with the 1 mm orifice. The experiments without silica powder were also carried out as reference experiments.

Result

Minor amount of low-Ca pyroxenes were found mainly with dominant olivines under the experiments without Si-rich gas source. While, a drastic change was observed from the experiments with Si-rich gas source: completely changed to low-Ca pyroxenes poikilitically enclosing rounded olivines were observed for the charges at 1450^{o}C, and low-Ca pyroxenes were observed mainly on the rim for the charges at 1350^{o}C and 1250^{o}C. The iron content increased on the decreasing temperatures.

Discussion

The collision frequency of the Si-rich gas on the melt of the Allende chondrite as a starting material is not so large to derive the crystallization of the massive low-Ca pyroxenes from the melt. Rather, the Si-rich gas helped the nucleation of low-Ca pyroxenes in the stability filed of low-Ca pyroxene. Massive crystallization of pyroxenes did not occur for the experiments without Si-rich gas source and here the forsterite continued to grow under metastable condition.

Hydration of amorphous forsterite grains in protoplanetary disks

YAMAMOTO, Daiki[1*] ; KURODA, Minami[1] ; TACHIBANA, Shogo[2]

[1]Department of Natural History Sciences, Hokkaido University, [2]Department of Natural History Sciences, Hokkaido University

Hydrous silicate dust can be thermodynamically stable at low temperatures (~200K) in protoplanetary disks with the solar-system abundance of elements. Theoretical and experimental investigation (Fegley and Prinn, 1989; Imae et al., 1999) have shown that the hydration reaction between crystalline Mg-silicates and water vapor is too sluggish to occur during a lifetime of protoplanetary disks. However, infrared spectroscopic observation and investigation of extraterrestrial materials have shown that both crystalline and amorphous Mg-silicates may be present in protoplanetary disks and in the protosolar disk. Amorphous silicates are thermodynamically unstable, and thus could be hydrated more rapidly at higher temperatures than crystalline silicates (Nagahara and Ozawa, 2011). If hydration of amorphous silicates occurs within a disk lifetime, hydrated dust could be a source of water to terrestrial planets.

In this study, in order to investigate hydration of amorphous Mg-silicates, we conducted closed-system reaction experiments of amorphous forsterite and water vapor in sealed glass tubes at temperatures of 1023-423K and P_{H2O} of 0.05 -50 bar for 2-1344 hours. Run products were analyzed with FT-IR and XRD. We found that samples reacted at temperatures below 723K and P_{H2O} of 5-50 bar showed sharp 3μm absorption features, clearly suggesting the formation of hydrous phase(s). XRD analyses of some run products showed that the hydrous phase was serpentine. Because the stable temperature of hydrous phase(s) at P_{H2O} of 5-50 bar is~523K, the present results indicate that hydrous Mg-silicates can be formed metastably from amorphous forsterite at higher temperatures than the thermodynamic prediction. Moreover, hydration of amorphous forsterite occurred after 2-hour heating at 623K and P_{H2O} of 5 and 50 bar, implying that the activation energy for hydration of amorphous forsterite is much smaller than that for crystalline forsterite.

Hydration reaction seems to have little P_{H2O} dependence at P_{H2O} of 5-50 bar, indicating that hydration is controlled by a reaction between amorphous forsterite with saturated adsorbing water molecules. No hydration occurred, however, at 523K and P_{H2O} <1 bar, which could be due to less effective adsorption of water molecules at low-pressure conditions.

Sticking probability for homogeneous nucleation of iron dust

KIMURA, Yuki[1*] ; TANAKA, Kyoko[2] ; INATOMI, Yuko[3] ; TAKEUCHI, Shinsuke[3] ; TSUKAMOTO, Katsuo[1]

[1]Tohoku University, [2]Hokkaido University, [3]ISAS/JAXA

Nucleation theories have been used to understand the condensation sequence, number density and size of cosmic dust in a gas outflow of dying stars or a gas plume after shock wave heating in the primitive solar nebula. However, it has been well known that nucleation rates obtained by nucleation theories and by experiments have a large difference. We believe that the reason is uncertainties of the physical parameters of nanometer sized particles. Therefore, it is still not successful to explain the characters of cosmic dust by a nucleation theory. To determine the physical parameters of nanoparticles and evaluate nucleation theories, we constructed an in-situ observation system of temperature and concentration during homogeneous nucleation in vapor phase using interferometry for both of ground based and microgravity experiments.

Nanoparticles are formed from a supercooled vapor after evaporation by electrical heating in a controlled gas atmosphere. Using the new system in lab, we succeeded to determine surface free energy and sticking probability of manganese nanoparticle from timescale for gas cooling and condensation temperature based on nucleation theories [1]. In this laboratory experiment, convection of gas atmosphere caused by thermal heating generates heterogeneity of nucleation environment, such as temperature and concentration profiles around evaporation source. If same kinds of experiments are performed in microgravity, evaporated vapor defuses uniformly and the temperature profile becomes concentric around the evaporation source. As the result, nucleation will occur at concentric position. Then, we can obtain physical properties with relatively smaller error bars and then we may be able to evaluate nucleation theories more precisely. Therefore, we also performed a microgravity experiments using an aircraft and the sounding rocket S-520-28 launched on December 17^{th}, 2012.

We prepared specially designed Mach-Zehnder-type interferometers with an evaporation chamber and camera recording systems to fit the space and weight limitations of the rocket. Three systems, named DUST 1 to 3, with same configuration except evaporation source and gas pressure in the chamber were installed into the nosecone of the rocket. The evaporation source and gas atmosphere were tungsten and gas mixture of oxygen (4000 Pa) and argon (36000 Pa) for DUST 1, iron and argon (20000 Pa) for DUST 2, and iron and argon (40000 Pa) for DUST 3. The experiments were run sequentially and automatically started from 100 s after launch of the rocket. The evaporation source of iron was electrically heated under microgravity. Evaporated iron vapor was diffused, cooled and condensed in the gas atmosphere. The temperature and concentration at the nucleation site are determined from the movement of the fringe in the interferogram. Here, we will show the results of the homogeneous nucleation and determine the sticking probability of iron atoms into a nanoparticle based on nucleation theories. The results will be compared with that by ground based experiment.

Ion-induce nucleation experiment I: development of a new apparatus

WATANABE, Naoki[1*] ; HIDAKA, Hiroshi[1] ; NAKAI, Yoichi[2] ; KOJIMA, Takao[3]

[1]Institute of Low temperature Science, Hokkaido University, [2]Nishina Center, RIKEN, [3]Atomic Physics Laboratory, RIKEN

Mechanisms of grain nucleation have attracted researchers in various fields of science in connection with e.g. atmospheric aerosols and cosmic dust grains. Although there have been many theoretical and experimental works approaching this issue, the details of nucleation mechanism is still in debate. Most of works are performed assuming homogeneous nucleation in gas phase or heterogeneous nucleation on the bulk surfaces. The homogeneous nucleation often suffers from a ”critical size” of particle and requires high supersaturation condition to gain the efficient formation rate, while the nucleation on the bulk surface may not be relevant to the first stage of grain formation in realistic environments. It is know that ion-induce heterogeneous nucleation would play an important role in the particle formation because in this mechanism ion-neutral interaction overcome difficulties expected in neutral-gas-phase homogeneous nucleation. We recently developed a new experimental apparatus to investigate the elementary process of the ion-induced nucleation. We present the importance of ion-induced nucleation and advantages of the newly developed apparatus. Using this apparatus, we have been successful in obtaining an important physical parameter, free energy, of water cluster ions.

Comets are the frozen reservoirs of the early solar nebula and are made of ice and dust. Dust grains in comets have been used to investigate the formation conditions of the solar system. A silicate feature is often observed in comet spectra in mid-infrared region, for example 11.3-micron, and may be used for probing early history of the solar system. In most cases the feature shows the existence of crystalline silicate together with amorphous silicate. Since the crystalline silicate grains are generally made through high-temperature annealing above 800K from amorphous ones, it is believed that the crystalline silicate grains produced at the inner part of the disk were transported to the outer cold regions where comet nuclei formed.

Comet C/2012 S1 (ISON) is a long-period Oort cloud comet, discovered in September 2012. In particular, comet ISON is a sungrazing comet, which is predicted to pass close by the Sun and Earth and becoming a bright object. Mid-infrared observations of this new comet and investigation of the 10-micron silicate feature help us to understand the formation of crystalline silicate grains in the early solar nebula.

We observed comet ISON in mid-infrared wavelength region using Cooled Mid-Infrared Camera and Spectrometer (COMICS) mounted on the Subaru Telescope on Mauna Kea, Hawaii. The observation of comet ISON was carried out on 2013 October 19th and 21st UT. Since the weather condition was not so good when we observed, we carried out N-band imaging observations (8.8 and 12.4 micron) and N-band low-resolution spectroscopy. The spectrum of C/ISON can be fit with 260–265 K blackbody spectrum when we use the 7.8–8.2 and 12.4–13.0 micron region as the continuum. The spectrum has only a weak silicate excess feature, which may be able to attribute to small amorphous olivine grains. We could not detect a clear crystalline silicate feature in the spectrum. We will compare the spectrum with other Oort cloud comets, such as comets C/2011 L4 (PanSTARRS) and C/2013 R1 (Lovejoy), and discuss the dust properties and the birthplace of the comet C/ISON.

Amorphous solid water (ASW) is one of the important materials in space because it exists an abundant and effects to evolution of interstellar molecules. In molecular clouds, it is well known that chemical reactions on icy interstellar dust grains which consist of ASW mantle and mineral particle core are key processes in the formations of important organic molecules (ie. H_2CO, CH_3OH) and deuterium-enriched molecules. Although ASW surface play an important role as a field of chemical reactions, the surface structure of ASW has yet to be revealed.

Recently, we developed a low temperature atomic force microscope (AFM) for study of the surface structure of ASW. AFM is a powerful tool to study the surface structure of ASW because it can work even if the surface do not have a conductive property. In this presentation, we show AFM images of ASW surfaces which were formed at several conditions. ASW were formed on Si(111) 7×7 at 103-135 K with various deposition rate (0.08-0.8 nm/min) and various thickness(2.5-22 nm). From the observations of surface structure, we discuss the relation between the surface structure and the condition of ASW formation.

Cosmic gases and dust grains ejected from dying stars gradually assemble under the influence of gravity to form interstellar clouds. Among these gases, heavy elements such as magnesium (Mg) and silicon (Si) are incorporated in dust. Lighter and chemically active elements (e.g., hydrogen, carbon, oxygen, and nitrogen; H, C, O, N, respectively) play important roles in the chemistry of interstellar clouds. After the temperature and photon field decrease when the density of dust particles increases in interstellar clouds, atoms (e.g., H, O, C, N) and molecules (e.g., CO) deposit onto the dust surfaces. Cold-surface reactions proceed on the grain surface, and an ice mantle, which is predominantly composed of H_2O combined with other molecules such as CO, CO_2, NH_3, CH_4, H_2CO, and CH_3OH, is formed.

The ice mantles are also subjected to substantial energetic processing by the prevailing ultraviolet radiation during the lifetime of a interstellar cloud. Followed by repeated processing when cycling between diffused clouds and dense clouds, new refractory organic molecules are formed in the ice mantles. The ice mantles undergo further photon radiations upon the formation of protoplanetary disks, and finally evolve to non-volatile complex organic residues by irradiation and thermal processing. However, the detail of the chemical evolution of the organic molecules has still been ambiguous. Although the previous laboratory studies using infrared spectroscopy can provide the presence of polar compounds such as amines, carboxylic acid or amides functions, it often suffers from the low sensitivity and the difficulty to obtain precise identifications of molecular species due to the overlapping of broad solid-state bands. Since dust grains and ice mantles are the precursors of planetary material, studying the photoprocesses is essential to understanding the origin of our solar system, and more powerful analytical techniques are required to unveil rich chemistry of the ices in interstellar clouds and protoplanetary disks.

Here, we are going to present a talk about a new apparatus which is now under construction to shed light on the chemical evolution of organic molecules in interstellar clouds and protoplanetary disks. The apparatus consists of three basic parts, i.e., a vacuum system, a copper-substrate equipped with a closed cycle helium refrigerator, and a vacuum ultraviolet source. Multi-component interstellar ice analogues are created on the cold (10 K) substrate by vapor deposition, and subjected to irradiation by the ultraviolet. The irradiated ice is subsequently heated up to 800 K. The gas composition desorbed from the ice during heating is analyzed by a high-resolution quadrupole mass spectrometer in the vacuum chamber. The survived organic residue from heating are studied using gas chromatography coupled to mass spectrometry (GC-MS) and high performance liquid chromatography coupled to mass spectrometry (HPLC-MS).

Hydrogen addition reactions of C_2H_2 on cold grains; clue to the formation mechanism of cometary C_2H_6

KOBAYASHI, Hitomi[1*] ; WATANABE, Naoki[2] ; HIDAKA, Hiroshi[2] ; HAMA, Tetsuya[2] ; WATANABE, Yoji[1] ; KAWAKITA, Hideyo[1]

[1]Koyama Astronomical Observatory, Kyoto Sangyo Univeristy, [2]Institute of Low temperature Science, Hokkaido University

Volatiles incorporated into comets were formed in the pre-solar molecular cloud and probably chemically altered in the proto-planetary disk of the Sun. Although physico-chemical evolution from a molecular cloud to the disk is basically understood, detailed evolutional processes are still in debate; e.g., the fraction of the materials originated in the molecular cloud incorporated into the disk without physico-chemical alterations (some fraction of materials might sublimate via accretion shock) and physical conditions (temperature, densities of materials, etc.). To reveal those links, we focused on the molecules formed through grain surface reactions, which occurred under quite low temperature conditions like 10K. We discuss the origin of such molecules in comets (icy small body of the Solar system), which might preserve the information about chemical and physical conditions of proto-planetary disk. Cometary ethane (C_2H_6) and acetylene (C_2H_2) have been observed in multiple comets since 1996 and their abundances relative to H2O (the major component of cometary ices) is ~10^{-3} but with variations. This variation might be caused by the difference in the mixing ratios between the materials originated in the molecular cloud and the disk-processed materials. C_2H_6 has never been detected in the molecular cloud and the formation mechanism of C_2H_6 detected in comets is still in debate. One of the candidates of formation reactions of C_2H_6 is the hydrogen addition reaction of C_2H_2 on the cold grain surface (C_2H_2 ->C_2H_3 ->C_2H_4 ->C_2H_5 ->C_2H_6). In the previous experimental studies, those reactions were evaluated qualitatively and it was concluded that the reaction from C_2H_4 to C_2H_6 occurred more rapidly than the reactions from C_2H_2 to C_2H_4 and it would be a reason for the nondetection of C_2H_4. To investigate these reactions more quantitatively in realistic conditions for molecular clouds, we performed the laboratory measurements of hydrogen addition reactions of C_2H_2 and C_2H_4 on the amorphous solid water (ASW), respectively.

The experiments were conducted by using laboratory setup for surface reaction in interstellar environment (LASSIE) at the institute of low temperature science, Hokkaido University3. A cryogenic aluminum substrate is located in the center of the main chamber and surrounded by a large copper shroud connected to a liquid-nitrogen reservoir. Atomic hydrogen used for the reactions were produced by the dissociation of H2 molecules in microwave-induced plasma. The kinetic temperature of hydrogen atoms were ~120 K and the H-atom flux was ~10^{13} cm^{-2} s^{-1}. The samples of pure solid C_2H_2, C_2H_4, and those on ASW were produced on the substrate at 10, 15 and 20K. Infrared absorption spectra of the ices were measured by FTIR before and during the exposure of H-atom.

Our measurements show basically the same trend as shown in the previous studies. We will discuss the temperature and thickness dependence of the time constant for the sample ices in the poster.

High Resolution Spectroscopy of Laboratory-Produced Interstellar Molecule having Response to Visible Light

ARAKI, Mitsunori[1*] ; WAKO, Hiromichi[1] ; NIWAYAMA, Kei[1] ; TSUKIYAMA, Koichi[1]

[1]Tokyo University of Science

Diffuse interstellar bands (DIBs) still remain the longest standing unsolved problem in spectroscopy and astrochemistry, although several hundreds of DIBs have been already detected. It is expected that identifications of DIBs can give us crucial information for extraterrestrial organic molecule. One of the best approaches to identify carrier molecules of DIBs is a measurement of DIB candidate molecule produced in the laboratory to compare their absorption spectra with astronomically observed DIB spectra.

Radical in a gas phase is a potential DIB candidate molecule. The electronic transitions of polyaromatic hydrocarbon radicals result in optical absorption. However, because radicals are unstable, their electronic transitions are difficult to observe using a laboratory spectrometer system. To solve this difficulty, we have developed a glow-discharge cell using a hollow cathode in which radicals can be effectively produced as a high-density plasma. The radicals produced were measured by using the cavity ringdown (CRD) spectrometer and the discharge emission spectrometer.

The CRD spectrometer, which consists of a tunable pulse laser system, an optical cavity and a discharge device, is an apparatus to observe an high-resolution optical absorption spectrum. The electronic transition of thiophenoxy radical C_6H_5S was observed in the discharge emission of thiophenol C_6H_5SH. The frequency of the electronic transition of thiophenoxy radical was measured.

A optical discharge emission was examined by a HORIBA Jobin Yvon iHR320 monochromator. We detected the phenoxy radical C_6H_5O in the discharge of phenol C_6H_5OH. The band observed at 6107 A in the discharge was assigned to the electronic transition of phenoxy radical on the basis of the sample gas dependences and the reported low resolution spectra. The frequency of the electronic transition of phenoxy radical was measured.

Comparison studies of thiophenoxy and phenoxy radicals were made with known DIB spectra.

Variation of organic compounds in the polar extract of Murchison meteorite

NARAOKA, Hiroshi[1*] ; YAMASHITA, Yohei[1] ; MITA, Hajime[2]

[1]Dept. Earth & Planet. Sci., Kyushu Univ., [2]Fukuoka Inst. Tech.

Various organic compounds have been found in carbonaceous chondrites, in which water-soluble bio-related organic compounds such as amino acids and carboxylic acids are fully studied mainly because of their great interests to origins of life in the universe and standards available for the analyses. The concentrations of these acids increase significantly after acid hydrolysis of the water extract. Even though a few studies attempted to identify the chemical structures of their precursors (Cooper and Cronin, 1995), the original structures remain largely unclear. The aqueous activity on the meteorite parent body also could proceed in a chemical oxidation (i.e. incorporation of oxygen by hydrous reaction), resulting in the alteration of original organic matter (Oba and Naraoka, 2009). The large abundance of carboxylic acids in the water extract may be attributable to such oxidation processes.

In contrast to the water extract, less polar methanol extract of chondrites has not been characterized well in spite of relatively high content of organic matter with the D- and 15N enrichment. Recently, ultrahigh-resolution mass spectral analysis on various solvent extracts of the Murchison meteorite (CM2) was performed by electrosplay ionization (ESI) using Fourier transform-ion cyclotron resonance/mass spectrometry (FT-ICR/MS) to reveal significant chemical diversity to tens of thousands of different mass peaks having CHO, CHOS, CHNO and CHNOS elemental compositions (Schmitt-Kopplin et al., 2010). With the assumption for molecular formulae calculation and no chromatographic separation, however, the detailed chemical structures of the compounds cannot be determined. In particular, the organic compounds with their elemental compositions of CH and CHN were not discussed. In this study, we performed high-performance liquid chromatography/high resolution mass spectrometry (HPLC/HRMS) analysis of organic compounds in polar solvent extracts of the Murchison meteorite.

Homologous series of alkylpyridines have been identified in the polar solvent extracts of the Murchison meteorite by liquid chromatography/high- resolution mass spectrometry. The wide range of saturated- and unsaturated-alkylated (C1 to C21) pyridines is more diverse relative to that previously found, which could be produced by aldehydes and NH3 through aldol condesation and Chichibabin-type synthesis on the meteorite parent body. This finding implies a high aldehyde activity under an alkaline condition with ammonia for the chemical evolution of organic matters in carbonaceous meteorites. In addition to the compound distribution of alkylpyridines, the occurrence of other compounds in the water extract will be also discussed with respect to their formation mechanisms in carbonaceous meteorites.

Heating and evaporation of icy dust in transient heating events induced by nebular shocks

MIURA, Hitoshi[1*] ; YAMAMOTO, Tetsuo[2] ; NAKAMOTO, Taishi[3]

[1]Nagoya City University, [2]Kobe University, [3]Tokyo Institute of Technology

Icy dust plays an important role in chemical evolution from molecular clouds to protoplanetary disks. Simple organic molecules such as formaldehyde (H_2CO) and methanol (CH_3OH) can form in H_2O-CO ice by consecutive addition of hydrogen atoms to CO molecule (Watanabe & Kouchi 2002). Deuterium enrichment in these organic molecules was confirmed to occur by H-D substitution on icy dust surfaces (Nagaoka et al. 2005). More complex organic molecules such as amino acids were detected in the room-temperature residue of an interstellar ice analogue that was ultraviolet-irradiated in a high vacuum at 12 K (Munoz Caro et al. 2002). Sublimation of such icy dust will change the chemical composition of a gas phase in molecular clouds or protoplanetary disks. It is important to elucidate the thermal history of icy dust because it affects the chemical evolution of these organic molecules significantly.

In this paper, we investigated the transient heating event of icy dust induced by nebular shocks. In protostellar or protoplanetary disks, gas accretion from its parent molecular cloud or formation of planetary systems induces shock waves in various conditions. When icy dust passes through the shock front together with the ambient gas, the gas changes its velocity suddenly but the icy dust retains its velocity because of its large inertia. This results in a large relative velocity between them. The high-velocity collision of gas molecules to the icy dust surface raises the dust temperature and leads to its evaporation. Since the relative velocity is reduced by collisions with gas molecules, the heating event should cease within a short period of time. We calculated thermal history and evaporation experienced by icy dust during shock passage for various shock conditions systematically.

The physical model is as follows. We assume that the temperature and density of the post-shock gas are uniform. For simplicity, we consider a spherical icy dust composed of pure H_2O or CO. The icy dust temperature changes much faster than its velocity because of its small thermal inertia. It is shown that the evaporation fraction of individual icy dust defined by the ratio of the decrease in radius to the initial one depends only on the post-shock gas density (ρ_g) and the relative velocity between icy dust and gas just behind the shock front (v_0). We calculated the equations of motion and evaporative shrinkage of the icy dust to obtain the peak temperature and evaporation fraction experienced by the icy dust.

In general, icy dust experiences high temperature and significant evaporation for large v_0 and ρ_g. In addition, we obtained the results as follows: (i) Icy dust does not evaporate completely before it stops relative to the ambient gas even for quite large v_0 and ρ_g. This is due to a negative feedback between the evaporative shrinkage and the duration of heating. (ii) Icy dust hardly evaporates if v_0 is smaller than a certain value. For example, when $v_0 <\sim 3$ km/s for pure H_2O ice or $v_0 <\sim 1$ km/s for pure CO ice, the icy dust shrinks less than by 1% in radius for any gas density. (iii) Icy dust can experience an extremely high temperature at which it would evaporate completely if it were in equilibrium. This is a remarkable feature of the transient heating event that the short heating duration allows the icy dust to survive against superheating.

We elucidated the conditions of icy dust evaporation induced by nebular shocks for various shock conditions systematically. Our results would be useful to discuss the relation between the changes in chemical composition of molecular clouds or protostellar/protoplanetary disks and the evaporation of icy dust by shocks.

Importance of deuterium fractionation of ethanol by grain surface reactions: experiment of H-D tunneling substitution

OSAKA, Kazuya[1*] ; OBA, Yasuhiro[1] ; KOUCHI, Akira[1] ; WATANABE, Naoki[1]

[1]Inst Low Temp Sci, Hokkaido University

Since we have demonstrated the importance of tunneling grain surface reactions in deuterium fractionation of molecules, many works have targeted this process. To date, we have shown that the grain surface reactions play a crucial role in deuterium enrichments of water, formaldehyde, methanol, and methylamine. In this talk, we present the results of experiment on H-D substitution tunneling reactions of ethanol on cryogenic surfaces. Although C_2H_5OH was observed toward interstellar clouds, its deuterated species have not been detected. However, it was found that its homologous, CH_3OH can be highly deuterated by H-D substitution reactions on grain surfaces and thus it should be reasonable to focus on the potential importance of this process for ethanol. We demonstrated that deuterated methanol is efficiently produced by tunneling reaction of H atoms at very low temperatures relevant to grain surfaces in clouds. H-D reactions predominantly occur in CH_3-CH_2- groups but were hardly observed in an ?OH group which is consistent with the methanol case.

Ion-induce nucleation experiment II: free energy of the water-cluster ion

HIDAKA, Hiroshi[1*] ; NAKAI, Yoichi[2] ; KOJIMA M., Takao[3] ; WATANABE, Naoki[1]

[1]Inst. Low Temp. Sci., Hokkaido Univ., [2]RIKEN Nishina Center, [3]RIKEN Atomic Physics Laboratory

Ion-induce nucleation in gas phase is an important mechanism for grain formation in various circumstances. However, the number of works regarding this formation mechanism is very limited. To investigate the elementally processes of ion-nucleation mechanism, we recently developed a new apparatus (See, the presentation by N. Watanabe in this session). Using this apparatus, the cluster ion formation with an ion core mass-selected, which is the first stage of nucleation, can be observed quantitatively. In this presentation, we show the results of experiment on water-cluster ion formation in which free energies with the size of cluster have been determined. The experiment was performed at temperatures in range of 230-400 K with the supersaturation ratio of about 10^{-3}-10^{-2}.

Detection of levitation dust around the asteroid by Hayabusa-2 LIDAR

OSHIGAMI, Shoko[1*] ; SENSHU, Hiroki[2] ; WADA, Koji[2] ; KOBAYASHI, Masanori[2] ; NAMIKI, Noriyuki[2] ; MIZUNO, Takahide[3]

[1]National Astronomical Observatory of Japan, [2]Planetary Exploration Research Center, Chiba Institute of Technology, [3]Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency

The micron-size particles are continuously produced at the surface of airless bodies like the Moon and asteroids by innumerable micro impacts and thermal stress related to large temperature difference between daytime and nighttime. Previous asteroid missions have revealed smooth appearance of topography on 951 Gaspra, 243 Ida, and 433 Eros suggesting that these asteroids are covered with particles smaller than resolution of camera images. Particularly, the exploration of Eros by NEAR Shoemaker has revealed as smooth surface as a liquid water at the base of craters whose diameter is between 20 and 300 m. This ”pond” is consistent with stagnant dusts of diameter smaller than 50 microns. Based on this observation, dust levitation hypothesis was proposed. According to this hypothesis, a photoelectric effect of solar UV positively charges both dust and the surface. Then a balance between electric repulsion and gravity causes 0.5-microns dusts to oscillate vertically over the surface of Eros long period of time. When a dust has a horizontal velocity, it transfers laterally until it reaches to a shadow of topography where electrostatic field is weaker than surroundings. Thus topographic depression such as a crater becomes a sink of levitating dusts.

LIDAR is one of four remote-sensing instruments onboard Hayabusa-2, and is used to measure altitudes of the spacecraft from a surface of the asteroid, 1999 JU3, for not only secure navigation but also scientific investigation of a C-type asteroid. Hayabusa-2 LIDAR has been improved from that onboard Hayabusa which explored and returned samples from asteroid 25143 Itokawa. A new function called dust count mode is implemented to Hayabusa-2 LIDAR to observe spatial distribution of dust number density in 8 levels with resolution of 20 m in bore sight direction. LIDAR can hardly observe lateral distribution of dusts, but distinguish a weak reflection of thin dust cloud from that of the surface. To plan an operation of the dust count mode observation is difficult because the number density of asteroid dust is not known at all. Instead, we evaluate the lower bound of number density that is geologically important for morphology of asteroid surface. For a given number density of dusts and under an assumption that a characteristic time of levitation is the rotation period of 1999 JU3, the rate of embayment of craters is calculated. If this rate of embayment is greater than that of crater production, we need to take into account a modification process for the study of crater morphology and crater counts of 1999 JU3. This lower bound is calculated to be 10^6 m^{-3} for a cloud of dusts whose radius is larger than a few microns. Then we set this value as a target of the dust count mode observation.

A detectability of dust count mode is dependent on sensitivity of Hayabusa-2 LIDAR and an altitude of the spacecraft. We calculate a reflection from dusts using Mie scattering model assuming that a diameter of dust particle is constant and is larger than the wavelength of laser, that is, 1064 nm. A characteristic distance between dusts is also assumed to be sufficiently larger than the wavelength so that interaction between dust particles is negligible. Using a lidar equation, we calculate a peak power of backscattering light from a dust cloud for various sets of the distance, the number density, and the dust radius. The peak power of reflection is generally stronger than noise level of the detector. The reflection from dust cloud is so weak that the targeted number density of 10^6 m^{-3} is hardly higher than the detection limit. Even at the lowest altitude, the reflection from a dust cloud of 10-microns radius for 10^6-m^{-3} number density is equivalent to the detection limit. If the dust radius is 5 microns, number density more than 10^7 m^{-3} is necessary to be detected. Therefore we plan to start the dust count operation from the HP and attempt to conduct as much operations as possible at low altitude.

Condensation of forsterite under protoplanetary disk conditions

TACHIBANA, Shogo[1*] ; TAKIGAWA, Aki[2] ; MIYAKE, Akira[2] ; NAGAHARA, Hiroko[3] ; OZAWA, Kazuhito[3]

[1]Dept. Natural History Sci., Hokkaido Univ., [2]Dept. Geol. Mineral., Kyoto Univ., [3]Dept. Earth Planet. Sci., Univ. Tokyo

Meteoritic evidence indicates that dust condensation occurred in the early stage of solar system evolution. In this study, we succeeded in performing condensation experiments of forsterite under controlled protoplanetary-disk conditions, which will make significant contribution to understanding silicate formation and chemical fractionation in protoplanetary disks.

Condensation experiments were carried out in the system of Mg_2SiO_4-H_2-H_2O. A mixed gas of H_2 and H_2O was flowed into a continuously evacuated infrared vacuum furnace at a controlled rate to keep a pressure constant. Synthetic forsterite powder in an It crucible was heated as a gas source. A part of evaporated gases were condensed on a Pt mesh located at a cooler region in the chamber. The pressure and temperature conditions were close to those of protoplanetary disks. The total pressure of the system was 5.5 Pa, and the substrate temperature ranged from 1320 to 1160 K. The H_2O/H_2 ratio was set at 0.015, which was about 15 times larger than the solar ratio. The SiO/H_2 ratio was evaluated to be about 0.7-2 % of the solar ratio from the weight loss rate of the gas-source forsterite. Experimental duration ranged from 6 to 237 hours.

Sub-micron to micron-sized condensates covered with Pt substrates at 1160 and 1275 K, but no condensates were found at 1320 K. The typical size of condensates at 1160 K was less than 1 micron irrespective of experimental duration and no effective growth of each condensed grain was observed. Condensates at 1275 K for $>$40 hours partly had several micron-sized flat regions. EDS analyses showed that chemical compositions of condensates were consistent with the stoichiometry of forsterite, and their EBSD patterns were well fitted with the patterns from crystalline forsterite. Coincident EBSD patterns were obtained from the flat region of condensates at 1275 K, suggesting that the area was covered with a single crystal. TEM observation of condensates at 1160 K also found that the condensates were polycrystalline forsterite with a thickness of 30-150 nm, and infrared absorption spectra of condensates show clear 10-micron absorption features resembling those of crystalline forsterite. These evidence indicates that polycrystalline forsterite condensed at 1275 and 1160 K.

The mean free path of gas molecules under the present experimental conditions is less than 1 mm, and the evaporated forsteritic gas and the ambient H_2-H_2O gas are expected to be well mixed. Supersaturation ratios (S) for experiments at 1320, 1275, and 1160 K are thus estimated to be $<$1.2, $<$10, and $<$1000-2000. These supersaturation ratios correspond to the supercooling of $<$5, $<$60 and $<$170 K, respectively.

No condensates were found at 1320 K because the degree of supersaturation was too small for nucleation of forsterite or even the vapor was not saturated with forsterite ($S<1$). The condensates at the supercooling of $<$170 K (1160 K) imply that heterogeneous nucleation of new grains occurred successively on preexisting grains. On the other hand, with the supercooling of $<$60 K (1275 K), some grains seem to have grown up to several microns, and some seem to have newly nucleated on preexisting grains, suggesting that both nucleation and growth of each condensate occurred.

These differences would result in a structural difference in forsterite dust condensed in protoplanetary disks. Fluffy aggregates of sub-micron sized fine particle would form with a supersaturation of $>$1000, while aggregates of micron-sized grains would form with S of 10 that could be an analogue of amoeboid olivine aggregates in chondrites.

A New Experiment for Organic Molecule Formation by Catalytic Reactions on the Surface at Low Temperature and Pressure

KIMURA, Yuki[1*] ; TSUCHIYAMA, Akira[2] ; NAGAHARA, Hiroko[3]

[1]Tohoku University, [2]Division of Earth and Planetary Sciences, Graduate School of Sciece, Kyoto University, [3]Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo

Abundant H_2, CO and N_2 gases react to be more complex molecules mainly on the cooled surface of cosmic dust particles in the molecular cloud and/or primitive solar nebula [1]. The production of organic molecules and subsequent evolution to organic materials in the solar nebula may contribute to the primordial organic system of the Earth. Catalytic chemical reactions are possible production pathway of organic materials in the solar nebula after the formation of simple molecules on nanometer sized cosmic dust particles in the molecular clouds. Experimentally, organic molecules ranging from methane (CH_4), ethane (C_2H_6), benzene (C_6H_6) and toluene (C_7H_8), to more complex species such as acetone (C_3H_6O), methyl amine (CH_3NH_2), acetonitrile (CH_3CN) and N-methyl methylene imine (H_3CNCH_2) have been produced using such as the Fischer-Tropsch type (FTT) and Haber-Bosch type (HBT) reactions on analogs of naturally occurring grain surfaces [2]. Previous studies were performed at higher-temperature ($>$573 K) and pressure ($\sim$1 atm) than the expected conditions in the solar nebula [3-6]. However, since the actual environment is at lower temperature and pressure, it is not clear whether the previous experimental results can be extrapolated to the solar nebula. Our group seeks to elucidate the reaction rates of chemical reactions including isotopic fractionation at lower temperature (100-500 K) and pressure (10^{-3}-10^{0}) and their contribution to the primordial organic system of the Earth.

We are constructing a vacuum chamber based on a new concept to conduct the experiments mentioned above. The chamber with a differential pumping system has a temperature-controlled substrate, a Fourier transform infrared spectrometer (FT-IR), and two quadrupole mass spectrometers (Q-MSs). The substrate has an iron or silicate thin film for FTT and HBT reactions and the FT-IR measures the vibration modes of adsorbed and produced molecules on the surface and the Q-MSs detect volatile and nonvolatile molecules, respectively. As a result, reaction rates of molecules such as H_2, CO, N_2 and NH_3 on iron or silicate substrate will be obtained as a function of temperature and pressure.

Dust movement and chemical evolution of proto-solar disk

NAGAHARA, Hiroko[1*] ; NAKATA, Mamoru[1] ; OZAWA, Kazuhito[1]

[1]Hiroko Nagahara

Origin and evolution of the protoplanetary system have been developed mostly from the dynamic point of view, which includes two competing theories, and whichhas been improved by astrophysical observation of exoplanets and extrasolar planetary systems. On the other hand, examination of meteorites and samples by planetary explorations such as lunar samples, cometary particles, and regolith particles of the asteroid Itokawa enable us to gain insight into the evolution of the Solar System. Although those primitive materials give various information, they are not linked to the physical processes in the primary Solar System.

The purpose of this study is to demonstrate how chemical composition distribution evolves over time in the early stage of the proto-solar disk. In order to combine physical processes and chemistry, we have developed a new model consisting of chemical equilibrium calculation and particle tracking equations. At first, we calculate the chemical composition of starting particles at each position in the protoplanetary disk, to track their each motion in the evolving disk, and to analyze the bulk composition of particles that came from various positions in particular time and space. Then, the dynamic evolution of individual particles is calculated in one-dimensional steady-state disk model. In an early stage, particle located in the inner region of the disk have a composition rich in refractory components and those outside have unfractionated CI-like composition. Particles in average move inward by the angular momentum conservation, but a little fraction of them move outward by the turbulent diffusion. Therefore, mixing of refractory particles from inside and CI-like materials from outside takes place, and the mixing ratio vary with time and space.

Because of inward movement of many particles, the relative fraction of particles from outside increases with time for one particular region in the disk, that is, the bulk chemical composition of particles is getting more CI-like. Similarly, the bulk chemical composition of particles at particular place is getting more CI-like with time. Calculations with model parameters of higher temperature of the disk suggest that longer time is needed to replace refractory-rich compositions by a CI-like composition. It is because the radial distance between fractionated particles with refractory-rich composition and unfractionated CI-like materials is longer in a high temperature disk.

Comparing these results and the composition of CM, CO, CV chondrites, it is concluded that CV composition can be reproduced at the most inner region, CO in the next, and CM most outer region in the disk. The present work shows that the composition of carbonaceous chondrites were formed at the asteroid belt region at the early stage of disk evolution with the wide spread of high temperature region.

Age-cytometry : new approach for meteorite anatomy

HIRATA, Takafumi[1*] ; ITOH, Shoichi[1]

[1]School of Science, Kyoto University

The chronology for meteorite samples has played an important role to decode the early sequence of the solar system. Among the chronometers based on the radio-active decay of long-lived nuclides, because of the high time resolution of the resulting age data, the U-Pb chronometry has been widely used to define the timing of formation of refractory inclusions or to understand the formation sequence of the chondrite parental body. The high time resolution on the U-Pb chronometers was achieved by the small contribution of the analytical uncertainties in the isotope ratio measurements onto the resulting age data, and also because of the well-defined decay constants for ^{238}U, ^{235}U and ^{232}Th nuclides. Moreover, the U-Pb isotope systematics has further advantages of evaluating of system closure since the sample formation or crystallization of minerals, and therefore, reliability of the resulting age data can be rigorously tested. Using the U-Pb chronometer, the resulting time-resolution can become as small as 0.2 ? 1 Ma range for chondritic materials, but this could not be high enough to understand the planetary formation during the runaway growth or to understand the timing of the core formation. To overcome this, we are trying to measure in-situ 238U/235U ratio from individual minerals by means of combination of two ion collectors. Details of the instrumentation and operational conditions would be demonstrated in this talk.

Cytometry is the quantitative analysis of cells and cell systems. Cytometry measures optical properties of cells, and most often uses fluorescence to measure specific antigen molecules, intracellular ions and DNA/RNA using antibodies, indicator dyes, or nucleic acid-specific probes. Cells may be live or fixed, depending on the application, and individual cells can often be physically sorted. ? Advantage of the cytometry are the analysis speed, detection sensitivity, the ability to measure many parameters simultaneously, and the ability to sort individual cells, and therefore, mechanism or process of elemental metabolism could be precisely evaluated based on the extensive number of cells (e.g., Benfall et al., Science, 2011; Bodenmiller et al., Nature Biotechnology, 2012). This approach can also be applied to understand the solar system evolution based on the numerous number of age data. In recent ten years, we have demonstrated the unique study approach using the distribution pattern of sample ages based on the series of precise age data collected from large number of samples (i.e., age-cytometry) [e.g., Rino et al., PEPI, 2008; Iizuka et al., Geology, 2008; Iizuka et al., Iizuka et al., Chem. Geol., 2009; Iizuka et al., GCA, 2010]. With the high-time resolution age data obtained by present analytical technique using the LA-ICPMS, further precise and quantitative discussion could be made on the solar system evolution through the age-cytometry. The newly developed high-resolution and high-throughput age determination system using a laser ablation-ICP mass spectrometry has a potential to become a significant tool to promote an age-cytometry.

147Sm-143Nd and 146Sm-142Nd chronology of a basaltic eucrite, Juvinas

KAGAMI, Saya[1*] ; YOKOYAMA, Tetsuya[1]

[1]Dept. Earth and Planetary Sciences, Tokyo Tech

Eucrites are interpreted to have originated from the asteroid 4-Vesta which differentiated into crust and mantle. The chronology of eucrites is important to understand the formation and differentiation of planets/ planetesimals in the early Solar System. The combination of two chronometers, short-lived ^{146}Sm-^{142}Nd system ($T_{1/2}$=6.8×10^{7}yr) and long-lived ^{147}Sm-^{143}Nd ($T_{1/2}$=1.06×10^{11}yr), is useful to decode the thermal history of the eucrite parent body, because they have the same closure temperature [1]. To obtain precise Sm-Nd ages for eucrites and other achondrites, it is indispensable to develop highly precise Nd isotope analysis.

We investigated the ^{147}Sm-^{143}Nd and ^{146}Sm-^{142}Nd chronometers for a brecciated basaltic eucrite, Juvinas. We examined samples of whole rock powder (W.R.), 400 mesh grains, plagioclase (Pl), and pyroxene (Px). Plagioclase and pyroxene grains were obtained by handpicking. Samples were dissolved using a mixture of concentrated pure acid ($HClO_4$, HF, and HNO_3) and heating at 195 ℃. About ten percent of the solution was removed and spiked with ^{149}Sm-^{145}Nd in order to precisely measure Sm and Nd concentrations by ID-ICP-MS (Thermo X-series II at Tokyo Tech). We separated Nd from the rest of the solution via a four-step column chemistry. Nd isotope ratios in W.R., 400mesh, Pl, and Px were analyzed by TIMS (Thermo TRITON-plus at Tokyo Tech) with the dynamic multicollection method.

The ^{147}Sm-^{143}Nd mineral isochron diagram of Juvinas, yielded an age of 4610±410 Ma. In contrast, the ^{146}Sm-^{142}Nd systematic for Juvinas yielded an initial ^{146}Sm/^{144}Sm ratio of 0.0157±0.0074. This gives ?4618?_(-63)^(+38) Ma for the age of Juvinas when an initial solar system ratio of ^{146}Sm/^{144}Sm=0.0094 at 4568 Ma is assumed [1]. The self-consistency of the ^{147}Sm-^{144}Nd and ^{146}Sm-^{142}Nd ages for Juvinas supports early crust-mantle differentiation on the eucrite parent body as was proposed by previous chronological studies on basaltic eucrites (e.g., Pb-Pb, Al-Mg, Mn-Cr, and Hf-W; [2-5]).

It has been suggested that cumulate eucrites provide internal isochron ages younger than basaltic eucrites due to a longer history in the deep crust or late thermal disturbance during later meteorite bombardment event(s) [6]. Because of the limited Sm/Nd variation in the meteorite components analyzed, the Sm-Nd ages obtained in this study have uncertainties several times larger than those in previous studies [6]. The ^{147}Sm-^{143}Nd age and the initial ^{143}Nd/^{144}Nd ratio for Juvinas are consistent with those obtained by the mineral isochrons of three cumulate eucrites within analytical error (4546±8 Ma; [6]). However, our ^{146}Sm-^{142}Nd age is older than the proposed ^{147}Sm-^{143}Nd age for cumulate eucrites, indicating that the crystallization of basaltic eucrites predates the timing when the Sm-Nd systematics for cumulate eucrites reached a closure temperature. It should be noted that Juvinas is a brecciated basaltic eucrite which may not record a correct Sm-Nd age. Further investigation is required to obtain more precise Sm-Nd ages utilizing unbrecciated basaltic eucrite to reveal the thermal history on the eucrite parent body.

Al-Mg mineral isochron of a Type C CAI from Allende

KAWASAKI, Noriyuki[1*] ; KATO, Chizu[2] ; ITOH, Shoichi[3] ; ITO, Motoo[4] ; WAKAKI, Shigeyuki[4] ; YURIMOTO, Hisayoshi[1]

[1]Hokkaido University, [2]Washington University in St. Louis, [3]Kyoto University, [4]JAMSTEC

Ca-Al-rich inclusions (CAIs) show the record of ^{26}Al, which is a short-lived radionuclide with a half-life of 0.73 Myr (e.g., MacPherson et al., 1995), thus a relative chronometer with Al-Mg systematics is applicable for determining a precise time interval of individual CAI formation process. In this work, we report full petrologic and mineralogical studies of a Type C CAI from Allende, EK1-04-2, with more detailed analyses of O isotopic distributions and Al-Mg systematics than presented by Ito et al. (2000).

FE-SEM equipped with EDS and EBSD system (JEOL JSM-7000F; Oxford X-Max 150; Oxford HKL) was used for petrologic and mineralogical studies. O and Al-Mg isotopic compositions were measured by SIMS (Cameca ims-1270).

The EK1-04-2 is a CAI fragment with a size of ~2 mm across. The CAI mainly consists of spinel, anorthite, olivine and diopside. The CAI has mantle and core structure. In the core part, euhedral spinel crystals are enclosed by other mineral grains. Anorthite and olivine grains show euhedral or subhedral shape. Diopside grains show anhedral shape and include spinel and olivine grains. Thus, crystallization sequences of core minerals are spinel, anorthite, olivine and diopside. The mantle part has a same mineral assemblage as the core part, however, amount of spinel is lower than the core part, and anhedral spinel and anorthite grains are present, and the diopside is more Mg-rich and Ti-poor comparing with core diopside.

O isotopic compositions of the minerals are distributed along CCAM line (delta-^{18}O = -44 to +9 permil). Spinel is ^{16}O-rich (delta-^{18}O ~-43 permil), while anorthite is ^{16}O-poor (delta-^{18}O ~9 permil). Any differences of O isotopic compositions are not observed for these minerals among core and mantle parts while olivine and diopside show different O isotopic compositions between core and mantle parts. Olivine and diopside in the core have an intermediate O isotopic composition between spinel and anorthite (delta-^{18}O ~-15 permil). In contrast, the oxygen isotopic compositions of olivine and diopside in the mantle are not homogeneous and distributed to ^{16}O-poor direction compared with those in the core (delta-^{18}O = -13 to -4 permil). Olivine and diopside grains in the mantle are not in chemically equilibrium with those in the core. The O isotopic distributions among mineral grains indicate that the CAI experienced multiple and individual crystallization events: a crystallization of spinel, a crystallization of core olivine and diopside, and a crystallization of mantle olivine and diopside.

On the Al-Mg isochron diagram, spinel grains are plotted on a line of $^{26}Al/^{27}Al_0 = (3.52\pm0.15) \times 10^{-5}$, while olivine, diopside and anorthite grains of core are plotted on a line of $^{26}Al/^{27}Al_0 = (5\pm5) \times 10^{-7}$. The difference of the initial values corresponds to a relative age of ~4.6 Myr. In contrast, olivine and diopside grains in mantle are plotted below the line of olivine and diopside in core. The ^{16}O-poor and low delta-$^{26}Mg_0$ compositions of mantle olivine and diopside suggest mixing of Al-rich chondrule-like materials. The composition of the mantle diopside is consistent with this scenario.

The petrographic, oxygen isotopic and chronological studies indicate that the CAI experienced multiple heating events after a precursor CAI formation. After ~4.6 Myr later than the precursor CAI formation, the CAI partially melted at ~1600K. The melt exchanged oxygen isotopes with the surrounding ^{16}O-poor solar nebular gas. ^{16}O-poor olivine, diopside and anorthite grains recrystallized from the partial melt. Subsequently, Al-rich chondrule-like materials accreted on the CAI and experienced partial melting and recrystallization, again. Distinctive ^{16}O-poor composition of anorthite is a result of a thermal metamorphism at the Allende parent body.

Our study revealed that the CAI has retained in the protosolar nebula at least for 4.6 Myr and experienced multiple melting events.

Water contents and hydrogen isotopic compositions of phosphate minerals from LL4-6 ordinary chondrites.

YANAI, Kaori[1] ; ITOH, Shoichi[2*] ; GREENWOOD, James[3] ; RUSSELL, Sara[4] ; YURIMOTO, Hisayoshi[1]

[1]Department of Natural History Sciences, Hokkaido University, [2]Department of Earth and Planetary Sciences, Kyoto University, [3]Department of Earth and environment Sciences, Wesleyan University, [4]Department of Earth Sciences, Natural History Museum, London

The origin of water on the earth is discussed by many researcher. The hydrogen isotopic compositions of earth ' s water were also studied to discuss the origin of water for Earth, Lunar and comet through the planetary scale in the solar system [Greenwood et al., 2011]. One of siginificant possible precursor of H20 in Earth ' s orbitary could be cometary ice but it is unclear. In preliminary results, we reported the hydrogen isotopic compositions of phosphate minerals (Merrilite and apatite) from Ensisheim LL6 ordinary chondrite (OC) on 2012 at JPGU and NIPR meeting in Japan. These D/H ratio are extremely duetrium-rich value (δD ˜15000permil). In addition, Deloule and Robert (1995) also reports that the hydrogen isotopic compositions of phyllosilicate from LL3.0 Semarkona OC is D-rich (˜4000permil) and suggest the origin of this D-rich isotopic compositions come from the interstellar space or in the outer regions of the solar nebula, like cometary ice. These results suggest that, as the Itokawa S-type asteroids with Earth ' s orbitary, the heavily hydrogen isotopic compositions of LL OCs resulted from cometary ice close to the earth. However, there is no sytematic study of hydrogen isotopic compositions of LL4-6 OCs because it is difficult to estimate the planetsimal hydrogen isotopic compositions of water due to very low water contents and contamination from adsorbed water. In this study, we applied the in-situ measurement technique of water content and hydrogen isotopic compositions of phosphate minerals from LL4-6 OCs by SIMS. All D/H ratio in the phosphate minerals are D-rich (δD ˜+2000 to +25000). The D/H ratio in the phosphate minerals from LL4 Soko-Banja and LL5 Tuxtuac could be resulting from degassing of H2 during Fe-water oxidation reaction but it is difficult to apply it for those of LL6 Ensisheim and Bandong LL6. These results suggest that the origin of D-rich hydrogen isotopic compositions of LL6 phosphate mineral is resulting from extra-planetary with cometary ice beause of extremely heavily hydrogen isotopic compositions.

Oxygen diffusion in perovskite with different Ca/Ti ratio

HASHIGUCHI, Minako[1*] ; SAKAGUCHI, Isao[1] ; HIROSE, Sakyo[2] ; OHASHI, Naoki[1]

[1]National Institute for Materials Science (NIMS), [2]Murata Manufacturing Co., Ltd.

<**Introduction**> Calcium-aluminum-rich inclusions (CAIs) in chondrites are believed to be the first solid formed in solar nebula and are composed of refractory minerals, such as spinel, mellilite, anorthite, and perovskite ($CaTiO_3$). Previous studies have been reported heterogeneous oxygen (O)-isotopic compositions among the CAI minerals [Clayton et al. (1973)]. The isotopic compositions are considered to be a marker of O-isotopic composition in the solar nebula [Yurimoto et al. (1998); Itoh and Yurimoto (2003); Park et al. (2012)]. Diffusion processes are important processes to affect the O-isotopic compositions of CAI minerals. To understand the effect, oxygen diffusivity of minerals should be investigated.

Perovskite crystals showed several order of larger oxygen diffusion coefficients than other CAI minerals [Gautason and Muehlenbachs (1993); Ryerson and McKeegan (1994); Sakaguchi and Haneda (1996)]. Thus, its O-isotopic compositions can provide us an important key to understand whether O-isotopic compositions of the CAI minerals have been modified or not. However, there still were a few reports on the oxygen diffusivity of perovskite, and the previously reported values are different by about one order of magnitude [Gautason and Muehlenbachs (1993); Sakaguchi and Haneda (1996)]. In this study, we focus on Ca/Ti ratio of perovskite and determined oxygen diffusion coefficients in perovskite with different Ca/Ti ratio experimentally.

<**Experimental**> Polycrystalline perovskite samples were prepared by a conventional sintering technique. High-purity reagent-grade powders of $CaCO_3$ and TiO_2 were used as the starting materials. These powders were mixed as Ca/Ti=0.098-1.002 by ball milling with PSZ balls. The powders were pressed as a sheet and were sintered at 1350 degC for 2 h in the atmosphere.. Then, perovskite samples with different Ca/Ti ratio were obtained. Because of a contamination of ZrO_2 from PSZ balls, Ca/Ti ratio of the samples may differ by 0.001-0.0015 from initial value.

The samples were polished and finished by a mechanical polishing using the several grade of diamond pastes. To remove damages by the polishing, the samples were annealed at 1200 degC for 1h in the atmosphere. The samples were annealed under $^{18}O_2$ gas at 750-1050 degC for several hours. Oxygen diffusion coefficients in the samples were determined using depth profiles of ^{18}O concentration of the samples obtained by secondary ion mass spectrometry (Cameca ims-4f).

<**Results and discussion**> Two contributions to the oxygen bulk diffusion mechanism are observed in depth profiles of ^{18}O concentration obtained from Ti-rich perovskite samples. One starts near surface (diffusion A) and the other starts from about a few 100 nm depth (diffusion B) of the sample. In Ca-rich perovskite samples, only a diffusion mechanism is observed.

We found that the oxygen bulk diffusion coefficients (D_b) in Ca-rich perovskite samples were larger than that of Ti-rich samples, in both diffusion A and B. The D_b value of 950 degC in a perovskite sample prepared by a powder with Ca/Ti=0.098 was $7x10^{-13}$ cm^2/s (diffusion A), $1x10^{-11}$ cm^2/s (diffusion B), whereas the value of a sample prepared by a powder with Ca/Ti=1.002 was $7x10^{-10}$ cm^2/s.

Previous reports showed ^{16}O-poor [Ito et al. (2004)] or ^{16}O-rich [Park et al. (2012)] perovskite in carbonaceous chondrites. It has been suggested that the former was changed from its original isotopic composition during thermal processes, the later was escaped the secondary processes. Larger oxygen diffusion coefficients of perovskite than that of other CAI minerals suggested that perovskite record the final thermal process, which the CAI experienced. Moreover, this study may suggest shorter timescale required for change of O-isotopic composition of perovskite than previously estimated and also indicates the importance of investigation on Ca/Ti ratio of perovskite to understand its oxygen diffusivity.

Newly identified hibonite-bearing FUN inclusions with low Al/Mg ratios

FUKUDA, Kohei[1*] ; HIYAGON, Hajime[1] ; SASAKI, Shogo[1] ; MIKOUCHI, Takashi[1] ; FUJIYA, Wataru[2] ; TAKAHATA, Naoto[3] ; SANO, Yuji[3] ; MORISHITA, Yuichi[4]

[1]Graduate School of Science, The Univ. of Tokyo, [2]Max Planck Institute for Chemistry, [3]AORI, The Univ. of Tokyo, [4]Graduate School of Science, Shizuoka Univ.

It has been recognized that a minor group of CAIs named FUN (*F*ractionation and *U*nknown *N*uclear effects) and some types of hibonite ($CaAl_{12}O_{19}$) inclusions show isotopic anomalies in ^{48}Ca, ^{50}Ti, and no or small excesses in ^{26}Mg from the decay of ^{26}Al. The existence of isotopic anomalies in Ca and Ti suggests that these inclusions formed at the earliest stage of the solar system evolution, when isotopic heterogeneity still existed. The lack of ^{26}Al may also be interpreted as their formation before the homogenization of ^{26}Al distribution in the early solar system. Hence, FUN inclusions and hibonite-bearing inclusions may have significant importance in studying the earliest stage of the solar system evolution.

In order to better understand the isotopic homogenization process(es) in the early solar system, I have conducted multiple isotopic analyses of three hibonite-bearing inclusions from the Murchison (CM2) meteorite using two ion microprobes (Cameca ims-1270 & NanoSIMS 50). I identified three new hibonite-bearing FUN inclusions (MC037, MC040, and MC003), which exhibit extremely large mass-dependent fractionation in Mg (up to ∼55 ‰/amu) but almost no excess in ^{26}Mg, and have resolvable isotopic anomalies in ^{48}Ca and ^{50}Ti. The results suggest that these inclusions formed during the isotopic homogenization process(es). The results of Mg isotopic compositions (extremely large isotopic fractionation) and elemental abundances (rather low Al/Mg ratios of 20-150) indicate that the precursors of these inclusions might have more Mg-rich (less refractory) compositions than the previously reported hibonite-bearing F(UN) inclusions (Al/Mg ratios from ∼500 up to ∼60000). In addition, their oxygen isotopic compositions are plotted on a mass-dependent fractionation line with Δ^{17}O values of ∼-23 ‰, similar to the value for the majority of typical CAIs. This suggests that oxygen isotopic compositions of their precursors are also ^{16}O-rich ($\delta^{17,18}$O ∼-50 ‰), identical to those of typical CAIs. Furthermore, the textual signatures suggests that a molten precursor of MC040 may have been quenched. Although the origin of FUN inclusions is still not known, the present results and previous works show that there are further variations in their precursor compositions, isotopic anomalies, and thermal processes.

O-16-rich olivine in igneous rim from NWA 3118 (CV)

MATSUDA, Nozomi[1*] ; SAKAMOTO, Naoya[2] ; YURIMOTO, Hisayoshi[3]

[1]Natural History Sciences, Hokkaido University, [2]CRIS, Hokkaido University, [3]Natural History Sciences, Hokkaido University

Ca-Al-rich inclusions (CAIs) and chondrules in chondrites show mass independent oxygen isotopic fractionation. Normally, CAIs are enriched in O-16 whereas chondrules are depleted in O-16. However, olivine grains having O-16-rich composition were reported in chondrule rims from CR2 chondrites (Takeda et al., 2002; Nagashima et al., 2013). Existence of O-16-rich grains in the rims indicates that the chondrule rims preserve information about chondrule precursor components with oxygen isotope in the chondrule formation region. In addition, abundance and distribution of O-16-rich olivine in chondrule rims have not been studied for other chondrite groups. Therefore, we study petrology and oxygen isotopic mapping of an igneous chondrule rim from a CV3 chondrite in order to reveal the distribution of O-16-rich materials.

The sample used in this study is a polished thin section from NWA 3118 CV3 chondrite. The petrographic observation and chemical analysis were performed by FE-SEM-EDS (JEOL JSM-7000F + Oxford X-Max 150). Crystal orientation analysis was studied by EBSD (Oxford HKL). Isotope mapping technique for oxygen was applied by an isotope microscope (Cameca ims-1270 + SCAPS).

The chondrule studied here has 1.4 millimeters in diameter and Mg-rich (type I) porphyritic texture mainly composed of forsterite, low-Ca pyroxene and feldspathic mesostasis. The chondrule is surrounded by rim that shows an evidence of igneous process with the thickness of up to 400 micrometers. The rim is mostly composed of ferromagnesian olivine and also contains low-Ca pyroxene, high-Ca pyroxene, Fe-Ni metal and sulfide. The Fe-rich olivine grains often show Fe-Mg zoning, suggesting that diffusional Fe-Mg exchange has occurred during metamorphism on the parent body.

In this study, seven O-16-rich olivine grains with 10-30 micrometers in diameter were found in the igneous rim. O-16-enrichments are observed in core of the olivine crystals. The oxygen isotope heterogeneity and the chemical composition are not correlated. This result suggests that these O-16-rich parts are relict and overgrown by O-16-poor olivine crystallized from melt during rim formation.

The existence of O-16-rich olivine in the rim from CV chondrite indicates that both O-16-rich and O-16-poor materials exist in the chondrule formation region.

Internal structure of chondrules and their possible origin

TAKAHASHI, Eiichi[1*] ; NAKAMOTO, Taishi[1]

[1]Earth & Planetary Sciences, Tokyo Institute of Technology

In order to clarify 3D shapes and internal structure of chondrules in Allende chondrite, we have separated 180 chondrules grains and investigated them with X-ray CT apparatus (Scan Xmate-D180RSS270) recently installed at the Museum of Natural History, Tohoku University (Tsuda et al., JPGU 2013). We also developed an optical device to measure 3D shape of chondrules or other spherical objects (Nishida et al. JPGU 2013). Our results revealed that chondrules shapes show wide distribution consisting of true spheres, prolate-spheres and oblate-spheres. Chondrules with porphyritic textures distribute in all shape categories. Chondrules with barred olivine texture (quenched from super-heated melt) show a distribution between true sphere and oblate-shape. Implication of the 3D shapes and internal texture of chondrules are consistent with the shock-wave heating model (e.g., Miura & Nakamoto, 2002, 2008).

Due to the density contrast, textures of Fe-FeS phase are most easily observed by X-ray tomography. By melting, coagulation and growth of Fe-FeS phase occur in chondrules. In some chondrules, coagulation resulted in mini-core formation (driven by surface energy minimization, see Fig.1). It is suggested that duration of heating episodes could be estimated by coagulation textures of Fe-FeS. If chondrules were formed by shock heating mechanism (e.g., Miura & Nakamoto, 2002, 2008), separation of molten silicate and coagulated Fe-FeS droplets would have taken place during acceleration and slow down of chondrules. Accordingly, significant chemical fractionation took place by dynamic processes during chondrules formation.

In X-ray CT images, many chondrules are surrounded by 50-200 micron thick rims. Coagulation and growth of Fe-FeS grains are observed in chondrules-rims as well as inside of chondrules indicating that temperature may have exceeded ˜1000C (eutectic point in the Fe-FeS) in the chondrule-rims. The common appearance of growth texture of Fe-FeS grains supports high-temperature origin of chondrule-rims rather than metasomatic origin. Clear textural distinction between chondrules and their ambient rims may correspond with presence or absence of melting in silicates. Most abundant element that volatilized below 1000C is sulfur. It is suggested that sulfur would have acted as a glue to coagulate dust particles onto molten droplets (chondrules) during shock heating episodes.

Artificial cosmic spherules produced by heating and quenching experiments

GONDO, Takaaki[1*] ; ISOBE, Hiroshi[1]

[1]Grad. Sch. Sci. Tech., Kumamoto Univ.

Micrometeorites (MMs) are extraterrestrial fine particles derived from asteroids and comets and continuously falling to the Earth. Depending on their velocity, mass and entry angle, micrometeorites have undergone various degrees of heating during the atmospheric entry within a few seconds. This heating lead to significant textural, mineralogical and chemical modifications to MMs. The MMs larger them 70 micron meters in diameter show variously melted textures. In particular, completely melted micrometeorites are known as cosmic spherules. Cosmic spherules have experienced large degrees of melting of primary phases during atmospheric entry, and form molten droplets. In this study, we carried out rapid heating and quenching experiments on fine particles of three kinds of meteorites (CV, CM and H chondrite) to reproduce cosmic spherules by atmospheric entry.

The run products of meteorites as starting materials show quite analogous textures to cosmic spherules including porphyritic olivine and barred olivine. The most of molten particles show spherical shape due to surface tension of the silicate melt. The outside shape of the particles is various depending on melt fraction of the particle. We successfully reproduced artificial cosmic spherules with remarkably analogous textures to natural ones. We can compare textural variations of cosmic spherules to run products and possible precursors of cosmic spherules. Analogy of the run products to cosmic spherules can be applied from textural, mineralogical and chemical modifications during atmospheric entry to estimate abundance of the interplanetary fine particles in the vicinity of the Earth’s orbit.

Keywords: micrometeorite, carbonaceous chondrite, H chondrite, atmospheric heating, cosmic spherule

Experimental reproduction of microtexutures of chondrules and CAIs by reducing-gas levitation technique

SETO, Yusuke[1*] ; ICHIMURA, Shun[1] ; MATSUNO, Junya[2] ; TAKAHASHI, Ryohei[2] ; TSUCHIYAMA, Akira[2] ; KOHARA, Shinji[3]

[1]Kobe Univ. Sci., [2]Kyoto Univ. Sci., [3]JASRI

Chondrules are the most abundant component in chondrites. They are mm-sized round (or irregularly) shaped particles mainly composed of silicates, which formed by the rapid cooling of droplets of molten or partially molten rock in space before they accreted. They show unique and diverse internal micro-textures (e.g., porphyritic olivine, barred olivine, radial pyroxene, etc.), even if they have same bulk compositions. These internal textures, therefore, should reflect not only stating material compositions, but also nebular conditions, such as gas species and their partial pressures, heating and cooling rate. CAIs are another major component in chondrites, which are also known to show the evidence of molten and quenching textures. The conditions of chondrule formation, however, remain poorly constrained, because the reproduction of the chondrule formation processes in a laboratory is experimentally difficult, especially in terms of container-less arrangement and reducing (low-fO_2) ambient. In the present study, we conducted gas-levitation and laser heating experiments in order to reproduce micro-textures of chondrules and CAIs, and constrain their formation conditions.

As stating materials, we used (i) natural olivine (Fo_{90}) from San Carlos, USA, (ii) matrices of Murchison CM meteorite, and (iii) mixed compounds of melilite ($Ca_2Al_2SiO_7$) + spinel ($MgAl_2O_4$) which are analogue to CAIs. The molten-quenched droplets of these samples were obtained using the gas-levitation and laser-heating experiments, which avoided both contamination of the molten samples and heterogeneous nucleation by crucible surfaces, at SPring-8 BL04B2. 1-2 mm-sized droplets were heated by a continuous-wave CO_2 laser, and were levitated in 96% Ar + 4% H_2 gas to achieve reducing ambient. The temperature during heating was monitored by a pyrometer. Surfaces and internal textures of the recovered samples were analyzed using SEM-EDX and -EBSD (JEOL, JSM-6480LAII and JSM-7100F).

(i) As a result of experiments using San Carlos olivine, olivine was re-crystallized under any condition. They show micro-porphyritic texture consisting of fine grained (1 to 5 μm) olivine, which are equal in composition to the starting material. Magnetite (Fe_3O_4) or hematite (Fe_2O_3) was completely absence, which suggests the low fO_2 (at least MFQ buffer) was maintained during the present experiments. (iii) The recovered sample of Murchison CM chondrite shows barred-olivine like texture. The platy (10 μm thickness) olivine crystals (Fa_{20-40}) are embedded in a FeO-SiO_2-rich glass. Idiomorphic fine (1 μm) magnetite are also observed in the glass. EBSD analyses revealed that most of the olivine plates are normal to b-axis, and the crystallographic orientations in a parallel platelet domain are identical. (iii) As a result of experiments using melilite and spinel compounds, dendritic spinel was always crystallized from surfaces to core irrespective of sample size and cooling rates, and they are embedded in Al-rich glass phase. The demonstrations of the present study show that reducing-gas levitation experiments is a powerful technique to simulate the molten-quenched texture of early solar materials.

A unique lithology in the NWA 1232 CO3 chondrite containing clasts of different metamorphic grades

MATSUMOTO, Megumi[1*] ; TOMEOKA, Kazushige[2] ; SETO, Yusuke[2] ; YAMAMOTO, Yukiko[2] ; UMEHARA, Mariko[2] ; MIYAKE, Akira[3] ; HAMANE, Daisuke[4]

[1]CSREA, Kobe Univ., [2]Graduate School of Science, Kobe Univ., [3]Graduate School of Science, Kyoto Univ., [4]ISSP, Tokyo Univ.

Northwest Africa 1232 (NWA 1232) is a CO3 carbonaceous chondrite consisting of three lithologies (A, B, and C) that went through different thermal histories [1,2]. Kiriishi et al. [3] found that lithology A contains many small clasts (100-400 micron in diameter) scattering throughout the lithology. These small clasts typically consist of one chondrule surrounded by matrix and show little evidence of thermal metamorphism. Such unique lithology has not been known in other CO3 chondrites and potentially provides new insights into the formation of CO3 chondrites. Here we report the results of detailed mineralogical and petrological study of NWA 1232. The study was performed using SEM-EDS, TEM (STEM)-EDS, EPMA, and SR-XRD.

The thin section of NWA 1232 studied consists of lithologies A (738 mm^2), B (624 mm^2), and C (196 mm^2) that are separated by sharp boundaries. In lithology C, olivine phenocrysts in type I chondrules have relatively homogeneous compositions (Fa_{3-13}) and exhibit weak Fe-Mg zoning; these correspond to metamorphic grade 3.4. The matrix consists mainly of fine grained (100-500 nm in diameter) olivine that is relatively homogeneous in composition ($\sim Fa_{60}$). In lithology B, olivine phenocrysts are more Fe-rich (Fa_{19-42}) and exhibit distinct Fe-Mg zoning; these correspond to metamorphic grade 3.7. The matrix is mainly composed of relatively coarse-grained ($>$500 nm in diameter) olivine that is very homogeneous ($\sim Fa_{40}$).

In contrast, chondrules and matrix in lithology A exhibit considerable chemical and textural diversities. Olivine phenocrysts in chondrules vary widely in composition from Fa_1 to Fa_{43}. Most of Mg-rich olivine phenocrysts in Mg-rich chondrules show almost no Fe-Mg zoning; these are similar to those in CO 3.0 chondrites. Their surrounding matrix consists mainly of very fine-grained Mg-Si-Fe-rich amorphous material. On the other hand, most of Fe-rich phenocrysts in Fe-rich chondrules show distinct Fe-Mg zoning and their surrounding matrix consists mainly of coarse-grained ($>$500 nm in diameter) Fe-rich ($\sim Fa_{40}$) olivine; these are similar to those in highly metamorphosed CO 3.7 chondrite. There are also many other chondrules whose olivine phenocrysts have compositions intermediate between the Mg-rich and Fe-rich olivines described above. The matrix surrounding these chondrules mainly consist of fine-grained (100-500 nm in diameter) Fe-rich olivine similar to those mildly metamorphosed CO chondrites.

The chemical and textural heterogeneities observed in lithology A cannot be explained by thermal metamorphism of a single lithology. The results suggest that lithology A is composed of many clasts that underwent various degrees of thermal metamorphism in different locations of the parent body. The results further imply that CO chondrites had once experienced various degrees of thermal metamorphism in different locations in the parent body and subsequently went through extensive brecciation and mixing.

Hydrothermal alteration experiments of the Allende meteorite

IIKUNI, Tsuneyuki[1*] ; TOMEOKA, Kazushige[1] ; SETO, Yusuke[1]

[1]Graduate school of Science, Kobe University

Among the processes that have affected early cosmic materials including carbonaceous chondrites, water perhaps played the most significant role in the chemical and mineralogical evolution of a range of small asteroidal bodies, by modifying the primary mineralogical characteristics of precursor materials. The obvious effect of aqueous alteration is the formation of secondary phases, such as serpentine and smectite. The diversity in alteration assemblages among various chondrites likely reflect the aqueous environment (e.g., temperature, dissolved ion, duration, water/rock ratio, fO_2, etc.) of the parent bodies. Although several hydrothermal experiments were made on olivine or pyroxene as starting materials[#1−#2], little is known about the actual behavior of chondrite toward aqueous fluid[#3]. Here we report hydrothermal alteration experiments of Allende meteorites.

We use Allende meteorites as starting materials. In order to observe micro-textures before and after alterations, we cut out block-shaped samples (2.5 mm×2.5 mm×6 mm) and never crushed. Hydrothermal alteration experiments were performed with PTFE double-vessels (1 ml and 25 ml) loaded into a steel autoclave. In order to maintain a reducing ambient, H_2 gas was generated in the outer vessel by reaction with HCl and magnesium,. All experiments were carried out at temperature of 200 deg.C, where the saturated vapor pressure reaches about 15 bar. As to reaction fluids, we use different pH solution (7, 8.5, 10, 14)[#4] with different water/rock (W/R) ratios (0.5, 2, 8 vol./vol.)[#5]. All run durations are 168 hours. Recovered products were analyzed by synchrotron X-ray diffraction (SR-XRD), scanning electron microscope (SEM) equipped with an energy-dispersive X-ray spectrometer (EDS).

As the results, except for condition of pH 7 and W/R 0.5, serpentine is observed in matrix, which formed at interstitial space of olivine grains of the matrix. As pH value increases, more abundance of matrix olivine are replaced by serpentine. Smectite is observed only under the condition of pH 14 and W/R 0.5. Calcite ($CaCO_3$) is formed on the sample surface under almost all conditions. Under pH 7 condition, anhydrite ($CaSO_4$) is also formed on the sample surface. The results of this study indicate that hydrated mineral formation easily proceeds compared with the previous studies where olivine or pyroxene were used as starting materials.

Small solar system bodies were formed as agglomerates of dust and ices 4.6 billion years ago. Several million years after asteroid formation [1], the ice melted due to radioactive heating inside the larger asteroids [2] and/or highly energetic impacts [3]. Then, water plays several major roles in the chemistry of asteroids, both in mineralization and in the formation of organic compounds. Currently, bulk liquid water no longer exists in meteorites. We see only the signature of water in ancient asteroids as veins of hydrothermally deposited minerals [4] or water trapped in salt crystals [5] in meteorites. The Tagish Lake meteorite, which is a unique Type 2 carbonaceous chondrite, has a signature of aqueous process in the matrix that is abundant micrometer-sized polyhedral particles of magnetite [6]. The framboids are three-dimensionally ordered colloidal crystals of magnetite nanoparticles. The uniformity of the size distribution and the similar morphology of the magnetite nanoparticles in each of the colloidal crystals suggest that they were formed through homogeneous nucleation from a highly supersaturated isolated solution in a single nucleation event.

Here we show evidence of how magnetite nanoparticles assembled into periodic structures based on a nanometer scale paleomagnetic method using electron holography in an examination of the framboidal magnetite in the Tagish Lake carbonaceous chondrite [7]. An attractive force such as magnetism never contributes to the formation of colloidal crystals [8], but the repulsive force caused by the surface charge of the magnetite is able to work. To overcome the repulsive force, the density of magnetite nanoparticles in a solution must be sufficiently high in an isolated solution as a water droplet parches in microgravity. We used electron holography to visualize the magnetization of the meteoritic minerals for the first time and found that magnetite grains in the framboid have no external magnetic force, i.e., they have a flux-closure vortex structure, which allowed the formation and preservation of the colloidal crystals. We conclude that these framboids formed in tiny water droplets with pH of 7-12 containing ions such as Ca^{2+} and Mg^{2+} at levels of 10^{-14}-10^{-15} mol m^{-2}, just before exhaustion of water during thermal alteration in a hydrous asteroid.

C-XANES analyses of carbonaceous solid inclusions from Monahans halite

KEBUKAWA, Yoko[1*] ; ZOLENSKY, Michael[2] ; KILCOYNE, David[3] ; RAHMAN, Zia[4] ; FRIES, Marc[2] ; CODY, George[5]

[1]Department of Natural History Sciences, Hokkaido University, [2]NASA Johnson Space Center, [3]Lawrence Berkeley National Laboratory, [4]Jacobs-Sverdrup, [5]Geophysical Laboratory, Carnegie Institution of Washington

Monahans meteorite (H5) contains fluid inclusion-bearing halite (NaCl) crystals [1]. Microthermometry and Raman spectroscopy showed that the fluid in the inclusions is an aqueous brine and they were trapped near 25^{o}C [1]. Their continued presence in the halite grains requires that their incorporation into the H chondrite asteroid was post metamorphism [2]. Abundant solid inclusions are also present in the halites. The solid inclusions include abundant and widely variable organics [2]. Analyses by Raman microprobe, SEM/EDX, synchrotron X-ray diffraction and TEM reveal that these grains include macromolecular carbon similar in structure to CV3 chondrite matrix carbon, aliphatic carbon compounds, olivine (Fo_{99-59}), high- and low-Ca pyroxene, feldspars, magnetite, sulfides, lepidocrocite, carbonates, diamond, apatite and possibly the zeolite phillipsite [3]. Here we report organic analyses of these carbonaceous residues in Monahans halite using C-, N-, and O- X-ray absorption near edge structure (XANES).

Approximately 100 nm-thick sections were extracted with a focused ion beam (FIB) at JSC from solid inclusions from Monahans halite. The sections were analyzed using the scanning transmission X-ray microscope (STXM) on beamline 5.3.2.2 at the Advanced Light Source, Lawrence Berkeley National Laboratory for XANES spectroscopy. C-XANES spectra of the solid inclusions show micrometer-scale heterogeneity, indicating that the macromolecular carbon in the inclusions have complex chemical variations. C-XANES features include 284.7 eV assigned to aromatic C=C, 288.4-288.8 eV assigned to carboxyl, and 290.6 eV assigned to carbonate. The carbonyl features obtained by C-XANES might have been caused by the FIB used in sample preparation. No specific N-XANES features are observed. Various degrees of 1s-$\sigma*$exciton shown in the C-XANES spectra indicate that the solid inclusions contain macromolecular carbon which experienced various degree of thermal processing. The natures of the macromolecular carbon in the solid inclusions observed by C-XANES are consistent with the previous studies showing that the solid inclusions have not originated from Monahans parent body [1-3].

3D shapes of Itokawa regolith particles: comparison with lunar regolith particles

TSUCHIYAMA, Akira[1*] ; MATSUSHIMA, Takashi[2] ; MATSUMOTO, Toru[3] ; NAKANO, Tsukasa[4] ; MATSUNO, Junya[1] ; SHIMADA, Akira[3] ; UESUGI, Kentaro[5] ; TAKEUCHI, Akihisa[5] ; SUZUKI, Yoshio[5] ; OHTAKE, Makiko[6] ; NAKAMURA, Tomoki[7] ; UESUGI, Masayuki[6] ; YADA, Toru[6] ; NISHIIZUMI, Kunihiko[8]

[1]Graduate School of Science, Kyoto University, [2]Graduate School of Systems and Information Engineering, [3]Graduate School of Science, Osaka University, [4]AIST/GSJ, [5]JASRI/SPring-8, [6]JAXA/ISAS, [7]Graduate School of Science, Tohoku University, [8]Space Sciences Laboratory, University of California

Regolith particles were returned from the surface of asteroid Itokawa by the Hayabusa spacecraft. The sample analysis elucidated a variety of surface processes on the asteroid (e.g., [1]): (1) Formation of regolith by impacts of small objects, with selective escape of the finest-scale particles. (2) Implantation of solar wind into the uppermost particle surfaces and formation of space-weathering rims. (3) Grain abrasion, probably due to seismic-induced particle motion. Processes (5) and (6) might have been repeated. (7) Final escape of particles from the asteroid by impact within the past 8 million years (1-3 million years [3]).

During the course of the analysis, 3D size and shape features of the Itokawa particles were obtained by SR-based x-ray microtomography to understand the origin and evolution of the regolith particles on Itokawa ' s surface [2,3]. In particular, the particle shape distribution with respect to their three-axial ratios was obtained and compared with that of fragments formed by high-speed impact in laboratory experiments [4,5] and of lunar regolith samples [6]. The 3D shapes of the lunar samples have been examined by tomography [6] but not grain-by-grain as performed for the Itokawa samples. In addition, the procedure for measuring the three axial lengths was different between the regolith particles and the impact fragments: the former was obtained from 3D external particle shapes by ovoid approximation [2,3,6], while the latter by bounding box method using a calliper [4,5]. In order to make strict comparison between them, lunar regolith particles were examined by the same method as the Itokawa particles, and the three axial lengths were measured from the tomography data by bounding box method that was newly developed in the present study.

The 3D shapes of 70 particles from 105-250 μm sieved fraction of Descartes highland (60501) and 74 particles from $<$1 mm sieved fraction of Mare Tranquillitatis (10084) were obtained by microtomography at BL47XU of SPring-8. Furthermore, the 3D shapes of new 24 Itokawa particles (3 of them are from Dr. M. Meier, personal communication) were also examined in addition to the previous 48 particles [3]. The three axial lengths were measured in the orders of short to long and long to short axes to compared with the data of [3] and [4], respectively. The shape distribution in a Zingg diagram was compared using the Kolmogorov-Smirnoff test.

The shape distribution of the Itokawa particles cannot be distinguished from that of the impact fragments of [4] but can be distinguished from that of [3]. This may suggest that the Itokawa particles resulted from mechanical disaggregation, as a response to impacts with a specific condition. In contrast, the shape distribution of the lunar regolith particles can be distinguished from that of the Itokawa particles and the impact fragments although lunar regolith is the product of impact on the lunar surface. The lunar particle shapes are more equant than the others. The both lunar samples examined are matured (Is/FeO = 80 and 78 for 60501 and 10084, respectively [7]). These regolith particles should become equant from the shapes similar to the impact fragments by mechanical disaggregation or abrasion due to repeated impacts during a long residence time in the regolith layer although a specific process for the shape change is not known.

Surface micromorphology of regolith particles from Asteroid Itokawa: Implication for space weathering of regolith

MATSUMOTO, Toru[1*] ; TSUCHIYAMA, Akira[2] ; MIYAKE, Akira[2] ; NOGUCHI, Takaaki[3] ; NAKAMURA, Tomoki[4] ; NAKAMURA, Michihiko[4] ; MATSUNO, Junya[2] ; SHIMADA, Akira[1] ; UESUGI, Kentaro[5] ; NAKANO, Tsukasa[6]

[1]Osaka University, [2]Kyoto University, [3]Ibaraki University, [4]Tohoku University, [5]JASRI/SPring-8, [6]GSJ/AIST

Spectral features of airless bodies are known to be modified by processes called space weathering. From Analysis of lunar samples, the space weathering is considered to be caused by mainly nano phase iron (npFe^0) formed by mainly vapor deposition produced by micrometeorite bombardments and solar wind irradiation [1].Space weathering of asteroid is also considered to progress by mainly solar wind irradiation and micrometeorite bombardments [1]. Detailed Space weathering processes on asteroids are expected to be revealed by analysis of asteroidal regolith samples. Hayabusa spacecraft recovered regolith particles from S-type asteroid 25143 Itokawa. In previous study, implantation of solar wind to Itokawa regolith particles was detected by noble gas isotope analysis [2]. The space weathering rims including npFe^0 were observed on regolith particles using transmission electron microscopes [3][4]. Surface micromorphology of regolith particles are expected to have information to reveal space weathering processes related to surface activity on Itokawa and applied to. So far, general surface features of regolith particles have not yet been clearly understood. Therefore, this study investigates Itokawa regolith particles focusing on their surface micromorphology.

Three-dimensional (3D) external shapes of the regolith particles were analyzed by microtomography. Surface morphologies of the regolith particles were observed by field-emission scanning electron microscopy (FE-SEM). It is revealed that the regolith surfaces can be classified into fractured surfaces formed by impact and surfaces formed by condensation from vapor in microdruses of original chondritic materials. Regardless of these surface types, there are matured surfaces, which have rounded edges. The matured surfaces are considered to be formed by abrasion processes on Itokawa [5]. Internal structures of space weathering rim of regolith particles was observed by transmission electron microscopy (TEM/STEM) and this was compared with the surface morphologies of the same surface observed by FE-SEM. Observed space weathering rim have vesicles and form blister structures. The blisters can be identified by FE-SEM, indicating that space weathering rims with blisters can be observed by FE-SEM without any destructive methods. Space weathering processes related to the surface activities on Itokawa is considered from observation of blister distribution on the regolith particles. It is revealed that there is no correlation between blister distribution and the roundness of the surface morphologies, indicating that dominant mechanism of the abrasion process is not solar wind sputtering but mechanical abrasion. The abrasion processes can peel off the space weathering rims. In addition, there are heterogeneous distribution of blisters suggesting migration and fragmentation of regolith particles. Two distinct time-scales for the spectral reddening of S-type asteroids due to space weathering were proposed [7]: solar wind irradiation for about 10^6 years and micrometeorite bombardment for about 10^9 years. This study proposes that spectral change of Asteroid Itokawa by space weathering would have gradually occurred for 10^6 years at the latest by regolith activities on Asteroid Itokawa such as mechanical abrasion, migration and fragmentation of regolith particles, while space weathering rims are developed on local surface of individual regolith particles for 10^3-10^4 years[4].

Extraction and Identification of Primitive Grains Driven by Magnetic Volume Force.

HISAYOSHI, Keiji[1*] ; UYEDA, Chiaki[1]

[1]Institute of Earth and Space Science, Graduate School of Science, Osaka University

Magnetic volume force caused by a field gradient has been commonly used to extract ferro-(or ferri-) magnetic materials from weak magnetic materials. The separation was realized because the field-gradient forces that operated on the spontaneous magnetizations of the above category of materials were considerably large with respect to terrestrial gravity. It was considered that dynamic motion of a weak magnetic material generally require a strong field above B = 10T .

Primitive materials are generally obtained as an ensemble of grains with different elemental composition with heterogeneous origins. At an initial stage of investigating this type of material, it is important to extract and identify the material of individual particles included in the ensemble. Such method should be non-destructive and easily performed. Moreover, it should be based on a well-established physical or chemical concept. In the case of analyzing a fluid sample of organic molecules, the stage separation and identification has been established by introducing the technique of chromatography; such method has not been established as yet on mixture of solid samples. Here we propose a new principle of grain separation that is driven by magnetic volume force. By comparing the measured χ_{DIA} of a particle by their published values, material of the particle is identified. This is because an intrinsic χ_{DIA} value is assigned to a material.

Microgravity was generated using a compact drop shaft system, which can be introduced in an ordinary laboratory. The length of the shaft was 1.8m, and the duration of microgravity time was about 0.5 second. The sample is released in the field-gradient produced by a by a magnetic circuit composed by a NdFeB permanent magnet. Maximum field intensity of the circuit was 0.8 T. The experimental apparatus was set inside a rectangle box which had a size of 30x30x20cm. The vacuum chamber equipped with an electric actuator, sample releasing signal reception device, the sample holder controller, the magnet, the battery, and the high-vision video camera are installed in the above box. [1-3]

The present results achieved on sub-millimetre-sized diamagnetic grain have a large significance as a step to realize the extraction and identification of micron-sized grains that compose the primitive materials. The technique described is useful in the search for new types of pre-solar grains that are not identified as yet.

Summay of the third stage of Next Decade Initiatives for Lunar Planetary Explorations

WATANABE, Sei-ichiro[1*]

[1]Dept. of Environmental Studies, Nagoya University

The Next Decade Initiatives for Lunar Planetary Explorations is now in the final phase of the third stage selection. The concept and progress of the third stage selection will be presented.

We have been discussed the mid-range (the next decade or two) future vision of planetary explorations providing the best mix of medium- to large-size flagship missions, small-size missions, and missions of opportunity for science payloads on foreign missions; the compelling concepts of the flagship missions that are central to the mid-range future vision, and strategy for unifying the planetary science community to the flagship missions. The final candidates for the flagship missions are (1) the lunar (or planetary) chronological mission based on the in-situ geochronology instruments, (2) the Mars lander and rover exploration with science payloads including the life-detection experiment system, and (3) the solar power sail mission for Trojan asteroids with cruising phase observation of the cosmic infrared background radiation. The selection committee are now reviewing the three mission concepts to polish up. I will report on the activity of the committee and discuss the relation to the ISAS's roadmap for space science approved by the Japanese Strategic Headquarter for Space Policy in September 2013.

MELOS1 Mars Exploration for Life-Organism Search

SATOH, Takehiko[1*] ; KUBOTA, Takashi[1] ; FUJITA, Kazuhisa[1] ; YAMAGISHI, Akihiko[2] ; MIYAMOTO, Hideaki[3] ; HASHIMOTO, George[4] ; SENSHU, Hiroki[5] ; USUI, Tomohiro[6] ; KOMATSU, Goro[7] ; DEMURA, Hirohide[8] ; ISHIGAMI, Genya[9] ; OGAWA, Naoko[1] ; OKADA, Tatsuaki[1]

[1]Japan Aerospace Exploration Agency, [2]Tokyo University of Pharmacy and Life Sciences, [3]University of Tokyo, [4]Okayama University, [5]Chiba Institute of Technology, [6]Tokyo Institute of Technology, [7]Universita' d'Annunzio, [8]Aizu University, [9]Keio University

Mars exploration is uniquely significant as it includes all of "scientific", "engineering", and "exploration" importances almos equally. Visiting Mars is, therefore, an essential milestone to expand the frontier of human being. In this paper, as part of JSPS "next decade" activity, we discuss MELOS1 with view points of science and engineering.

The target of MELOS1 is direct detection of lives on Mars. It will be a simplified mission with just a rover plus a cruise stage, no orbiter at all. It may not be unreasonable to expect relay orbiters in Mars orbit when MELOS1 will arrive at the red planet as there are a number of mission plans from the U.S.A., Europe, and Russia.

The MELOS1 rover will weigh about 60 kg, equipped with a life-detection microscope (LDM) and meteorology sensors to monitor its environment. Details of LDM will be presented elsewhere. In brief, the LDM uses the highest possible sensitivity technique, dyeing cells with pigment and observe them by fluorescent light. This technique will give us 3 orders of magnitudes higher sensitivity of life detection than was done on Viking Landers.

If discovered, it should undoubtedly be the biggest discovery in science. The surface area of Mars is so wide and so different from one place to another. Yet, we had only 7 landers, basically at places similar to each other. The best places for life-detection experimetn, fluvial feasures or mud volcanoes (may be methane hot spots) are still intact. In MELOS1, we will perform high-precision landing to such a place and will search for lives for the first time. The current status of planning will be presented. In addition, the position in Japan's future missions will be discussed with

audience of greater variety.

In-situ geochronology measurements have long been a key goal for planetary science.We propose a mission, which is designed to determine formation age of young Aristillus crater of the Moon. The correlation of crater frequency measured with remote-sensing data with the obtained age provides information about the cratering history in the inner solar system.

Applicability of a laser-ablation in-situ K-Ar dating method on the Moon: insights from lunar samples

CHO, Yuichiro[1*] ; MIURA, Yayoi N.[2] ; MOROTA, Tomokatsu[3] ; SUGITA, Seiji[4]

[1]Department of Earth and Planetary Science, University of Tokyo, [2]Earthquake Research Institute, University of Tokyo, [3]Nagoya University, [4]Department of Complexity Science and Engineering, University of Tokyo

We have been developing an in-situ K-Ar isochron dating method for future landing missions. Potassium-argon ages are measured with the combination of laser-induced breakdown spectroscopy (LIBS) and mass spectrometry using a quadrupole mass spectrometer (QMS). In our previous studies, we reported that isochron ages for gneiss samples with 30% accuracy and 10-20% precision.

However, such experimental results using test samples do not guarantee the applicability of our LIBS-QMS isochron method for actual rock samples on planetary surfaces. Depending on geologic units, the types of rocks and K concentration vary greatly on planetary surfaces.

Thus, we assess the capability of our in-situ K-Ar dating method taking the petrologic properties including K abundance and possible age range of the lunar surfaces into account. First, we examined the global maps of K obtained with the Gamma Ray Spectrometers onboard remote sensing satellites. We found that the concentrations of K and Ar of KREEPy materials are well above the detection limits of our LIBS-QMS approach. Then, the elemental compositions and textures of KREEP basalt were investigated. We found that Si-rich glasses contained in mesostasis are measurable with K-Ar dating on the Moon because of the high K concentration (˜7 wt%), while other minerals (i.e., pyroxene, olivine, and plagioclase) contain virtually no K. Since the textures of these samples were heterogeneous at the scale of laser spot (˜500 microns), the ”isochron” ages would be obtained by measuring the different portions containing K-bearing phases in various ratios.

The major problem concerning in-situ K-Ar dating is partial 40Ar loss due to thermal events after crystallization. This suggests that K-Ar dating only yields the lower limit for the real crystallization age. Furthermore, brecciation by impacts and contamination by solar wind will inhibit accurate in-situ dating. In order to avoid such problems and obtain meaningful age data by in-situ dating, we aim to measure fresh impact melt rocks exposed by a very recent (tens of Ma) impact on the Aristillus crater floor.

Finally, we evaluated how our method can constrain the absolute chronology models of the Moon and Mars based on the precisions of age measurements achieved by this study. For example, the absolute age of impact melt rocks in Aristillus crater, whose ages correspond to the ”missing ages” of the current lunar crater chronology model (i.e., between 3.0 Ga and 0.1 Ga), would be measured with ˜20% precision when the K concentration of the glass in KREEP basalt is assumed. Then, our method would be able to discriminate the constant flux model [Neukum, 1983] and the decreasing flux model [Hartmann et al., 2007]. The implications of in-situ dating in Aristillus crater include refining the crater chronology model, determining the age of the youngest mare basalts, and understanding the dynamical evolution of the asteroids in the last three billion years.

Exploration of Jovian Trojan asteroids by Solar Power Sail

NAKAMURA, Ryosuke[1] ; SEKINE, Yasuhito[2*] ; MATSUURA, Shuji[3] ; YANO, Hajime[3] ; MORI, Osamu[3] ; SOLAR SAIL, Working group[3]

[1]AIST, [2]Universit of Tokyo, [3]JAXA

Solar Power Sail is a novel concept with hybrid propulsion of large-area solar sail and ion engine driven by thin-film solar panel. It enables us to bring relatively large mission payloads to the outer solar system without nuclear technology. The Solar Power Sail spacecraft is currently planned in Japan to explore Jovian Trojan astereoids. There exist two competing hypotheses on their origin. The classic model suggests that Trojan asteroids are mainly survivors of building blocks of the Jupiter system, while NICE model claims that they must be intruders from outer regions after the planetary migration of gas planets settled. This mission will provide invaluable clues to the genesis of the planets, asteroids ana comets through remote sensing, in-situ sample analysis and comparison of the results with other small body missions, such as Dawn, Rosetta, Osiris-ReX and Hayabusa-2. Another target of this mission is novel astronomy; measurement of the infrared extragalactic background light without foreground contamination of the zodiacal light thanks to low-density environment at deep space, polarization measurement of the gamma-ray burst and accurate determination of its direction based on the interplanetary network technique. The Solar Power Sail mission will thus develop a new direction of space astronomy and planetary science providing us an interplanetary telescope site and will play an important roll to form a new interdisciplinary science field.

Current status of mission study for small scale planetary exploration in JSPS

ARAKAWA, Masahiko[1*]

[1]Graduate School of Science, Kobe University

Recent success of launching a new Japanese rocket named as Epsilon gives us a new chance for planetary exploration. So, we just begin to discuss a new planetary exploration mission suitable for this Epsilon rocket in Japanese Society of Planetary Science (JSPS) . Future planning section in JSPS has examined the small size mission for planetary exploration since last summer, and the special working group for this purpose in this section was organized to submit our report showing the scientific feasibility in a small size mission to a vice-president of JSPS. The final report is shown on the web-site of https://www.wakusei.jp/~shourai/wiki/epsilon/. A new load map for space science in Japan by JAXA was released last september, and it showed that the exploration of solar system would be planned in a small scale mission in order to overcome technical problems and develop new devices for the future planetary exploration planned after 10 years. According to this new load map related to planetary science, we have decided to discuss a future mission of small scale planetary exploration by using Epsilon rocket in JSPS fall meeting. We are going to hold a symposium to discuss a future plan regularly in 2014, and our symposium is open not only for JSPS member but also for every scientist and engineer who are interested in a small scale planetary exploration.

This is what I learned from the development of EXCEED

YOSHIKAWA, Ichiro[1*]

[1]University of Tokyo

I will present my plan for the next 10-year instrumental development based on my heritage on the Sprint-A/EXCEED.

An earth-orbiting Extreme Ultraviolet (EUV) spectroscopy (EXCEED) is the first mission of the Small scientific satellite Platform for Rapid Investigation and Test -A (Sprint-A) conducted by ISAS/JAXA. A single science instrument (EXCEED) is boarded on Sprint-A. EXCEED has started to observe the solar planets in the EUV spectral range, and will extend to the identification of extrasolar planet atmosphere.

Deep Space Explorer DESTINY

KAWAKATSU, Yasuhiro[1*]

[1]ISAS/JAXA

DESTINY which stands for "**D**emonstration and **E**xperiment of **S**pace **T**echnology for **IN**terplanetary vo**Y**age" is a mission candidate for the next space science small program. The next mission is planned to be decided in 2014, and the select one is scheduled to be launched in 2018.

As illustrated in the Figure, DESTINY will be launched by an Epsilon launch vehicle and firstly placed into a low elliptical orbit, where then its altitude raised by the use of ion engine. When the orbit raising reaches the Moon, DESTINY subsequently is injected into transfer orbit for L_2 Halo orbit of the Sun-Earth system by using lunar gravity assist. Upon arrived at L_2 Halo orbit, DESTINY will conduct its engineering experiment as well as scientific observations for at least a half year. If conditions permit, DESTINY will leave L_2 Halo orbit, and transfer to the next destination.

On the way to L_2 Halo orbit, DESTINY will conduct demonstration and experiment on key advanced technologies for future deep space missions. Major items of the technology demonstration are listed as follows.

1) High energy mission by Epsilon rocket.

We investigate appropriate rocket configurations and flight path designs, and evaluate the performance of Epsilon rocket to insert spacecrafts into high energy orbits. It provides basic data of Epsilon rocket application to deep space missions.

2) Ultra-Lightweight solar panel.

In order to generate large electric power to run μ20 ion engine, "Ultra-Lightweight Solar Panel", which is under development at JAXA, is applied and its performance is evaluated. This solar panel is estimated to achieve power to mass ratio at least double to conventional ones. Future application is expected in outer planet probes (JMO, MELOS) or probes with large ion engines.

3) Large scale ion engine μ20.

DESTINY is inserted into an elliptical orbit and reaches to a Halo orbit by its own orbital maneuver. For this maneuver, a large ion engine (μ20) which is under R&D at JAXA will be adopted and its performance is evaluated. This ion engine has thrust five times as much as μ10 used by Hayabusa and will be expected to be applied to large probes such as SOLAR-D or Hayabusa Mk2.

4) Advanced thermal control.

In order to manage large amount of heat generated by the large ion engine, advanced thermal control techniques by way of Loop Heat Pipe will be adopted.

5) Orbit determination under low thrust operation.

DESTINY will reach to Halo orbit by running ion engine over long duration. In order to reduce burdens to shut down the ion engine each time of orbit determinations, orbit determination under ion engine operation is conducted and its performance is evaluated.

6) Automatic/autonomous onboard operation.

In order to increase the efficiency of operation, autonomous and highly functioned spacecraft management system is developed demonstrated on board. This technique is expected to be adopted especially in the deep space missions usually operated under severe communication condition.

7) Halo orbit transfer and maintenance.

DESTINY will reach to Halo orbit and maintains the orbit more than one period. In order to reduce the risks of Halo orbit insertion and suppress the amount of orbital maneuvers, the orbit control technique using dynamical system theory is used and its operability is evaluated. This technique will be adopted in SPICA, which will be operated in Halo orbit.

DESTINY itself is an engineering experiment probe which destines L_2. However, its mission profile is naturally applied to lunar missions and escape missions by forking the profile at the lunar encounter. Moreover, the spacecraft's high astronautic performance makes its application to other launch method attractive, such as dual launch with GEO satellite or another deep space probe. The significance of DESTINY from the point of its opening new opportunities for low-cost deep space mission is discussed in the presentation as well.

Introduction of SLIM, a small and pinpoint lunar lander

SAKAI, Shin-ichiro[1*] ; SAWAI, Shujiro[1] ; SLIM, Working group[1]

[1]ISAS/JAXA

Small experimental spacecraft ”SLIM” is proposed to demonstrate accurate ”pinpoint” landing technology on a celestial body with gravity. Conventional landing missions, such as Apollo or Chang’e achieved lunar landing with km-order accuracy. Since modern spacecraft provided extensive high-resolution data on the Moon, such as the fruits of SELENE spacecraft, now the place of interest comes to be ”exactly that point”, not ”somewhere on the Moon”. Marius Hill’s Hall (MHH), which is one of the candidates of SLIM landing target, is an interesting vertical hall, for example, and to carry out some exploration on MHH, pinpoint-landing with 100 meter-order accuracy is desired. To enable such 100 meter-order landing accuracy on a celestial body with gravity, several novel technologies has been researched and developed with the effort of SLIM working group members. Practical crater detection and recognition algorithms were proposed for image based guidance system, which can be implemented on an existing space qualified FGPA device. Novel landing radar system was newly developed, and was already evaluated with a bread board model in the field flight test. Detection and avoidance of harmful obstacles around the landing point based on camera image were also researched.

SLIM spacecraft is designed as a small 500 kg-class spacecraft, to pursue lower project cost and shorter development time. To realize lunar lander in this restricted size and weight, unique ideas have been also investigated. Improved ceramic thruster will be applied based on the heritage from AKATSUKI mission, and inherited one is now discussed to be a candidate main thruster for future ESA mission. Propellant tank is designed as a part of spacecraft main structure, to minimize the total weight of SLIM spacecraft. Unique aluminum foam based landing gear is also studied and experimentally demonstrated, and electrical power system is designed with novel ultra-lightweight space solar sheet. Numbers of these engineering researches have been carried out in many universities, and with these efforts, the SLIM is just proposed to the third mission of Epsilon launch vehicle.

SLIM mission is important for its original purpose, to demonstrate the accurate landing technology, and at the same time, key technologies to realize lunar lander in small size and light weight will contribute a lot to the future exploration missions based on Epsilon launcher. In the presentation, the detail of each technology researched and developed by the member of SLIM working group will be introduced, with the result of the system design of SLIM spacecraft. The future perspective on the Epsilon exploration missions based on the SLIM design will be also discussed.

Proposal for Demonstration of Penetrator Technology by Small Satellite and Epsilon Launch Vehicle

SHIRAISHI, Hiroaki[1*] ; YAMADA, Ryuhei[2] ; ISHIHARA, Yoshiaki[1] ; OGAWA, Kazunori[1] ; OKAMOTO, Taro[3] ; TAKEUCHI, Nozomu[4] ; ISHIHARA, Yasushi[5] ; MURAKAMI, Hideki[6] ; TANAKA, Satoshi[1] ; KOBAYASHI, Naoki[1] ; HAYAKAWA, Masahiko[1] ; HAYAKAWA, Hajime[1] ; ARAYA, Akito[4] ; GOTO, Ken[1] ; MIZUNO, Takahide[1] ; ISHII, Nobuaki[1] ; TSUDA, Yuichi[1] ; HABU, Hiroto[1] ; KAKEHASHI, Yuya[1] ; ISHIMURA, Kosei[1] ; TOKUDOME, Shinichiro[1]

[1]Department of Solar System Sciences, Institute of Space and Astronautical Science, JAXA, Japan, [2]National Astronomical Observatory of Japan, RISE project, [3]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [4]Earthquake Research Institute, University of Tokyo, [5]IFREE, JAMSTEC, [6]Department of Applied Science,Faculty of Science,Kochi University

A new mission to validate the penetrator technology and to investigate the shallow structure of the Moon, using a small satellite and a penetrator module developed for the former LUNAR-A project is proposed. The lunar penetrator module consists of a penetrator main body, a de-orbit motor and an attitude control system. The de-orbit motor attached at the rear end of the penetrator module is used to cancel the orbital velocity, and the attitude control system which consists of a small gas jet and a sun-sensor is also attached to the central part of the module. The penetrator probe is a missile-shaped instrument carrier and is about 75 cm in length, 14 cm in maximum diameter and about 14 kg in weight. The penetrator contains a two-component seismometer and a heat flow probe, together with electronics, primary batteries, a tiltmeter, an accelerometer, and radio communication system. The primary objective of this mission is to demonstrate the technical issues in penetrator system; (1) holding and separation mechanism, (2) sequence of de-orbit, attitude control and subsurface deployment, (3) data-relay and remote operation by way of an orbital spacecraft, and (4) long-term geophysical observation on the Moon. The flight-proven penetrator system could be applied to the future lunar mission for a full-scale network.

The Epsilon launch vehicle lifts off a spacecraft (or lunar orbiter) with a solid propellant motor newly developed as the upper stage. The spacecraft, which should be play roles of the carrier of penetrator module and of data-relay orbiter, is assumed to revolve in a near-circular orbit of 100-200 km by 25-45 km altitude around the Moon and to release the penetrator module to deploy on the low latitude zone of the lunar nearside or terminator. The penetrator will hit on the lunar surface with a velocity of 270 to 300 m/sec and penetrate into the regolith up to a depth of 2 or 3 meters, and then it will measure the acceleration record and the stop angle at the rest position. These data would be also useful for data reduction of seismic and heat-flow data. After that, it will observe the near-surface and internal structures on the geological unit different from the past Apollo and Luna landers. Ground-based optical telescopes will continuously monitor meteoroid impact flashes on the night side of the Moon, which should frequently occur during the observation period of penetrator seismometer. These landmarks detected in the vicinity of the penetrator will be available for seismological study as known moonquake foci.

This paper describes the spacecraft design, the mission profile from launch to deployment and an operational scenario of geophysical instruments.

Lunar and planetary explorations in a coming decade: Summary of 4 years and problems remained

NAMIKI, Noriyuki[1*] ; KOBAYASHI, Naoki[2] ; DEMURA, Hirohide[3] ; OHTSUKI, Keiji[4]

[1]PERC/Chitech, [2]Department of Planetary Science, ISAS, [3]The University of Aizu, [4]Kobe University

Future Planetary Exploration Working Group of Japanese Planetary Science Society is discussing next generation of planetary explorations that need to be strongly supported by planetary science community. We started ”Planetary Exploration in a Coming Decade” activity in 2010 aiming to organize a new mission to be launched between 2017 and 2027. The first stage of the activity is ending in March, 2011. A summary of the first stage was reported by 5 panels; (1) terrestrial solid planets, (2) terrestrial atmosphere and magnetosphere, (3) minor body, (4) Jovian planets, icy satellites, and exoplanets, and (5) astrobiology. Each panel received proposals regarding ”top sciences” of each category from the community in the summer of 2010. On September 10 in 2010, an open meeting was held at Kobe University to discuss top sciences among the community of planetary scientists. From the summer of 2011, the second stage began. Proposals for new mission and instruments were submitted by 13 groups and were adivsed by the second-stage committee not only to improve the proposal, but also to raise and develop exploration groups. In 2012 May, the thrid stage started. The main purpose of the third stage is to polish up the proposls in the view of feasibility. In September 14 and 15, 2012, we held a workshop to integrate individual proposals into a few comprehensive mission plans, such as in-situ chronology and interior exploration of the moons and planets, primitive small body exploration, and sercha of life on Mars. The mission concepts of these comprehensive mission plans are now being discussed for later evaluation by the third stage committee. Thsi activity will be closing in the summer of 2014, and the final report will be published in October.

Development and evaluation of heat flow probe for the precise measurement of lunar and planetary heat flow

HORIKAWA, Yamato[1*] ; TANAKA, Satoshi[2] ; SAKATANI, Naoya[1] ; TAKITA, Jun[3]

[1]The Graduate University for Advanced Studies, [2]Japan Aerospace Exploration Agency, [3]The University of Tokyo

The precise measurement of lunar and planetary heat flow contributes to a better understanding of bulk composition and thermal history of the solid bodies. In order to conduct the in situ measurement, a high speed penetration probe, penetrator, which can be buried into a depth of 1 to several meters, has been developed. Since the shock durability at the penetration and the weight saving are required prior to scientific measurements, the heat flow sensors are installed on the surface of the penetrator. However, the sensors must have an uncertainty by disturbances of temperature distribution around the penetrator due to a large difference of thermal conductivities between the penetrator and the surrounding regolith.

In this study, we propose to develop an extension mechanism of needle probes from the buried penetrator which can avoid the thermal disturbance and measure heat flux with an uncertainty better than 10%. The temperature sensing part is required to be placed at a distance as far as possible from the penetrator body. Although the theoretical solution has been obtained to estimate thermal conductivity of the particulate material at the tip part of the probe, no research has yet been carried out to measure thermal conductivity of regolith by the needle probes whose temperature sensing parts are at the tip part. We developed a prototype model of the probe and evaluated the measurement uncertainty of thermal conductivity of glass beads as the regolith simulant material under vacuum condition.

The prototype of the needle probe consists of a wire heater, a K-type thermocouple, a stainless pipe as the needle probe's sheath, and epoxy resin fixing the heater and the thermocouple in the pipe. The length of the probe is 10cm which is the equivalent size of inner diameter of the penetrator body. Thermal conductivity of the glass beads under 200Pa can be controlled to be about 0.02W/m/K, which is almost the same thermal conductivity of the lunar environment at a depth of 1 to several meters. The needle probe was placed at the center of the sample container and surrounded by three sets of line heat source conductivity sensors for reference calibration.

Under 200Pa, we obtained 0.0165W/m/K by the theoretical solution of the probe, and 0.0207W/m/K by the average values of three line heat source sensors. The measurement uncertainty of thermal conductivity by the probe was calculated to be about 31%. However, the thermal conductivity by the probe can't be estimated directly from the theoretical solution because the conditions of the solution differ from the properties of the actual probe, such as the diameter of the probe, the thermal contact between the probe and the glass beads, and the axial heat flow of the probe. Therefore, we conducted the heat-transfer simulation whose numerical model included the properties of the actual probe, and estimated the thermal conductivity by the probe from increases in temperature after heating of the simulation. In addition, we confirmed an agreement with the temperature profiles of the theory and the simulation whose model condition was the same as the condition of the theory.

As a result, the thermal conductivity by the probe was estimated to be 0.0212W/m/K, and the measurement uncertainty of thermal conductivity was calculated to be about 3%, which was well satisfied with the requirement uncertainty of better than about 5%. In future, in order to estimate thermal conductivity of the regolith in lunar and planetary surface layer by using our probe, the measurement uncertainties are required to determine for the probable thermal conductivities by using the heat-transfer simulation.

The ERG (Exploration of energization and Radiation in Geospace) is Japanese geospace exploration project. The project focuses on relativistic electron acceleration mechanism of the outer belt in the context of the cross-energy coupling via wave-particle interactions. The project consists of the satellite observation team, the ground-based network observation team, and integrated-data analysis/simulation team. The ERG satellite will be launched in FY2015. Comprehensive instruments for plasma/particles, and field/waves are installed in the ERG satellite to understand the cross-energy coupling system. In the ERG project, several ground-network teams join; magnetometer networks, radar networks, optical imager networks, etc. Cooperative observations between the in-situ satellite and ground-based observations are important. Some simulation codes including both macro-scale phenomena and micro-physics are developed in Japan, which are very helpful quantitatively to understand the observational results and to incorporate the observations. In this presentation, the overview of the projects will be presented and possible collaborations with other geospace satellite missions as well as the ground-based observations will be discussed.

Upper Atmosphere phenomena in Geomagnetic Anomaly Region in association with Magnetosphere Disturbances

MAKITA, Kazuo[1*]

[1]Takushoku University

Since 1999, we continuously study/observe upper atmosphere phenomena in Geomagnetic Anomaly Region (South Atlantic Anomaly: SAA) by using several equipments and obtained several interesting results. We show several remarkable phenomena in SAA on the basis of imaging riometer data and CCD imager data obtained at Southern Space Observatory (SSO; 29.4S, 307E) in Brazil and other stations.

(1) Particle precipitation in SAA seems to be related with polar disturbances. From imaging riometer data, enhancement of Cosmic Noise Absorption (CNA) occurs simultaneously with magnetic disturbances in polar region. On the other hand, CNA at Kakioka imaging riometer can be also seen during polar disturbance (not so frequently observed). It may suggest that particle precipitations are occurred in association with substorm at Kakioka as well as SAA.

(2) In sometimes, strong CNA is observed in association with sharply decreasing of electron flux (GOES satellite data) after moderate polar disturbance period. It may indicate that injection and drifting of electrons after polar disturbances precipitate in SAA during this period.

(3) It is well known that VLF waves trigger precipitation of radiation belt particles.

Although the longitudinal difference is 94 degrees (6 hours local times) between Syowa Station, Antarctica and SSO, CNA at SSO is nearly simultaneously observed with VLF emissions at Syowa Station. It may suggest that particles are more easily precipitating and observed in SAA through the wave particle interactions in radiation belt.

(4) Static multiple bands are singularly observed at SSO. The characteristics of static multiple bands are different from atmospheric gravity waves. They are fixed at the ground and rotate with earth rotation. This phenomena is very seldom and looks like occurs in winter season. The luminosity of these phenomena are not clear but less than 150R like airglow level..

We almost finished to construct South America Riometer Network (SARINET; 7 stations) and hope to collect data continuously during one solar cycle.

Loss of geosynchronous relativistic electrons by EMIC waves during quiet geomagnetic conditions

KIM, Khan-hyuk[1*] ; HYUN, Kiho[1] ; LEE, Ensang[1] ; LEE, Dong-hun[1]

[1]School of Space Research, Kyung Hee University, Gyeonggi, Korea.

We have examined relativistic electron flux losses at geosynchronous orbit under quiet geomagnetic conditions. Two 3-day periods, from 11 to 13 October and from 29 November to 1 December, in 2007 were chosen for analysis because geomagnetic conditions were very quiet (3-day average of Kp $<$1) and significant losses of geosynchronous relativistic electrons were observed. During both intervals, there were no geomagnetic storm activities. Thus, the loss processes associated with geomagnetic field modulations caused by ring current buildup can be excluded. The flux of geosynchronous relativistic electrons with energy $>$2 Mev shows typical diurnal variations with a maximum near noon and a minimum near midnight for each day. The flux level of the daily variation gradually decreased from first day to third day for each 3-day period. The total magnetic field strength (Bt), however, is relatively constant for each day. Unlike electron flux decreases, the flux of protons with energy between 0.8 and 4 MeV adiabatically responses to the daily variation of Bt. That is, there is no significant decrease of the proton flux when the electron flux decreases. During both 3-day periods, well-defined electromagnetic ion cyclotron (EMIC) waves were detected at geosynchronous spacecraft. Low-altitude polar orbiting spacecraft observed the precipitation of energetic electrons and protons in the interval of EMIC waves enhancement. From these observations, we suggest that the EMIC waves are a major factor to control the electron flux decrease under quiet geomagnetic conditions.

Characteristics of dayside SAPS structures observed by the SuperDARN Hokkaido radar

NISHITANI, Nozomu[1*] ; HORI, Tomoaki[1] ; NAGANO, Hiroki[1]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

Sub-Auroral Polarization Streams (SAPS) are intense westward ionospheric flows in the subauroral ionosphere, and considered to be generated as a result of magnetosphere-ionosphere coupling during relatively disturbed periods. SAPSs are usually located in the evening to midnight sector, but occasionally it extends to earlier magnetic local times close to local noon. Owing to limitation of the observation techniques, no detailed studies of its local time extent have been made so far. In this study we use the data from the SuperDARN Hokkaido radar, one of the midlatitude SuperDARN radars located at the lowest geomagnetic latitude, to discuss the detailed characteristics of dayside SAPS, with focus on their relation to solar wind and geomagnetic parameters.

Amplification of EMIC waves by Pc3-4 waves

NOMURA, Reiko[1*] ; KEIKA, Kunihiro[2] ; TERAMOTO, Mariko[4] ; KLETZING, Craig[3]

[1]IGEP, TU Braunschweig, [2]Solar-Terrestrial Environment Laboratory, Nagoya University, [3]Japan Aerospace Exploration Agency, [4]Department of Physics and Astronomy, The University of Iowa

Electromagnetic ion cyclotron (EMIC) wave is one of the key phenomena for the dynamics of high energy electrons in the radiation belt, since EMIC waves can scatter particles and make them precipitate into the ionosphere from the inner magnetosphere. The EMFSIS of Van Allen Probes observed the proton-band EMIC wave with the frequencies 2-6Hz at ∼3RE in the GSM coordinates at 1110-1140UT on 29 June 2013. It was during the recovery phase of the magnetic storm started on 27 June. This event has significant enhancements of wave amplitudes up to ∼10nT at 1123 and 1130UT. At these times, the magnetic field variations in the Pc3-4 range are also observed. We present the relation between amplitudes of EMIC waves and Pc3-4 wave occurrences, and discuss the amplification mechanism of EMIC waves by ULF waves with longer periods.

Study of Pc1 pearl structures observed at multi-point ground stations at Russia, Japan and Canada

JUN, Chae-woo[1*] ; SHIOKAWA, Kazuo[1] ; SCHOFIELD, I.[2] ; CONNORS, M.[2] ; PODDELSKY, I.[3] ; SHEVTSOV, B.[3]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, Nagoya, Japan, [2]Center for Science, Athabasca University, Athabasca, Canada, [3]Institute of Cosmophysical Research and Radiowave Propagation, Far Eastern Branch of the Russian Aca

We have investigated possible generation mechanisms of pearl structures of Pc1 geomagnetic pulsations using ground-based multi-point induction magnetometers at Athabasca in Canada, at Magadan in Russia and at Moshiri in Japan. During 3-years of observation (January 1, 2009 to December 31, 2011), we found two Pc1 pulsations with similar dynamic spectrum shapes at three stations simultaneously. For the case 1, which occurred on April 8, 2010, Pc1 pulsations were clearly identified at the three stations in the frequency range of 0.4 to 1.2 Hz. Coherence between the two stations was high ($r > 0.8$). The cross-correlation of the upper envelope of Pc1 waves between the ATH and the MGD, which indicates amplitude modulation of Pc1 due to pearl structures, was also high ($r > 0.8$). In some time interval during the case 1, however, correlation decreased down to 0.5. The case 2 occurred on April 11, 2010 in the frequency range of 0.2 to 0.8 Hz showed that the coherence and cross-correlation between ATH and MGD were both high ($r > 0.8$) throughout the event. The high coherence indicates that the Pc1 pulsations observed at these different stations were propagated from the same source region. However, in case 1, the Pc1 pearl structures were slightly different for different stations. The case 1 showed polarization angle variation depending on frequencies, while the case 2 does not show such dependence, suggesting that the case 1 has a spatially-distributed ionospheric source at high latitudes. In order to understand these different features of Pc1 pearl structures, we made two model calculations of Pc1 peal structures under the different conditions. One model is that the Pc1 waves come from a north-south extended ionospheric source region with slightly different frequencies at different latitudes. This source distribution, causes the Pc1 pearl structure by beating during the duct propagation in the ionosphere. The other model is that the Pc1 waves with different frequencies are mixed at the point source in the ionosphere, assuming that the pearl structures were already made in the magnetosphere. The Pc1 from the point source shows an identical waveform among the different stations. On the other hand, the Pc1 from distributed source region shows slightly different waveforms at different stations. This result suggests that the distributed source region is able to create the different Pc1 pearl structures at different stations through the beating, as observed for the case 1. We conclude that the Pc1 pearl structures are created by both magnetospheric processes and ionospheric beating processes before they reach the ground-based magnetometer at low latitudes.

Gradual Diffusion and Punctuated Enhancements of Highly Relativistic Electrons: Van Allen Probes Observations

BAKER, Daniel N.[1*]

[1]University of Colorado Boulder

The dual-spacecraft Van Allen Probes mission has provided a new window into megaelectron Volt (MeV) particle dynamics in the Earth′ s radiation belts. Observations (up to E ˜10 MeV) show clearly the behavior of the outer electron radiation belt at different time scales: months-long periods of gradual inward radial diffusive transport and weak loss being punctuated by dramatic flux changes driven by strong solar wind transient events. Analysis of multi-MeV electron flux and phase space density (PSD) changes during March 2013 are presented in the context of the first year of Van Allen Probes operation. This March period demonstrates the classic signatures both of inward radial diffusive energization as well as abrupt localized acceleration deep within the outer Van Allen zone (L ˜4.0±0.5). This reveals graphically that both ″ competing ″ mechanisms of multi-MeV electron energization are at play in the radiation belts, often acting almost concurrently or at least in very rapid succession. It also shows in remarkable ways how the coldest plasmas in the magnetosphere intimately control the most highly energetic particles.

[1]School of Physics, University of Sydney, Sydney, NSW, Australia, [2]Space Sciences Laboratory, University of California, Berkeley, CA, USA, [3]School of Physics and Astronomy, University of Minnesota, Minneapolis, MN, USA, [4]Department of Physics and Astronomy, University of Iowa, Iowa City, IA, USA, [5]Department of Physics and IEOS, University of New Hampshire, Durham, NH, USA, [6]Los Alamos National Laboratory, Los Alamos, NM, USA

The Van Allen Probes have revealed the presence of a broad spectrum of narrow scale Alfvén eigenmodes in the inner magnetosphere during geomagnetic storms. Here we use observations from the Van Allen Probes to build a reduced MHD model for these waves in a dipolar geomagnetic field. This model is then used to explore the manner through which particles may be accelerated in these wavefields. Test particle simulations show that the narrow perpendicular scale and parallel electric fields carried by these waves lead to the violation of the 1st and 2nd adiabatic invariants for ions. This can drive the heating of the thermal ion population to multi-keV temperatures and the acceleration of a small fraction of these particles to energies exceeding 100 keV. This process has obvious implications for the storm time ring current, but also for the acceleration/loss of radiation belt electrons.

Van Allen Probes observations of oxygen torus in the inner magnetosphere

NOSE, Masahito[1*] ; KEIKA, Kunihiro[2] ; KLETZING, C. A.[3] ; SMITH, C. W.[4] ; MACDOWALL, R. J.[5] ; KURTH, W. S.[3] ; DE PASCUALE, S.[3]

[1]Graduate School of Science, Kyoto University, [2]Solar-Terrestrial Environment Laboratory, Nagoya University, [3]Department of Physics and Astronomy, University of Iowa, [4]Institute for the Study of Earth, Oceans and Space, University of New Hampshire, [5]NASA Goddard Space Flight Center

The oxygen torus is found in the deep inner magnetosphere as enhancements of O^+ ion density in a limited L range. It was first reported by Chappell [1982] who used the DE-1/RIMS instrument. Horwitz et al. [1984, 1986] showed that the O^+ density sometimes becomes comparable to or exceeds the H^+ density at L=3-4. Following studies revealed that the oxygen torus is observed just inside the plasmasphere at all local time with higher occurrence frequency in the late evening and morning sectors. A recent study by Nosé et al. [2010] cast a new light on the oxygen torus as a one of essential factors of O^+-rich ring current generation. They proposed that thermal O^+ ions preexisting in the oxygen torus are locally and nonadiabatically accelerated by fluctuations associated with dipolarization in the deep inner magnetosphere and contribute to ring current O^+ ions. Therefore investigation of the oxygen torus is important to understand the dynamics of ions of ionospheric origin in the inner magnetosphere.

We study the oxygen torus, using the magnetic field and plasma wave data obtained by the Electric and Magnetic Field Instrument Suite and Integrated Science (EMFISIS) instrument onboard the Van Allen Probes. We examine a few events on the dawnside in which toroidal standing Alfven waves appear clearly. From the frequency of the toroidal waves, the magnetospheric local mass density (ρ) is estimated by solving the MHD wave equation for realistic models of the magnetic field and the field line mass distribution. We also estimate the local electron number density (n_e) from the plasma wave spectrograms by identifying narrow-band emission at the upper-hybrid resonance frequency. Assuming the quasi-neutral condition of plasma, we infer the local average ion mass (M) by ρ/n_e. It is found that M is generally less than 4 amu in the plasma trough, while it shows an enhancement of $>$6 amu near the plasmapause. This indicates an existence of the oxygen torus in the vicinity of the plasmapause. We will present the result and discuss possible formation mechanisms of the oxygen torus. Possible contribution of the oxygen torus to the formation of the O^+-rich ring current will be also discussed.

Akebono observations of EMIC waves in the slot region of the radiation belts

SAKAGUCHI, Kaori[1*] ; KASAHARA, Yoshiya[2] ; SHOJI, Masafumi[3] ; OMURA, Yoshiharu[4] ; MIYOSHI, Yoshizumi[3] ; NAGATSUMA, Tsutomu[1] ; KUMAMOTO, Atsushi[5] ; MATSUOKA, Ayako[6]

[1]National Institute of Information and Communications Technology, [2]Information Media Center, Kanazawa University, [3]Solar-Terrestrial Environment Laboratory, Nagoya University, [4]Reserach Institute for Sustainable Humanosphere, Kyoto University, [5]Department of Geophysics, Graduate School of Science, Tohoku University, [6]Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency

We present a unique observation of electromagnetic ion cyclotron (EMIC) waves in the deep inner magnetosphere at L = 2.5-5 made by the Akebono satellite at altitudes of 3,300-8,700 km. The mode conversion, i.e., L mode (He+ band)→R mode (He+ band)→L mode (O+ band) was clearly identified from the equator to high latitudes. In addition, we found rising tone structures, recently identified as EMIC triggered emissions, which could lead to bursty precipitation of relativistic electrons. First, we estimated the ion composition ratio (H+, He+, O+) = (83%, 16%, 1%) from polarization analysis. Second, we estimated minimum resonant electron energies with the observed EMIC waves and triggered emissions to be 1?10 MeV. The satellite trajectory during the wave observation was primarily through the slot region of electron radiation belts. The collocation implies possible contribution of EMIC waves to formation of the slot region of radiation belts after a magnetic storm.

Oxygen ion acceleration and transport in the near-Earth plasma sheet during an isolated substorm

NAKAYAMA, Yohei[1*] ; EBIHARA, Yusuke[1] ; TANAKA, Takashi[2]

[1]Research Institute for Sustainable Humanosphere (RISH), Kyoto university, [2]SERC, Kyushu University

Rapid enhancements of energetic ions during a substorm are one of the unsolved issues in the inner magnetospheric research (<7 Re). Previously, two distinct processes have been suggested to explain the enhancements. The first one is transport from the near-earth plasma sheet, and the other one is local acceleration. To test the both process, we performed test particle simulation under the electric and magnetic fields that are self-consistently obtained by the global MHD simulation developed by Tanaka et al. (2010, JGR). Oxygen ions are released in the lobe region with an interval of 1 minutes. The distribution function in the lobe is assumed to be drifting Maxwellian. The temperature is assumed to be 20 eV, the density is 105 cm-3, and the parallel velocity is given by the MHD simulation. In total, a few hundreds of millions of particles are traced. Each test particle carries the real number of particles in accordance with the Liouville theorem. After tracing particles, we reconstruct 6-dimensional phase space density of the oxygen ions, as well as the directional differential number flux so as to be able to make a direct comparison with in-situ satellite observations. Just after a substorm onset, the differential flux of the ions is rapidly enhanced in the energy range from 50 to 150 keV at radial distance R greater than 7 on the nightside in the equatorial plane. The region of the enhanced flux propagates duskward, then to dayside because of grad-B and curvature drift of the ions. We also plotted energy versus time spectrograms of the differential flux at a fixed position to make a direct comparison with the CRRES satellite observation. At 7.2 Re and at 22.4 MLT, the ion flux is suddenly enhanced about 10 minutes after the onset. The enhancement appears first at 120 keV, followed by lower energy as time proceeds. The energy-time dispersion is similar to that observed by CRRES [Fu et al., 2002]. The steepness of the energy-time dispersion depends on the source location of the ions. After a while, a high energy ion flux appears first, followed by that at lower energies. This is a called a drift echo, arising from the ions that encircled the Earth by the grad-B and curvature drift. We will discuss the acceleration processes in more detail, the role of pre-existing ions, and the total kinetic energy of the oxygen ions and its dependence on the source distribution function in terms of the ring current development.

On the formation of overshielding triggered by a substorm onset: Global MHD simulation study

EBIHARA, Yusuke[1*] ; TANAKA, Takashi[2] ; KIKUCHI, Takashi[3]

[1]RISH, Kyoto Univerisity, [2]Emeritus Professor, Kyushu University, [3]Emeritus Professor, Nagoya University

The dawn-dusk convection electric field is a significant driver of transport of charged particles in the inner magnetosphere. When the dawn-disk convection electric field is enhanced, the ring current is developed, and the plasmasphere is shrunk. Ground-based observations have shown that, sometimes, the polarity of the convection electric field is reversed after a substorm onset. The presence of the dusk-dawn electric field is called an overshielding condition. Here, we demonstrate that the overshielding condition can appear after a substorm onset on the basis of a global MHD simulation. Immediately after the substorm onset manifested by a sudden decrease in the AL index and auroral brightening, the plasma pressure is enhanced in the inner magnetosphere. The simulated magnetic field on the ground shows a negative excursion in the polar cap, a positive excursion at auroral latitudes, and a negative excursion at sub-auroral latitudes at dusk. At noon and at equator (0 MLAT), the eastward electrojet starts to decrease just after the onset, and the westward electrojet appears about 10 min after the onset. All these variations are consistent with the observations. We discuss generation mechanisms, evolution of the overshielding condition in the ionosphere and the magnetosphere, and the redistribution of the charged particles trapped in the inner magnetosphere during the overshielding condition on the basis of the simulation solving drift transport equations.

Nonlinear wave particle interactions in oblique whistler-mode chorus emissions

NUNN, David[2] ; OMURA, Yoshiharu[1*]

[1]RISH, Kyoto University, [2]ECS School, Southampton University

The highly nonlinear phenomena of VLF chorus and triggered VLF emissions are of great interest due to their role in electron heating and precipitation, and are widely believed to be due to nonlinear cyclotron resonance between the narrow band wavefield and the anisotropic energetic electron population (∼keV), the dominant mechanism being identified as nonlinear phase trapping. Considerable advances have been made in the theory and numerical simulation by assuming parallel (ducted) propagation [Nunn et al., 1997, 2009;Omura et al., 2008, 2009; Omura and Nunn, 2011]. Here we address the important issue of nonlinear wave particle interaction in oblique VLF wavefields. The treatment is of necessity non self-consistent. The narrow band wavefield is arbitrarily, but here chosen to be a CW field or a sophisticated model of a VLF chorus element based upon the theory of Omura et al.[2008, 2009]. We develop the electron equations of motion and then by backward trajectory integration compute resonant particle distribution function , resonant currents and thus local nonlinear growth rates. This may be done for any resonance order n and any field. As shown in Omura et al. [2008] nonlinear trapping for n=1 cyclotron resonance gives rise to a phase space hole in distribution function at the trap. Such a hole is also noted at higher order resonances (e.g. n=2) for sufficient wave amplitude and obliquity. For n=1 we find a marked saturation effect due to adiabatic effects, growth maximising at about 25pT and 2000km from the equator. For moderate obliquity ϑ<20 degrees the n=1 resonance is relatively unaffected but growth rolls off sharply at high obliquity. For the n=0 resonance for obliquity ϑ >20 degrees nonlinear trapping may occur giving a peak in phase space density. As trapped electrons are moving away from the equator adiabatic effects do not occur and maximum damping rates are at ∼6000kms and at obliquities ∼55 degrees. For the lower band rising chorus element model maximum n=1 growth is close to the equator, but maximum n=0 damping is found at the top of the frequency band at ∼10000km downstream. Due to the coincidence of group and resonance velocities particles may be trapped near the equator and dragged a long way before detrapping.

Relativistic electron microbursts induced by EMIC triggered emissions in the dipole magnetic field

KUBOTA, Yuko[1*] ; OMURA, Yoshiharu[1]

[1]Research Institute for Sustainable Humanosphere, Kyoto University

We perform test particle simulations of relativistic electrons interacting with electromagnetic ion cyclotron (EMIC) triggered emissions with rising-tone frequencies. We assume that the geomagnetic field is dipole because EMIC triggered emissions and radiation belt electrons are observed in the inner magnetosphere [1]. EMIC triggered emissions are generated by energetic protons injected into the inner magnetosphere and drifting westwards in the longitudinal direction. We study trajectories of relativistic electrons drifting eastwards interacting with EMIC triggered emissions over different longitudinal ranges. When relativistic electrons in the radiation belt interact with EMIC triggered emissions, some of them are trapped by a wave potential and efficiently guided down to lower pitch angles. Repeated interactions result in scattering of relativistic electrons into the loss cone [2]. Counting relativistic electrons which fall into the polar region, we find that half of the relativistic electrons interacting with EMIC triggered emissions are precipitated. We derive conditions of kinetic energies and pitch angles for efficient precipitation of relativistic electrons.

Investigating the upper and lower energy cutoffs of EMIC-wave driven precipitation events

HENDRY, Aaron[1*] ; RODGER, Craig[1] ; CARSON, Bonar[1] ; CLILVERD, Mark[2] ; RAITA, Tero[3]

[1]University of Otago, New Zealand, [2]British Antarctic Survey, UK, [3]SGO, Sodankyla, Finland

For some time theoretical modelling has shown that electromagnetic ion cyclotron (EMIC) waves should play an important role in the loss of relativistic electrons from the radiation belts, through precipitation of the electrons into the polar ionosphere. However, there are limited direct experimental observations of relativistic electron precipitation occurring, despite the indirect evidence for its importance.

Relativistic electron resonance takes place through ”anomalous resonance” where the electron overtakes the wave. Until recently, it was through that EMIC wave scattering interactions were limited to electrons with energies greater than 1-2 MeV. Recent theoretical modelling [Omura et al., JGR, 2012] has suggested that this lower limit may be as small as 100 keV when considering EMIC waves more like those experimentally observed (i.e. non-constant frequency which ramps with time on one second timescales). Using data from the POES satellites we confirm the presence of lower energy ($<$1 MeV) electron precipitation most likely driven by EMIC waves.

We report on a continuing study that determines the typical flux impacting the ionospheric D-region during EMIC-driven precipitation events, and the effect this has on ionospheric conditions. We examine a very large set of EMIC-driven electron precipitation events detected using data from the POES satellite constellation [Carson et al., JGR, 2013] and determine the typical precipitating electron and proton fluxes.

As part of this study, we investigate the response of the MEPED instruments on-board the POES satellites to better characterise the EMIC-driven precipitation. Using the results of a previously reported Monte-Carlo simulation of the MEPED electron and proton telescopes [Yando et al., JGR, 2011], we characterise the typical energy range and flux for both the precipitating electrons and protons observed in these events. We go on to show that such events will produce very significant D-region changes detectable using the ground-based Antarctic-Arctic Radiation-belt (Dynamic) Deposition - VLF Atmospheric Research Konsortium (AARDDVARK) worldwide VLF receiver network.

Plasmaspheric Content as Revealed by Spaceborne GPS Observations

TSAI, Ho-fang[1*] ; CHOU, Min-yang[1] ; CHEN, Chao-yen[2] ; LIN, Charles[1] ; LIU, Jann-yenq[2]

[1]Dept. of Earth Sciences, National Cheng Kung University, Taiwan, [2]Institute of Space Science, National Central University, Taiwan, [3]National Space Organization, Taiwan

The FORMOSAT-3/COSMIC (F3/C) mission has been operating for more than seven years. The F3/C low earth orbit (LEO) satellites receive the signals from the global positioning system (GPS) for sounding of the atmosphere and the ionosphere of the earth, including the plasmasphere. The plasmasphere above ionosphere acts like a reservoir; it takes plasma from the ionosphere by day, stores it in a loss-free environment, and returns it to the ionosphere at night. For the non-radio occultation observation of the F3/C, we study the morphology of the plasmaspheric electron content (PEC) derived from F3/C raw observation data, which includes the diurnal variations of the time-series PEC, two-dimensional distribution and the interaction with the ionosphere.

Polarization and occurrence statistics of VLF/ELF chorus waves at sub-auroral latitudes at Athabasca, Canada.

MARTINEZ CALDERON, Claudia[1*] ; SHIOKAWA, Kazuo[1] ; MIYOSHI, Yoshizumi[1] ; OZAKI, Mitsunori[2] ; SCHOFIELD, Ian[3] ; CONNORS, Martin[3]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, Nagoya, Japan, [2]Kanazawa University, Kanazawa, Japan, [3]Athabasca University, Athabasca, Canada

Chorus waves are whistler-mode emissions in the very low frequency (VLF) range that are one of the most intense and common natural emissions. They are generated in the inner magnetosphere at the geomagnetic equator and follow the geomagnetic field lines into the ionosphere and the ground. They are believed to be *one of the major contributions to the acceleration and scattering of radiation belt particles* (e.g., Inan et al., 1982; Omura et al., 2007). Consequently we are interested in the *spatial and temporal motion of the acceleration region of radiation belt electrons*, which might be directly linked to the motion of the Ionospheric footprints of VLF/ELF waves.

For a period of 9 days, from February 17 to 25, 2012, the VLF-CHAIN campaign observed VLF/ELF emissions at sub-auroral latitudes using two loop antennas at Athabasca (MLAT=61.31, L=4.3) and Fort Vermillion (MLAT=64.51, L=5.4), Canada.

Several interesting features of chorus emissions have been observed such as quasi-periodic emissions, falling-tone and rising-tone chorus, as well as *Bursty-Patch* emissions. We have applied polarization and spectral analysis to make **the first comprehensive study of the physical properties of VLF/ELF chorus waves at sub-auroral latitudes**. Combining these analyses with a triangulation method we have also identified the location and motion of the Ionospheric exit points of these various types of chorus waves.

Furthermore, after September 24, 2012, continuous measurements of VLF/ELF waves with a sampling rate of 100 kHz have been made at Athabasca. Based on this data we show in this presentation the preliminary results of a one-year statistical analysis of frequency and occurrence rate of VLF/ELF chorus waves at sub-auroral latitudes.

Nonlinear analysis of magnetospheric wave-particle interactions

SUMMERS, Danny[1*] ; TANG, Rongxin[2] ; OMURA, Yoshiharu[3]

[1]Memorial University of Newfoundland,St John's,Canada, [2]Nanchang University,China, [3]Kyoto University,Japan

The dynamics of the Earth's radiation belts are largely controlled by wave-particle interactions. Gyro-resonant whistler-mode chorus - electron interactions can generate relativistic (MeV) electrons in the outer zone during magnetic storms. Whistler-mode waves can pitch-angle scatter electrons and induce precipitation loss from the inner magnetosphere. Here we analyze the growth of magnetospheric whistler mode waves with particular emphasis on the nonlinear growth phase. We show that nonlinear wave growth can only take place over a restricted parameter space. We examine the conditions under which chorus wave growth can take place,and discuss how the results can be compared with computer simulations and experimental observations.

Retrieval of plasmaspheric He+ density field-aligned distributions from EUV imaging data

KEIKA, Kunihiro[1*] ; BRANDT, Pontus C.[2] ; TOIGO, Anthony[2] ; ROBERT, Demajistre[2]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]The Johns Hopkins University Applied Physics Laboratory

We retrieve the spatial distributions of He+ density (n_{He+}) in the Earth ' s plasmasphere from EUV imaging data, by using a forward modeling technique. We use a parametric model for the density distribution to simulate line-of-sight integrated He+ densities (i.e., EUV images), and then find parameters that give the best fit to real EUV images. The parametric model used in this study is described as a function of L and magnetic latitude (λ): $n_{He+} = n_0 (L_0/L)^{alpha\_L} \times (r_0/L_0 \cos\lambda^2)^{alpha\_f}$, where n_0 and L_0 are He^+ density and L value at the inner boundary of this model (i.e., the topside ionosphere), and α_L and α_f are parameters that represent L and field-aligned dependence of He^+ density, respectively.

In this paper, we evaluated how well our forward model can retrieve the He^+ density spatial distribution, by performing the following analysis. (1) EUV emission intensities were simulated through the EUV camera response function, given a vantage point of the IMAGE satellite. (2) EUV images were simulated for a large number of (α_L, α_f) pairs: α_L was chosen from 4.0 to 6.0 with 0.1 increment, and α_f was from 0.0 to 2.0 with 0.1 increment. (3) The EUV image corresponding to the (α_L, α_f)=(5.0, 1.0) pair was chosen as our synthetic EUV image. After noise was added to the synthetic image, the forward modeling was applied to all simulated images made in (2). The reduced χ^2 ($\chi_r{}^2$) was used to determine how well simulated image data fit to the synthetic image. The results of this analysis confirm that the He^+ density distributions can be retrieved with good certainty within |40 deg.|MLAT. However, beyond this magnetic latitude it is difficult to determine the L dependence or field-aligned dependence of plasmaspheric He^+ density.

Next, in order to decouple the synthetic data from the parametric formula, we will use density distributions provided by physics-based ionosphere/plasmasphere models as our synthetic data. We will also apply our forward simulation model to real EUV image data from the EUV imager onboard the IMAGE spacecraft.

Solar-cycle variation of the plasmasphere observed from the Akebono PWS data

HASEGAWA, Shuhei[1*] ; MIYOSHI, Yoshizumi[1] ; KITAMURA, Naritoshi[1] ; KEIKA, Kunihiro[1] ; SHOJI, Masafumi[1] ; KUMAMOTO, Atsushi[2] ; MACHIDA, Shinobu[1]

[1]Solar-Terrestrial Environmment Laboratory, Nagoya University, [2]Department of Geophysics, Graduate School of Science, Tohoku University

Plasmaspheric density structures have been studied for a long time. Although it has been clarified that the density is roughly constant along field lines in the outer plasmasphere, field-aligned density distributions of the inner plasmasphere has not been studied intensively. Moreover, continuous observations longer than one-solar cycle have not been reported. Consequently, long-term variations of the plasmaspheric density over a solar cycle remain unknown. In this study, using electron density data based on plasma wave observations from the PWS experiments on board the Akebono satellite from 1989 to 2008, we conduct statistical analyses on variations of structures of the plasmasphere and plasmatrough. In order to investigate the latitudinal distribution of the electron density, we assumed that electron density distribution along field lines are described by a power law form N_e = $N_{e0}(LR_E/R)\alpha, where N_{e0}$ is the equatorial electron density. Using the dataset during geomagnetically quiet periods and altitude higher than 4000 km, we derived solar cycle variations of the equatorial density N_{e0} and field-aligned density distributions α. N_{e0} and α are almost constant for the solar cycle ($N_{e0} \approx$ 2000 cm^{-3} and α = 0 – 1) in the inner plasmasphere at L = 2.1 – 2.3, which distribution is close to diffusive equilibrium. In contrast, $N_{e0}\sim$200 cm^{-3} and α=0 – 1 at solar minimum which distribution is close to diffusive equilibrium and N_{e0} $\sim$30 cm^{-3} and α= 2 – 3 at the solar maximum which distribution is close to collisionless in the outer plasmasphere at L = 4.2 – 4.7.

Statistical analysis of EMIC waves in the inner magnetosphere from the Akebono observations

KATO, Yuichi[1*] ; MIYOSHI, Yoshizumi[1] ; SAKAGUCHI, Kaori[2] ; KASAHARA, Yoshiya[3] ; KEIKA, Kunihiro[1] ; KITAMURA, Naritoshi[1] ; SHOJI, Masafumi[1] ; HASEGAWA, Shuhei[1] ; KUMAMOTO, Atsushi[4] ; SHIOKAWA, Kazuo[1]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, Japan, [2]National Institute of Information and Communications Technology, [3]Information Media Center, Kanazawa University, [4]Department of Geophysics, Graduate School of Science, Tohoku University

Electromagnetic ion cyclotron (EMIC) waves in the inner magnetosphere are important since EMIC waves cause the pitch angle scattering of ring current ions as well as relativistic electrons of the radiation belts. Although the spatial distributions of EMIC waves have been investigated by several spacecraft such as CRRES, THEMIS and AMPTE, there have been little studies on their latitudinal distributions. Up to this point, we developed the automatic detection algorithm to use the magnetic field data observed by the ELF instrument on board the Akebono satellite, and demonstrated that EMIC waves exist inside the plasmasphere. Since the Akebono satellite measures the thermal plasma density, we investigate the fp(plasma frequency)/fc(cyclotron frequency) dependence and derive the resonance energies of the observed EMIC waves. In this presentation, we report the spatial distributions of EMIC waves, and discuss the dependence of fp/fc and the resonant energy.

Dispersion relation of Pc1 geomagnetic pulsations using ground-magnetometer observations

NOMURA, Reiko[1*] ; PLASCHKE, Ferdinand[2] ; NARITA, Yasuhito[2] ; GLASSMEIER, Karl-heinz[1] ; FUJITA, Shigeru[3] ; MANN, Ian[4]

[1]IGEP, TU Braunschweig, [2]Space Research Institute Austrian Academy of Sciences, [3]Meteorological College, Japan Meteorological Agency, [4]University of Alberta

Pc1 geomagnetic pulsation (Pc1) observed on the ground at subauroral latitudes (L∼4) is the signature of ion cyclotron waves with frequencies 0.2-5.0Hz near the plasmapause. When the waves reach onto the ionosphere, they induce the Pedersen and Hall currents which generate both Alfven and fast mode waves in the ionospheric duct. On the ground we observe the variations of the magnetic field caused by both of the Alfven and the fast mode wave in the ionospheric duct. Previous studies based on the theoretical models showed the frequency dependence of attenuations, and the spatial distribution of wave polarisations, and furthermore, predicted the dispersion relation in the ionospheric duct. Especially for the characteristics of attenuations and polarisations, previous studies have been established using ground magnetometer observations. Yet, no study has demonstrated the Pc1 dispersion relation experimentally. In our presentation, we show the Pc1 dispersion relation obtained by the wave telescope analysis using CARISMA ground magnetometers.

A Brief History of Collaborative Study on Equatorial MLT Dynamics using Meteor and MF Radars in Indonesia

TSUDA, Toshitaka[1*] ; DJAMALUDDIN, Thomas[2] ; YATINI, Clara[2] ; BUDIYONO, Afif[2] ; VINCENT, Robert[3] ; REID, Iain[3]

[1]Research Institute for Sustainable Humanosphere (RISH), Kyoto University, [2]Indonesian National Institute of Aeronautics and Space (LAPAN), [3]Department of Physics, University of Adelaide

In the tropics active cumulus convection generates various atmospheric waves, such as Kelvin waves, planetary waves, tides, and gravity waves. The wave energy and momentum are transported upward though propagating of these waves. Wave-mean flow interactions are crucially important for understanding of dynamical processes in the equatorial atmosphere, including the formation of peculiar long-term variations such as quasi-biennial oscillation (QBO) and semi-annual oscillation (SAO) in both the stratosphere and the MLT (mesosphere and lower thermosphere) region (70-120 km).

We constructed a total of five meteor and medium frequency (MF) radars in Indonesia since 1992 under close collaboration between RISH, LAPAN and the University of Adelaide. The MLT radar network has been expanded in India, Central and Eastern Pacific, and China. These radars have clarified the behavior of atmosphere dynamics in the MLT region. This paper gives an overview of our collaborative studies as well as highlights of scientific achievements using the MLT radar network

Atmospheric Waves in the MLT: A Review

VINCENT, Robert[1*]

[1]University of Adelaide

Through their efficient transfer of energy and momentum, atmospheric waves propagating up from the lower atmosphere play an important role in determining the structure of the Mesosphere/Lower Thermosphere (60-100 km). A wide range of wave types are involved, with periods ranging from minutes to days. Here we review developments in our understanding of wave coupling and impacts on the MLT, with an emphasis on developments in the past decade.

Behavior of non-migrating tides in the MLT region

MIYOSHI, Yasunobu[1*] ; FUJIWARA, Hitoshi[2]

[1]Kyushu University, [2]Seikei University

It is well established that non-migrating tides have significant amplitudes in the mesosphere and lower thermosphere (MLT). Using a general circulation model that contain the region from the ground surface to the upper thermosphere, behavior and excitation sources of non-migrating tides are examined. In this study, behaviors of the westward moving semidiurnal tide with zonal wavenumber 1 (SW1), the semidiurnal tide with zonal wavenumber 0 (S0) and the diurnal tide wit zonal wavenumber 0 (D0) are examined in detail. There are two main sources for non-migrating tides. One is latent heat release due to the cumulus convection in the troposphere. The other is the nonlinear interaction between the migrating tide and the stationary planetary wave in the middle atmosphere. Our results indicate that the amplitudes of SW1, S0 and D0 are enhanced when the stationary planetary wave in the stratosphere and mesosphere is active. This means that SW1, S0 and D0 are mainly excited by the nonlinear interaction between the migrating tide and the stationary planetary wave. Furthermore, we discuss excitation sources of other non-migrating tides, such as the eastward moving diurnal tide with zonal wavenumber 3 (DE3) and the eastward moving semidiurnal tide with zonal wave number 2 (SE2).

Long-term observations from medium-frequency and meteor radars (1993-2012) and rocket soundings (1979-1990 and 2002-2007) are used to study mesosphere lower thermosphere (MLT) zonal wind variations in relation to the stratospheric winds over Northern low-latitudes. The combined dataset provide a complete height profile of amplitude of semiannual oscillation (SAO) up to 100 km, with an exception around 75-80 km. The SAO signal has maxima around 50 km and 82 km and a minimum around 65 km. The MLT zonal winds show remarkable inter-annual variability during spring equinox and much less during fall equinox. Zonal wind mesospheric spring equinox enhancements (MSEE) appear with a periodicity of 2-3 years suggesting a modulation by the quasi-biennial oscillation, which we identified with the strength of stratospheric westward winds. Out of 20 years of observations, the stratospheric westward winds are strong during 11 years (non-MSEE) and weak during 9 years. Six of these years show large MLT winds (MSEE) and 3 years (1999, 2004 and 2006) show small MLT winds (missing-MSEEs). These unexpected small winds occur in years with global circulation anomalies as identified with strong sudden stratospheric warmings and an early spring transition of zonal winds, along with a minor enhancement in the tidal amplitudes.

The saturation of gravity waves traveling from the lower to the upper atmosphere observed by the MU radar and understood

KATO, Susumu[1*] ; TSUDA, Toshitaka[1] ; YAMAMOTO, Mamoru[1] ; NAKAMURA, Takuji[2]

[1]Research Institute for Sustainable Humanosphere, Kyoto University, [2]National Polar Research Institute)

The MU radar of Kyoto University was constructed in 1984. One of the main purpose of the radar construction is to observe atmospheric gravity waves particularly to find how gravity waves saturate in traveling from the lower atmosphere to the upper atmosphere. In the 1980s Matsuno, Geller and others put forwards an idea suggesting that the gravity wave saturation may release momentum for driving the mesosphere general circulation. Their idea is based on rocket and satellite global- observation of winds and temperature varying peculiarly with seasons in the mesosphere.

Our MU radar observation has been successful in proving the gravity wave momentum release to be in a good agreement with the required quantity for the mesosphere general circulation. Also our success of precise measurements of the saturated gravity wave power spectrum strongly supports to explain the gravity wave saturation idea in terms of a simple theory based on the linear or monochromatic gravity wave theory by Hines in 1960.

Our theory on the basis of our MU radar observation shows that the gravity wave saturation is attained for each gravity wave in amplitude reaching the phase speed due to a balance between the increasing amplification expected by the linear theory and non-linear braking effects. We can consider that the original gravity wave dispersion relation is maintained upon the saturation.

Gravity waves should experience a number of such saturations before
reaching the thermosphere on the way.

Ducted Concentric Gravity Wave Observed by IMAP/VISI Associated with Super Typhoon Haiyan

PERWITASARI, Septi[1*] ; SAKANOI, Takeshi[1] ; YAMAZAKI, Atsushi[2] ; OTSUKA, Yuichi[3] ; HOZUMI, Yuta[4] ; AKIYA, Yusuke[4] ; SAITO, Akinori[4] ; SUZUKI, Shin[3]

[1]PPARC, Tohoku University, [2]JAXA/ISAS, [3]STEL, Nagoya University, [4]Geophysics Dept., Kyoto University

Although the convection activity in the troposphere is generally accepted as one of important source of gravity waves in the mesosphere and lower thermosphere, however it is still uncertain how these waves can reach these regions and what types of waves are generated. For decades, the study of gravity waves has been classified into two categories; first is that the waves travel directly from the source and the second is that the waves are ducted or trapped. Many studies tried to explain both categories yet all studies focused on gravity waves produced by transient events. There were almost no observation reports of airglow emissions during a large storm and what type of gravity waves and typical wavelength can be produced from such event. To address this issue, a space-based observation is more preferable since it covers wider area. Until recently, IMAP/VISI is the only space-based instrument that capable of imaging gravity waves above the troposphere in the nadir direction. The Visible and near-Infrared Spectral Imager (VISI) of the IMAP mission was launched successfully on July 21, 2012 with H-IIB/HTV-3 and installed onto the International Space Station (ISS). IMAP/VISI is now operated in the night side hemisphere with a range of +/- 51 deg. GLAT. IMAP/VISI is measuring three different airglow emissions of OI at 630 nm, the OH Meinel band at 730 nm and the O_2 (762 nm) atmospheric band at 762 nm at an altitude of ˜400 km with the typical spatial resolution of 16-50 km.

We found concentric gravity waves events in the southeastern part of Australia that was observed around 13-15 UT for 3 days from 6-8 November 2013 in O_2 (0-0) airglow emission by IMAP/VISI. The waves have horizontal wavelength vary from 80 – 210 km. By using the least squares method, the curvature of the waves was fitted to a perfect circle. The center of the wave was found to be around 155^0E; -42^0S with the radius varies from 400-1200 km. From the meteorological satellite, we cannot locate any convective source around the center of the wave. The nearby local convective source was located a few hundreds km to the south of the wave center and the rainfall rate was less than 10 mm/hr. Therefore, we rule out the possibility of local convective activity as the source of these waves. From the past studies, there were evidences that the gravity waves may be ducted and traveled a great distance away from a specific convective source (e.g. Nakamura et al., 1999; Walterscheid et al., 1999; Hecht et al., 2001). Their studies suggested that the gravity waves observed in Australia were originated from convective activity several thousands km north of Australia. During the observed events, the Typhoon Haiyan was underway. On November 6, the typhoon was categorized as 5 – equivalent of super typhoon and reached its peak on November 7 and then made a landfall in Philippine on November 8. In this study, we argue that the concentric gravity waves seen by IMAP/VISI could be generated by the intense convective activity associated with the Haiyan Typhoon event. Background wind data from TIDI (TIMED Doppler Interferometer) and MF Radar will be used to examine the plausibility for the formation of a ducted/trapped region that can explain the long distance propagation of these waves. The temperature profile from MSISE-90 model will also be used to examine the mesospheric inversion layer and if it ′ s possible to get the data, we will also use the ground-based airglow imager data from Adelaide and Alice Spring.

Keywords: IMAP/VISI, O2 (0-0), concentric gravity wave, ducted, typhoon Haiyan

The MF Radar Technique: a Review

REID, Iain[1*]

[1]Department of Physics, University of Adelaide, [2]ATRAD Pty Ltd

The Medium Frequency (MF) radar technique has been applied for more than five decades to measure winds and turbulence in the upper atmosphere in the region between 60 and 100 km during the day, and between 80 and 100 km at night. It is one of the few techniques able to provide winds reliably in the 60 to 80 km height region during the day. Although some care is needed in interpretation of the results, it remains a powerful and very useful technique. In this paper, we review the technique and highlight some recent recent results.

Tidal periodicity of mesospheric gravity waves observed with MF radar at Poker Flat, Alaska and at Tromso, Norway

MURAYAMA, Yasuhiro[1*] ; KINOSHITA, Takenari[1] ; KAWAMURA, Seiji[1] ; NOZAWA, Satonori[2] ; HALL, Chris[3]

[1]National Institute of Information and Communicatoins Technology, [2]Solar-Terrestiral Physics Laboratory, [3]Toromso University

The interaction between gravity waves and tidal waves has been studied by using observations, although the phase relation between them was not fully understood (e.g., Saskatoon, Canada (Manson et al. 1998), Rothera, Antarctica (Beldon and Mitchell, 2010)). The neutral wind velocity data from mesosphere to lower thermosphere observed by MF radars at Poker Flat in Alaska and Tromso in Norway has been observed since the late 1990s. The long-term wind velocity data at Poker Flat and Tromso was analyzed for 10 years of 1999 ? 2008 to show daily and seasonal behaviors and climatology of mesospheric gravity waves and horizontal wind of the 12 and 24 hour components. First, we extracted these waves from the MF radar observation data. In this study, harmonic analysis was carried out for periods of 48, 24, 12, and 8 hours, which are extracted from the 5 day time series of wind velocity using. Gravity waves are defined as the 1 ˜12 hour period component of difference between observed wind velocity and these harmonic components. The method is applied to 30-minute-average data to calculate the 5 day running mean amplitude and phase of zonal wind of the 12 and 24 hour components. We made 1- day composite plots of kinetic energy of gravity waves for periods of 1 ˜4 hours and harmonic components. The results show that the kinetic energy of gravity waves in Tromso has a peak in 6UT from November to February which tends to coincide with the time when zonal wind of 24 hour component is easterly maximum and easterly wind of 12 hour components is switched westerly. This feature is different from results in Poker Flat and Saskatoon. On the other hand, the phase relation between 12 hour components of zonal wind and kinetic energy of gravity waves shows that their phase agrees for more than 10 days in several years in both observation points. We confirmed the phase agreement in Tromso continued about 10 days at the same time when that in Poker Flat is continued more than 20 days from November to December in 2000. However, the phase of gravity wave kinetic energy is shifted 90 degrees between Tromso and Poker Flat. We plan to discuss more detail of underlying physical processes, focusing on migrating and non-migrating tidal waves and background state of horizontal wind velocities.

Characteristics of Short Period Tidal Components in Antarctic MLT above Syowa and Davis

TSUTSUMI, Masaki[1*] ; MURPHY, Damian[2]

[1]National Institute of Polar Research, Japan, [2]Australian Antarctic Division

The behaviour of short period atmospheric tidal components in the Antarctic mesosphere and lower thermosphere is studied based on long term observations over Syowa (69.0S, 39.6E) and Davis (68.6S, 78.0E) stations. Semidiurnal tides in the Antarctic mesosphere and lower thermosphere have been extensively studied through the recently established Antarctic radar network [e.g., Murphy et al., 2006; 2008]. However, details of shorter period components such as terdiurnal and six-hour tides are less investigated and poorly known because of their smaller amplitudes compared to the semidiurnal and diurnal tides in the height region of conventional MF radar observations of around 70-90 km. These short period tides also fall in the frequency range of inertial gravity waves and are often hard to distinguish from these waves.

The characteristics of the terdiurnal tide above Davis and Syowa have been measured on a short-term to seasonal basis in the mesosphere and lower thermosphere using long-term simultaneous MF radar data at the two sites (1999-). The terdiurnal tide achieves moderate amplitudes in the winter at these heights but there are subtle differences between the two stations. These differences are explored further by differencing tide phasors in local time and checking the amplitude of the result on a seasonal basis. If the terdiurnal tide was made up entirely of migrating components, this difference would yield a zero-average amplitude. However, the observed non-zero values suggest that the terdiurnal tide at these latitudes contains strong non-migrating tidal components.

The Syowa MF radar has a great advantage over other MF radars in that it has been conducting simultaneous meteor wind measurements together with the conventional correlation based measurements, which enables wind observations in a very wide height range of 65-120km [Tsutsumi and Aso, 2005]. A clear enhancement in terdiurnal amplitudes is seen in early winter months of March-June. The amplitudes can reach 20 m/s around 110 km even in the composite plot made with more than 10 years of data. These amplitudes can be comparable or sometimes even larger than those of diurnal and semidiurnal tides, and indicate a possible significant role of short period tidal components in the polar lower thermosphere.

The SMILES observations of mesospheric ozone during the solar eclipse

IMAI, Koji[1*] ; AKIYOSHI, Hideharu[2] ; TAKAHASHI, Kenshi[3] ; YAMASHITA, Yousuke[2] ; IMAMURA, Takashi[2] ; SUZUKI, Makoto[1] ; EBISAWA, Ken[1] ; SHIOTANI, Masato[3]

[1]Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency, Sagamihara, [2]National Institute for Environmental Studies, [3]Research Institute for Sustainable Humanosphere, Kyoto University

Solar eclipse temporally reduces the amount of solar radiation, providing an opportunity to verify the ozone photochemistry under changing solar radiation. During the longest annular solar eclipse in this millennium occurred on 15 January 2010, Superconducting Submillimeter-Wave Limb-Emission Sounder (SMILES) successfully captured increased ozone mostly in the mesosphere with a decrease in solar illuminations. The ozone increment shows altitude dependence in the mesosphere. Using an atmospheric chemistry box model, it is found that the dependence results from the difference in chemical reaction rates to the solar radiation change. The model also predicts the difference in the ozone concentration evolution between the sunlight decreasing and increasing phases, although SMILES observation does not resolve the difference.

Contribution of the IUGONET data analysis system to upper atmospheric researches

SHINBORI, Atsuki[1*] ; YAGI, Manabu[2] ; TANAKA, Yoshimasa[3] ; SATO, Yuka[3] ; YATAGAI, Akiyo[4] ; UMEMURA, Norio[4] ; UENO, Satoru[5] ; KOYAMA, Yukinobu[6] ; ABE, Shuji[7]

[1]Research Institute for Sustainable Humanosphere (RISH), Kyoto University, [2]Planetary Plasma and Atmospheric Research Center, Graduate School of Science, Tohoku University, [3]National Institute of Polar Research, [4]Nagoya University Solar Terrestrial Environment Laboratory Geospace Research Center, [5]Kwasan & Hida Observatories, School of Science, Kyoto University, [6]Data Analysis Center for Geomagnetism and Space Magnetism Graduate School of Science, Kyoto Universi, [7]International Center for Space Weather Science and Education, Japan

Various kinds of atmospheric disturbances and long-term variation as seen in several parameters (temperature, mean wind etc.) in the upper atmosphere (mesosphere, thermosphere and ionosphere) is caused by energy input from solar radiation, momenta and energies from the lower atmosphere (stratosphere and troposphere) via atmospheric waves, and chemical reaction. Such atmospheric phenomena observed by ground-based and satellite instruments are the result of such complicated processes. In order to investigate the mechanisms of the atmospheric disturbances and long-term variations in the upper atmosphere, which may be affected by solar activities and global warming, researchers need to conduct comprehensive analyses with various kinds of long-term observation data that have been continued by means of a global network of MST (Mesosphere-Stratosphere-Troposphere) radars, optical sensors, radiosondes, etc. The IUGONET (Inter-university Upper atmosphere Global Observation NETwork) project initiated in 2009 aims at the establishment of a cross-reference system for various kinds of ground-based observation data. The IUGONET participants consist of five universities/institutes: the National Institute of Polar Research (NIPR), Tohoku University, Nagoya University, Kyoto University, and Kyushu University. We have developed a metadata database (MDB) of ground-based observations and IUGONET data analysis software (UDAS) in order to provide researchers in a wide range of disciplines with a seamless data environment to link databases spread across the IUGONET institutions. In particular, the MDB and UDAS will be of great help in data acquisition and integrated analyses to understand the dynamics on the mesosphere-lower thermosphere (MLT) throughout the Sun-Earth system. Therefore, the IUGONET MDB and UDAS will greatly contribute to upper atmospheric researches on the basis of integrated analysis of various kinds of long-term observation data covering a wide region from both the poles to the equator. In this talk, we introduce a brief overview of the IUGONET project and an application of the IUGONET products for upper atmospheric researches.

Vertical and lateral wave coupling observed with network of MLT/MST Radars over Indian region

M, Venkat ratnam[1*] ; S., Eswariah[2] ; N., Venkateswara rao[1] ; S., Vijayabhaskar rao[2] ; K., Kishore kumar[3] ; S., Sathish kumar[4] ; S., Gurubaran[4]

[1]National Atmospheric Research Laboratory, [2]Sri Venkateswara University, [3]Space Physical Laboratory, [4]Indian Institute of Geomagnetism

It is well known that gravity waves and tides play an important role in delineating the middle atmospheric structure and dynamics. There have been several studies in recent years, using different measurement techniques, to understand significant roles played by gravity waves and tides in the lower, middle and upper atmospheres. However, only a few studies addressed this problem with simultaneous observations of all the three regions. Moreover, no efforts have been made so far to understand the lateral forcing of these waves and tides since such a study needs a network of radars located nearby which was missing. With the establishment of an advanced meteor radar at Sri Venkateswara University, Tirupati (13.63oN, 79.4oE), India, and up gradation of MF radar at Kolhapur (16.8oN, 74.2oE) together with MST radar at Gadanki (13.5oN, 79.2oE), Meteor radar at Thumba (8.5oN, 77oE) and MF radar at Tirunalveli (8.7oN, 77.8oE) forms a unique network of radars in the tropical region. Importantly, all these radars are located within 1000 km distance. Accordingly, this network is suitable to study the lower atmospheric forcing and its impacts on middle and upper atmospheric structure and dynamics. For the present study, all these radars were simultaneously operated for a few days in September 2013. These observations show the presence of short period gravity waves and tides (diurnal, semi-diurnal and ter-diurnal) at all locations. Large day-to-day day variability in gravity waves and tides is observed within a station and among different stations providing insight on lateral coupling. Phase propagations of the three tidal components at different stations is used to further understand the lateral coupling. Using simultaneous MST radar, Rayleigh lidar and SVU meteor radar (which are nearly co-located), lower atmospheric forcing and its impacts on the mesosphere and lower thermosphere are investigated. This study showed need for long-term measurements, with simultaneous operation of all the above mentioned network of radars, to effectively address the problem of vertical and latitudinal wave forcing.

Diurnal tide and QTD wave in the tropical stratosphere and MLT region: Long-term trends and solar cycle influence

NARUKULL, Venkateswara rao[1*] ; M., Venkat ratnam[1] ; C., Vedavathi[2] ; S., Gurubaran[3] ; B.V., Krishna murthy[4] ; S., Vijaya bhaskara rao[2]

[1]National Atmospheric Research Laboratory, [2]Sri Venkateswara University, [3]Indian Institute of Geomagnetism, [4]B1, CEEBROS, 47/20, IIIrd Main Road, Chennai

In the present study, long-term trends and solar cycle influence on the diurnal tide (DT) and quasi two day wave (QTDW) in the stratosphere, mesosphere and lower thermosphere (MLT) region over a tropical station Tirununveli (8.7oN, 77.7oE) are investigated using ERA-Interim datasets and MF radar observations available since 1993. As no ground truth is available over Tirununveli, suitability of the ERA-Interim data for the present study is ascertained using simultaneous radiosonde and MST radar observations over Gadanki (13.5oN, 79.2oE) and good consistency is found between the two. Amplitudes of the DT and QTDW over Tirununveli show a long-term linear increasing trend, which becomes prominent in the MLT region. Role of solar cycle on the DT and the QTDW is investigated by separating them with respect to the solar activity (minimum and maximum of solar cycles). Both the DT and QTDW show higher amplitudes during solar minimum and vice versa. Significant higher amplitudes in the recent extended solar minimum are noticed in the MLT region. However, no consistent relation is found between solar activity and DT in the stratosphere although increasing trend is clearly observed. Though increasing trend in the tropical convection is noticed at nearby locations, similar to the DT, it varies from location to location which may be due to large scale circulation effects. This demands data from network of radars located across the globe to see the combined effects of lower atmospheric forcing, circulation and their effects on MLT region.

MQBE and Amplitude Modulation of SAO in the MLT

MATSUMOTO, Naoki[1*] ; SHINBORI, Atsuki[2] ; TSUDA, Toshitaka[2]

[1]Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, [2]Research Institute for Sustainable Humanosphere (RISH), Kyoto University

Characteristics of various atmospheric waves in the mesosphere and lower thermosphere (MLT) have been investigated by long-term ground-based and satellite-based observation. In the equatorial region, the westward monthly mean wind is enhanced in March in 2 or 3 years in MLT, which is called Mesosphere Quasi-Biennual Enhancement (MQBE) [Rao et al., 2012]. Recently, They showed that MQBE appears once in 2 or 3 years until 2002, based on data analysis of meteor/MF radars in the Asia-Oceania region. However, the occurrence features remained unknown due to no sufficient wind data with high-time resolution from 50 to 80 km.

We analyzed the long-term wind data from 1990 to 2013 obtained from meteor/MF radars in the Asia-Oceania region, such as Kauai, Christmas island, Tirunelveli, Koto Tabang in order to identify the occurrence features and mechanism of MQBE. And also we investigated relationship of the monthly-mean wind between MLT stratosphere using MERRA retrospective-analyses data provided by NASA. We used integrated analysis tool " UDAS " provided by " IUGONET " (Inter-university Upper atmosphere Global Observation NETwork). And We use Stockwell-transform to detect the temporal variation of frequency and amplitude in time series data.

As a result, we found that MQBE occurred in spring of 2005, 2008 and 2011 with amplitude over 32 m/s in an altitude from 80 to 100 km . From an S-transform spectral analysis of zonal wind in MLT, MQBE coincides with the enhancement of the amplitude of 6-months component of zonal wind. Furthermore, comparing the 6-month component in the lower thermosphere at 90 km and stratosphere using retrospective-analyses data of MERRA, 6-months component of lower thermosphere(90 km) and stratopause (1 hPa) are well negative correlated. And also 6-months component of lower thermosphere and lower stratosphere (70 hPa) are well positive correlated. Their correlation coefficients are about 0.6, and lags are under 3 month. the former result is consistent with the fact that the phase of SAO are reversal in the lower thermosphere and in the stratosphere.

Although Rao et al.,[2012] reported that MQBE did not appear after 2002, the present results showed that MQBE takes place after 2002. Next, the SAO amplitude in MLT obtained from the S-transform analysis tends to be enhanced significantly, corresponding to the occurrence of MQBE. This relationship can be a clue of occurrence features of MQBE. Furthermore, the relationship of mean wind between in MLT and stratosphere indicates that MQBE is driven by coupling process of the mesosphere-stratosphere system. We can infer that MQBE is caused by atmospheric gravity waves, which is similar to the generation mechanism of QBO.

In addition, we need to detect and analyze the gravity wave in equatorial region to identify the mechanism of MQBE.

Meteor Wind Radar Application for the study the dynamics of the neutral winds above at Kototabang and Biak station

ACHMAD, Effendy[1] ; TSUDA, Toshitaka[2] ; SHINBORI, Atsuki[2*]

[1]National Institute of Aeronautics and Space Indonesia (LAPAN), [2]Research Institute for Sustainable Humanosphere

Currently for meteor observations is not only done with the naked eye and optical equipment such as a telescope, the latest development to detect natural phenomena meteor shower rained almost every day the Earth can be detected using radar technology. Meteor Wind Radar (MWR) is a radar system used to detect, analyse and display meteor entrance events to the Earth's atmosphere. By using of radar meteors (SKiYMET Meteor Radar) was used to observe the meteor trail (ionized air columns) that moves with the wind neutral layer of mesosphere. When a meteor enters the atmosphere it rapidly vaporises leaving behind a trail of ionised gas along its path of travel, this trail can form a target for a radar transmission. Generally the frequencies used for the detection of radar, located on the VHF band wave spectrum. The results of the analysis of radar data output consists of 7th meteor parameter can be used to study the behavior of neutral winds in the Mesosphere. In this paper the utilization of SKiYMet shown to detect Wind speed Meridional and Zonal Wind speed, Temperature in the Mesosphere and the number and received Flux meteor in the Earth, as a sources of data to better understand the dynamics of the neutral winds at an altitude of 70-110 km region of observation locations. Simultaneously measurement data will be shown at Kototabang observations that have been operating since year 2006 and in Biak Station since year 2011. All of the radar installation is a collaboration between LAPAN and RISH - Kyoto, NICT Japan.

Concentric structures in molecular oxygen emission observed by ISS-IMAP/VISI

AKIYA, Yusuke[1*] ; SAITO, Akinori[1] ; SAKANOI, Takeshi[2] ; HOZUMI, Yuta[1] ; YAMAZAKI, Atsushi[3] ; OTSUKA, Yuichi[4] ; NISHIOKA, Michi[5] ; TSUGAWA, Takuya[5]

[1]Department of Geophys., Kyoto Univ., [2]PPARC, Tohoku University, [3]ISAS/JAXA, [4]STE Lab., Nagoya Univ., [5]NICT

Concentric structures in airglow emissions were often observed from ground based imagers. Some of them were thought to be caused by the active clouds in the troposphere. It was not able to observe the overall structures from the imagers on the ground under the cloudy condition. Field of views of the imagers were not enough to observe whole structure. Space borne imagers are able to observe the structures caused by the disturbances in the lower atmosphere with wider field of view. Concentric structures of the O_2 airglow emission in 762-nm wavelength were found by the Visible and near-infrared imager on the International Space Station on June 1, 2013 over the U. S. This is the first case which took the image from edge to the center of the concentric structure. Spatial scale of this concentric structures were estimated to be 1,200 km. Fine structures with 80 km wavelength and no dumping in the intensity were observed in this VISI observation. Amplitude in these fine structures were about 10 % to the background intensity. Circular structures were also observed in the GPS-TEC observations before the VISI observation. These concentric structures were estimated to be caused from the active clouds after tornado and atmospheric gravity waves had propagated in horizontal direction in the emission layer.

Background Lamb waves coupled with thermospheric gravity waves

NISHIDA, Kiwamu[1*] ; KOBAYASHI, Naoki[3] ; FUKAO, Yoshio[2]

[1]ERI, Univ. of Tokyo, [2]IFREE, Jamstec, [3]ISAS, JAXA

Lamb waves of the Earth's atmosphere in the millihertz band have been considered as transient phenomena excited only by large events. Nishida et al. (2014) showed the first evidence of background Lamb waves in the Earth's atmosphere from 0.2 to 10 mHz, based on the array analysis of microbarometer data from the USArray in 2012. The observations suggest that the probable excitation source is atmospheric turbulence in the troposphere. Theoretically, their energy in the troposphere tunnels into the thermosphere at a resonant frequency via thermospheric gravity wave because the Lamb-wave branch intersects that of thermospheric gravity waves at 3.5 mHz and that of acoustic waves trapped near the mesopause at 6.5 mHz [Garrett 1969]. The observed FK spectrum shows a local minimum of Lamb-wave amplitudes at around 3.5 mHz, where the Lamb-wave branch is crossed by the thermospheric gravity-wave branch. Coupled Lamb waves leak a certain amount of energy from the troposphere to the thermosphere, reducing the Lamb-wave amplitudes at the crossover frequency relative to those at neighboring frequencies, when their excitation sources exist in the troposphere. The energy tunnels from the troposphere to the thermosphere at the resonant frequency, although Lamb waves themselves cannot induce an upward flux [Lindzen 1972]. The RMS amplitudes of the coupled modes are estimated to be 0.3 m/s at 150 km and 0.1 m/s at 120 km, respectively. These modes might contribute to the thermosphere energy balance by heating via viscous dissipation [Hickey et al. 2001]. The amplitude suggests that the Lamb waves partly contribute to the excitation of thermospheric wave activity associated with severe convection activity [Hunsucker1982].

A proposal of simple resonance scattering lidar using an alkali metal vapor laser for monitoring the MLT region

ABO, Makoto[1*] ; MIURA, Natsumi[1] ; NAGASAWA, Chikao[1] ; SHIBATA, Yasukuni[1]

[1]Tokyo Metropolitan University

Many observations of metal atomic layers such as Na, Fe, K, Ca and Ca ion in the mesopause region have been conducted in many parts of the world. We have observed several mesospheric metallic layers at Tokyo and Indonesia using resonance scattering lidars consisting of a dye laser and a Ti:Sapphire laser [1]. Especially, in order to solve the formation mechanism of metallic sporadic layers occurred in the mesopause region, the simultaneous observation of Ca ion and the neutral metal atom is necessary. However since the output power of the Ti:Sapphire laser has a low damage threshold of a crystal, it is difficult to improve the output average power. We propose the resonance scattering lidar consisting of the alkali vapor laser for monitoring the MLT region. Optically pumped alkali vapor lasers have attracted increasing attention because of their potential of achieve high power in a high quality beam. The alkali vapor laser can easily realize narrow-linewidth and precise tuning.

Metal atomic layers in the mesosphere are an excellent tracer of the atmospheric wave motion in the region between 80 and 100km. sudden formation of thin metallic layers, superposed in the background mesospheric metallic layers was discovered and these enhanced layers are called the sporadic metallic layers. We have observed frequently the sporadic sodium layers (Nas) at Hachioji, Japan (35.6N, 139.4E) and the sporadic sodium and iron layers (Fes) at Kototabang, Indonesia (0.2S, 100.3E). The ion recombination mechanism invoking wind shear and sporadic E layers appears to be consistent with many observed characteristics, but their cause is still an open question.

Zhdanov et al. presented optically pumped continuous wave potassium vapor laser operating in a single longitudinal and a single transverse mode at 770 nm [2]. Zweiback et al. demonstrated a high efficiency potassium vapor laser using a 0.15nm bandwidth alexandrite laser as the pump source [3]. The alkali vapor laser operates in a three level scheme. The optical pump source excites the D2 line of alkali atom and lasing occurs on the D1 line. To provide a population inversion, fast quenching must be provided by using a buffer gas. We are developing a high peak power pulsed potassium vapor laser using alexandrite laser as the optical pump source. Sealed potassium vapor cell had AR coated windows, and filled with metallic potassium and helium. The cell was assembled inside an oven which had temperature controlled heaters. A pump beam polarized in the horizontal plane was focused through the polarizing beam splitting cube into the potassium vapor cell with a lens. A laser cavity was created for the vertical polarization by two mirrors and the beam splitting cube.

The development of these kinds of lasers is identified as one of the key topics for advancing the application of resonance scattering lidar systems.

Study of Coupling Processes in the Solar-Terrestrial System: Project Overview

TSUDA, Toshitaka[1*]

[1]Research Institute for Sustainable Humanosphere (RISH), Kyoto University

We promote a project named ”Coupling Process in the Solar-Terrestrial System” under close collaboration among universities and research institutess. We aim to study the solar energy inputs to the Earth, and responses of the Geospace (magnetosphere, ionosphere and atmosphere) to them. The solar energy can manly be divided into two parts; the solar radiation, involving infra-red, visible, ultra-violet and X-ray, and the solar wind, which is a high-speed flow of plasma particles.

The solar radiation becomes the maximum on the equator, then, atmospheric disturbances are actively generated near the Earth’s surface. They further excite various atmospheric waves, which propagate upward carrying energy and momentum. On the other hand, electro-magnetic energy associated with the solar wind converges into the polar regions. Disturbances are also generated there, and a part of the energy is transported toward lower latitudes and lower atmospheric regions. We propose to establish large atmospheric radars with active phased array antenna on the equator and the Arctic region. Among the equatorial regions, we focus on Indonesia where the atmospheric disturbances are most intense in the world, and we will establish a comprehensive observatory in Indonesia with the Equatorial MU radar as its main facility. While, we will also construct the state-of-the-art radar, called EISCAT-3D, in Scandinavia under international collaboration. An observation network of portable equipment for will be expanded in Asia and Africa to clarify the global flow of energy and materials.

A Review on Equatorial Atmosphere Radar (EAR) Observations of Lower Atmosphere

HASHIGUCHI, Hiroyuki[1*] ; TSUDA, Toshitaka[1] ; YAMAMOTO, Mamoru[1] ; YAMAMOTO, Masayuki[1] ; SHIBAGAKI, Yoshiaki[2] ; SHIMOMAI, Toyoshi[3] ; EDDY, Hermawan[4]

[1]Research Institute for Sustainable Humanosphere (RISH), Kyoto University, [2]Osaka Electro-Communication University, [3]Shimane University, [4]National Institute of Aeronautics and Space (LAPAN), Indonesia

The Equatorial Atmosphere Radar (EAR) is an atmospheric radar located in Kototabang, West Sumatra in Indonesia (0.20S, 100.32E). The EAR has a circular antenna array of approximately 110 m in diameter, consisting of 560 three-element Yagis. It is an active phased array system with each Yagi driven by a solid-state transceiver module. It is operated by collaboration between the Research Institute for Sustainable Humanosphere (RISH), Kyoto University and National Institute of Aeronautics and Space of Indonesia (LAPAN), Indonesia since 2001. RISH has conducted a collaborative research program (EAR collaboration) by using the EAR and its related facilities since 2005. The EAR can observe winds and turbulence in the lower atmosphere and echoes from ionospheric irregularities. In the presentation, observation results of the lower atmosphere with the EAR are reviewed.

Ionospheric observations by SEALION and the Equatorial Atmosphere Radar

YOKOYAMA, Tatsuhiro[1*] ; TSUGAWA, Takuya[1] ; ISHII, Mamoru[1]

[1]National Institute of Information and Communications Technology

Equatorial spread F (ESF) is a well-known phenomenon in the equatorial ionoshperic F region. As it causes severe scintillation in the amplitude and phase of radio signals, it is important to understand and forecast the occurrence of ESF from a space weather point of view. Ionospheric observation with the 47-MHz Equatorial Atmosphere Radar (EAR) in West Sumatra, Indonesia (0.20S, 100.32E, 10.36S dip latitude) has been conducted since 2001, and its unique observational data has been obtained for more than one solar cycle. The EAR is sensitive to 3-m scale ionospheric irregularities, which can be regarded as a tracer of ESF. Along with the EAR observations, Southeast Asia Low-latitude Ionospheric Network (SEALION) project by NICT started in 2003 for the purpose of monitoring and forecasting ESF. The SEALION consists of multiple ionosondes, GPS receivers and several other instruments in the Southeast Asian region. Since the developed ESF usually drifts eastward, monitoring ESF in this region can provide important space weather information for the Japanese longitude sector. We will summarize observational results with the SEALION and EAR, and discuss future potential of the ionospheric observation in the Southeast Asian region.

Development of Indonesian Monsoon Index (IMI) Based on EAR and other Facilities at Kototabang

EDDY, Hermawan[1] ; HASHIGUCHI, Hiroyuki[2*]

[1]National Institute of Aeronautics and Space (LAPAN), Indonesia, [2]Research Institute for Sustainable Humanosphere (RISH), Kyoto University

This study is mainly concerned on developing of the Indonesian Monsoon Index (IMI) based on the Equatorial Atmosphere Radar (EAR) at Kototabang, West Sumatera (0.2S; 100.32E, 865 m from MSL). We have analyzed the zonal and meridional wind data of EAR for period of July 2001 to July 2008. By applying the bandpass filtering method that we call as the Fast Fourier Transform (FFT) and Wavelet (WL) technique, we have identified the characteristics of meridional wind velocity in frequency domain. The predominant peak oscillation that appear is Annual Oscillation (AO) for the meridional wind velocity between 8 to 18 km above mean sea level (MSL). While, the strongest is located around 14.1 km from MSL (It's equal to 200 hPa). At the same time period observation of EAR, we analyzed also the Global Monsoon Index as represented by the Indian Summer Monsoon Index (ISMI), Western North Pacific Monsoon Index (WNPMI), and Australian Monsoon Index (AUSMI), respectively. We found a 12 months oscillation for Global Monsoon Index that we call as the AO. By comparing them with meridional wind velocity of EAR, we found a good agreement between AUSMI and the meridional wind velocity of EAR, especially. By this preliminary result, we suspect that we can use the AUSMI parameter to detect the Monsoon Signal over Indonesia, especially for the Western part of Indonesia region, especially at about the 200 hPa. We wish to develop these results by investigating the Monsoonal Onset, especially, including their anomalies, since we know that Monsoon is still a pre dominant peak oscillation at the Indonesian Maritime Continent (IMC) which have big effect to control the complexity of atmospheric dynamic over Indonesia. If it looks possible, we wish also to develop the IMI model that suitable for Indonesia region. Detailed information due to that preliminary results including the basic idea of this proposal research will be discussed at our presentation.

Vertical and horizontal coupling processes in the equatorial atmosphere

YAMANAKA, Manabu D.[1*]

[1]JAMSTEC/Kobe U

Future targets of the equatorial atmosphere dynamics are discussed from viewpoints of recent progress of the lower-atmospheric parts including increase of climatological interests and rapid developments of tropical countries. From recognition of the importance of land-sea heat contrast on Earth we must consider again two types of diurnal cycles: sea-land breeze circulations and atmospheric tides, which have local and global phase structures, respectively. We must consider also two types of Earth rotation effects: solar radiation heating and Coriolis force, which are stronger and weaker, respectively, in the equatorial region. Furthermore, in the lower atmosphere, clouds govern winds in the equatorial region, in contrast to opposite relationship in middle and high latitudes. Because the equatorial convective clouds are dependent not only on dynamical and thermal instabilities but also by water and electrical budgets, we need to study again dynamical-chemical and atmosphere-ionosphere couplings.

Vertical wind measurement in the equatorial troposphere by the Equatorial Atmosphere Radar: A review

YAMAMOTO, Masayuki[1*] ; HASHIGUCHI, Hiroyuki[1] ; YAMAMOTO, Mamoru[1]

[1]Research Institute for Sustainable Humanosphere, Kyoto University

Measurements of vertical wind are important not only for clarifying transportation processes of energy and momentums but also for quantifying dynamical processes of precipitation and clouds. Because 50-MHz atmospheric radars measure vertical and horizontal wind velocity by using scatterings caused by irregularities of radio refractive index, they can measure vertical wind both in clear and precipitation regions. Using the capability, EAR has resolved the fine-scale vertical wind motions in the equatorial troposphere. In the presentation, the measurement results of vertical wind obtained by the EAR are reviewed. Future plans of vertical wind measurement using the Equatorial MU radar are also proposed.

Science and design overview of the EISCAT_3D radar

MCCREA, Ian[1*]

[1]STFC Rutherford Appleton Laboratory

For thirty years, the EISCAT Scientific Association (www.eiscat.se) has operated a network of leading facilities for ground-based research in solar-terrestrial physics. The UHF and VHF radars at Tromso in northern Norway, together with the receiver sites at Kiruna, Sweden and Sodankyla, Finland and the EISCAT Svalbard Radar near Longyearbyen, represent a uniquely capable group of instruments serving a worldwide user community. The EISCAT mainland radars in particular, however, are based on ageing transmitters and antennas which are slow-moving and increasingly hard to maintain. For several years now, EISCAT (with support from international partners including the European Union) has been planning to replace the current set of mainland radars with a new state-of-the-art radar system, better suited to the current needs of the research community. EISCAT_3D (www.eiscat3d.se) will be the next-generation radar for the high-latitude atmosphere and geospace, with capabilities going beyond anything currently available. The facility will consist of large phased arrays in three countries. EISCAT_3D will comprise tens of thousands, up to more than 100 000, antenna elements. The new facility combines volumetric imaging and tracking, aperture synthesis imaging, multistatic configuration, improved sensitivity and transmitter flexibility. EISCAT_3D will be the first multistatic phased array ISR. A network of five sites is planned, with receivers located around 120 km and 250 km from the active site, providing optimal geometries for vectors in the middle and upper atmosphere. At the passive sites, the design allows the transmitted beam to be imaged using multi-beam techniques. EISCAT_3D will be a modular system, allowing an array to be split into sections for imaging. The result will be a new data product, range-dependent images of small structures, with sizes down to a few tens of metres. The antenna gain and array size will deliver large increases in the figure-of-merit relative to the existing EISCAT radars. An active site comprising 16,000 elements will exceed the sensitivity of the present VHF radar by an order of magnitude. In this talk the technical specifications and science case for EISCAT_3D will be discussed and the current progress reviewed. Studies of the atmospheric energy budget, exploration of small-scale and large-scale processes, as well as geospace environment monitoring and potential space weather service applications will be presented.

The EISCAT_3D System and Status

HEINSELMAN, Craig[1*]

[1]EISCAT Scientific Association

The EISCAT Scientific Association has been operating incoherent scatter radars in the arctic since the early 1980s. Those systems have been extremely productive over the decades, supporting a wide range of scientific topics within geospace research and resulting in more than 2000 publications in peer-reviewed journals. For the past several years the EISCAT community, with significant support from the European Commission, has been working toward a new set of radar systems to replace the now aging infrastructure. This distributed radar, called EISCAT_3D, will provide the scientific community with new measurement capabilities that far exceed, both quantitatively and qualitatively, those presently available.

EISCAT_3D, when it is fully implemented, will consist of five phased array antennas strategically positioned in northern Norway, Sweden, and Finland. One of the antennas will include a distributed 10 MW peak power transmitter with full polarization capabilities, rapid steering, and antenna aperture coding options. The receive antenna arrays will be capable of instantaneously covering the entire transmit beam, thus providing a large number of intersecting volumes for vector drift measurements. The overall system will, furthermore, have sufficient sensitivity to provide order of magnitude improvements in both spatial and temporal resolution over the present radars.

We will present an overview of the system in this talk along with an update on the present status of the overall project.

Thermospheric neutral density observations using the EISCAT incoherent scatter radars

KOSCH, Michael[1*] ; VICKERS, Hannah[2] ; OGAWA, Yasunobu[3]

[1]Physics Dept., Lancaster University, Lancaster, UK, [2]Institute for Physics and Technology, University of Tromso, Norway, [3]National Institute of Polar Research, Tachikawa, Japan

We exploit a recently-developed technique, based on ion-neutral coupling, to estimate the thermospheric neutral density at ˜350 km using measurements of ionospheric plasma parameters made by the EISCAT radars. The passive version of the technique is applied to a 13-year long data set from the EISCAT Svalbard Radar (ESR). Here we show that the thermospheric density in the polar cap is decreasing, consistent with satellite drag estimates at lower latitudes. The active version of the technique requires the EISCAT Heater to artificially induce ion up-flow by heating the electrons, with observations from the EISCAT UHF radar. Here we show that ion up-flow is consistent with the plasma pressure gradient, and we extract the thermospheric neutral density. At an altitude of ˜500 km, where neutral composition is not always pure atomic oxygen, problems with the technique are discussed.

3D ionospheric electron density determination in Scandinavia with TomoScand and EISCAT 3D

AMM, Olaf[1*] ; NORBERG, Johannes[1] ; VIERINEN, Juha[3] ; ROININEN, Lassi[4] ; LEHTINEN, Markku[4] ; NAKAMIZO, Aoi[1]

[1]Finnish Meteorological Institute, Arctic Research Unit, Helsinki, Finland, [2]STEL, Nagoya University, Japan, [3]Haystack Observatory, Massachusetts Institute of Technology, Westford, Massachusetts, USA, [4]Sodankyla Geophysical Observatory, University of Oulu, Finland

The TomoScand network for ionospheric tomography in Scandinavia consists of a network of newly designed Beacon receivers and an extensive, dense array of GPS receivers. A novel tomographic inversion technique allows for a multi-frequency analysis for reconstruction of ionospheric electron densities, and is also able to include information of a multitude of ground-based measurements into the inversion, such as data from ionosondes, from the EISCAT radar, and from the magnetometers of the MIRACLE network in Scandinavia. We present the current status of the TomoScand network, and show latest inversion results on 2D profiles in meridional direction, together with test results that allow to evaluate the performance of the inversion technique. Further, we discuss the future development into a full 3D inversion scheme, and how the TomoScand network can be used as a ”partner instrument” for the upcoming EISCAT 3D radar.

[1]National Institute of Polar Research, [2]STEL, Nagoya University, [3]EISCAT Scientific Association

The EISCAT(European Incoherent SCATter) Scientific Association is an international research organization, which operates incoherent scatter radars at 931MHz, 224MHz and 500MHz in northern Scandinavia and Svalbard for studies of physical and environmental processes in the middle/upper atmosphere and near-Earth space. Affiliated in the EISCAT scientific association in 1996, Japanese science community has jointly contributed to achieve further understanding of the magnetosphere-ionosphere-thermosphere coupling processes using the integrated ground-based instruments and rocket/satellite simultaneous observations with EISCAT radars.

EISCAT_3D is the major upgrade of the existing EISCAT radars in the northern Scandinavia.With a multi-static phased array system composed of one central active (transmit-receive) site and several receive-only sites, the EISCAT_3D system is expected to provide us 10 times higher temporal and spatial resolution and capabilities than the present radars.

In this presentation, we will overview our scientific activity and achievements with the EISCAT facility and our strategic plan of national funding for EISCAT_3D as well as the science targets which we expect to be unraveled by EISCAT_3D.

Study on ion upflow and outflow based on EISCAT_3D and its related observations

OGAWA, Yasunobu[1*]

[1]National Institute of Polar Research, JAPAN

An important phenomenon of magnetosphere-ionosphere coupling is the formation of upwelling ions in the topside polar ionosphere. These upflows can be a significant loss of atmospheric gasses into interplanetary space and a significant source of magnetospheric plasma, which may also affect the dynamics of the magnetosphere. Key processes for upward ion flows in the topside ionosphere are suggested to be frictional heating, ambipolar diffusion driven by a heated electron gas, and transverse ion acceleration produced by plasma waves. It is critical to determine the relative importance of the different mechanisms in operation and to understand the 3D distribution and composition of the upflowing ions and neutrals. Moreover, there are several transitions of upflowing ions, for examples, from chemical to diffusion dominance at 500-800 km altitude, from subsonic to supersonic flow at 1000-2000 km altitude, and from collisional to collisionless region at 1500-2500 km altitude.

EISCAT_3D is one of the most suitable measurements to investigate such transitions because of its wider height coverage (up to about 2000 km) along the field line. EISCAT_3D will have more transmitter power density and higher sensitivity than those of the current Tromso UHF radar, and will give information of accurate thermal ion velocity, upward flux, and ion composition (O^+, H^+, and hopefully NO^+). A combination of the EISCAT_3D, ground-based optical instruments, and in-situ measurements is definitely essential to solve several key questions of ion upflow and outflow study. In this paper, we show potential investigations of ion upflow and outflow using the EISCAT_3D, and also discuss a desirable combination of the EISCAT_3D and its related observations for the ion upflow and outflow study.

Meteor head echo observation with a high power large aparture (HPLA) radar and an open database of precise meteor orbit

NAKAMURA, Takuji[1*] ; KERO, Johan[2]

[1]National Institute of Polar Research, [2]Swedish Institute of Space Physics (IRF)

Mass influx from the space into the terrestrial atmosphere is mainly caused by meteors. Meteors delivers various elements into the atmosphere, but the meteoric dust particles are also of great importance in the terrestrial atmosphere, as they act as nucleus for condensation and clouds and affect the various atmospheric phenomena both in physical and chemical aspects. Thus, to investigate the meteor flux, orbits and their interactions in the upper atmosphere is very important but at the same time the method of investigation is limited, especially for the precise measurements.

A high power large aperture (HPLA) radar technique is one of the recent technique to provide useful information on meteor influx and orbital information, as well as interactions with atmosphere. The recent development of the technique carried out using the middle and upper atmosphere radar (MU radar) of Kyoto University at Shigaraki (34.9N, 136.1S), which is a large atmospheric VHF radar with 46.5 MHz frequency, 1 MW output transmission power and 8330 m^2 aperture array antenna, has established very precise orbit observations with meteor head echoes. Since 2009, orbital data of about 120,000 meteors have been collected. A database is now being created as an open database for research and education. In this

study, we present the physical quantities and precisions obtained by our radar meteor head echo observations and the detail of the database.

Maritime Continent of the Indonesian (MCI) archipelago is one of the world's most convectively active areas and thereby affects the global climate system. It consists of thousands of islands with different size. The island coastlines' complex shape and geography, as well as their orientation, contribute to the uniqueness of this region. Not surprisingly, maritime continent receives a large amount of rainfall throughout the year, and the precipitation varies considerably across the region. Global climate models exhibit systematic errors in their mean precipitation over the MCI due to such variability. In this study, the behavior of convective activity over Sumatera during the Coupling Processes in the Equatorial Atmosphere (CPEA) campaign I and II is examined using 1-hourly satellite infrared data. Sumatra Island is elongated and oriented from northwest to southeast and its elevated orography temporarily blocked the eastward propagation of precipitation system. The dynamics of Sumatra weather systems remains poorly understood and part of the problem lies in the lack of atmospheric data and high-resolution gridded data analyses and realistic model simulations. Therefore, the data of two intensive observation periods as the international observation campaign of the CPEA will also be used. Cloud propagation statistics (speed, span, life time, size, etc.) of the individual cloud episodes and the physical basis behind the results will be discussed.

SuperDARN global observation of energy input and coupling processes and recent technical development

YUKIMATU, Akira sessai[1*] ; NISHITANI, Nozomu[2] ; NAGATSUMA, Tsutomu[3]

[1]NIPR/SOKENDAI, [2]STEL, Nagoya Univ., [3]NICT

SuperDARN (Super Dual Auroral Radar Network) [Greenwald, et al., 1995] is an international collaborative HF-radar network [Greenwald, et al., 1985] operated by more than 15 institutions in over 10 countries, and the number of the radars is currently more than 30 and it is still growing and the fields-of-view (FOVs) have been expanding to both higher and mid-latitudes covering considerable portions of global upper atmosphere in both hemispheres.

SuperDARN was originally designed to measure line-of-sight plasma Doppler spectra and ionospheric electric field to obtain global large scale two-dimensional polar ionospheric plasma convection patterns and polar cap potential drop in both hemispheres with a temporal resolution of 1 to 2 minutes in real time since 1995, which have never been possible by any other observational techniques, and this capability provides us very important and essential information on solar energy input to our geospace, magnetosphere and polar ionosphere, which has greatly contributed to basic understanding of coupling processes in Sun-Earth system as well as space weather researches.

SuperDARN is a powerful tool to be applied to many scientific issues [Chisham, et al., 2007 and references therein]. It can be used not only to deduce dynamics of global large-scale convection patterns, but also to study dynamics of transient meso-scale phenomena like FTEs and TCVs, and polar cap boundary or open-closed field line boundary (OCB), to detect reconnection sites and to deduce reconnection rates, to study substorms, storms and phenomena related to subauroral regions like sub-auroral polarisation stream (SAPS), to deduce field aligned currents (FACs), to study MHD waves in a variety of frequency ranges, and also to study ionospheric irregularities in D-, E-, and F-regions. Moreover, it can be utilised not only to ionospheric researches but also to neutral atmospheric studies, e.g., on atmospheric waves like TIDs, tides and gravity waves, neutral winds around mesopause region, and also polar mesospheric summer echoes (PMSEs), etc.

These days, the fields-of-view (FOVs) of SuperDARN have been expanded to higher latitude (PolarDARN) and mid-latitude (StormDARN) which covers considerable portions of mid- and polar latitudes of earth's ionosphere in both hemispheres and enables us to address much wider ranges of scientific questions including inner magnetospheric physics. There are also ongoing discussions to expand the SuperDARN radars field of view to even lower latitudes, up to low latitude and equatorial regions.

SuperDARN has extensively evolved successfully and has been extremely productive by strong cooperation and competitions within the community and also by collaborative studies with other ground-based and satellite/rocket observations and theoretical researches, which has greatly contributed to a variety of studies especially on magnetosphere-ionosphere coupling processes and ionosphere and neutral atmosphere coupling.

As SuperDARN could have provided basic and important physical parameters in global upper atmosphere, collaborative studies with other projects like IS-radars like EISCAT and PANSY providing many detailed physical parameters at fix points as well as satellite missions like THEMIS, VAP, and ERG and rocket campaigns providing in-situ measurements will be particularly important to contribute to our deeper understanding of the Sun-Earth coupling processes.

Also some SuperDARN radars has developed new technical upgrade including imaging radar capabilities providing higher spatial resolution. New science targets with SuperDARN with new capabilities will also be discussed.

Low Latitude Ionospheric Scintillation Research Using GISTM Network over Indonesia

HUSIN, Asnawi[1*] ; ABADI, Prayitno[1] ; JIYO, Harjoswito[1] ; YAMAMOTO, Mamoru[2] ; OTSUKA, Yuichi[3]

[1]Space Science Center, LAPAN, [2]RISH, Kyoto University, [3]STEL, Natoya University

The ionosphere plays an active role in the space weather relationships, so the permanent monitoring of the ionosphere state on global and regional is required. The advancement of Global Navigation Satellite Systems (GNSS) such as GPS (Global Positioning System) receiver technology provides a low cost solution for monitoring and research the ionosphere on global and regional basis. National Institute of Aeronautics and Space (LAPAN) Indonesia has been installed GPS Ionospheric Scintillation and TEC Monitor (GSV4004b) to monitor and study ionospheric irregularities.

This paper reports a statistical study of the occurrences characteristic of GPS ionospheric scintillation and irregularity in low latitude Indonesia sector. These measurements were made by GPS Ionospheric Scintillation and TEC Monitor System (GISTM) at Pontianak (0.03S 109.33E), Bandung (6.93S 107.6E), Manado (1.34N 124.83E), Kupang (10.16S 123.66E), and Kototabang (0.12S 100.12E). For the GPS station at Kototabang, we use ISM (ionospheric scintillation monitor) under collaboration with STELAB Nagoya Univeristy. We distinguish scintillation occurrences rate between post sunset and after midnight by using S4 index during maximum solar activity period in 2013. We analyze the occurrence rate using azimuth-elevation coordinate (sky plot). The following figure is to show observation geometry which is used in this study.

Future direction of the ground-based network observations of the magnetosphere and the upper atmosphere

SHIOKAWA, Kazuo[1*] ; OTSUKA, Yuichi[1]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

Multi-point ground-based instruments are powerful tools to investigate global dynamics of the magnetosphere, ionosphere, and the upper atmosphere. Airglow imagers and multi-point GPS receivers provide two- and three-dimensional view of these regions. The ring-current and radiation-belt particles in the inner magnetosphere round the earth with a time scale from a few tens of minutes to a few hours. Interactions of these particles with Pc5 (times scale of ˜minutes), Pc1 (˜Hz) and VLF/ELF chorus (˜kHz) causes acceleration and loss of these particles. Thus, longitudinal chain of ground-based stations to observe these various waves and auroras is essentially needed to understand the acceleration and loss of the plasma in the inner magnetosphere. The auroral energy input from the solar wind and magnetosphere to the high-latitude ionosphere is a major energy source of the dynamic variation of the upper atmosphere. Intense convective activity in the equatorial troposphere gives another energy source of the dynamic variation of the upper atmosphere. Thus, meridional chain stations are essentially needed to understand these dynamic variations and their global coupling. In this presentation we discuss possible future directions of these ground-based network observations to understand the global dynamics of the magnetosphere, ionosphere, and the upper atmosphere.

ICSWSE/ MAGDAS Project: Research for global electromagnetic coupling from polar to equatorial ionosphere

YOSHIKAWA, Akimasa[1*] ; NAKAMIZO, Aoi[2] ; OHTANI, Shinichi[3] ; TANAKA, Yoshimasa[4] ; IMAJO, Shun[5] ; MATSUSHITA, Hiroki[5] ; CARDINAL, Maria gracita[1] ; ABE, Shuji[1] ; UOZUMI, Teiji[1] ; YUMOTO, Kiyohumi[1]

[1]International Center for Space Science and Education, Kyushu University, [2]Finish Meteorological Institute, [3]The Johns Hopkins University Applied Physics Laboratory, [4]National Institute of Polar Research, [5]Earth and Planetary Science , Kyushu University

International Center for Space Weather Science and Education (ICSWSE) has developed a real time magnetic data acquisition system (the MAGDAS project) for space environment monitoring around the world. The number of observational sites is increasing every year with the collaboration of MAGDAS host countries. Now at this time, the MAGDAS Project has installed 73 real time magnetometers ? so it is the largest magnetometer array in the world.

Applying equivalent current method to this network data, we analyze a global ionospheric current system from polar to equatorial ionosphere. Our results suggest that Dp2 type disturbances excited by solar wind variation, Pi2 type pulsations accompanied by aouroral substorm onset process and Pc3 type pulsations accompanied by dayside cavity type oscillation show the same type of global current system, which are produced by primary bipolar electric field accompanied by field-aligned current system and Hall polarization electric field excited at the dawn-dusk conductivity terminator and at the magnetic dip equator.We will discuss how the electromagnetic coupling between polar and equatorial ionosphere is regulated by the formation of global Cowling channel in the ionosphere.

Contribution of the IUGONET data analysis system to a study on coupling processes in the solar-terrestrial system

SHINBORI, Atsuki[1*] ; YAGI, Manabu[2] ; TANAKA, Yoshimasa[3] ; SATO, Yuka[3] ; YATAGAI, Akiyo[4] ; UMEMURA, Norio[4] ; HORI, Tomoaki[4] ; UENO, Satoru[5] ; KOYAMA, Yukinobu[6] ; ABE, Shuji[7]

[1]Research Institute for Sustainable Humanosphere (RISH), Kyoto University, [2]Planetary Plasma and Atmospheric Research Center, Graduate School of Science, Tohoku University, [3]National Institute of Polar Research, [4]Solar-Terrestrial Environment Laboratory, Nagoya University, [5]Kwasan & Hida Observatories, School of Science, Kyoto University, [6]Data Analysis Center for Geomagnetism and Space Magnetism Graduate School of Science, Kyoto Universi, [7]International Center for Space Weather Science and Education, Japan

Various kinds of disturbance phenomenon and long-term variation as seen in several observation parameters (electric and magnetic fields, temperature, mean wind etc.) in a wide area from space surrounding the Earth to the atmospheric layers are caused by energy input from solar radiation, solar wind, momenta and energies from the lower atmosphere via atmospheric waves, and chemical reaction. Such a disturbance phenomenon and long-term variation observed by various kinds of ground-based and satellite instruments are the result of such complicated processes. Then, in order to investigate the mechanisms of these phenomena in this region, researchers need to conduct comprehensive analyses with various kinds of long-term observation data that have been continued by means of a global network of radars, magnetometers, optical sensors, helioscopes, etc. The IUGONET (Inter-university Upper atmosphere Global Observation NETwork) project initiated in 2009 aims at the establishment of a cross-reference system for various kinds of ground-based observation data obtained from different techniques. The IUGONET participants consist of five universities/institutes: the National Institute of Polar Research (NIPR), Tohoku University, Nagoya University, Kyoto University, and Kyushu University. We have developed metadata database (MDB) and IUGONET data analysis software (UDAS) of ground-based observation data managed by these IUGONET universities/institutes with an international collaboration in order to promote a study on coupling process in the Sun-Earth system. The MDB provides researchers in a wide range of disciplines with a seamless data environment to link databases spread across the IUGONET universities/institutes. In particular, UDAS will be of great help in conducting integrated analyses and visualization of various kinds of solar-terrestrial observation data to investigate the long-term variation in the upper atmosphere throughout the Sun-Earth system. Then, the IUGONET products will greatly contribute to a study on coupling process in the Sun-Earth system on the basis of integrated analysis of various kinds of long-term observation data covering a wide region from both the pole to the equator. In this talk, we introduce a brief overview of the IUGONET project, and an application of the IUGONET products to typical examples of upper atmospheric researches.

Statistical characteristics of nighttime MSTIDs observed by an airglow imager over sub-tropical site Yonaguni (19.3N dip)

VISWANATHAN, Lakshmi narayanan[1*] ; SHIOKAWA, Kazuo[1] ; OTSUKA, Yuichi[1] ; SAITO, Susumu[2]

[1]Solar Terrestrial Environment Laboratory, Nagoya University, Nagoya, Japan, [2]Electronic Navigation Research Institute, Tokyo, Japan

The nighttime medium-scale travelling ionospheric disturbances (MSTIDs) are frequently observed in the mid-latitude ionosphere. They very often moves toward the southwest direction in the northern hemisphere with phase fronts aligned along the northwest to the southeast. However they do not extend to the equatorial latitudes and are rarely sighted at dip latitudes below 15^o. In this study we investigate the characteristics of MSTID features observed over Yonaguni (24.5^oN, 123.0^oE; 19.3^oN dip latitude), Japan with all-sky imaging of OI 630.0 nm airglow emission. We selected two year period for analysis in which one year corresponds to the solar minimum conditions and another year corresponds to solar maximum conditions. It is found that the MSTIDs occur more frequently during solar minimum conditions. The observed range of wavelengths, phase speeds and directions of MSTIDs are similar to those observed at typical mid-latitude sites. On many occasions the phase fronts of the observed MSTIDs do not extend over the whole field of view of imager indicating that some process hinders their extension to further lower latitudes. Herein, we also investigate the possible reason for the disappearance of phase fronts when they reach lower latitudes.

Thermospheric wind variations in the pulsating aurora measured with FPI and IS radars

OYAMA, Shin-ichiro[1*] ; KURIHARA, Junichi[2] ; TSUDA, Takuo[3] ; SHIOKAWA, Kazuo[1] ; MIYOSHI, Yoshizumi[1] ; WATKINS, Brenton J.[4]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Graduate School of Science, Hokkaido University, [3]National Institute of Polar Research, [4]Geophysical Institute, University of Alaska Fairbanks

Pulsating aurora is a typical phenomenon of the recovery phase of magnetic substorm and is frequently observed in the morning sector. While our understanding of pulsating aurora has not yet reached maturity, the widely accepted generation mechanism causing pulsations in precipitating electrons is related to wave-particle interactions around the equatorial plane in the magnetospheric tail. The closure current system in pulsating aurora may not be as strongly evolved as compared to that in the discrete arc because of smaller precipitation flux (or upward field-aligned current) and weaker perpendicular electric field (or the Pedersen current). Thus one may assume that Joule energy dissipation and/or Lorentz force does not play an important role for modifications of the thermospheric wind dynamics in pulsating aurora. However, we found thermospheric-wind variations in the pulsating aurora during simultaneous observations with a Fabry-Perot Interferometer (FPI; 557.7 nm), an all-sky camera (557.7 nm), and the European Incoherent Scatter (EISCAT) UHF radar. Of particular interest is that the location of the fluctuations was found in a darker area that appeared within the pulsating aurora. During the same time period, the EISCAT radar observed sporadic enhancements in the F-region backscatter echo power, which suggests the presence of low-energy electron (1 keV or lower) precipitation. Using other data sets archived by the EISCAT radar, a statistical analysis shows that the F-region enhancement tends to coexist with hard-particle precipitation or the pulsating aurora. This presentation will summarize our experimental evidences showing several events of the pulsating aurora, and discuss application of the phased-array IS radar to this study.

ISS-IMAP mission is a space-borne mission to investigate the mesoscale structures in the ionosphere, the mesosphere, and the plasmasphere by imaging observations of instruments on International Space Station. It consists of two imaging instruments. Visible-light and infrared spectrum imager (VISI) observes the airglow in the MTI region. Extra ultraviolet imager (EUVI) observes the resonant scattering from ions in the ionosphere and the plasmasphere. The objective of this mission is to clarify the upper atmospheric structures whose horizontal scale is 50-500km, and the effect of the structures on the space-borne systems in the low- and mid-latitude regions. VISI observes the airglow of 730nm (OH, Alt. 85km), 762nm (O2, Alt 95km), 630nm(O, Alt.250km) in the Nadir direction to investigate the mesoscale structures in the mesosphere and the ionosphere. The coordinated observations of ISS-IMAP with ground-based measurements have been carried out. The MU radar and Equatorial Atmosphere Radar (EAR) observe the ionosphric density structures and field-aligned irregularities while ISS-IMAP observe the large and mesoscale ionospheric structures with the 630nm airglow, and the atmospheric gravity waves in the mesosphere with the 762nm airglow. The two-dimensional distribution of total electron contents derived with the ground-base GPS receiver array is also compared with the ionospheric and mesospheric structures observed by ISS-IMAP. The results of the ISS-IMAP mission by VISI and EUVI, and its coordinated observations with the ground-based instruments will be introduced in the presentation.

Current status of Program of the Antarctic Syowa MST/IS radar (PANSY)

SATO, Kaoru[1*] ; TSUTSUMI, Masaki[2] ; SATO, Toru[3] ; NAKAMURA, Takuji[2] ; SAITO, Akinori[3] ; TOMIKAWA, Yoshihiro[2] ; NISHIMURA, Koji[2] ; KOHMA, Masashi[1] ; YAMAGISHI, Hisao[2] ; YAMANOUCHI, Takashi[2]

[1]Dept Earth & Planetary Sci., The University of Tokyo, [2]National Institute of Polar Research, [3]Kyoto University

The PANSY radar is the first Mesosphere-Stratosphere-Troposphere/Incoherent Scatter (MST/IS) radar in the Antarctic. It is a VHF monostatic pulse Doppler radar operating at 47 MHz, consisting of an active phased array of 1,045 Yagi antennas and an equivalent number of transmit-receiver modules with a total peak output power of 500 kW. The first stage of the radar was installed at Syowa Station (69^{o}00'S, 39^{o}35'E) in early 2011, and is continuously operating with 228 antennas and modules since April 2012. The full radar system operation will start in 2015. This paper reports the project's scientific objectives, technical descriptions, and the preliminary results of observations made to date. The radar is designed to clarify the role of atmospheric gravity waves at high latitudes in the momentum budget of the global circulation in the troposphere, stratosphere and mesosphere, and to explore the dynamical aspects of unique polar phenomena such as polar mesospheric/stratospheric clouds. The katabatic winds as a branch of Antarctic tropospheric circulation and as an important source of gravity waves are also of special interest. Moreover, strong and sporadic energy inputs from the magnetosphere by energetic particles and field-aligned currents can be quantitatively assessed by the broad height coverage of the radar which extends from the lower troposphere to the upper ionosphere. From engineering points of view, the radar had to overcome restrictions related to the severe environments of Antarctic research, such as very strong winds, limited power availability, short construction periods, and limited manpower availability. We resolved these problems through the adoption of specially designed class-E amplifiers, lightweight and tough antenna elements, and versatile antenna arrangements. We will show highlights of several interesting results from the radar observations regarding severe snow storms, gravity waves, multiple tropopauses, and polar mesosphere summer/winter echoes.

Importance of coordinated ground-based, satellite observations

MIYOSHI, Yoshizumi[1*] ; OYAMA, Shin-ichiro[1] ; SAITO, Shinji[1]

[1]STEL, Nagoya University

The ERG (Exploration of energization and Radiation in Geospace) is Japanese geospace exploration project. The project focuses on the geospace dynamics in the context of the cross-energy coupling via wave-particle interactions. The project consists of the satellite observation team, the ground-based network observation team, and integrated-data analysis/simulation team. The ERG satellite will be launched in FY2015. Comprehensive instruments for plasma/particles, and field/waves are installed in the ERG satellite to understand the cross-energy coupling system. In the ERG project, several ground-network teams join; magnetometer networks, radar networks, optical imager networks, etc. Moreover, the modeling/simulations play an important role for the quantitative understanding. In this presentation, we will discuss the importance of coordinated observations toward the ERG era. As an example, we show the cooperative observations between the geospace satellite Van Allen Probes an EISCAT to observe the pulsating aurora. The EISCAT measured the height profile of the electron density that can provide the energy of the precipitating electrons. The Van Allen Probes measured the plasma waves in the magnetosphere, which can be used to investigate the origin of the pulsating aurora. In fact, the GEMSIS-RBW simulation that used the observed plasma waves as an input reproduces characteristics of the observed precipitation. Such coordinated observations including the modeling provide a comprehensive view on cause and result.

[1]National Institute of Polar Research, [2]Research Institute for Sustainable Humanosphere, Kyoto University, [3]Applied Physics Laboratory, Johns Hopkins University

A large observation network with the SuperDARN radars and other ground-based instruments at manned and unmanned stations is currently developed in the Antarctic area from sub-auroral latitudes to polar cap region and from nightside to dayside hours under international collaboration. Such a widespread circumpolar observation network is very unique and powerful for studies on the phenomena which occur due to the Sun-Earth interaction, e.g., direct entry of solar wind energy and momentum into the cusp and polar cap regions, explosive energy dissipation during substorm-time, highly energetic particle precipitation into the atmosphere during storm-time. Coordinated observations with several low-altitude satellites (e.g., NOAA, DMSP, etc.) and magnetospheric satellites (e.g., THEMIS/ARTEMIS, Geotail, MMS, ERG, etc.) can be also expected In our presentation, current status and future plan of NIPR-related project will be introduced, and importantce of such a widespread ground-based observation network in Antarctica will be explained and discussed.

A review of selected data-analysis techniques for determining ionospheric electrodynamic parameters on mesoscales

VANHAMAKI, Heikki[1*] ; AMM, Olaf[1]

[1]Finnish Meteorological Institute, Helsinki, Finland

We present a review of selected data-analysis methods that are applied in studies of ionospheric electrodynamics and magnetosphere-ionosphere coupling using ground-based and space-based data sets. At present, there is no single measurement device that can measure all ionospheric electrodynamic parameters directly and simultaneously, with good spatial and temporal resolution and coverage. Therefore data-analysis techniques are needed to combine different types of measured data and to obtain unobserved ionospheric parameters from the observed ones, possibly using some additional assumptions in the process. We concentrate on methods that are data driven and applicable to single events (not simulations or statistical models), and which can be used in mesoscale studies, where the analysis area is typically some hundreds or thousands of km across.

The primary focus of this review is in ionospheric electrodynamics, so we do not include variables like chemical composition, temperature, etc. in our discussion. Furthermore we concentrate on analysis techniques that have been developed to be used with data from the MIRACLE network (Magnetometers - Ionospheric Radars - All-sky Cameras Large Experiment) situated in Northern Europe, possibly in combination with satellite observations, such as Cluster or CHAMP. However, the techniques can be applied to data from any other mesoscale network with similar observations.

The full set of ionospheric electrodynamic parameters that we are interested in consist of the ionospheric horizontal electric field, height integrated Hall and Pedersen conductances, horizontal sheet current and field aligned current (FAC). Additionally, the ground magnetic perturbation is an important input parameter in many analysis methods.

Most of the reviewed methods are used in 2-dimensional (latitude - longitude) regions of the ionosphere, but some methods have also 1-dimensional variants. In 1D analysis it is assumed that ionospheric parameters vary only in one horizontal direction (e.g. as a function of geomagnetic latitude), so input data is required along a single chain or a satellite track only. The 1D methods are especially useful when analyzing data from an overpassing satellite or from a meridional magnetometer chain.

Fine-scale electrodynamic structure behind auroral vortex street

HOSOKAWA, Keisuke[1*]

[1]University of Electro-Communications

One of the primary scientific objectives of the planned EISCAT_3D system would be “3D imaging of aurora”, especially 3D imaging of dynamically moving auroral arcs at the time of substorm expansion phase onset. In order to discuss the specification of the EISCAT_3D system in detail, we have to know how such an effort of multi-dimensional imaging of aurora has been made by using currently-working radar systems in the high-latitude region. For this purpose, I present a fine-scale electrodynamic structure behind an auroral vortex street observed immediately before substorm expansion phase onset, as inferred from high spatial and temporal resolution measurements of auroral breakup with an all-sky TV camera (ATV) and a coherent HF radar of Super Dual Auroral Radar Network (SuperDARN) in Iceland. During the interval of interest, the ATV observed eastward propagating auroral vortices in the initial brightening arc of a substorm just prior to the poleward expansion. During the sequential passage of the vortices across the radar beams, the radar detected large velocity flow shears whose magnitude was in excess of 1.5 km/s. The observations suggest that flow shears were located very close to the center of the vortices; thus, they corresponded to electric fields converging toward the vortices, which is consistent with the existence of upward field-aligned currents (FACs) flowing out of the vortices. The temporal and spatial resolutions of the current radar measurement were still insufficient for fully resolving the detailed electrodynamic structure behind the fast moving auroral vortices. At least, however, the observations suggest the existence of highly localized filamentary FAC structures behind the auroral vortex street. Such a fine-scale structuring process of an auroral arc would be one of the possible targets of the 3D imaging observations of the planned EISCAT_3D system.

Study of the physical meanings of ionospheric tidal signatures using theoretical models

LIN, Charles[1*] ; CHEN, Yu-tsung[1] ; CHEN, Po-cheng[1] ; CHANG, Loren[2] ; LIN, Jia-ting[1] ; HUBA, Joseph[3] ; CHEN, Chia-hung[1]

[1]Department of Earth Science, National Cheng-Kung University, Tainan, Taiwan, [2]Institute of Space Science, National Central University, Chung-Li, Taiwan, [3]Plasma Physics Division, Naval Research Laboratory, Washington, D.C., USA

Variations the ionospheric electron density structures related to the tidal forcing propagating upward from the lower atmosphere have been studied intensively recently. The longitudinal variations of ionospheric electron density are related to the themospheric nonmigrating tidal signatures produced in-situ or propagating upward from below. During a stratospheric sudden warming, thermospheric migrating tidal signatures are modified and lead to the phase shift of ionospheric electron density structures at low latitudes. With the increasing number of global ionospheric observations, it is desirable to relate the thermospheric tidal signatures to corresponding tidal signatures of ionospheric electron density, since the neutral thermospheric temperature and wind observations are rather limited. In this paper we perform theoretical simulations to study the interconnections between tidal modes in thermospheric neutral parameters and ionospheric plasma. The migrating and nonmigrating tides of thermospehric winds output from NCAR GSWM/TIEGCM runs are incorporated to NRL SAMI-3 to investigate the responses of corresponding tidal modes in ionospheric electron density and their physical meanings.

Wavelike Structures in the Low-Latitude F region Using Beacon Satellites

TSUNODA, Roland[1*]

[1]SRI International

The low-latitude F-region plasma is produced by solar radiation, and its gross structural features arise from plasma transport and re-distribution (1) along geomagnetic field (B) lines by a meridional neutral wind, and (2) in planes transverse to B by an electric field (E). The fundamental process is often referred to as the equatorial fountain, in which an eastward electric field, applied over the magnetic dip equator, drives the plasma upward; this transverse transport is accompanied by downward and outward transport along B, which is driven by gravity and diffusion. The enhancements in plasma density that form, one in each hemisphere, are known as the equatorial ionization anomalies. Embedded within these largest-scale structures is a hierarchy of smaller-scale wavelike perturbations that extend downward from perhaps 1000 km to nearly 10 cm. These structures include large-scale wave structure, traveling ionospheric disturbances, equatorial plasma bubbles, as well as the small-scale irregularities that are responsible for radio wave scintillations and radar backscatter. Because of the complex hierarchy of structures that can be present, comprehensive investigations require a network of sensors that can provide both spatial and temporal information with adequate spatial resolution, while providing the necessary geographical coverage. A brief review of some of the recent results regarding wavelike structures, obtained from studies using a broad network of instruments distributed throughout the Southeast Asian sector, is presented.

Preliminary study of equatorial ionization anomaly characteristic from GRBR chain in southeast Asia

WATTHANASANGMECHAI, Kornyanat[1*] ; YAMAMOTO, Mamoru[1] ; SAITO, Akinori[2] ; MARUYAMA, Takashi[3]

[1]Research Institute for Sustainable Humanosphere, Kyoto University, [2]Department of Geophysics, Graduate School of Science, Kyoto University, [3]National Institute of Information and Communications Technology

To study the equatorial ionization anomaly (EIA) characteristic, comparison of total electron content (TEC) obtained from the GNU Radio Beacon Receiver (GRBR) network in southeast Asia with the data from SEALION ionosonde network, Equatorial Atmosphere Radar (EAR), and the SAMI2 model are employed. Five GNU Radio Beacon Receivers (GRBRs) were aligned along 100 degree geographic longitude. Their observations started in March 2012 to enable monitoring the ionosphere during the high solar activity. The GRBR network in southeast Asia is a unique observation network of which the field of view covers $\pm$ 20 degree magnetic latitude including the magnetic equator to capture the ionospheric irregularities including the EIA. As a preliminary result, the day-to-day variability of the EIA was captured by GRBR chain. The asymmetry of the EIA was investigated. As generally known, the neutral wind is a primary source of the EIA asymmetry, while the zonal electric field is the secondary one. Using the GRBR network, the EIA asymmetry is compared with the data from SEALION ionosonde network and from SAMI2 model to clarify the source mechanism of the EIA asymmetry.

Performance evaluation of plasma bubble monitoring by VHF radars for GNSS augmentation systems

SAITO, Susumu[1*] ; YAMAMOTO, Mamoru[2] ; OTSUKA, Yuichi[3] ; YOSHIHARA, Takayuki[1]

[1]Electronic Navigation Research Institute, [2]RISH, Kyoto University, [3]STEL, Nagoya University

For global navigation satellite systems (GNSS), ionospheric plasma is one of the most serious error sources. Especially in air navigation where safety is extremely important, augmentation systems corresponding to flight phases are used. Even with augmentation systems of current design, such as ground-based augmentation system (GBAS) or satellite-based augmentation system (SBAS), probability of miss-detection of ionospheric anomalies prevent them from more advance operations. In the low latitude region, ionospheric anomaly detection is a challenge because of frequent occurrence of plasma bubbles.

In this study, plasma bubble detection by a VHF backscatter radar is proposed as an external ionospheric monitor. Multi-beam observation of plasma bubbles can detect two dimensional shapes of plasma bubbles in a plane perpendicular to the magnetic field. When satellite-receiver path of GNSS signals pass crosses the magnetic field line, the signals shall be discarded because it may be affected by plasma bubble.

To evaluate the performance of this system, a VHF radar-GNSS receivers combined experiment has been conducted. The Equatorial Atmosphere Radar (EAR) is used to detect plasma bubbles. Sets of GNSS receivers around the EAR and in Bangkok are used as the pseudo-user and reference station. The observation started from
October 2012, and continues with some technical interruptions.

At the meeting, first results of the experiment will be presented.

Future direction of operational ionospheric research

ISHII, Mamoru[1*]

[1]NICT

We are now facing new aspect of oprational ionospheric research. International Civil Aviation Organization (ICAO) is planning to revise their protocol and in near future all civil aviation must use space weather information for their operation.

Space weather information is important for aviation mainly in the following three factors; HF communication, aviation and radiation. Space weather phenomena in polar region are tend to be focused on in many cases, however, it is important also in equatorial region, e.g., equatorial plasma bubbles.

There are still some unknown process in space weather and they make the forecast difficult and low precision. We are required two different approach; understand the unknows process, and make empirical forecast methods which works even though we have still unknown process. Especially we need domestic/international cooperation in the former approach e.g., EISCAT-3D and Equatorial MU radar, because it is impossible to cover these ovservation in only one institute. ICAO issue is one of the important outcome for space weather and we should unify our activity to contribute the operation.

Importance of EISCAT 3D as space weather reseach

NAGATSUMA, Tsutomu[1*]

[1]National Institute of Information and Communications Technology

These days, importance of space weather is significantly realized by international community, such as ICAO, WMO etc. NICT has been responsible for national space weather forecast in Japan for a long time. Since NICT's space weather forecast center belongs to the International Space Environment Service (ISES) as the Regional Warning Center (RWC) Japan, our operational activities are supported by international cooperation. To understand the current conditions of "space weather", monitoring networks of space weather observations are operated and used. For future objective and advanced space weather monitoring, we have been developing a space weather numerical simulation codes, too. These activities are strongly related to the space weather research for improving space weather forecasting.

EISCAT 3D is a quite unique facility to measure many kinds of physical parameters which cannot be obtained from other instruments. Therefore, it is expected that the EISCAT 3D can contirbute to the evaluation and improvement of space weather models. The future perspective of space weather research and our expectation to EISCAT 3D are introduced in our presentation.

Thunderstorm Activity in Asia Maritime Continent and Global Cloud Variation

TAKAHASHI, Yukihiro[1*] ; SATO, Mitsuteru[1] ; YAMASHITA, Kozo[2]

[1]Department of Cosmosciences, Hokkaido University, [2]Salesian Polytechnic

Global relationship among the thunderstorm activities especially in Asia Maritime Continent, cloud variations in tropical regions and solar parameters was examined based on lightning data measured by Global ELF observation Network (GEON) operated by Hokkaido University and Outgoing Longwave Radiation (OLR) intensity. A correlated analysis between the number of the lightning strokes, cloud variation in the tropical regions, and solar parameters was examined, looking into the variation with ˜one month periodicity. It was found that the number of lightning stokes in Asia Maritime Continent (AMC) varies with about month periodicity in the period from February to June 2004 and shows positive correlation (R= ˜0.8) with OLR in the Western Pacific Warm Pool (WPWP). On the other hand, OLR in the central Africa shows negative correlation with the number of lightning stokes in the AMC in that period. It is also found that the galactic cosmic rays or UV intensity associated with solar activity shows good correlation with tropical OLR or lightning activity in AMC. One explanation to connect such global variations in thunderstorm / cloud amount with solar parameters would be the electrical circuit between lower and upper atmospheres. The radars distributed globally would provide some essential information for this hypothesis, such as conductivity in the lower ionosphere, which may determine the strength of electrical connection in the vertical and horizontal directions.

Equatorial MU Radar project

YAMAMOTO, Mamoru[1*] ; HASHIGUCHI, Hiroyuki[1] ; TSUDA, Toshitaka[1]

[1]RISH, Kyoto University

Research Institute for Sustainable Humanosphere, Kyoto University (RISH) has been studying the atmosphere by using radars. The first big facility was the MU (Middle and Upper atmosphere) radar installed in Shiga, Japan in 1984. This is one of the most powerful and multi-functional radar, and is successful of revealing importance of atmospheric waves for the dynamical vertical coupling processes. The next big radar was the Equatorial Atmosphere Radar (EAR) installed at Kototabang, West Sumatra, Indonesia in 2001. The EAR was operated under close collaboration with LAPAN (Indonesia National Institute for Aeronautics and Space), and conducted the long-term continuous observations of the equatorial atmosphere/ionosphere for more than 10 years. The MU radar and the EAR are both utilized for inter-university and international collaborative research program for long time. National Institute for Polar Research (NIPR) joined EISCAT Scientific Association together with Nagoya University, and developed the PANSY radar at Syowa base in Antarctica as a joint project with University of Tokyo. These are the efforts of radar study of the atmosphere/ionosphere in the polar region. Now we can find that Japan holds a global network of big atmospheric/ionospheric radars. The EAR has the limitation of lower sensitivity compared with the other big radars shown above. RISH now proposes a plan of Equatorial MU Radar (EMU) that is to establish the MU-radar class radar next to the EAR. The EMU will have an active phased array antenna with the 163m diameter and 1055 cross-element Yagis. Total output power of the EMU will be more than 500kW. The EMU can detect turbulent echoes from the mesosphere (60-80km). In the ionosphere incoherent-scatter observations of plasma density, drift, and temperature would be possible. Multi-channel receivers will realizes radar-imaging observations. The EMU is one of the key element in the project ”Study of coupling processes in the solar-terrestrial system” for Master Plan 2014 of the Science Council of Japan (SCJ). We show the EMU project and its science in the presentation.

Development of a configurable digital receiver for atmospheric radars

YAMAMOTO, Masayuki[1*] ; GAN, Tong[1] ; FUJITA, Toshiyuki[1] ; NOOR HAFIZAH BINTI, Abdul aziz[1] ; OKATANI, Yoshikazu[1] ; HASHIGUCHI, Hiroyuki[1] ; YAMAMOTO, Mamoru[1]

[1]Research Institute for Sustainable Humanosphere, Kyoto University

Recent progress in radar imaging techniques enables high-resolution measurements of wind and turbulence by atmospheric radars. In order to implement radar imaging techniques to existing atmospheric radars, a cheap multi-channel receiver needs to be developed. Further, for improving and verifying radar imaging techniques, a digital receiver which can change its real-time signal processing is highly useful. We are now developing a low-cost configurable digital receiver. Because the digital receiver comprises a general-purpose software-defined radio receiver and a personal computer, its purchase cost is low and its real-time signal processing is easy to be implemented. In the presentation, we report the current development status of the digital receiver.

Statistical study of F-region field-aligned irregularities based on Equatorial Atmosphere Radar in Indonesia

DAO, Tam[1*] ; OTSUKA, Yuichi[1] ; SHIOKAWA, Kazuo[1] ; YAMAMOTO, Mamoru[2]

[1]STEL, Graduate School of Science, Nagoya University, [2]Research Institute for Sustainable Humanosphere, Kyoto University

I examined the statistical characteristics of Field-Aligned Irregularities (FAIs) echoes from the F-region of Ionosphere using Equatorial Atmosphere Radar (EAR) in Indonesia during three years from 2010 to 2012. We investigated the differences between post-sunset and post-midnight FAIs. Some results are analyzed in the daily and monthly average of echo power, spectral width, and Doppler velocity. We found that post-midnight FAIs occurred mostly in summer solstices from May to August in 2010 and 2011, and only in June and July in 2012. We realized some different characteristics between post-sunset and post-midnight FAIs observed from EAR as follow. (1) Echo intensity of the post-midnight FAIs is weaker than that of post-sunset FAIs. (2) The post-sunset FAIs often exceed an altitude of 450 km, whereas the post-midnight FAIs mostly occur in a range from 200 to 450 km in F-region. (3) Spectral width of the post-midnight FAIs is smaller than that of the post-sunset FAIs. These results suggest that plasma instability operates more actively at post-sunset than at post-midnight.

Statistical study of ionospheric irregularities by using Equatorial Atmosphere Radar

MARTININGRUM, Dyah rahayu[1*] ; YAMAMOTO, Mamoru[1]

[1]RISH, Kyoto University

The equatorial region is the source of many unique atmospheric processes that couple the entire atmosphere vertically from bottom to top and horizontally from equator to pole. The dynamical, electrodynamical, and electrical process of lower and upper atmosphere of equatorial region contribute to ionospheric irregularities through propagation of atmospheric waves, and magnetosphere-ionosphere interaction. Those process are responsible for the large degree of variabilities observed in the low latitude ionosphere.

Study of ionospheric irregularities was made during 2008-2013 by using 47 MHz Equatorial Atmosphere Radar (EAR) in Kototabang, Indonesia (0.20S, 100.32E; 10.36S dip latitude). Characteristic of echoes from ionospheric Field Aligned Irregularities (FAI) classified based on structure of E and F backscattered echoes power of EAR radar both of spatially and temporally. The results base on intermittent observations (2008-2010) and continuous observations (2011-2013). During the observations were obtained percentage of Equatorial Spread F (ESF) occurrences, diurnal and seasonal characteristics of ionospheric irregularities from the E region and also from F region. Furthermore, occurrence correlation between E and F region irregularities are also observed.

Lidar observations for study of coupling processes over the equatorial region

ABO, Makoto[1*] ; NAGASAWA, Chikao[1] ; SHIBATA, Yasukuni[1]

[1]Tokyo Metropolitan University

Stratosphere-troposphere exchange is important for the budget of ozone in the lower stratosphere as well as in the troposphere. Upward transport occurs in the tropical region (Brewer-Dobson circulation), but the exact mechanism controlling the transport is not clear. We have constructed the lidar facility for survey of atmospheric structure over troposphere, stratosphere, mesosphere and low thermosphere over Kototabang (100.3E, 0.2S), Indonesia in the equatorial region [1]. The lidar system consists of the Mie and Raman lidars for tropospheric aerosol, water vapor and cirrus cloud measurements, the Rayleigh lidar for stratospheric and mesospheric temperature measurements and the Resonance lidar for metallic species such as Na, Fe, Ca ion measurements and temperature measurements in the mesopause region. The laser system included in this lidar facility consists of three pulsed Nd:YAG lasers, a pulsed Ti:Sapphire laser seeded by a ring Ti:Sapphire laser and a dye laser. The most parts of this lidar system are remotely controlled via the Internet from Japan. The full lidar observations started from 2004. The routine observations of clouds and aerosol in the troposphere and stratosphere are continued now.

We found the top height of the stratospheric aerosol layer descend with time, synchronized with the QBO in the zonal wind. The QBO signals of the aerosol layer are noticed in the altitude range from 30 to 40 km. In addition, the tropospheric aerosol amount observed around the tropopause over Kototabang is much more than at mid-latitudes. They suspect that this is an evidence of active material exchange between the troposphere and the stratosphere over the equatorial region.

We have installed DIAL (differential absorption lidar) system for high-resolution measurements of vertical ozone profiles in the equatorial tropopause region over Kototabang, Indonesia. We will contribute to the elucidation of the climate change by getting observational information about high-resolution ozone density profiles, and the wave-propagation and material transportation using ozone as a tracer from the troposphere to the lower stratosphere over the equator.

There were many ozone DIAL systems in the world, but almost systems are optimized for stratospheric ozone layer measurement [2] or tropospheric ozone measurement [3]. Because of deep ozone absorption in the UV region, the wavelength selection is important. Simulation results show that we can measure above 20km with height resolution of 500m within 5% random error.

Microstructure of Precipitation over Indonesia from a Network of Parsivel disdrometers

MARZUKI, Marzuki[1*] ; HASHIGUCHI, Hiroyuki[2] ; YAMAMOTO, Masayuki[2] ; MORI, Shuichi[3] ; TAKAHASHI, Yukihiro[4]

[1]Department of Physics, Andalas University, Padang, Indonesia, [2]Research Institute for Sustainable Humanosphere (RISH) Kyoto University, Gokasho, Uji, Kyoto 611-001, [3]Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Yokosuka, Japan, [4]Hokkaido University, Sapporo, Japan

Insight into the regional variability of raindrop size distribution (DSD), is of primary importance for estimation of rainfall using remote sensing techniques, cloud/precipitation microphysical processes and numerical weather modeling. In order to quantify the regional variability of the DSD over Indonesia, a network of 4 Parsivel disdrometers along equatorial Indonesia has been designed. The disdrometers were installed at Kototabang (KT; 100.32E, 0.20S), Pontianak (PT; 109.37E, 0.00S), Manado (MN; 124.92E, 1.55N) and Biak (BK; 136.10E, 1.18S). It was found that the DSD at PT has more large drops than at the other three sites. The DSDs at the four sites are influenced by both oceanic and continental systems, and majority of the data matched the maritime-like DSD that was reported in a previous study. Continental-like DSDs were somewhat dominant at PT and KT. The combination of World Wide Lightning Location Network, wind profiler and the Tropical Rainfall Measuring Mission (TRMM) Precipitation Radar (PR) allows a discussion on physical basis behind the regional variability of DSD over Indonesia.

Feature studies of the polar lower thermosphere by EISCAT_3D

NOZAWA, Satonori[1*]

[1]STEL, Nagoya University

The new EISCAT_3D radar will give us with great opportunities. Its 3D volumetric observations of ion velocity will provide high quality neutral wind data in the lower thermosphere. Furthermore, its continuous observations will make it possible to study planetary waves in the lower thermosphere in more detail as well as day-to-day variabilities of tides. In this talk, we will describe our future study targets.

The lower thermospheric wind dynamics has been paid great attention for several decades to understand the Magnetosphere-Ionosphere-Thermosphere coupling, since the neutral atmosphere plays a key role. In particular, it has been an issue how the lower thermosphere will response to the solar wind energy input. IS radar measurements of the polar lower thermosphere begun about 40 years ago by a pioneer work of Brekke et al. [JGR, 78, 8235, 1973], and significant number of studies have been conducted since then. However, our understanding of the lower thermosphere is still limited. One of reasons is that the lower thermosphere is significantly influenced by atmospheric waves propagating from below. Thus, the day-to-day variability is very prominent. Owing to high running cost, long term datasets are hard to be obtained by IS radar a decade ago. In 2007-2008, EISCAT Svalbard radar was operated almost continuously for 1 year. However, only about 20% of the data sets can be used for deriving the ion velocity vector. If we have wind velocity datasets on daily basis like meteor and MF radars usually made for the mesospheric wind measurements (70-100 km), our understanding of the lower thermosphere wind dynamics will be much more progressed. EISCAT_3D will make it possible.

Furthermore, the EISCAT_3D radar will give us higher temporal resolution data sets of neutral winds in the lower thermosphere with multi volumes. The observations will allow us to distinguish the temporal and spatial variations of winds. One of scientific targets is to investigate wind variations nearby the auroral arc in the E-region. By combining sodium and Rayleigh LIDARs as well as meteor and MF radars, which provide neutral temperature and wind velocity, respectively, we expect we can investigate dissipation process of gravity waves in more details as well as effects of auroral precipitation on the middle atmosphere.

Observation of non-thermal planetary radio emissions with EISCAT 3D

TSUCHIYA, Fuminori[1*] ; MISAWA, Hiroaki[1]

[1]Tohoku University

EISCAT 3D is developing as incoherent scatter radar to study the terrestrial ionosphere and atmosphere. Due to large aperture area and low noise temperature of the receiving system of EISCAT 3D and the uniqueness of the receiving frequency of 233 MHz, it can also be a useful tool to study non-thermal radio emissions from the solar system planets. In this paper, feasibility and advantage of EISCAT 3D for observing non-thermal planetary radio emissions are presented. Following topics will be discussed. (1) Time variability of Jovian synchrotron radiation, (2) Radio emissions from lightning discharges occurred in the atmospheres of Mars and Saturn, and (3) Recent trials to detect incoherent radio emissions from extra-solar planets.

Numerical simulation of Generalized Auroral Computed Tomography toward its application to the EISCAT_3D project

TANAKA, Yoshimasa[1*] ; OGAWA, Yasunobu[1] ; KADOKURA, Akira[1] ; GUSTAVSSON, Bjorn[2] ; ASO, Takehiko[3] ; BRANDSTROM, Urban[4] ; MIYAOKA, Hiroshi[1] ; UENO, Genta[5] ; SAITA, Satoko[6]

[1]National Institute of Polar Research, [2]University of Tromso, [3]The Graduate University for Advanced Studies (Sokendai), [4]Swedish Institute of Space Physics, [5]The Institute of Statistical Mathematics, [6]Research Organization of Information and Systems

The EISCAT_3D is a next-generation phased-array incoherent scatter radar, which is capable of measuring three-dimensional (3D) ionospheric plasma parameters at ten-times higher temporal and spatial resolution. Thus, it is expected that the EISCAT_3D will provide new insights into auroral physics. On the other hand, optical imaging observation will be still useful for studying the auroral dynamics, because high-sensitivity camera can generally measure horizontal 2D distribution of the aurora at higher temporal resolution than the radars. We demonstrate by numerical simulation how useful monochromatic auroral images taken at multi-point camera network are for the study of aurora dynamics in the EISCAT_3D project. We apply the generalized - aurora computed tomography (G-ACT) to simulated observational data from real instruments, that is, the Auroral Large Imaging System (ALIS) and the EISCAT_3D radar. The G-ACT is a method to reconstruct three dimensional (3D) distribution of auroral emission and ionospheric electron density (corresponding to horizontal 2D distribution of energy spectra of precipitating electrons) from multi-instrument data. It is assumed that a core site of the EISCAT_3D radar is located at Skibotn (69.35N, 20.37E), Norway, and scans an area of 0.8 degrees in geographic latitude and 3 degrees in longitude at 130km altitude with 21x21 beams. Two neighboring discrete arcs are assumed to appear in the observation region of the EISCAT_3D radar. The reconstruction results from the G-ACT are compared with those from the normal ACT as well as those from only the electron density observed by the EISCAT_3D radar. It is found that the G-ACT can interpolate the ionospheric electron density at much higher spatial resolution than the original one observed by the EISCAT_3D radar. Furthermore, the multiple arcs reconstructed by the G-ACT are more precise than those by the normal ACT. Even for the case that the reconstruction by the ACT is difficult due to unsuitable location of the camera sites relative to the discrete arcs and/or a small number of available images, the G-ACT allows us to achieve the reconstruction.

Sodium atom layer is generally distributed at 80-100 km. One of mysterious subjects on high-latitude sodium layers is relationship between auroral particle precipitation and sodium atom layer variation. A previous study suggested a sodium column density decrease during a geomagnetic active period due to that the particle precipitation accompanied by electron density enhancement could induce ionization of sodium atom through their ion-molecule chemistry. Another study pointed a possibility of sodium density increase. For this reason, it is suggested that auroral precipitating particle bombardment on meteoric smoke particles can sputter sodium atoms from the smoke particles. On the other hand, ionospheric electric field, which may become more significant near auroral precipitating regions, could induce ion motions (i.e. can generate sodium ion convergence and/or divergence), and then also could affect generation and/or loss processes of sodium atoms through their ion-molecule chemistry. Thus, for the examination of the causality, it is vitally important to distinguish the effects of auroral particle precipitation and ionospheric electric field. Using a sodium lidar (which was installed in early 2010) and European incoherent scatter (EISCAT) radar at Tromsoe, Norway (69.6N, 19.2E), we have investigated, for the first time, that the actual effect of the particle precipitation to the sodium density variations without electric filed injection. In the nighttime observation on 24-25 January 2012, we detected a significant decrease of sodium atom density coincied with electron density enhancements (implying strong particle precipitations) and low ion temperatures (implying no electric field injections). These results strongly suggested that auroral particle precipitations induced sodium atom density decrease. Furthermore we discuss observed time response in the sodium density decrease.

The spatial and temporal evolution of equatorial plasma bubble observed using ground based GPS TEC measurement.

M BUHARI, Suhaila[1*] ; ABDULLAH, Mardina[2] ; HASBI, Alina marie[3] ; OTSUKA, Yuichi[4] ; NISHIOKA, Michi[5] ; TSUGAWA, Takuya[5]

[1]Physics Department, Universiti Teknologi Malaysia, [2]Space Science Centre, Universiti Kebangsaan Malaysia, [3]Department of Electrical, Electronics & Systems Engineering, Universiti Kebangsaan Malaysia, [4]Solar-Terrestrial Environment Laboratory, Nagoya University, [5]National Institute of Information and Communications Technology

The equatorial plasma bubble (EPB) commonly occurs near the equatorial region after post sunset period. The generation process of EPB has been well understood where it is commonly developed near the magnetic equator and elongated along magnetic field lines through Rayleigh-Taylor instability mechanism. However, the source of seeding perturbation leads to the generation of Rayleigh-Taylor instability is still unknown. The temporal and spatial properties of EPB have been well studied using airglow imager. However, the observation using airglow imager is impossible during sunset time where the EPB starts to develop due to light from the sun while the observation during night time is always interfered by moon and clouds.

In this study, we obtain the GPS data from Malaysia Real-Time Kinematics GNSS Network (MyRTKnet), International Ground Station (IGS) network and Sumatera GPS Array (SUGAR) network. The networks contains 127 receivers in South East Asia (SEA) region covers 8^{o}N to -8^{o}S latitude and 92^{o}E to 120^{o}E longitude geographic coordinates. In this study, we detected the structure of EPB using two-dimensional map of rate of TEC index (ROTI) calculated from ground based GPS TEC measurement in. The average ROTI value for all visible satellites at 300 km altitude is binned into 0.45^o x 0.45^o grid in geographic latitude and longitude. The advantage of this technique is the GPS data is always available and we are able to observe the spatial and temporal properties of EPBs continuously without distracted by light.

On the 17th March 2011, we observed the appearance of EPB structure pass through the SEA territory for 5 hours from 1300 UT (2100 LT) - 1900 UT (0200 LT). The initial ROTI-enhancement region is at 1300 UT is propagating to eastward direction and the information of the structure is lost due to the limited coverage of GPS receiver. At 1340 UT, a new ROTI-enhancement region appeared as a point source at geographic coordinate 2^{o}N and 98^{o}E as shown in Figure (a). After 20 minutes, the point source of ROTI-enhancement region expand to ˜600 km in the North and ˜200 km South direction as shown in Figure (b) while the zonal size ˜50 km remains the same. The perturbation region is expanding faster towards dip magnetic equator might associated with field-aligned irregularities. The structure travelled in eastward direction with velocity ˜133 ms^{-1} until the development process stopped. After 60 minutes, we assumed the structure is fully developed as illustrated in Figure (c) when no development in zonal size and ROTI value is observed anymore. The developed structure has 200 km zonal size continuously moves to eastward directions with slower velocity ˜111 ms^{-1}. The slower velocity incidentally with no development in zonal size and ROTI value might indicates the ”fossil” bubble where the plasma density is equal with background density and the structure velocity following the background plasma density. At 1440 UT the second structure is coming ˜600 km away from the first structure with velocity ˜111 ms^{-1} and zonal size 200 km same as the previous structure as shown in Figure (d). The first and second structure has the same zonal sizes and velocities might due to the same temporal and spatial evolution during the generation process.

The two-dimensional structure of EPB has been presented using GPS networks in SEA region is an alternative tool to observe the temporal and spatial properties of EPB structure from the initial perturbation until the decaying process without being distracted by light. The temporal and spatial properties of EPB can contribute towards understanding the generation mechanism of the Rayleigh-Taylor instability process.

Relationship between Latitudinal Extension of Scintillation and Pre-reversal Enhancement in the Southeast Asian Region

ABADI, Prayitno[1*] ; OTSUKA, Yuichi[2] ; HUSIN, Asnawi[1] ; JIYO, Jiyo[1] ; YAMAMOTO, Mamoru[3] ; TSUDA, Toshitaka[3]

[1]National Institute of Aeronautics and Space (LAPAN), [2]STEL, Ngoya University, [3]RISH, Kyoto University

We have investigated the relationship between the maximum latitude extension of observed scintillations (Lmax) and the maximum altitude of the equatorial F-region bottomside (h'Fmax), peak of eastward electric field (Emax), and time duration of eastward electric field (TE) during PRE period in the equatorial region. We used three GPS receivers installed in Kototabang (0.2S, 100.3E; 10.0N magnetic latitude), Pontianak (0.02S, 109.3E; 8.9S magnetic latitude), and Bandung (6.9S, 107.6E; 17.5S magnetic latitude), Indonesia for observing scintillation activity in period 18.00-22.00 LT (LT=UT+7h) and two frequency modulated-continues wave (FM-CW) ionosondes installed near equator magnetic, Chumphon (10.7N, 99.4E; 3.3N magnetic latitude), Thailand and Bac Lieu (9.3N, 105.7E; 1.7N magnetic latitude), Vietnam for measuring PRE parameters, such as h'F, vertical drift (dh'F/dt) which indicates eastward electric field, and TE. Our observation period is during equinox months (March, April, September, and October) in 2010, 2011, and 2012. We divide the relationships into two groups; 1) the relationships between PRE parameters obtained from Chumphon ionosonde and Lmax observed by Kototabang and Bandung GPS receivers and 2) PRE parameters obtained from Bac Lieu ionosonde and Lmax observed by Pontianak and Bandung GPS receivers. The following table is to show the coefficient correlation (R) of the relationships for each group. The results indicate that duration of eastward electric field does not play an important role for extension of the plasma bubble or latitudinal extension of scintillation, and that the peak of h'F and magnitude of E at the initial phase of plasma bubble generation (PRE period) is a primary factor for the plasma bubble extension. Therefore, the maximum latitude of scintillation is determined at the initial phase of plasma bubble generation (PRE period) in the equatorial region.

Relationship	R (group 1)	R (group 2)
h'Fmax vs Lmax	0.596	0.471
Emax vs Lmax	0.489	0.270
TE vs Lmax	0.054	0.090

Geolocation of lightning discharge in the Maritime Continent based on radio observation in 0.1-40 kHz band

YAMASHITA, Kozo[1*] ; OHYA, Hiroyo[2] ; TAKAHASHI, Yukihiro[3] ; TSUCHIYA, Fuminori[4] ; MATSUMOTO, Jun[5]

[1]Salesian Polytechnic, [2]Chiba University, [3]Hokkaido University, [4]Tohoku University, [5]Tokyo Metropolitan University

Recent researches based on observation and data assimilation of lightning discharge indicate a possibility of now-cast and forecast of severe weather such as torrential rain. In these works, lightning data is focused on as a proxy for the presence or absence of deep convection which generates thunderstorm.

In previous works, occurrence of cloud-to-ground (CG) lightning discharges has been mainly used due to the ease of data availability. However, lighting observation based on electromagnetic measurement shows that there is extremely huge scale lightning whose scale is more than hundreds times bigger than that of averaged event. Lightning data including ″ occurrence ″ and ″ scale ″ enable us to evaluate not only existence but also intensity of atmospheric convection. Quantitative evaluation of atmospheric convection would make it possible to make a now-cast and forecast for intensity distribution of precipitation.

The Maritime Continent (MC) is one of the most important regions for lightning observation in the world. Thunderstorm activity causes enormous human and economic damage to countries in MC. However, until now, only few statistical studies on the lightning activity with scale information of lightning discharge have been done.

In this works, lightning observation network in the MC based on electromagnetic measurement in 0.1-40 kHz band is summarized. This network is developed to estimate not only spatial distribution but also scale one of lightning discharges. We have already constructed observation stations at Tainan in Taiwan (23.1N, 121.1E), Saraburi in Thailand (14.5N, 101.0E), Pontianak in Indonesia (0.0N, 109.4E), Los Banos in Philippines (14.2N, 121.25E) and Son Tay in Viet Nam (21.1N, 105.5E). Data obtained by multipoint observation is synchronized by GPS receiver installed at each station.

At the presentation, we show evaluation of accuracy for geolocation and detection efficiency of signal radiated from lightning discharge based on comparisons with World Wide Lightning Location Network (WWLLN) data.

A study on a low Earth orbit (LEO) satellite mission using radio propagation characteristics

TAKEDA, Yuji[1*] ; TSUDA, Toshitaka[1]

[1]Research Institute for Sustainable Humanosphere, Kyoto University

We study in this paper an Earth observation mission with a low Earth orbit (LEO) satellite using radio propagation characteristics on L (1.2-1.6 GHz for GPS) and Ka (17.3-20.2 GHz for O3b satellite) bands . In particular, applying GPS radio occultation (GPS RO) technique, we aim to obtain profiles of atmospheric parameters (humidity, temperature and electron density) with a good height resolution, covering a wide area. We also measure cloud water content and vapor distribution by using radiometer technique on Ka-band.

Radio occultation employs propagation delay and bending of radio waves in the atmosphere. Though GPS satellites hitherto has been used for observing radio occultation, we use not only GPS but also other GNSS satellites (GLONASS, Galileo, Beidou, and QZSS), moreover we further use O3b(Other 3 billion people), which is a communications satellite, then, we can increase number of observation points of RO.

Because the observation point of RO is determined by the relative location between the LEO satellite and transmitting satellites, we used a numerical model to investigate the data distribution of RO and proposed an optimal satellite orbit for a new LEO satellites mission. The model analysis shows that using GNSS and O3b satellites for RO the total number of RO data becomes approximately three times larger than those by using only GPS satellites. The analysis also shows that the longitudinal distribution of RO data does not depend on orbit of the LEO satellite, but, the latitudinal distribution is largely affected by an inclination angle of LEO satellite. Data distribution as function of local time varies by inclination and longitude of ascending node of LEO satellite.

We also investigate application of O3b operated on Ka-band, which is approximately ten times higher than L-band. So Ka-band is less sensitive to the ionosphere, but it is greatly attenuated by cloud water and vapor. In GPS RO on L band, atmospheric profiles at high-altitude (50km-) are not determined accurately because of influence of ionosphere. But using Ka-band of O3b we will be able to increase the maximum height of the profiles. Moreover, we expect to measure cloud water content and vapor distribution by using attenuation of Ka-band.

The Global Lightning and sprIte MeasurementS (GLIMS) on the International Space Station (ISS) is a mission to detect and locate optical transient luminous events (TLEs) and its associated lightning simultaneously from the non-sun synchronous orbit, and was launched successfully in July, 2013 as part of the multi-mission consolidated equipment on Japanese Exposure Module (JEM). Our mission goals are to identify temporal and spatial evolutions of lightning and TLEs and to clarify the occurrence conditions of TLEs and global occurrence locations and rates of TLEs from the nadir observation. To achieve these goals, two CMOS cameras, six Photometers, VLF receiver, and VHF interferometer with two antennas, are installed at the bottom of the module to observe the TLEs as well as causative lighting discharges at nadir direction during day and night time. Though the luminous events so-called sprite, elves and jets have been investigated by numerous researchers all over the world based mainly on the ground observations, some important problems have not been fully understood yet such as generation mechanisms of columniform fine structure and horizontal offset of some sprites from the parent lightning discharges. In the JEM-GLIMS mission, observations from our synchronized sensors are going to shed light on above-mentioned unsolved problems regarding TLEs as well as causative lighting discharges.

The optical instruments are two CMOS cameras (LSI-1, LSI-2) and six-channel spectrophotometers (PH1 - PH6). The FOV of LSI is 28.3 deg. x 28.3 deg., and LSI-1 (LSI-2) equips a 766-832 nm wide band filter (a 762+/-7 nm narrow band filter). Each PH channel equips the optical band-pass filter, and these photometers measure the N2 1P, N2 2P, N2 LBH, and N2+ 1N emissions of lightning and TLEs. The radio receivers consist of one VLF receiver (VLFR) and two sets of VHF receivers (VITF). In order to detect TLE-associated whistler waves, VLFR employs a nadir-directing monopole antenna and an electronics unit recording waveform data with a sampling frequency of 100 kHz with 14-bit resolution. VITF consists of two patch-type antennas separated by 1.5 m and an electronics unit, and VITF mainly observes VHF pulses in the frequency range of 70-100 MHz excited by lightning discharges with a sampling frequency of 200 MHz with 8-bit resolution.

JEM-GIMS was successfully launched and transported to the ISS by the H-II Transfer Vehicle (HTV) No.3 cargo transporter at the end of July 2012, and started its operation from December 2013. So far, more than one thousand events were recorded. In this presentation, mission history and overview will be given as an introdution.

The present study analyzes satellite optical data to evaluate the effectiveness of spaceborne spectrophotometric measurement in characterizing properties of lightning flash. The main data analyzed here are those obtained by FORMOSAT-2/ISUAL limb observation and ISS/GLIMS nadir observation. While ISUAL spectrophotometer observes optical emissions of 150-280, 316, 337, 392, 762, 600-900 nm at a sampling rate of 10 kHz, GLIMS observes emissions of 150-280, 337, 762, 600-900, 316, 392 nm at a rate of 20 kHz. These data for the first time derive fine spectral and temporal properties of lightning emission observed from space. By analyzing the ISUAL optical data and ground-based radio data, we found that spectral intensity ratio is a new parameter to discriminate intra-cloud (IC) and cloud-to-ground (CG) lightning discharges: the blue/red intensity ratio of CG strokes tends to be lower than that of IC pulses. We also found similar tendency in GLIMS lightning events. A case study showed that the color of lightning turned to red when a very bright impulsive emission, which is consistent with a ground return stroke, occurred. These results consistently suggest that the color of CG component is redder than that of IC component, and we explain this as a result of the Rayleigh scattering which effectively attenuates blue light emissions in the case of light sources located at lower-altitudes such as CGs. Using this technique, we will further examine the lightning characteristics on a global level, focusing on latitudinal dependences and land/ocean contrast for example.

In this paper we report the preliminary results of ionospheric perturbation and causative lightning discharges observed by JEM-GLIMIS mission to study the electromagnetic coupling mechanism between the tropospheric lightning and overlaying ionosphere. Continuous nadir optical observations of lightning discharges are performed by ISS JEM-GLIMS mission and many lightning images have been observed globally. Ionospheric perturbations and electrical properties of causative lightning discharges such as polarity and vertical charge moment changes are derived by the data from UEC's ground-based observation networks of VLF/LF transmitter signal reception and of ELF waveforms respectively. We discuss the electrical coupling efficiencies from the tropospheric lightning to the ionosphere by comparing the area of the lightning flash and corresponding subionospheroic VLF disturbances and lightning properties.

The building of multipoint measurement network for observing electrostatic field changes caused by lightning discharge

SAKAI, Rikuma[1*] ; TAKAHASHI, Yukihiro[1] ; SATO, Mitsuteru[1] ; KUDO, Takeshi[1]

[1]Cosmosciences, Hokkaido Univ.

It’s not easy to understand the developing process of thunderstorm only with existing meteorological measurements because of its small spatial scale (less than an order of 1 km) and rapid change of the complicated structure. Electrostatic field under the thundercloud or its predecessor reflects the distribution of electrical charges, which is the result of frictions between ice crystal and hail due to strong vertical wind inside the thundercloud. If we measure the vertical electric field at multipoints on the ground, we could estimate the 3 dimensional distribution or the changes of the distribution of electrical charges, from which we may know the detailed development of thunderstorm. The traditional equipment for atmospheric electrostatic filed measurement is filed-mill sensor, which costs an order of 1 M JPY. In order to increase the number of observing stations, we should reduce the price of the instrument. Here we introduce a thunderstorm observation campaign, carried out in mountain area of Yamanashi prefecture, August 2013.We developed new plate-type electric filed sensor, which costs about 0.2 M JPY or less including recording device and battery for one site.This sensor was placed at seven locations in every 4 km with recording system and GPS clock.As a result, we succeeded to record the electrostatic field changes at the same time in multi points, which occured due to lightning strikes for three days.

Global Lightning and sprIte Measurements (GLIMS) mission is now ongoing on Exposed Facility of Japanese Experiment Module (JEM-EF) of the International Space Station (ISS). This paper focuses on an electromagnetic (EM) payload of JEM-GLIMS mission, very high frequency (VHF) broadband digital InTerFerometer (VITF). JEM-GLIMS mission is designed to conduct comprehensive observations with both the EM and the optical payloads for lightning activities and related transient luminous events (TLEs) expecting to give us many scientific impacts to the field.

VITF consists of two sets of antennas, band-pass filters, amplifiers, and 2-channel-AD-converter. Impulsive EM radiations received by the antennas are digitized by the AD converter synchronizing with another channel through the filters and the amplifiers. A patch type antenna is developed within the size of 200∗200 mm. It is mounted on the antenna base made of aluminum alloy and Teflon block with the total height of 100 mm to gain its bandwidth and to reduce the interference from other structural objects. The same two units of antennas are installed with the separation of 1.6 m. Their bandwidths with the higher return loss than -3 dB are from 70 to 100 MHz. The signals received by the antenna are transmitted along cables with the same lengths to the electronics. The AD converter records 130 waveforms as maximum of one dataset with the duration of 2.5 μs with 200 MS/s. The developments of VITF are based on the heritage of VHF sensor on Maido-1 satellite.

JEM-GIMS mission payload was successfully launched at the end of July 2012, and transported and installed to the ISS. After the initial checkout and maintenance, its nominal operation is continued from December 2012. Through the operation period, VITF corrects numerous VHF EM data synchronized with optical signals. About 650 VITF datasets were obtained in January and February 2013, for instance. The estimations of the EM direction-of-arrival (DOA) are attempted using the broadband digital interferometry. Some results agree with the optical observations, even though DOA estimation has difficulties caused by its very short baseline of the antennas and multiple pulses in short time, namely burst-type EM waveforms. VITF is designed expecting to estimate the DOA with about 10 km resolution that is equivalent to the scale of a thundercloud. The results on narrow bipolar pulses (NBPs) and/or transionospheric pulse pairs (TIPPs) are also expected as well as TLEs. The recorded VHF EM signals and the results of their DOA estimations, and the comparisons with optical observations will be introduced in the presentation.

Numerical Modeling of the Three-Dimensional Magnetic Fields and Eruption in the Solar Active Region 11158

INOUE, Satoshi[1*]

[1]School of Space Research, Kyung Hee University

Solar flares and coronal mass ejections (CMEs) are considered as sudden liberation of magnetic energy in the solar corona, which affect geospace in the form of electromagnetic disturbance called geomagnetic storms. Unfortunately, measurement based on vector field observations only provide the two-dimensional information of magnetic field on the photosphere, therefore, we could not reach on a common understanding yet regarding to the three-dimensional (3D) magnetic structure causing the eruptive phenomena and associated dynamics. In order to clarify them, in this study we first extrapolate a 3D coronal magnetic field under the Nonlinear Force-Free Field (NLFFF) approximation based on the vector field, using the Magnetohydrodynamic (MHD) relaxation method developed by Inoue et al. 2014, and then compare the 3D structures before and after the flare. Next we perform an MHD simulation to clarify the dynamics during the flare where the NLFFF prior to the flare is set as an initial condition. Photospheric vector field was observed at 00:00 UT and 03:00 UT on February 15 corresponding to before and after the X2.2-class flare taking place around at 01:50 UT, taken by the Helioseismic And Magnetic Imager (HMI) on board the Solar Dynamics Observatory (SDO) satellite.

As a result, we found that the NLFFF has strongly twisted field lines; most of them are in the range from half-turn to one turn twist, being resided above the polarity inversion line. Furthermore, we found that a distribution of these footpoints well captures the flare ribbons observed by Hinode where Ca II emission is strongly enhanced. On the other hand, because the most of these strongly twisted lines disappear after the flare, consequently the twisted field lines having more than half-turn twist play an important role on causing the large flare. The MHD simulation successfully shows an eruption of the more strongly twisted lines whose values are over one-turn twist, which are produced through the magnetic reconnection in strongly twisted lines of the NLFFF. Eventually, we found that they exceed a critical height at which the flux tube becomes unstable to the torus instability determining the condition that whether a flux tube might escape from the overlying field lines or not. In addition to these, during the eruption, we found that the distribution of the observed two-ribbon flares is similar to the spatial variance of the footpoints caused by the reconnection of strongly twisted lines with more than half-turn twist. Furthermore, because the post flare loops obtained from MHD simulation well capture that in EUV image taken by SDO, these results support the reliability of our simulation.

Study on Triggering Process of Solar Flare on the basis of Satellite Observation

BAMBA, Yumi[1*] ; KUSANO, Kanya[1] ; IMADA, Shinsuke[1]

[1]STEL, Nagoya Univ.

Solar Flares are explosive phenomena driven by magnetic energy stored in the solar corona. Because interplanetary disturbances associated with solar flares sometimes impact terrestrial environments and infrastructure, understanding the flare-triggering process is important not only from a solar physics perspective but also for space weather forecasting. There are numerous observational studies and simulations which attempted to reveal the onset mechanism of solar flares. Because different observations support different models, the underlying mechanism of flare onset remains elusive. Thus the predictability of flare occurrence remains limited.

We have analyzed several flare events obtained by the Solar Optical Telescope (SOT) onboard the Hinode Satellite in order to elucidate flare trigger mechanism [*Bamba et al.* 2013]. We investigated the spatio-temporal correlation between the detailed magnetic field structure and the chromospheric pre-flare emission at the central part of flaring regions for several hours prior to the onset of flares. We observed that the magnetic shear angle in the flaring regions exceeded 70 degrees, as well as that characteristic magnetic disturbances developed at the centers of flaring regions in the pre-flare phase. The observed signatures strongly support the idea of flare trigger mechanism presented by *Kusano et al.* (2012), which proposed that solar flares can be triggered by the interaction between the sheared arcade and one of the two types of small magnetic disturbances. Hence, we could classify the events into two groups depending on the structure of their magnetic polarity inversion lines; to the so-called " Opposite-Polarity (OP) " and " Reversed-Shear (RS) " magnetic field. Furthermore, we studied how small magnetic field can work for triggering flares based on the Hinode observations. The results indicate that the critical amount of magnetic flux for the small magnetic field to trigger flares, depends on the magnetic connectivity in the flaring site, and it varies even within an active region.

However, only four Hinode data sets habe been utilizable for the analyze of this study because of the SOT ' s limited field of view (FOV) (328 " × 164 " for Narrow-band Filter Imager, 218 " × 109 " for Broad-band Filter Imager). Therefore, we applied the analysis method of *Bamba et al.* (2013) to the data obtained by the Helioseismic and Magnetic Imager (HMI) and the Atmospheric Imaging Assembly (AIA) onboard the Solar Dynamics Observatory (SDO), which has a full-disk FOV (2000 " × 2000 ") in order to increase the number of event analysis. We chose the flare events observed by SDO until 31 Jan. 2014, larger than M5.0 GOES class. Eleven X-class and twenty M-class events meet this condition, and we classified these events into independent 6 types by using following three conditions: (1) whether the initial flare kernels has obvious and sheared two-ribbon structure, (2) whether the chromospheric brightening was observed at the center of sheared ribbon, (3) the results of measurement of the magnetic shear angle θ and the azimuth of flare trigger field ϕ.

In this presentation, we would like to report the result of comparative study of Hinode and SDO. We would like to also introduce our preliminary result of statistical flare trigger study using SDO/HMI and AIA.

X5.4 flare on 7 March 2012: magnetic and velocity properties at the solar surface

SHIMIZU, Toshifumi[1*] ; LITES, Bruce[2] ; BAMBA, Yumi[3]

[1]ISAS/JAXA, [2]HAO/NCAR, [3]Nagoya University

Solar flares abruptly release the free energy stored as a non-potential magnetic field in the corona and may be accompanied by eruptions of the coronal plasma. Formation of non-potential magnetic field and the mechanisms on triggering the onset of flares are still unclear; Especially, dynamical behaviors observed around polarity inversion lines producing major flares observationally. This presentation will discuss X5.4 flare on 7 March 2012 with emphasis on magnetic and velocity field properties at the solar surface. The coronal mass ejection launched at the same time as the X5.4 flare propagated through interplanetary space and caused a large geomagnetic storm on 9 March. One of remarkable properties to be discussed is a high-speed material flow existing along the polarity inversion line located between flare ribbons at the main energy release side. The high-speed material flow was observed in the horizontally oriented magnetic field formed nearly in parallel to the polarity inversion line and it existed at least from 6 hours before the onset of the flare and continued at least for several hours after the onset of the flare. Observations suggest that the observed material flow represents neither the emergence nor convergence of the magnetic flux. It may be rather considered as material flows working for increasing the magnetic shear along the polarity inversion line and for developing the magnetic structures favorable for the onset of the eruptive flare.

Estimation of Astronaut Dose inside the Kibo Module during Large Solar Flare Events

SATO, Tatsuhiko[1*] ; KATAOKA, Ryuho[2] ; NAGAMATSU, Aiko[3]

[1]Japan Atomic Energy Agency, [2]National Institute of Polar Research, [3]Japan Aerospace Exploration Agency

Forecast of radiation doses for astronauts as well as aircrews due to the exposure to solar energetic particles (SEP) is one of the greatest challenges in space weather research. In last 3 years, we have developed a warning system of aviation exposure to solar energetic particles: WASAVIES, which can predict the SEP doses at any flight conditions within 2.5 hours after the onset of ground level enhancements (GLE). In this system, the SEP fluxes incident to the atmosphere are calculated by physics-based models [1,2], and they are converted to radiation doses using a database developed on the basis of air-shower simulation [3]. In this study, we applied the same physics-based models to the estimate of the SEP fluxes on the orbit of International Space Station, and converted the fluxes to radiation doses for astronauts staying inside the Kibo module. For this conversion, we performed Monte Carlo cosmic-ray transport simulation, using the Particle and Heavy Ion Transport code System PHITS [4] in combination with the realistic 3D model of the Kibo module. A brief outline of WASAVIES together with the results of the astronaut dose estimation will be presented at the meeting.

WASAVIES: Warning System for Aviation Exposure to Solar Energetic Particles

KATAOKA, Ryuho[1*] ; SATO, Tatsuhiko[2] ; KUBO, Yuki[3] ; SHIOTA, Daikou[4] ; KUWABARA, Takao[5] ; YASHIRO, Seiji[6] ; YASUDA, Hiroshi[7]

[1]NIPR, [2]JAEA, [3]NICT, [4]Nagoya University, [5]Delaware University, [6]CUA, [7]NIRS

Solar energetic particles (SEP) sometimes induce air shower that significantly increase the radiation dose at flight altitudes. In order to inform the situation of such a space radiation hazard to aircrews, a physics-based forward model is developed as WASAVIES (Warning System for Aviation Exposure to SEP) based on focused transport equation and Monte Carlo particle transport simulation code PHITS. WASAVIES gives the fastest and simplest way to predict the time profile of dose rate during ground-level enhancements (GLEs).

Plan of large SPE search by the 14C content measurement in Japanese trees for the past 5000 years

MIYAKE, Fusa[1*] ; MASUDA, Kimiaki[1] ; HAKOZAKI, Masataka[2] ; NAKAMURA, Toshio[2] ; KIMURA, Katsuhiko[3]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Center for Chronological Research, Nagoya University, [3]Faculty of Symbiotic Systems Science, Fukushima University

Radiocarbon (^{14}C) is produced by incoming cosmic rays to the Earth. Produced ^{14}C becomes $^{14}CO_2$ and is absorbed by trees by photosynthesis. Then,tree-rings record the past cosmic ray intensity. Rapid yearly increases in the ^{14}C content have been detected for the period from AD 774 to AD 775 and from AD 993 to AD 994. Althogh some candidates for the cause of these cosmic-ray invents have been considered, it has been considered that the solar activity (large SPE) is the most plausible cause.

There is the possibility that a lot of ^{14}C increase events like the AD 775 one are hidden in the periods when the ^{14}C content has not been measured with a 1-year resolution. If we detect such events, we are able to discuss a detailed occurrence rate of large SPE which is very important factor to prepare for future large SPEs.

We are planning to search for ^{14}C increase events by the measurements of ^{14}C content in Japanese trees for this 5000 years. In this thesis, we are going to explain the plan and problems.

End-Cretaceous mass extinction driven by the encounter with a dark cloud

NIMURA, Tokuhiro[1*] ; EBISUZAKI, Toshikazu[2] ; MARUYAMA, Shigenori[3]

[1]Okayama Astronomical Museum, [2]RIKEN, [3]Earth-Life Science Intitute, Tokyo Institute of Technology

We found that a significant positive broad component of iridium in a pelagic deep sea sediment core (886C) around an iridium peak by asteroid impact corresponds at the K-Pg boundary. The 886C is core sample was taken by the Ocean Drilling Program (ODP) in the central portion of the North Pacific. This site has been in Pelagic from the End-Cretaceous periods. The accumulation rate is 0.5 m Myr^{-1}. Kyte et al., (1995) measured iridium density in the 886C core of 0.75-72.2 m which corresponds of $\sim$80 Ma from the present. In this data, there is one sharp peak around 65.5 m correspond at K-Pg boundary. In addition, we found that there are broad components across $\sim$20 m above the back ground which have some sharp peak component. The Ir value of the broad component which is about dozen times of back ground. This broad component is difficult to be explained by the materials on the surface of the Earth, and requires the contribution from the iridium-rich extraterrestrial materials, such as CI chondrite. And it is difficult to explain the broad component by diffusion and bioturbation of an iridium peak by asteroid impact. Platinum-group-element such as Pt, Re and Ir are redistributed by changes in sedimentary redox condition. However such change can probably account for many of small $<$10 cm (Colodner et al., 1992) and the mean global depth of marine bioturbation was calculated to be 9.8$\pm$4.5 cm (Boudreau, 1994). And also an evidence of bioturbation was not found from lithofacies (Proc. ODP, Init. Repts., 145).

We consider that the broad component can be caused by an encounter of the solar system with a dark cloud with a size of $\sim$100 pc and the central density of over 2000 protons/cc in the galactic disk and estimated that the flux of exosolar material began $\sim$73 Ma and has run through $\sim$8 Myr. By the Kataoka's "Nebula Winter model" (Kataoka 2013), dark cloud can lead to an environmental catastrophe to the Earth from a few kiloannum to megaannum. The dark cloud encounter enhances a flux of cosmic dust particles and cosmic rays which lead to global cooling and destruction of the ozone layer.

The solid particles from the dark cloud accrete on the Earth and in the stratosphere, stay for a several months; their sunshield effect is as large as -9.3 W m^{-2}. The climate cooling in the End-Cretaceous period is also suggested by the variations of stable isotope rations in oxygen and strontium (Brian and Huber, 1990; Barrera and Savin, 1999; Li and Keller, 1998). Any photosynthetic plants had heavy damaged, and loss of biodiversity began to the top of food chain.

The mass extinction at K-Pg boundary, which is widely thought to be caused by an impact of an asteroid (e. g., Schulte et al., 2010). However, a complete extinction of level of family by asteroid impact seems rather difficult. First, a severe environment turn-over would finish few years after impact, the solid particles and sulphate launched by the asteroid impact was settled down for only few month (troposphere) to few years (stratosphere) and negative radiative forcing became negligible after a few years from the impact (Pierazzo, 2001).The number of individuals would recover completely after the environmental catastrophe was over, if a few percent of individuals of one species survived.

Second, in spite of there were similar impacts without catastrophic on the Earth, for example, Alamo, Woodleigh, and Popigai crater, there are no evidences of association for extinction. However, because the encounter with the dark cloud perturbs the orbit of asteroid or comet by its gravitational potential and may lead an asteroid or comet shower, the asteroid impact at K-Pg may be one of the consequences of the dark cloud. For a certainly, only an asteroid impact cannot involve mass extinction, however may be role cruncher. The multiple impact and volcanism in a short period of time (Keller, 2005) may have been caused by encounter the dark nebula and attendant cosmic ray, respectively.

Update on the US GIC activities and generation of benchmark geomagnetic disturbance (GMD) scenarios

PULKKINEN, Antti[1*]

[1]NASA GSFC

The awareness about potential major impacts of geomagnetically induced currents (GIC) has drawn a high level action in the US and in Canada. More specifically, regulatory process has been launched to generate standards for GIC hazard assessments and mitigation procedures. All US high-voltage power transmission-related entities need to follow the standards in the near future. One of the central GIC activities in the US has been the North the American Electric Reliability Corporation's (NERC) GMD Task Force that has allowed in-depth communication and collaboration between US federal organizations, power transmission operators and scientific research community. I will discuss these activities in this paper and outline the road ahead for some of the key US GIC activities.

As a part of the GMD standards drafting process and the US GIC hazards assessments, substantial effort has been made for generating benchmark GMD scenarios. These scenarios that quantify extreme geoelectric field magnitudes and temporal waveforms of the field fluctuations are the foundation for subsequent engineering analyses. The engineering analyses will include the transmission system voltage stability and transformer heating assessments. The work on the GMD scenarios has been a major collaboration between a number of US and Canadian entities involved in GMD research and transmission system operations. I will discuss in this paper also the key elements of the benchmark GMD generation process and show the latest results from our NASA GSFC work on the topic.

Spatial distribution of nonthermal electrons in an X-class flare on 13 May 2013

MASUDA, Satoshi[1*]

[1]STEL, Nagoya Univeristy

Four X-class flares took place in May 2013. Fortunately three of four were observed with Nobeyama Radioheliograph (NoRH). One of them occurred behind the east limb on 13 May 2013. It is a good chance to investigate the height distribution of nonthermal electrons in the solar corona. In the framework of the standard flare model based on magnetic reconnection, Minoshima et al. (2011) showed that the height distribution of accelerated/heated electrons depends on the energy of the electrons. NoRH has a capability to observe a solar flare in 17 and 34 GHz with a high time resolution (100 ms). The energy of electrons emitting microwaves is very high (˜MeV), and the mean-energy emitting 34 GHz is higher than that for 17 GHz. Hard X-rays are emitted by relatively lower-energy (˜100 keV) electrons. So this dataset can cover a wide energy range of accelerated electrons. In order to understand the electron acceleration/transport/loss processes, multi-wavelength observation is crucially important. The 13 May 2013 flare was simultaneously observed with NoRH and RHESSI (The Reuven Ramaty High Energy Solar Spectroscopic Imager). Investigating the distribution of these emission sources in the solar corona, we discuss the electron acceleration/transport/loss processes.

An energetics study of X-ray jets using Hinode/XRT observation

SAKO, Nobuharu[1*] ; SHIMOJO, Masumi[2] ; WATANABE, Tetsuya[2] ; SEKII, Takashi[2]

[1]The Graduate University for Advanced Studies, [2]National Astronomical Observatory of Japan

For plasma acceleration in X-ray jets in the solar corona, three mechanisms have been considered, based on the model of X-ray jets by magnetic reconnection (Shibata et al. 1992); The reconnection jet produced by magnetic tension, the evaporation flow produced by pressure gradient, and the twisted jet produced by magnetic pressure. There are some evidences of X-ray jets in active regions (ARs) produced by pressure gradient. On the other hands, there is no observational evidence of X-ray jets by the other forces except the result of a high-speed jet. In order to distinguish the evaporation flow from the other types of jets, I have studied the energetics of the X-ray jets.

Using over 100 X-ray jets greater than 3×104 km in length in ARs, quiet regions (QRs), and coronal holes (CHs), I have found no large differences in the life time, the width of the jets, and the area of the footpoint flares in such regions. On the other hands, the plasma number density of the X-ray jets and flares in ARs is ten times larger than those in QRs and CHs. Assuming the energy balance between conductive flux and heat flux by the footpoint flare, we estimate the temperature of the jets. The AR jets has a wide range of the temperature (1 MK-9 MK), while the temperature of most X-ray jets in CH and QR is $1\sim2$ MK. In my presentation, I will discuss a relationship of the speed with the temperature of the jets.

Lower temperature response of an EUV wave observed by Hinode/EIS and SDO/AIA

LEE, Kyoung sun[1*] ; KWON, Ryun young[2] ; BROOKS, David[2] ; SHIMIZU, Toshifumi[1]

[1]ISAS/JAXA, [2]George Mason University

We investigate an EUV wave observed by Hinode/EIS and SDO/AIA on 2011 August 04. The EUV wave propagates across the solar disk and the wave front passing through a remote active region (AR 11263) is observed by EIS. This EUV wave has already been analyzed using coronal lines, but the lower temperature response to the EUV wave has not been investigated. Using multi-wavelength observations from EIS and AIA, we determined the intensity and Doppler velocity variation of different temperature lines and compared them. From the comparison, we found an enhancement of the intensity at lower temperatures before the intensity increase seen in the coronal filters of AIA. And a significant enhancement of the red shift (10 km/s) in the lower temperature line (Si VII, log T ˜5.8) compared to the increase of the red shift (˜3 km/s) in coronal lines (Fe XII, FeXIII, and Si X, log T ˜6.1-6.2) when the EUV wave interacts with the active region. We will discuss the impact of the EUV wave on the lower temperature emission.

Imaging, spectroscopic and stereoscopic observations of the bi-directional inflow in the solar flare

MATSUI, Yuki[1*] ; YOKOYAMA, Takaaki[1]

[1]University of Tokyo

The standard model of solar flares based on the magnetic reconnection includes bi-directional inflow toward the reconnection point. Corresponding to the bi-directional inflow, high temperature loops like a cusp shape are formed due to the magnetic reconnection. By combination of imaging, spectroscopic and stereoscopic observations, we succeeded in capture the three-dimensional structure of a bi-directional reconnection inflow of a solar flare.

We analyzed a C-class flare that occurred on 2012 September 11 beyond the solar limb. The bi-directional inflow was found in the images of coronal temperature filter taken by AIA onboard SDO. Hinode EUV Imaging Spectrometer (EIS) also observed this flare and provide the Doppler velocity of the bi-directional inflows. At the same time, cusp loops were observed with the raster scans of FeXXIV emission line (over 10 MK) at the region surrounded by the bi-directional inflow. This is clear evidence that 1MK loops are heated over 10MK by the magnetic reconnection. STEREO A/SECCHI was observing this flow from a different line of site. Inflowing angle in STEREO A/SECCHI images is consistent with the angle speculated by apparent velocity of SDO/AIA and line of sight velocity of Hinode/EIS. By combining these data sets, we constructed a self-consistent three-dimensional picture of the flows.

Diagnosis of coronal shock strength using the activation of large amplitude prominence oscillation

TAKAHASHI, Takuya[1*] ; ASAI, Ayumi[2] ; SHIBATA, Kazunari[3]

[1]Graduate School of Science, Kyoto University, [2]Unit of Synergetic Studies for Space, Kyoto University, [3]Kwasan and Hida Observatories, Kyoto University

X5.4 class solar flare occurred on March 7,2012 which was the second largest flare in this solar cycle. The flare was associated with very fast coronal mass ejection(CME) with the velocity of over 2500km/s. Associated with this flare, a wave-like coronal disturbance(known as EUV wave) was observed to propagate along the solar surface. The observed EUV wave propagated with the average speed of about 670km/s towards the north and 'hit' a polar prominence leading to its large amplitude oscillation. The activated prominence strongly brightened when EUV wave 'pushed' it.

Because of the difficulty in direct observation of physical quantities in the corona, the physical nature of the EUV waves is still under discussion. Two main interpretations of EUV waves are the 'fast mode MHD wave/shock' interpretation, and 'non-wave' interpretations.

In the images taken with Inner coronagraph(COR1) of the Sun Earth Connection Corona and Heliospheric Investigation(SECCHI) on board *Solar Terrestrial Relations Observatory(STEREO)-Behind*, we could see a coronal disturbance detached from expanding CME plasma. The time evolution of the disturbance seen in COR1 images was consistent with that of observed EUV wave. Also, Type II radio burst which is thought to be evidence of coronal shock wave was observed simultaneously. Because of that observational evidence, we regard the observed EUV wave as MHD fast mode shock front. Assuming the shock nature of the observed EUV wave, we could also explain prominence acceleration and brightening consistently.

Using the initial velocity of activated prominence, we could estimate the coronal shock strength of the EUV wave with the help of linear wave theory. We also check the applicability of linear theory to the shock problem with one dimensional numerical model and ascertained that it is applicable when the shock strength is not strong. Estimated fast mode mach number of the EUV wave was between 1.20 and 1.42, and we could say that the EUV wave was a weak shock front in the corona.

Influence of interplanetary solar wind sector polarity on the ionosphere

LIU, Jing[1*]

[1]Beijing National Observatory of Space Environment, Institute of Geology and Geophysics, CAS

Knowledge of solar sector polarity effects on the ionosphere may provide some clues in understanding of the ionospheric day-to-day variability and 'hysteresis' effect on foF2. In this study, a solar-terrestrial connection ranging from solar sector boundary crossings, geomagnetic disturbances and ionospheric perturbations has been demonstrated. The increases in interplanetary solar wind speed within three days are seen after SB crossings, while the decreases in solar wind dynamic pressure and magnetic field intensity immediately after SB crossings are confirmed by the superposed epoch analysis results. Furthermore, the interplanetary magnetic field (IMF) Bz component turns from northward to southward in March equinox and June solstice as the Earth passes from a solar sector of outward to inward directed magnetic fields, whereas the reverse situation occurs for the transition from toward to away sectors. The IMF Bz component for the same solar sector polarity has opposite signs between March equinox and September equinox, and also between June solstice and December solstice. In order to know how the ionosphere reacts to the interplanetary solar wind variations linkage of SB crossings, the F2 region critical frequency (foF2) covering about four solar cycles and total electron content (TEC) during 1998?2011 are utilized to extract the related information, revealing that they are not modified significantly and vary within the range of 15% on average. The responses of the ionospheric TEC to SB crossings exhibit complex temporal and spatial variations and have strong dependencies on season, latitude, and solar cycle. This effect is more appreciable in equinoctial months than in solstitial months, which is mainly caused by larger southward Bz components in equinox. In September equinox, latitudinal profile of relative variations of foF2 at noon is featured by depressions at high latitudes and enhancements in low-equatorial latitudes during IMF away sectors. The negative phase of foF2 is delayed at solar minimum relative to it during other parts of solar cycle, which might be associated with the difference in longevity of major interplanetary solar wind drivers perturbing the near-Earth environment in different phases of solar cycle.

Ensemble Data Assimilation for Thermospheric Mass Density Specification and Forecasting

MATSUO, Tomoko[1*] ; LEE, Ite[3] ; ANDERSON, Jeffrey[4]

[1]University of Colorado at Boulder, CO, USA, [2]National Oceanic and Atmospheric Administration, CO, USA, [3]National Central University, Taiwan, [4]National Center for Atmospheric Research, CO, USA

Even though the Earth's upper atmosphere density is tenuous, it is substantial enough to exert significant drag on orbiting spacecraft and debris. The largest uncertainty in low-Earth orbit prediction is aerodynamic drag estimation. Thermospheric mass density variation is the major source of drag estimation errors at altitudes below about 700 km. This paper demonstrates how the limit of predictability of thermospheric mass density variability can be extended by means of ensemble data assimilation.

To assimilate observations of the thermosphere and ionosphere, we use an ensemble data assimilation procedure constructed with the Data Assimilation Research Testbed and the Thermoshere-Ionosphere Electrodynamics General Circulation Model, two sets of community software offered by NCAR. An important attribute of our approach is that the ionosphere-thermosphere coupling is self-consistently treated in both the forecast model and the assimilation scheme. This enables the inference of unobserved thermospheric states from the relatively plentiful observations of the ionosphere. Given the ever-expanding global navigation satellite infrastructure, this is indeed a promising prospect for upper atmosphere data assimilation. Another relevant strategy is using data assimilation to estimate the model forcing parameters that control states of the thermosphere and ionosphere. In comparison to the lower atmosphere, the upper atmosphere is a dissipative, strongly forced dynamical system, so estimation of model forcing parameters can have a dramatic impact on the quality of ensemble forecasting and assimilation of the upper atmosphere.

In this paper, we present results from our ensemble assimilation experiments with thermospheric mass densities obtained from the accelerometer on board the CHAMP satellite, and electron density profiles obtained from the COSMIC/FORMOSAT-3 mission.

Forecast of ionospheric disturbances using a high-resolution atmosphere-ionosphere coupled model

SHINAGAWA, Hiroyuki[1*] ; JIN, Hidekatsu[1] ; MIYOSHI, Yasunobu[2] ; FUJIWARA, Hitoshi[3] ; YOKOYAMA, Tatsuhiro[1]

[1]NICT, [2]Kyushu University, [3]Seikei University

Space weather forecasts are about to enter a stage incorporating numerical forecasts based on realistic numerical simulation, in addition to conventional methods used by forecasters to make predictions based on observational data and experience. At the National Institute of Information and Communications Technology (NICT) of Japan, we have developed an atmosphere-ionosphere coupled model, which includes the whole neutral atmosphere and the ionosphere. The model is called GAIA (Ground-to-topside model of Atmosphere and Ionosphere for Aeronomy). The present version has spatial resolution of about 1 degree in horizontal direction. In addition, we are also developing a high-resolution regional ionospheric model, which has a horizontal resolution of about 10 km. We plan to combine GAIA and the regional model to reproduce mesoscale ionospheric phenomena, such as plasma bubbles and SED (storm enhanced density). The model will be a useful tool for space weather forecast. We will report previous results, and a plan for the new model.

Projection of substom processes from the plasma sheet to the polar ionosphere

TANAKA, Takashi[1*]

[1]Emeritus Professor, Kyushu University

It has been believed that auroras observed in the ionosphere have their corresponding counterpart in the plasma sheet (Haerendel, 2011). Localized auroral breakup should reveal the location of explosive dissipation in the plasma sheet. Similar correspondence is supposed even during the growth phase. While it is well known that the prebreakup arc breakups first during the substorm, the equatorial location and relating formation mechanism of equatormost arc are long-standing questions in the understanding of the growth phase (Sergeev et al., 2012). Another aurora during the growth phase is the poleward bright arc that is believed to be an ionospheric projection of the reconnection separatrix. Also the equatorward extension of the N-S auroral arc has been suggested to be associated with eathward fast bursty flows (Nishimura et al., 2010). The region of aurora indicates that the width of oval is 7^o (64^o to 71^o), near midnight just prior to the breakup. Pich angle isotropy boundary at 65.5^o is critical for the prebreakup arc, since the isotropy boundary coincides with the prebreakup arc. Seen from the structure of isotropy boundary, the breakup arc is somewhere in the transition region between the dipole-like region and the current sheet region. A phenomenon closely related to the projection of the aurora is the distribution of FAC and its tracing. A traditional understanding for the driver of disturbances is the fast flow, both for the growth phase and the onset. The BBF was expected for a wide range of activity including localized auroral brightenings, N-S auroras and streamers (Nakamura et al., 2001). At the same time, the BBF can be a source of the FAC. The cross-tail current is diverted via downward FAC into the ionosphere on the eastward side of the bubble and is connected to upward FACs west of the bubble. The overall region 1-sense FACs is expected to emerge from 64^o to 70^o (Yang et al., 2012). The plasma ahead of the bubble is compressed, resulting in a high plasma pressure and the region 2-sense FACs that are as thin as 1^o, centered at 63^o.

Recent M-I coupling simulation reproduces almost all signatures of the substorm, including the preonset arc, and the onset that start from the low-latitude side of the oval (Tanaka et al., 2010). From the numerical solution just prior tp the onset, the BBF region from x=-10 Re to x=-20 Re in the plasma sheet is projected down along the magnetic filed to a quite narrow region in the ionosphere from 65.7^o to 66.8^o latitudes. Even the outmost field line of the plasma sheet is traced down to 68^o latitude in the ionosphere. So that the observed high-latitude part of the oval (68^o~71^o) is outside the plasma sheet. The N-S arc that usually starts from higher latitude than 70^o cannot be the reflection of the BBF. Near the midnight, in the numerical solution, the region 1 FAC distributes from 65^o to 69^o (with strong part 67^o~68^o) and the region 2 FAC distributes from 62^o to 64^o latitude. From this result, the growth phase region 1 FAC cannot be from the plasma sheet. The result of current line tracing shows that the growth phase region 1 FAC extends into the magnetosphere as far as x=-20Re through the east-west flow shear between the tail plasma sheet and the lobe. If we look at only the latitude it is barely possible that the onset FAC strating from the lowest-latitude area of the region 1 FAC around 65^o could be from the CW that should to be inside x=-10 Re (65.7^o). However, it is implausible from the current line tracing. The onset region 1 FAC is mapped to the cusp-mantle region through the near earth flow shear between the plasma sheet and the lobe. Correspondence beween the plasma sheet and the ionosphere so far believed is quite confusing. It is doubtful to consider that all auroras observed in the ionosphere have their corresponding counterpart in the plasma sheet.

One-month periodicity in thunderstorm, OLR and solar parameters

TAKAHASHI, Yukihiro[1*] ; SATO, Mitsuteru[1]

[1]Department of Cosmosciences, Hokkaido University

Recently the relationship between the global circuit and solar-climate connection was pointed out. Here we introduce an example, which indicates the roles of thunderstorm or its resultant electric circuit in solar-climate connection. Global relationship between thunderstorm/cloud activities and solar parameters are examined based on lightning measurement by Global ELF observation Network (GEON) operated by Hokkaido University and Outgoing Longwave Radiation (OLR) intensity. It was found that the number of lightning stokes in Asia Maritime Continent (AMC) varies with about month periodicity in the period from February to June 2004 and shows positive correlation (R= ˜0.8) with OLR in the Western Pacific Warm Pool (WPWP). On the other hand, OLRs in the central Africa and some other tropical areas show negative correlation with the number of lightning stokes in the AMC in that period. It is also found that the galactic cosmic rays or UV intensity associated with solar activity indicates good correlation with tropical OLR or lightning activity in AMC. One explanation to connect such global variations in thunderstorm / cloud amount with solar parameters would be the electrical circuit involving lower and upper atmospheres. Global electric circuit model was proposed log time ago, in 1930s, in which thunderstorm plays a role of generator, and the ground and the ionosphere work as a spherical capacitor. However, now we need to reconstruct this simple model, taking into account 3 aspects: 1) global-scale nonuniformities both of ionospheric conductivity and of the distribution of the generators, 2) connections between the troposphere and D-region, considering the effects of TLEs, such sprites and blue jets, 3) establishing the observational methodology for global electric field, excluding the effect of cloud existing just above the observation sites. If the ionospheric electric field modulates the potential gradient in the lower atmosphere, it could cause the re-distribution of ionized atmospheric particles, which may, in turn, change the generation / reduction speed of cloud particles.

Influence of solar wind on climate: On the factors such as Quasi Biennial Oscillation

ITOH, Kiminori[1*] ; MATSUO, Shinya[1] ; YAMASHITA, Kazuyoshi[1]

[1]Yokohama National University, Graduate School of Env. & Inf. Sciences

In spite of long history of research, the influence of solar changes on the climate is not convincing enough yet. We have employed solar wind parameter (e.g., Pα (energy flowing into magnetosphere) and aa index) to successfully show their correlation with the temperatures of the stratosphere, troposphere and surface. For further analyses, OLR (outgoing longwave radiation) and the participation of QBO etc. are studied. For instance, January OLR during 1975-2011 showed high correlation with Pα at particular regions. At the QBO westerly phase, high correlation coefficient (r = 0.76) was found near Indonesia. The correlation map at the easterly phase resembled that for the Arctic Oscillation, and r = 0.81 at the Siberia region.

Laboratory experiment with various radiation sources for verification of cloud condensation nucleation by cosmic rays

SUZUKI, Asami[1*] ; MASUDA, Kimiaki[1] ; TAKEUCHI, Yuya[1] ; ITOW, Yoshitaka[1] ; SAKO, Takashi[1] ; MATSUMI, Yutaka[1] ; NAKAYAMA, Tomoki[1] ; UEDA, Sayako[1] ; MIURA, Kazuhiko[2] ; KUSANO, Kanya[1]

[1]Solar-Terrestrial Environment Laboratory,Nagoya University, [2]Tokyo university of science

It is considered that the solar activity may affect the global climate,but the correlation mechanism is still not understood.

One of the possible mechanisms for the correlation is the cloud formation by the galactic cosmic rays, which are modulated by the variation of solar activity. This relation was clearly indicated by the good correlation observed for the galactic cosmic-ray intensity and the global low-cloud amount.

This hypothesis includes the ion-induced nucleation model, in which new particles in the atmosphere are created efficiently through atmospheric ions produced by cosmic rays, and finally these particles grow up to the size of

cloud condensation nuclei.

In this study, a laboratory experiment for verification of the hypothesis has been conducted with a reaction chamber. A flow of clean air, water vapor, ozone and sulfuric dioxide was introduced to a metallic chamber, where we irradiated UV light for solar irradiance and beta-rays or accelerator beam for cosmic rays. The beam of the heavy ion accelerator HIMAC at National Institute of Radiological Sciences was used in the present experiment.

As a result, ions produced by the ionizing radiation and increased particle density were observed for beta rays.

Some results with the accelerator beam are the following.

Ion density in the chamber increased as the beam intensity and particle density increased with ion density.

Particle size distribution was measured and the peak particle size and the particle density became to larger with time after start irradiation, but the density stopped to increase or decreased after irradiation stopped although the peak size continued to increase.

It is shown that our system is ready for more detailed measurements.

Study on symmetry-breaking between the northern and southern hemispheres of the solar dynamo

SHUKUYA, Daishi[1*] ; KUSANO, Kanya[1]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

Solar dynamo is a mechanism whereby the kinetic energy of the plasma in the sun is converted to the magnetic energy. This mechanism works to generate and maintain all solar magnetic activities. Because the Earth's climate can be influenced by solar activities, variability of the solar dynamo is an important issue to understand long-term evolution of the Earth's climate.

Comparisons of the solar activities in each solar hemisphere show hemispheric asymmetry. Sunspots were found preferentially in one hemisphere and not the other in often long periods of time (Spoerer, 1889; Maunder, 1890, 1904). This asymmetry was extended to other measures of activity including faculae, prominences and flares (Waldmeier, 1971; Roy, 1977). The asymmetry happens in the solar polar magnetic field reversals. The polarity of the solar magnetic fields on the north and south poles periodically reverses at every sunspot maxima. However, the reversals at both poles actually don't occur at the same time. In other words, the reversal at one pole is followed by that on the other pole. This time difference of magnetic field reversals between the poles was first noted by Babcock (1959) from the very first observation of polar field. Recently, it was confirmed by detailed observations with the HINODE satellite (Shiota et al. 2012). As above, we have ever obtained many observation facts. However, the mechanisms of hemispheric asymmetry of the solar dynamo haven't been revealed theoretically yet.

In this paper, we study the asymmetric feature of the solar dynamo based on the flux transport dynamo model (Chatterjee et al. 2004) to explain the time difference of magnetic polarity reversal between the north and south poles. In order to calculate long-term variations of solar activities, we use the mean field kinematic dynamo model, which is derived from magnetohydrodynamics (MHD) equation through the mean field and other approximations. We carried out the mean field dynamo simulations using the updated SURYA code which was developed originally by Choudhuri and his collaborators (2004). We decomposed the symmetric and asymmetric components of magnetic field, which correspond respectively to the quadrupole and dipole-like components (Nishikawa and Kusano 2008), and analyzed the phase relation between them. As a result, we found that the two components are mixed even if the dipole-like component is predominant and that the two components spontaneously form 90 or -90 degree out of phase oscillation. The solutions with 90 and -90 degree out of phase oscillation form the different attracters of dynamo solutions. We found that the time difference of the polar field reversals between the different hemispheres can be explained by the out of phase relation between the different components of magnetic field.

Climate responses in central Japan and Taiwan to the cosmic ray intensifications during the Maunder Minimum

SAKASHITA, Wataru[1*] ; YOKOYAMA, Yusuke[1] ; MIYAHARA, Hiroko[2] ; AZE, Takahiro[3] ; YONENOBU, Hitoshi[4] ; OHYAMA, Motonari[5] ; HOSHINO, Yasuharu[6] ; NAKATSUKA, Takeshi[7]

Relationship between solar variations and climate has been long discussed for various time scales. It is difficult to distinguish the impacts of the multiple solar parameters (total solar irradiance (TSI), solar ultraviolet (UV) radiation, and galactic cosmic rays (GCRs)) on climate, because these variations are nearly synchronized. However, GCR fluctuations related to solar magnetic activity have slightly different features compared to the other external forcing factors (TSI, UV). According to previous studies, the cosmic ray fluctuation was particularly unique during the Maunder Minimum (A. D. 1645-1715), when almost no sunspots were observed. Annually measured tree-ring Δ^{14}C and ice-core ^{10}Be data have shown that decadal variations of GCRs had been remarkably amplified during the Maunder Minimum. This characteristic amplification may be utilized to shed light on the GCR influence on climate.

In this study, we employ tree rings that can reconstruct both annual climate (δ^{18}O) and cosmic ray fluctuations (Δ^{14}C) during the Maunder Minimum. By using these proxies, we can directly compare these reconstructions without any dating error. Annually measured tree-ring δ^{18}O records from central Japan have shown significant wet climate at every remarkable GCRs enhancement. On the other hand, there is no significant climate response in tree-ring δ^{18}O record from Taiwan. We suggest that these climate responses may be related to a stationary position of the Baiu front. Recent satellite observations have shown that GCRs may cause the increase of low cloud amount at tropical western Pacific region. It can be suggested that cooling of tropical western Pacific region caused by GCR enhancement might have caused the weakening of Pacific high and indirectly brought wet rainy seasons in central Japan.

Dynamical estimation of external/internal acceleration processes of the outer radiation belt using data assimilation

MIYOSHI, Yoshizumi[1*] ; TOYAMA, Haruto[1] ; UENO, Genta[2] ; KOSHIISHI, Hideki[3] ; MATSUMOTO, Haruhisa[3] ; SHIOKAWA, Kazuo[1]

[1]STEL, Nagoya University, [2]The Institute of Statistical Mathematics, [3]JAXA

Dynamical evolution of the outer belts should be a delicate balance among several processes. It has been believed that there exist two different acceleration mechanisms: the radial diffusion as the external source process, and the non-adiabatic wave particle interactions as the internal source process. In order to discriminate when and where these processes are dominant for the large flux enhancement of the outer belt electrons, we have developed a data assimilation code on the outer belt electrons. In our data assimilation, the particle filter and the particle smoother are used which are effective for non-linear/non-Gaussian distribution problems. We include the radial diffusion coefficient and the internal source model in the state vector and estimate the dynamical variations of these parameters. The Tsubasa satellite electron data are used as the observation vector. The results indicate that only the radial diffusion process is always too small to explain the observed flux enhancement and the internal source process should be necessary. The assimilation result suggests that the internal source process tend to take place around the storm recovery phase, which is consistent with the observations.

Evaluation of Relativistic Electron Flux Forecast at GEO Satellite

NAGATSUMA, Tsutomu[1*] ; SAKAGUCHI, Kaori[1] ; SAITO, Shinji[2] ; MIYOSHI, Yoshizumi[2] ; SEKI, Kanako[2]

[1]National Institute of Information and Communications Technology, [2]Solar Terrestrial Environment Laboratory, Nagoya University

We have developed near real time prediction model for relativistic electron flux at GEO satellite. This model is based on a multivariate autoregressive model with using solar wind speed, north-south component of the magnetic field and dynanmic pressure as inputs. Detailed description of this model can be found in Sakaguchi et al. [2013]. We have started relativistic electron flux forecast service as a test product since Apr. 2013. Forecast information can be found in the following web pages (URL: http://seg-web.nict.go.jp/radi/).

There are several difficulties in operating a near-real time forecast model. One is the quality of the real-time solar wind data. Because quality of real-time solar wind density data is quite poor, we avoid using solar wind density data for our operational model. The other one is the lead-time of the solar wind data. Currently, we can use only ACE data for solar wind input. The lead-time of this data is only about one hour. Threfore, we also 'predict' solar wind condition for two or three days in advance from current solar wind information. Anyway, prediction efficiencies of our forecast for 1day, 2day, and 3day ahead in 2013 are 81%, 63%, 48%, respectively. Evaluation and future parspective of our forecasting model will be introduced in our presentation.

The recently launched ESA Swarm spacecraft mission is the first dedicated multi-satellite ionospheric mission with two low-orbiting spacecraft that are flying in parallel in a distance of ˜100 km, thus allowing to derive spatial gradients of ionospheric parameters not only along the orbits, but also in the direction perpendicular to them. In addition, a third satellite with a slightly higher orbit regularly crosses the paths of the lower spacecraft pair. Using the Swarm magnetic and electric field instruments, we present a novel technique that allows to derive 2-dimensional (2D) maps of ionospheric conductances, currents, and convection in the area between the trajectories of the two parallel flying spacecraft, and even to some extent outside of it. This technique is based on Spherical Elementary Current Systems (SECS). We present several test cases of modelled ionospheric situations from which we calculate virtual Swarm data, and show that the technique is able to reconstruct the model electric field (or convection), horizontal currents, and conductances with very good to excellent accuracy. Larger errors arise for the reconstruction of the 2D field-aligned currents (FAC) map, especially in the area outside of the spacecraft orbits. However, even in this case the general pattern of the model FAC is recovered, and the magnitudes are valid in an integrated sense. Finally, using an MHD model run, we show how our technique allows to estimate the ionosphere-magnetosphere coupling parameter K, if conjugate multi-point observations of the magnetospheric magnetic and electric field are available, as they can be obtained, e.g., from the ESA Cluster mission.

MLT and seasonal dependence of auroral electrojets: IMAGE magnetometer network observations

GUO, Jianpeng[1*] ; LIU, Huixin[2]

[1]SIGMA Weather Group, State Key Laboratory of Space Weather, CSSAR, Chinese Academy of Sciences, [2]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

Total eastward and westward electrojet currents (EEJ and WEJ) and their central latitudes derived from the IMAGE network magnetic measurements are analyzed for the combined MLT and seasonal dependence during the period 1995-2009. EEJ shows a strong MLT variation with significant dependence on season. During summer months the maxima occur around 1600-1800 MLT, whereas during winter months the maxima occur at a later local time sector around 1800-2000 MLT. Moreover, the summer maxima are much larger than the winter maxima, and appear at higher latitudes. The summer maxima are mainly associated with the solar EUV conductivity effect, while the winter maxima are mainly due to the contribution of northward convective electric field. EEJ exhibits a dominant annual variation with maximum in summer and minimum in winter. WEJ also exhibits a strong MLT variation with significant dependence on season. The maxima occur around 0200-0400 MLT during summer months, around 0000-0200 MLT during winter months, and around 0000-0400 MLT during equinoctial months. Moreover, the equinoctial maxima are much larger than the summer and winter maxima, and appear at relatively lower latitudes. The seasonal variations in WEJ are the combinations of annual variations and semiannual variations. Both annual and semiannual variations show significant dependence on MLT. These results increase our knowledge on what factors contribute to the auroral electrojets as well as their magnetic signatures, and hence help us better understand the limitations of global auroral electrojet indices, such as the AE and SME indices.

Temporal variations of nitric oxide in the mesosphere and lower thermosphere over Syowa station, Antarctica

ISONO, Yasuko[1] ; MIZUNO, Akira[1*] ; NAGAHAMA, Tomoo[1] ; MIYOSHI, Yoshizumi[1] ; NAKAMURA, Takuji[2] ; KATAOKA, Ryuho[2] ; TSUTSUMI, Masaki[2] ; EJIRI, Mitsumu[2] ; FUJIWARA, Hitoshi[3] ; MAEZAWA, Hiroyuki[4] ; UEMURA, Miku[1]

Energetic particle precipitation (EPP) related to solar proton events or geomagnetic storms induce ion-neutral reactions and change abundance of some minor molecules such as NO_x and HO_x in the mesosphere and lower thermosphere. To investigate the temporal variations of NO by EPP, we installed a millimeter-wave spectroscopic radiometer at Syowa Station (69.00S, 39.85E), and we have carried out ground-based observations of spectral line of nitric oxide (NO) at 250.796 GHz since January 2012.

We obtained 197 and 172 daily averaged NO spectra in 2012 and 2013 (until 30 September; DOY 273), respectively. The daily NO spectra are characterized by narrow line width with a Full-Width-at-Half-Maximum (FWHM) of about 0.5 MHz. These NO spectra are well fitted by a single Gauss function or by a single Lorenz function. From the spectral line shape, we conclude that the NO emitting region is between 75 and 100 km.

We found two temporal variation patterns of NO column density. One is a seasonal variation with a maximum in the winter and a minimum in the summer. The column density of NO during the winter was about 4 times larger than that during the summer. This seasonal variation is considered to be related to the atmospheric transport and the NO dissociation by solar radiation. The other is the short-term variation in a timeframe of 5-10 days associated with EPP events such as solar proton events and geomagnetic storms. At Syowa Station, short-term variations were caused mainly by the precipitation of electrons rather than that of protons. In the electron precipitation events, the column density of NO gradually increases just after the main phase of the geomagnetic storm and gradually decreases soon after its peak.

One of the short-term events related to a large geomagnetic storm in April 2012 was the most prominent single event among those observed at Syowa Station since January 2012. From the high time resolution (~ 3-hour) data, we revealed a diurnal tendency that NO column density increased about twice at UT 0, which is interpreted to be caused by the dawn-dusk asymmetry of the precipitated electrons with energies 30-300 keV.

The Impacts of Space Weather on Society and the Economy

BAKER, Daniel N.[1*]

[1]University of Colorado Boulder

This presentation describes possible extreme space weather impacts and their economic and societal costs. Modern society depends heavily on a variety of technologies that are vulnerable to the effects of intense geomagnetic storms and solar energetic particle (SEP) events. Strong currents flowing in the ionosphere can disrupt and damage Earth-based electric power grids and contribute to the accelerated corrosion of oil and gas pipelines. Magnetic storm-driven ionospheric disturbances interfere with high-frequency radio communications and navigation signals from Global Positioning System (GPS) satellites. Exposure of spacecraft to solar particles and radiation belt enhancements can cause temporary operational anomalies, damage critical electronics, degrade solar arrays, and blind optical systems such as imagers and star trackers. Moreover, intense SEP events present a significant radiation hazard for astronauts during the high-latitude segment of the International Space Station (ISS) orbit as well as for future human explorers of the Moon and Mars. In addition to such direct effects as spacecraft anomalies or power grid outages, a thorough assessment of the impact of severe space weather events on present-day society must include the collateral effects of space-weather-driven technology failures. For example, polar cap absorption events due to solar particles can degrade — and, during severe events, completely black out — radio communications along transpolar aviation routes, requiring aircraft flying these routes to be diverted to lower latitudes. This can add considerable cost to the airlines and can greatly inconvenience passengers. Modern technological society is characterized by a complex set of interdependencies among its critical infrastructures. A complete picture of the socioeconomic impact of severe space weather must include both direct as well as collateral effects of space-weather-driven technology failures on dependent infrastructures and services.

GEMSIS-Sun Numerical Model of Sun-Earth System (SUSANOO): Application for Extremely Strong IMF CMEs

SHIOTA, Daikou[1*] ; KATAOKA, Ryuho[2] ; MIYOSHI, Yoshizumi[1] ; KUSANO, Kanya[1]

[1]STEL, Nagoya University, [2]National Institute of Polar Research

Solar wind including coronal mass ejections (CMEs) is a main driver of various space weather disturbances. MHD modeling of the solar wind is a powerful tool to understand the solar-terrestrial environment and to forecast space weather accurately. Recently, we developed an MHD model of the inner heliosphere on the basis of minimal input, namely, time series of daily synoptic observation of the photospheric magnetic field. The time series of MHD parameters at the Earth position is passed to a radiation belt model [Miyoshi et al. 2004] for forecasting of the radiation belt energetic electron flux. These programs are executed everyday on a server in STEL, Nagoya University and the results are uploaded on the web site (http://st4a.stelab.nagoya-u.ac.jp/susanoo/). This system is named as Space-weather-forecast-Usable System Anchored by Numerical Operations and Observations (SUSANOO).

Carrington event that occurred in September 1859 is the most violent solar storm in the human records. Since the magnetic storm associated with the event influenced globally, aurora was observed in wide area in the world. The magnetic response recorded in Bombay shows a rapid decrease of -1600 nT / h (Tsurutani et al. 2003). The induced electric field to explain the rapid decrease in the ground level is estimated to be 355 mV/m associated with a magnetic cloud influence. The time lag between onsets of solar flare and sudden commencement is 17.5 hours, and therefore shock propagation speed is estimated as 2380 km/s. The magnetic field strength in the associated magnetic cloud is needed to be 150nT. However, it is not clear how such a strong magnetic field can be kept while the strength of ordinary interplanetary magnetic field (IMF) is the order of 10 nT at 1 au.

In order to examine which condition of coronal mass ejections (CMEs) associated with an extreme event such as the Carrington event should be satisfied, we modeled a series of CMEs with the inner heliosphere MHD simulation (used in SUSANOO). In the model, multiple CMEs are injected as a twisted magnetic flux rope accompanying with a velocity pulse through the inner boundary of the simulation and propagate into the solar winds. Because there is almost no information associated with the Carrington event and the solar wind, instead, we used observational data of CMEs associated recent large-scale active regions: NOAA 10486 in October to November 2003 (Halloween event) and NOAA 11520 in July 2012 (far side STEREO event, Russell et al. 2013). Only fast (V $>\tilde{}$1000 km/s) and wide (angular width $>$60 degree) CME data are extracted from LASCO CME catalog (http://cdaw.gsfc.nasa.gov/CME_list/). As a result, the strength of compressed magnetic field becomes as high as about four times of background IMF when a CME interacts with the background solar wind. However, successive CMEs interact with each other to form much stronger magnetic filed due to compression of the magnetic cloud of the preceding CME by shock associated the following CME.

Discovery of Two Sun-like Superflare Stars Rotating as Slow as the Sun

NOGAMI, Daisaku[1*] ; NOTSU, Yuta[1] ; HONDA, Satoshi[2] ; MAEHARA, Hiroyuki[3] ; NOTSU, Shota[1] ; SHIBAYAMA, Takuya[1] ; SHIBATA, Kazunari[1]

[1]Kyoto University, [2]University of Hyogo, [3]The University of Tokyo

We report on the results of high dispersion spectroscopy of two ‘superflare stars’, KIC 9766237, and KIC 9944137 with Subaru/HDS. Superflare stars are G-type main sequence stars, but show gigantic flares compared to the Sun, which have been recently discovered in the data obtained with the Kepler spacecraft. Though most of these stars are thought to have a rotation period shorter than 10 days on the basis of photometric variabilities, the two targets of the present paper are estimated to have a rotation period of 21.8 d, and 25.3 d. Our spectroscopic results clarified that these stars have stellar parameters similar to those of the Sun in terms of the effective temperature, surface gravity, and metallicity. The projected rotational velocities derived by us are consistent with the photometric rotation period, indicating a fairy high inclination angle. The average strength of the magnetic field on the surface of these stars are estimated to be 1-20 G, by using the absorption line of Ca II 8542. We could not detect any hint of binary in our spectra, although more data are needed to firmly rule out the presence of an unseen low-mass companion. These results claim that the spectroscopic properties of these superflare stars are very close to those of the Sun, and support the hypothesis that the Sun might cause a superflare.

Cosmic-ray exposure Space weather information during aircraft operation

AKUTSU, Retsu[1*] ; ASADA, Kazuaki[1]

[1]Airline Pilots' Association of Japan

Effects of exposure to cosmic-ray during aircraft operation are divided into exposure of aircrew and operational impact.

International Commision on Radiological Protection (ICRP) issued a recommendation to include occupational exposure of aircrew with a jet operated exposure from natural radiation source in 1990. Radiation Council consists of the Ministry of Education, Culture, Sports, Science and Technology, the Ministry of Health, Labour and Welfare, the Ministry of Land, Infrastructure, Transport and Tourism establised Guidelines for management of aircrew exposure to cosmic radiation in 2006. In response to this, airlines keep record of assessed doses on each aircrew using Japanese Internet System for Calculation of Aviation Route Doses (JISCARD-EX) developed by National Institute of Radiological Sciences (NIRS).

Impacts of space weather on aircraft operations can be classified into communications and navigations.

For communicaton, it includes difficulties on HF radio due to Dellinger Phenomenon while flying out of range of VHF coverages as international flight. And also includes difficulties on SATCOM voice communication and Controller Pilot Data Link Communication (CPDLC) in oceanic region.

Modern navigation by Global Navigation Satellite System (GNSS) is becoming mainstream. GNSS are used all phase of aircraft operation during on the ground, depareture, en-route, and approach. Future of operations aim high category precision approach using automatic approach and landing by GNSS even extremely low visibility until stop on runway. Cosmic-ray re-write the data in memory known as soft error on electronic equipment onboard aircrafts.

Use of SpaceWeather forecast, how to provide the information to aircrew and how to make decisions are urgent consideration.

For these problems International Airways VolcanoWatch Operations Group (IAWOPSG) which one of operations group of International Civil Aviation Organization (ICAO) is making draft Concept of Operations (ConOps) for international space weather information in support of international air navigation. Adoption of ConOps is targeted for ICAO/WMO divisional meeting in 2014.

Rdiation exposure management for astronauts

MATSUMURA, Chiemi[1*] ; SATO, Masaru[1] ; KANEKO, Yuki[1] ; OGATA, Katsuhiko[1]

[1]JAXA

On the International Space Station (ISS), a habitable artificial satellite that orbits the Earth at an altitude of about 400 km, astronauts receive space radiation exposure 0.5-1.0mSv in one day which is equivalent to what humans on the Earth receive in six months.

The Japan Aerospace Exploration Agency (JAXA) employs radiation exposure management for JAXA astronauts to minimize the health damage caused by space radiation exposure.

Because of we must take action at space environment anomaly, the space environment monitoring and space weather is important information.

In this report, we introduce space radiation exposure management by JAXA.

On a new antenna system for reception of real-time solar wind data

WATARI, Shinichi[1*] ; KUBO, Yuki[1] ; ISHII, Mamoru[1]

[1]National Institute of Information and Communications Technology

In-situ solar wind data are important for space weather to estimate effects of solar wind disturbances on magnetosphere and ionosphere of the Earth and investigate their solar sources. Since 1997, National Institute of Information and Communications Technology (NICT) contributes reception of real-time solar wind data from Advanced Composition Explorer (ACE), which observes solar wind at L1 point, for 24-hour data coverage. Deep Space Climate Observatory (DSCOVR) following on mission of ACE is plan to be launched in the end of 2014. NICT renews the antenna system, which enables to receive real-time data from DSCOVR. We will report on details of the new antenna system completed in March, 2014 and our application of real-time solar wind data in the presentation.

Solar cell degradation of Akebono satellite due to space radiation and effect of temperature variation

MIYAKE, Wataru[1*] ; MIYOSHI, Yoshizumi[2] ; MATSUOKA, Ayako[3]

[1]Tokai University, [2]Solar Terrestrial Environment Laboratory, Nagoya University, [3]Institute of Space and Astronautical Science

Solar cells on any satellite degrade gradually due to severe space radiation environment. We have analyzed the degradation of the solar cells of the Akebono satellite, and found a fair correlation between the decrease rate of the solar cell output current and the trapped proton flux between 1989 and 1996. The previous studies demonstrated that we can deduce information of proton radiation belt from degradation of solar cells of the Akebono satellite. The relationship cannot be discernible after 1996. The previous studies suggested more prominent temperature effect in the later years because of progress of the degradation. In order to expand studies by using solar cells as a radiation monitor, we must separate exactly the contribution of temperature and of proton radiation. Since the sensor for solar cell temperature failed in 1991 and no temperature is available after 1991, we try to model the temperature variation at solar cells from the temperature of other surface parts. Once we establish the method, we correlate the temperature with solar cell output current and deduce the contribution of proton radiation.

Development of space weather prediction algorithm using big data analysis

HADA MURANUSHI, Yuko[1*] ; MURANUSHI, Takayuki[1] ; SHIBAYAMA, Takuya[1] ; ISOBE, Hiroaki[1] ; NEMOTO, Shigeru[2] ; SHIBATA, Kazunari[1]

[1]Kyoto University, [2]BroadBand Tower, Inc.

To predict and forecast the occurrence of solar flares and coronal mass ejections automatically without human power is one of the major goals in the space weather forecast research. Many studies have been performed in space weather prediction until today; For example, there are heuristics studies from the correlation of flares and the physical quantity being observed from the shape of the each sunspot. We always have required human power in such studies.

In recent years, the accuracy of the satellite and observation equipment has been increasing with the development of technology. Given that observation data is fast increasing, it is difficult for us to directly survey all data. On the other hand, big data analysis has developed rapidly in the field of information processing technology; Methods of machine learning and processing of unstructured large amounts of data by the parallel/distributed processing have been widely adopted in various fields of science. Therefore, we began to research fully automated flare prediction methods, in aim to utilize entire exhaustively large amount of data available for space weather forecast research. We set our goal to predict the X-ray flux with GOES satellites (Geostationary Operational Environmental Satellite.) More specifically, our goal is to predict the maximum of the X-ray flux from the present to 24 hours in the future.

First, we tried to predict GOES X-ray flux from past data of GOES X-ray flux and magnetic field data (Helioseismic and Magnetic Imager HMI) with SDO (Solar Dynamics Observatory), then evaluated the flare prediction accuracy using HSS (Heidke Skill Score) and TSS (True Skill Statistic) (see figure). Next, we added the extreme ultraviolet data observed with SDO/AIA (Atmospheric Imaging Assembly, wavelength: 193$\mathring{A}$) to the original dataset that consists of HMI and GOES data, and evaluated the flare prediction accuracy in the same way.

The reason for adding the AIA data is twofold. First, flare prediction studies using extreme ultraviolet full-disk image data with SOHO (Solar and Heliospheric Observatory) have revealed that we can construct a good indicator of flare activity of active regions by integrating over only pixels brighter than certain threshold in extreme ultraviolet images (threshold integral). Second, we expected to improve prediction accuracy by adding the AIA data, because magnetic field data cannot capture precursory phenomena of flare occurring in the rim of the sun, while AIA data can.

By our comparison study we found that adding full-disk integral of the AIA images to the data set improve the prediction accuracy, particularly that of X- class flares. In this presentation, we will try flare prediction based on the data set with additional features obtained by preprocessing AIA images, such as the threshold integral values, and report the results. This study is a joint research program with BroadBand Tower, Inc.

Statistical study on generating factors of white light solar flares

KITAGAWA, Jun[1*] ; MASUDA, Satoshi[1] ; WATANABE, Kyoko[2]

[1]STEL. Nagoya University, [2]JAXA/ISAS

'White Light Flare' is a flare with enhancement of visible continuum and is mainly associated with energetic flares like GOES X-class flares. But it could not be always observed in energetic flares and recently it is observed in relatively weak flares like GOES C-class flares (Matthews et al. 2003; Hudson et al. 2006). Its occurring mechanism has not been well understood yet and hence a key question remains; "What is needed to enhance white light emission in solar flares?"

In this study, we chose 37 events observed with Hinode/SOT and RHESSI among M- and X-class flares from January 2011 to August 2013. Out of the 37 events, Using running difference images of SOT three continuum bands (red, green, blue), we identified 13 White Light (WL) events. Remaining 24 events are classified into No White Light (NWL) events. We compare these two groups in several parameters (e.g., duration, distance between flare ribbons, and so forth) to find a generating factor of White Light event.

We found the following characteristics of WL events. (1) Most of WL events show a short duration within 20 minutes in GOES soft X-rays. (2) WL events show high (>15MK) temperature and relatively low emission measure at the peak of GOES soft X-rays. (3) The distance between two ribbons in WL events is short as 10arcsec. (4) Assuming the thick-target model, the mean dissipation rate of non-thermal energy in WL events is larger than that of NWL events. (5) WL events do not tend to coincide with CME comparing to NWL. These results indicate that precipitation of large amount of accelerated electrons into a compact area within a short time plays a key role to generate a WL event.

Influence of solar wind and ozone on the temperatures of the troposphere and stratosphere

YAMASHITA, Kazuyoshi[1*]

[1]YOKOHAMA National University

The correlation between global atmosphere and solar magnetic activity is evident though the cause is not clear. In this presentation, we analyze the influence that solar wind and ozone give to the global atmosphere to examine the cause on the basis of the previous observations [1].

The AE and Dst index data were used to detect the influence of the solar wind on the total ozone and the air temperature change of the troposphere and stratosphere.

In the analysis, the following factors were taken into account: 1)EPP-NOx effects on ozone at low latitudes may be comparable to the effects of solar UV radiation [Callis et al., 2000, 2001; Langematz et al., 2005; Rozanov et al., 2005]. 2) Since the ozone generated at low latitude is conveyed to the pole aria of the winter hemisphere, EPP-NOx has affected the ozone reduction of the pole area.

Thus, changes in the stratospheric ozone due to the influence of the solar wind appears to affect the climate of the troposphere.

On the influence of the luni-solar oscillation on the climate

ITOH, Kiminori[1*] ; AI, Yang[1] ; KAWANO, Shoh[1]

[1]Yokohama National University, Graduate School of Env. & Inf. Sciences

We have demonstrated a close relation between solar wind and regional temperatures, and suggested the participation of the Arctic oscillation. On the other hand, a link between the luni-solar oscillation and the Arctic oscillation has also been suggested [1]. Thus, both the sun and the moon appear to be important climatic factors to consider.

An interesting mechanism was proposed recently for the luni-solar oscillation cycle associated with the population change of the snowshoe hare in Canada [2]; that is, the position of the moon changes the intensity of the ionizing cosmic ray to induce changes in the activity of plants, which results in the changes in the forage quality.

This mechanism suggests a combination between the influences of the sun and the moon on the climate while their mutual independence is also possible. Thus, we try to examine the possible contribution of the luni-solar oscillation for establishing the effect of the solar wind on the climate.

VarSITI - Variability of the Sun and Its Terrestrial Impact

SHIOKAWA, Kazuo[1*] ; GEORGIEVA, Katya[2]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Space Research and Technologies Institute, Bulgarian Academy of Sciences

The Scientific Committee on Solar Terrestrial Physics (SCOSTEP) is an interdisciplinary body of the International Council for Science (ICSU) to run international interdisciplinary scientific programs and promotes solar-terrestrial physics research. The last solar minimum in 2008-2009 and the current solar maximum of sunspot cycle 24 show much lower activities compared with the previous two solar cycles 22 and 23. The scientists in the solar-terrestrial physics are watching very low solar activities and their consequences on Earth, which have never been observed since modern scientific measurements become available. The SCOSTEP program "Variability of the Sun and Its Terrestrial Impact (VarSITI)" (2014-2018) will focus on this particular low solar activity and their consequences on Earth, for various times scales from the order of thousands years to milliseconds, and for various locations and their connections from the solar interior to the Earth's atmosphere. In order to elucidate various sun-earth connections, we encourage communication between solar scientists (solar interior, sun, and the heliosphere) and geospace scientists (magnetosphere, ionosphere, and atmosphere). Campaign observations will be promoted for particular interval in collaboration with relevant satellite and ground-based missions as well as modeling efforts. Four scientific projects will be carried out in VarSITI as (1) Solar Evolution and Extrema (SEE), (2) International Study of Earth-Affecting Solar Transients (ISEST/Minimax24), (3) Specification and Prediction of the Coupled Inner-Magnetospheric Environment (SPeCIMEN), and (4) Role Of the Sun and the Middle atmosphere/thermosphere/ionosphere In Climate (ROSMIC).

Specification and Prediction of the Coupled Inner-Magnetospheric Environment (SPeCIMEN)

MIYOSHI, Yoshizumi[1*] ; OMURA, Yoshiharu[2] ; KATOH, Yuto[3] ; JACOB, Bortnik[4] ; CRAIG, Rodger[5]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]RISH, Kyoto University, [3]Graduate School of Science, Tohoku University, [4]UCLA, US, [5]University of Otago, NZ

Specification and Prediction of the Coupled Inner-Magnetospheric Environment (SPeCIMEN) is a focus group of next SCOSTEP project: VarSITI. The goals and objectives are the quantitative prediction and specification of the Earth inner magnetospheric environment based on Sun/solar wind driving inputs. Our question is how the inner magnetosphere responds as a coupled system to Sun/solar-wind driving, which will be solved by a combination of physical and statistical modeling, theory and observations from various platforms under this project. The satellite missions such as NASA/Van Allen Probes (US), JAXA/ERG (Japan) and ground-based network observations provide a comprehensive picture on the dynamical evolutions of geospace and reveal processes and consequences of the inner magnetosphere. Anticipated outcome should be a series of coupled, related models that quantitatively predict the dynamical evolution of the inner magnetospheric state including radiation belts, ring current, plasmasphere, plasma sheet. In this presentation, we give an overview of the SpeCIMEN project and the strategy of the project to gain the science output.

Geotail observation of magnetic reconnection

NAGAI, Tsugunobu[1*] ; SHINOHARA, Iku[2]

[1]Tokyo Institute of Technology, [2]Institute of Space and Astronautical Science/JAXA

The spacecraft Geotail was launched on July 24, 1992. The main objective of the Geotail mission is to explore magnetic reconnection with in situ observations, and the Geotail mission has revealed various physical processes of magnetic reconnection. The ion-electron decoupling region where electron outflow speed differs from ion outflow speed is formed in the magnetic reconnection site. Ion and electron dynamics in the ion-electron decoupling region is derived with magnetic field and plasma observations by the spacecraft Geotail in near-Earth magnetotail magnetic reconnection. The ion-electron decoupling region has a spatial extent of approximately 11 ion inertial length along the GSM x direction, and the dawn-dusk current sheet with main current carriers of electrons exists over this region. An intense electron current layer with a spatial extent of 0.5?1 ion inertial length occupies in its center around the X line. High-speed electron outflow jets are formed just outside the central intense electron current layer. They are decelerated and become non-jet outflows with speed slightly higher than ion outflow speed. Electrons have flattop distribution functions indicating heating and acceleration in both the outflow jets and the non-jet outflows; however, heating and acceleration are weak in the central intense current layer. Inflowing ions enter the central intense electron current layer, and these ions are accelerated up to 10 keV inside the electron outflow jet regions. Ion acceleration beyond 10 keV and thermalization operate mostly in the non-jet electron outflow regions. Electrons show thermal distributions without any heating/acceleration signatures immediately beyond the edge of the ion-electron decoupling region, while higher-energy ions pervade even beyond the edge and hot MHD plasma flows are produced.

Global dynamics of the inner magnetosphere derived from long term observation by Akebono

KASAHARA, Yoshiya[1*] ; MATSUOKA, Ayako[2] ; NAGAI, Tsugunobu[3] ; KUMAMOTO, Atsushi[4] ; ABE, Takumi[2]

[1]Kanazawa University, [2]JAXA/ISAS, [3]Tokyo Inst. Tech., [4]Tohoku Univ.

Akebono is a Japanese scientific spacecraft which was launched in February, 1989 for observations of the Earth's magnetosphere, and has been operated successfully for 25 years. The regular data acquisition of MGF, PWS, VLF, TED, and RDM is still continued at stations in Japan and Sweden. The operation of the Akebono will be extended until March, 2015 (FY2014) in order to realize collaborative measurements with the Van Allen Probes, and further extension to the end of FY2016 is expected as an optional mission. Because of its unique orbit, the stored data is quite valuable for studying plasma physics in the auroral region as well as the radiation belt. In the present paper, we introduce important achievements of Akebono observation and discuss future science to be obtained from the long term observation data.

ERG Science Center

KEIKA, Kunihiro[1*] ; MIYOSHI, Yoshizumi[1] ; SEKI, Kanako[1] ; HORI, Tomoaki[1] ; MIYASHITA, Yukinaga[1] ; SHOJI, Masafumi[1] ; SEGAWA, Tomonori[1] ; SHINOHARA, Iku[2] ; TAKASHIMA, Takeshi[2] ; TANAKA, Yoshimasa[3] ; ERG, Science center team[4]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency, [3]National Institute of Polar Research, [4]ERG Science Center Team

ERG (Exploration of energization and Radiation in Geospace) is a Japanese geospace exploration project, and the ERG satellite will be launched in Japanese FY 2015. The project consists of the satellite observation team, the ground-based network observation team, and the integrated data analysis/simulation team. Besides these research teams, the ERG Science Center has been organized to promote close collaborations of these teams and thereby maximize scientific output. For studies of geospace, where different plasma populations are dynamically coupled with one another via cross-energy and cross-regional couplings, the environment for integrated data analysis is critical for comprehensive understanding using various kinds of data sets including data from physics-based models developed by the GEMSIS (Geospace Environment Modeling System for Integrated Studies) project of the Solar-Terrestrial Environment Laboratory, Nagoya University.

A standard data format and integrated data analysis tools are essential to realize the seamless data analysis environment. The ERG project data after Level-2 will be open to the public in the NASA CDF format. The integrated data analysis tool is developed as a plug-in tool of SPEDAS (Space Physics Environment Data Analysis System) in collaboration with the THEMIS (Time History of Events and Macroscale Interactions during Substorms) and IUGONET (Inter-university Upper atmosphere Global Observation NETwork) teams. It should be noted that other project data, such as THEMIS and Van Allen Probes, can be easily analyzed with SPEDAS if the data are converted to the CDF format. Thus the integrated data analysis using many kinds of data is truly realized through SPEDAS. Other useful tools in the web browser have been developed by the science center: ERGWAT (ERG Web Analysis Tool) is an interactive visualization tool, and CEF (Conjunction Event Finder) is a web-based tool enabling users to easily find conjunctions between satellites and ground-based observations. These tools will contribute to a part of the capacity building activity of the SPeCIMEN (Specification and Prediction of the Coupled Inner-Magnetospheric Environment) project carried out under the VarSITI (Variability of the Sun and Its Terrestrial Impact) program for 2014-2018.

[1]International Center for Space Weather Science and Education

International Center for Space Weather Science and Education (ICSWSE) has developed a real time magnetic data acquisition system (the MAGDAS project) to monitor the space environment around the world. The number of observational sites is increasing every year in collaboration with MAGDAS host countries. Up to now, the MAGDAS Project has installed 73 real time magnetometers: It is the largest magnetometer array in the world. Using data from this global network, we are developing many research projects. In this talk, we introduce our research projects planned during the VarSITI program interval, as follows:

(1) Global electromagnetic coupling from polar to equatorial ionosphere
(2) Vertical coupling among the atmosphere, the ionosphere and the magnetosphere
(3) Plasmaspheric diagnosis using the Field line resonance
(4) Magnetospheric diagnosis using geomagnetic disturbances
(5) Monitoring of Space weather phenomena using solar and magnetospheric indices
(6) Modeling of Space weather parameters
(7) Sun-atmosphere coupling

Energetic electron precipitation during magnetic storm and substorm: Subionospheric VLF/LF observation

TSUCHIYA, Fuminori[1*] ; OBARA, Takahiro[1] ; MORIOKA, Akira[1] ; MISAWA, Hiroaki[1] ; YAGI, Manabu[1] ; MIYOSHI, Yoshizumi[2] ; SHIOKAWA, Kazuo[2] ; OGAWA, Yasunobu[3] ; CONNORS, Martin[4]

[1]Tohoku University, [2]Solar-Terrestrial Environment Laboratory, Nagoya University, [3]National Institute of Polar Research, [4]Athabasca University

Subionospheric VLF/LF radio observation is useful probe to investigate precipitation of high-energy (>100keV) electrons into the atmosphere and the observation at Ny-Alsound, Norway (NAL) and Athabasca, Canada (ATH) are used to detect energetic electron precipitation in auroral and sub-auroral regions during storm and substorm. At the NAL station, radio signals which are transmitted in mid-latitude and propagate across the auroral and sub-auroral regions are recorded. During magnetic storms, the strong phase variation associated with the substorm induced electron precipitation has been detected and the phase change quantitatively corresponds to the precipitating energetic electron flux observed by the NOAA/POES satellites over the radio propagation path. Onsets of the phase change were delayed by ten to several tens of minutes from the substorm onset in the morning and noon sectors, which is consistent with the drift time of energetic electrons with energy of ˜100 keV. On the other hand, the phase change in the dusk sector occurred shortly after the substorm onset and is often accompanied by Pc1 or Pi1B observed on the ground station near the radio path. These results show that the energetic electron precipitation is strongly connected with the dynamics of energetic ions and electrons and wave generations in the inner magnetosphere. The ATH station is located in the subautoral region and subionospheric signals from lower latitude are measured. The phase fluctuations with time scales of Pc5 or longer period were sometimes found during main and early recovery phases of magnetic storms. The phase fluctuations found on 5 June 2011 show good correlation with the GOES magnetic field data, suggesting Pc5 modulation of either electron injection or precipitation rates. Subionospheric radio observation provides opportunities to investigate various kinds of energetic electron precipitation processes. Part of observed data is provided through the IUGONET metadata database.

A longitudinal network of VLF/ELF antennas and induction magnetometers at subauroral latitudes - Contribution to VarSITI

SHIOKAWA, Kazuo[1*] ; MIYOSHI, Yoshizumi[1] ; OZAKI, Mitsunori[2] ; NAGATSUMA, Tsutomu[3] ; ISHII, Mamoru[3] ; CONNORS, Martin[4] ; PODDELSKY, Igor[5] ; SHEVTSOV, Boris[5]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Kanazawa University, [3]National Institute of Information and Communications Technology, [4]Athabasca University, [5]Institute of Cosmophysical Research and Radiowave Propagation (IKIR), FEB RAS

We report observations of VLF/ELF chorus waves (~kHz) using loop antennas and Pc1 waves (~Hz) using induction magnetometers at longitudinally-distributed stations at subauroral latitudes. Continuous measurements of VLF waves with a sampling rate of 100 kHz have been made since September 2012 to monitor daily variations of chorus waves and their detailed structures at Athabasca (54.72N, 246.69E, MLAT=61.3). We observe various chorus emissions, such as quasi-periodic (Q-P) emissions, patchy burst emissions, rising and falling tone emissions at Athabasca. New loop antennas will be installed at Fredericton in the east-coast of Canada and at Zhigansk in the east-Siberia in Russia in 2014-2015. The induction magnetometer chain observes Pc1 geomagnetic pulsation which corresponds to electromagnetic ion cyclotron (EMIC) waves in the inner magnetosphere. The magnetometers have deployed in Athabasca, Magadan and Paratunka in far-eastern Russia, Moshiri and Sata in Japan, and will be deployed at Fredericton in the east-coast of Canada in 2014. These chorus waves and EMIC waves are known to contribute to the acceleration and loss of radiation belt particles. The longitudinal network of these measurements will provide continuous monitor of global distribution of the occurrence of these waves. These observations will contribute the next SCOSTEP program VarSITI, particularly to the SPeCIMEN Project.

[1]ISAS/JAXA, [2]Nagoya University, [3]CfA-Harvard, USA, [4]Indian Institute of Science Education and Research, India, [5]IZMIRAN, Russia, [6]SRTI, Bulgaria

Following the recent unsual solar activities, the next SCOSTEP international scientific program 'Variability of the Sun and Its Terrestrial Impact (VarSITI)' was launched as a 5 years program covering 2014-2018. It will focus on the the unusual solar activities and their consequences on Earth, for various times scales from the order of thousands years to milliseconds, and for various locations and their connections from the solar interior to the Earth's atmosphere.

The program consists of four elements:

(1) Solar Evolution and Extrema (SEE), (2) International Study of Earth-Affecting Solar Transients (ISEST/Minimax24), (3) Specification and Prediction of the Coupled Inner-Magnetospheric Environment (SPeCIMEN), and (4) Role Of the Sun and the Middle atmosphere/thermosphere/ionosphere In Climate (ROSMIC).

Among these elements, SEE will address, by promoting coordination of various projects between the Sun and the Earth, the following scientific questions:

(a) Are we at the verge of a new grand minimum? If not, what is the expectation for cycle 25? (b) Does our current best understanding of the evolution of solar irradiance and mass loss resolve the "Faint Young Sun" problem? What are the alternative solutions? (c) What is the largest solar eruption/flare possible? What is the expectation for periods with absence of activity?

An overview of SEE element will be presented.

Solar Magnetic Activity and Their Influence on the Earth's Environment

SAKURAI, Takashi[1*]

[1]National Astronomical Observatory of Japan

The Sun affects the environment of the Earth in diverse ways. In a time scale of a few days, XUV emission and energetic particles from solar flares and disturbances in the solar wind (coronal mass ejections) cause various phenomena in the ionosphere and the magnetosphere. In a time scale of 2-4 weeks, the rotation of the Sun modulates its irradiance and solar wind properties. In a time scale of 11-year solar cycle, total and spectral irradiance changes in phase with the sunspot number. In this presentation I will pick up new results obtained with the Hinode mission and other ground-based instruments.

Hinode, launched on 23 September 2006, is a Japan-US-UK joint mission with contributions for downlink connections from ESA. The three primary instruments on Hinode are

(1) solar optical telescope/magnetograph (SOT),

(2) soft X-ray telescope (XRT), and

(3) extreme ultraviolet imaging spectrometer (EIS).

Ulysses spacecraft showed in 1998 that fast and steady solar wind comes from polar regions, and slow and variable solar wind comes from low-latitude regions. Since low-latitude regions are basically characterized by closed magnetic field lines by the presence of active regions with bipolar magnetic field configuration, it was not clear how the solar wind could flow out of the regions. However, Hinode/XRT discovered continuous outflow from the edges of active regions. Later, EIS observations confirmed the outflow by its Doppler shift. Now this outflow is believed to be the long-sought source of the slow solar wind.

The fast solar wind originates from polar regions which are basically unipolar. Since quiet-sun magnetic field of 10 gauss or less was known to consist of intense flux tubes with a kilo-gauss field strength occupying 1% of the area, the same might be expected for polar fields. Hinode/SOT showed clearly with its high spatial resolution observations of vector magnetic fields that it is the case. Hinode/SOT observations also track the polar field reversal with an unprecedented accuracy. The time delay of the south pole reversal compared with the north pole is seen in Hinode/SOT polar field observations as well as other indices, and is speculated to be related to an unusually low activity of the present solar cycle.

Coronal mass ejections (CMEs) are the major source of geomagnetic disturbances. How such an ejection of plasma cloud takes place is explained by several models. In one scenario, a solar magnetic configuration evolves by supplies of magnetic flux and magnetic helicity from below the surface. The accumulation of magnetic helicity leads to abrupt instability of magnetic configuration, leading to a CME. Magnetic helicity is distributed basically anti-symmetrically with respect to the equator, but anomaly is often observed. Long-term observations of magnetic helicity by ground-based instruments and high accuracy measurements of helicity by Hinode/SOT are providing interesting information on the nature of magnetic field generation in the solar convection zone.

Modeling of the geomagnetically induced electric field in Japan

FUJITA, Shigeru[1*] ; ENDO, Arata[2] ; FUJII, Ikuko[3]

[1]Meteorological College, [2]Meteorological College, [3]Magnetic Observatory

The geomagnetically induced current (GIC) happens to damage transformers of electrical power line systems in high-latitude countries like Canada and Sweden where the geomagnetic disturbances are enhanced. Thus, since it is important to evaluate the GICs associated with geomagnetic disturbances in these countries, there have been many works about GIC [Pulkkinen et al., 2005]. On the other hand, the low-latitude countries like Japan seem to be regarded to be free from dangers of the GIC disasters [Pulkkinen et al., 2008]. Indeed, Watari et al. [2009] revealed that the GICs measured along the power line in Hokkaido (the northernmost part of Japan) are as small as several Ampere. These values are negligibly small compared with the permissible current of a transformer. It is noted that the measurements by Watari et al. [2009] were carried out in the period of extremely quiet solar activity.

The result by Watari et al. [2009] seems to indicate that Japan is safe from the GIC disasters. However, it should be noted that the ground conductivity structure is quite different between Hokkaido and other Japanese areas like the most industrialized and highly-populated Kanto plain. This difference invokes the following geoelectric characters in Japan; the geomagnetically induced electric field at Kakioka in Kanto plain is sometimes about 10-times larger than that at Memambetus in Hokkaido. This difference probably comes from difference in the ground conductivity structure. As a result, we have to employ a realistic 3D ground conductivity model to present a reliable conclusion on the GIC.

In the talk, we will present the first numerical result of the geomagnetically induced electric field in Japan based on the 3D electric conductivity in the Earth. The conductivity is compiled after the resistivity suitable to the characteristic layers based on the crustal layer structure after the database on the bathymetry and that on the thickness of the sediment layer together. Our initial results reveal several localized enhancements of the induced electric field in the coastline regions when the induced electric current tends to converge into a bay-shaped area. The enhanced electric field appears in the different areas depending on the direction of the external source current in the magnetosphere. Combination of the induced electric field calculated and quantities of the severe space weather event yields the info for evaluation of the extreme severe GIC in Japan.

Role of magneto-convection from the point of view of large-scale magnetic structure formation on the solar surface

IIDA, Yusuke[1*]

[1]ISAS/JAXA

The roles of magneto-convection on the solar surface in the formation of large scale magnetic field, which are revealed by the recent observation, are reported in this presentation.

Many energetic activities on the solar surface, e.g. filament formation, solar jet, and slow solar wind etc., root in the large-scale magnetic configurations. The circumstances around the photosphere, e.g. actual visible surface, is at high plasma beta condition. So the magnetic field is transported mainly by the surface convection there. Simultaneously its configuration is significantly affected and changed from its birth to solar surface. Hence, understanding of magneto-convection on the solar surface is thought to be a basic but an important issue in the solar physics for long time.

Despite of its importance, it is very difficult to give the conclusion to roles of solar surface convection to global structure, namely to answer how does it transport magnetic field and how does it change states of magnetic field. The difficulties come from the smallness and short time scale of the element structures of magneto-convection on the solar surface (<1,000km and order of minutes). The first difficulty is its smallness and short time scale in absolute value. We need stable high spatial and temporal resolution to catch up their element structure. We can say this difficulty is nearly solved thanks to the recent satellite observation. However, there is the second difficulty, smallness and short time scale compared to large scale structure (˜700,000km and order of years). We need a new method of analysis to overcome the problem, huge scale difference.

To solve this problem, we develop auto-recognition and tracking method of patches and apply it to the actual data. In the presentation, we report the results about reformation of patch structures by surface convection, especially the frequency distribution of flux content in each patch structure. We find that it is re-formed in 30 minutes, which is much shorter than flux supply time scale. This result indicates that most magnetic structures on the solar surface is decided by the local convection nature.

Solar Magnetism: Exploration with Local Convective Dynamo Modeling

MASADA, Youhei[1*]

[1]Department of Computational Science, Kobe University

A grand challenge in astrophysics is the origin of self-organizing properties of the magnetic field in highly turbulent flows. The solar magnetism is the front line in this area. The solar magnetic field shows a remarkable spatiotemporal coherence though it is generated by turbulent convective dynamo operating within its interior. Our understanding on the solar magnetism has been accelerated over the past decade in response to broadening, deepening and refining of numerical dynamo modelings. However, it is still unclear what dynamo mode is excited in the solar interior and how it regulates magnetic cycle with equatorward sunspot migration and periodicity of 22 years. To gain a deeper understanding of the solar dynamo mechanism, we are currently working on the convective dynamo simulation in a local stratified system.

Here we report a successful direct numerical simulation (DNS) of oscillatory large-scale dynamo spontaneously excited in a rotating stratified convection. The figure shown below is the simulation result; the time-radius diagram of the mean horizontal magnetic fields. Our simulation model consists of three layers like as the solar interior: bottom and top stably stratified layers and mid-convection zone (the area between white-dashed lines). It is found that the large-scale magnetic field is organized in the bulk of the convection zone and shows a well-regulated oscillatory behavior. The mean-field component is the strongest at around the mid-convection zone and propagates from there to top and base of the convection zone. The polarity is then gradually reversed over the period of about 200 convective turn-over time. It is noteworthy that there is a phase difference of about $\pi/2$ between B_x and B_y . The simulated spatiotemporal evolution of the large-scale magnetic field is quite reminiscent of the solar butterfly diagram although there is a difference in the propagation direction between the simulated field and the sunspot field.

To explore the underlying dynamo mechanism, we construct a mean-field electrodynamics model with dynamo coefficients directly computed from the DNS. The nonlinear back-reaction of the mean-field on the dynamo coefficients (both α- and η-quenching) is self-consistently taken into account. We demonstrate that the simulated large-scale dynamo is quantitatively reproduced by our DNS-driven mean-field dynamo model, and is interpreted as a manifestation of oscillatory α^2-dynamo mode. We will describe the basic physics which characterizes the cycle period and amplitude of the large-scale magnetic field sustained by the α^2-dynamo, and then discuss its playing role in the solar magnetism. This is the first to quantitatively demonstrate the presence of the oscillatory α^2-dynamo mode as a natural outcome of the rotating stratified convection, and raises an unignorable question about the conventional solar dynamo model relying strongly on the profiles of the mean flows, such as the differential rotation and meridional circulation.

From Deep Space Explorer DESTINY towards Solar Polar Region Observer SOLAR-D

KAWAKATSU, Yasuhiro[1*]

[1]ISAS/JAXA

DESTINY which stands for "**D**emonstration and **E**xperiment of **S**pace **T**echnology for **IN**terplanetary vo**Y**age" is a mission candidate for the next space science small program. The next mission is planned to be decided in 2014, and the select one is scheduled to be launched in 2018.

As illustrated in the Figure, DESTINY will be launched by an Epsilon launch vehicle and firstly placed into a low elliptical orbit, where then its altitude raised by the use of ion engine. When the orbit raising reaches the Moon, DESTINY subsequently is injected into transfer orbit for L_2 Halo orbit of the Sun-Earth system by using lunar gravity assist. Upon arrived at L_2 Halo orbit, DESTINY will conduct its engineering experiment as well as scientific observations for at least a half year. If conditions permit, DESTINY will leave L_2 Halo orbit, and transfer to the next destination.

On the way to L_2 Halo orbit, DESTINY will conduct demonstration and experiment on key advanced technologies for future deep space missions. Major items of the technology demonstration are listed as follows.

1) Ultra-Lightweight solar panel.

In order to generate large electric power to run μ20 ion engine, "Ultra-Lightweight Solar Panel", which is under development at JAXA, is applied and its performance is evaluated. This solar panel is estimated to achieve power to mass ratio at least double to conventional ones. Future application is expected in outer planet probes (JMO, MELOS) or probes with large ion engines.

2) Large scale ion engine μ20.

DESTINY is inserted into an elliptical orbit and reaches to a Halo orbit by its own orbital maneuver. For this maneuver, a large ion engine (μ20) which is under R&D at JAXA will be adopted and its performance is evaluated. This ion engine has thrust five times as much as μ10 used by Hayabusa and will be expected to be applied to large probes such as SOLAR-D or Hayabusa Mk2.

3) Advanced thermal control.

In order to manage large amount of heat generated by the large ion engine, advanced thermal control techniques by way of Loop Heat Pipe will be adopted.

4) Orbit determination under low thrust operation.

DESTINY will reach to Halo orbit by running ion engine over long duration. In order to reduce burdens to shut down the ion engine each time of orbit determinations, orbit determination under ion engine operation is conducted and its performance is evaluated.

5) Automatic/autonomous onboard operation.

In order to increase the efficiency of operation, autonomous and highly functioned spacecraft management system is developed demonstrated on board. This technique is expected to be adopted especially in the deep space missions usually operated under severe communication condition.

The technologies demonstrated by DESTINY will be applied to various future solar system exploration programs. One of them is a solar polar region observer, SOLAR-D, which is planned to be launched in 2020s.

SOLAR-D aims at the observation of the polar region of the Sun from out-of-ecliptic view point. It requires the observation from the high latitude point of the Sun, namely 45deg. To observe the Sun from the high latitude point, the space observatory (spacecraft) must be on the orbit largely inclined with the ecliptic plane. It is not an easy task to inject the spacecraft into the orbit largely inclined with the ecliptic plane. The mission plan under consideration supposes the use of solar electric propulsion, whose major technology challenges are going to be demonstrated in DESTINY.

The over view of DESTINY mission, and its effect on the future SOLAR-D mission will be introduced in the presentation.

Overview of CAWSES II: Advancing the understanding of the Sun-Earth interaction

TSUDA, Toshitaka[1*]

[1]Research Institute for Sustainable Humanospherer (RISH), Kyoto University

CAWSES (Climate and Weather of the Sun-Earth System) was established as an international program by SCOSTEP (Scientific Committee on Solar-Terrestrial Physics) in order to enhance our understanding of the Solar Terrestrial relations, which impacts on life and society. In particular, we put special emphasis on the short and long-term variability of solar activity and its effects on the geospace and Earth's environment.

We carried out the first five-year project of CAWSES in 2003-2007. On the basis of its successful achievements, we conducted the second phase of CAESES during 2009-20013. CAWSES-Phase II especially promoted science and application of the following four themes, which are related to the fundamental questions of the Sun-Earth system.

TG1: What are the solar influences on the Earth's climate?
TG2: How will geospace respond to an altered climate?
TG3: How does short-term solar variability affect the geospace environment?
TG4: What is the geospace response to variable waves from the lower atmosphere?

We have enhanced international collaboration of ground-based observations, numerical modeling and satellite missions. Database is also very important for CAWSES-II. We also help capacity building activities to involve researchers in developing countries as well, and provide educational opportunities for students of all levels. We review in this talk recent achievements of CAWSES-II.

The Role of ICSU World Data System in VarSITI

WATANABE, Takashi[1*]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]ICSU-WDS International Programme Office (NICT)

Solar-terrestrial physics is a typical example of interdisciplinary science, covering a wide variety of research fields. Interdisciplinary usage of observational data and information are essential in the research works to be conducted under VarSITI. ICSU has a long history to promote international collaborations in long-term provision of interdisciplinary data and information. In the IGY era (1957-58), the initial World Data Center (WDC) System was created under the policy of Full and Open Access to data and information. By the early 2000s, about 50 data centers were registered as WDCs, mainly for geophysical researches. ICSU also had another international data-oriented service under the name of Federation of Astronomical and Geophysical data-analysis Services (FAGS), which was created also in the IGY era, including ten services, e.g. International Space Environment Service (ISES). The World Data System (WDS) has been created by the 29th General Assembly of ICSU in 2008 as an Interdisciplinary Body to expand the range of data and information activities conducted by WDC and FAGS to much wider research fields, including social sciences. WDS strives to become a world-wide community of excellence providing trusted data services for global science with searchable common data directories and catalogues, which ensures the long-term stewardship and provision of quality-assessed data and data services. The VarSTEP will be one of the important partners of WDS because WDS includes many data centers came from former WDC and FAGS communities.

International Study of Earth-affecting Solar Transients (ISEST)/MiniMax24

KATAOKA, Ryuho[1*] ; SHIMIZU, Toshifumi[2] ; ASAI, Ayumi[3] ; ZHANG, Jie[4] ; MANUELA, Temmer[5] ; GOPALSWAMY, Nat[6]

[1]NIPR, [2]JAXA, [3]Kyoto University, [4]George Mason University, [5]University of Graz, [6]NASA/GSFC

We introduce the project ISEST (International Study of Earth-affecting Solar Transients)/Minimax24 of VarSITI, internationally led by Jie Zhang (USA), Manuela Temmer (Austria), and Nat Gopalswamy (USA). Goals and objectives are to understand the propagation of solar transients through the space between the Sun and the Earth, and develop space weather prediction capability. How do coronal mass ejections (CMEs) and corotating interaction regions (CIRs) propagate and evolve, drive shocks and accelerate energetic particles in the heliosphere? To answer this question, we need data/theory/modeling as follows: Establish a database of Earth-affecting solar transient events including CMEs, CIRs, flares, and energetic particle events based on remote sensing and in-situ observations from an array of spacecraft, run observation campaigns such as MiniMax24, develop empirical, theoretical, and numerical models of CME propagation and prediction, validate models using observations. As anticipated outcome, a comprehensive database of Earth-affecting solar transients will be created, and space weather prediction capability will be significantly improved.

The next-generation space solar observatory SOLAR-C

HARA, Hirohisa[1*]

[1]National Astronomical Observatory of Japan

The SOLAR-C is a planned satellite mission that is led by the JAXA SOLAR-C working group as the 4th Japanese space solar observatory that follows the 3rd satellite mission, Hinode. Hinode equips three major science payloads to cover from the photosphere to the corona simultaneously and has revealed the ubiquitous emergence/submergence of small-scale bipolar fields and the formation of kilo Gauss magnetic flux tubes from vector magnetic field measurements on the photosphere, unexpected dynamical phenomena in the chromosphere, spectral signatures of small-scale coronal heating events near the chromosphere below its spatial resolution, and so forth. These are the universal magnetized plasma activity in the nearest star, and the essential energy source of the phenomena is of magnetic-field origin coupled with photospheric convective motion. To elucidate the newly-found solar active phenomena and the problems that have been tackled for a long time in solar physics, we try to understand the causal linkage between solar magnetic fields and active phenomena on the Sun in the true sense by high-resolution (0.1-0.3 arcsecs) instruments in space. SOLAR-C will observe photospheric and chromospheric activity by imaging and measure chromospheric magnetic fields by spectro-polarimetry, in addition to photospheric magnetic fields. It visualizes the site of dynamical events for chromospheric and coronal heating by imaging and spectroscopy with comparable resolution and by high-resolution chromospheric magnetometry. In addition, SOLAR-C essentially contributes to space weather by estimating the stored magnetic energy in the corona via measurements of chromospheric magnetic fields.

Statistical analysis of the gyroresonance sources using Nobeyama Radioheliograph and sunspot sketches

OTSUJI, Kenichi[1*] ; SHIBASAKI, Kiyoto[1] ; TANAKA, Yuuki[2] ; MIYAGOSHI, Takehiro[3]

[1]NAOJ, [2]Kyoto University, [3]JAMSTEC

Nobeyama Solar Radio Observatory of National Astronomical Observatory of Japan has continued the solar fulldisk observation using Radioheliograph (NoRH) since 1992. NoRH can measure the intensity and circular-polarization intensity of solar radio waves and identify the regions where the gyroresonance occurs. Gyroresonance is the mechanism in which the strongly circular-polarized radio waves are emitted from the resonance of the electrons gyrating around the magnetic field lines of sunspots. The radio flux coming from the gyroresonance mechanism depends on the magnetic field strength of its source and the observing wavelength. NoRH adopts 17 GHz radio waves and detects the gyroresonance emission from the strong magnetic field region with more than 2000 gauss. The statistical analysis combining gyroresonance sources and their magnetic field, or identifying them as the NOAA (National Oceanic and Atmospheric Administration) active region, however, has not been done sufficiently. So, the database including these informations is urgently needed.

In this study, we developed the database which combines the gyroresonance sources with NOAA active region number and the photospheric field strength. We listed up the location, radio flux and the circular-polarization ratio of each gyroresonance source with its area, using NoRH observation data. We also examined the area, McIntosh sunspot group classification, sunspot number and the magnetic classification of sunspots of each active region corresponding to the gyroresonance source. We used the sunspot sketches from Mt.Wilson and Crimea observatories because of the merits of covering solar fulldisk and being free from the saturation effect at the strong field. The temporal coverage of our database is from 1992 to 2013, which corresponds to almost two solar cycles.

The statistical analysis using our database clarified that the ratio of the active regions accompanied by the gyroresonance emissions increases in the latter half of cycle 23 (2002-2007). This phenomenon is not confirmed in cycle 22. There is a quadratic correlation between the number of occurrences of gyroresonance and the total number of active regions. This means that the ratio of the active regions accompanied by the gyroresonance emissions is proportional to the total number of active regions. Furthermore, we classified the active regions with the gyroresonance by their magnetic classification of sunspots and found that the complex magnetic configurations (beta-gamma-delta etc.) were predominant. Our statistical analysis provides new diagnostics to the past solar cycles and the prediction for the future solar activities.

Particle acceleration in a 3D current sheet of a Solar flare and comparison with solar radio observations

NISHIZUKA, Naoto[1*] ; NISHIDA, Keisuke[2]

[1]National Astronomical Observatory of Japan, [2]Kwasan and Hida observatories, Kyoto Uni.

Solar flares show intermittent time variability in nonthermal emissions, because particles are impulsively accelerated in small acceleration regions, i.e. multiple X-points, reconnection outflows, colliding plasmoids and internal shocks in a fragmented current sheet. We performed 3D MHD simulation of a solar flare, in which a horizontal flux rope in an unstable but equilibrium state are triggered by small amplitude of perturbation to be flown upward. The eruption of a flux rope forms a current sheet just below the flux rope, and when the width of a current sheet becomes enough thin, it becomes unstable for the tearing instability and generate small scale plasmoid inside. The formation and interaction of the plasmoids make the current sheet complex and turbulent structure. When a small scale plasmoid is ejected out or when two plasmoids collide with each other, the electric field in a current sheet is locally and intermittently enhanced.

In this 3D MHD simulation result, we inserted test particles, which are forced by electromagnetic field varying in time. Particles are trapped in the turbulent current sheet, or more exactly between multiple plasmoids, and accelerated by locally enhanced electric field along the current sheet. At that time, particles are intermittently accelerated at several heights and repeat multistep acceleration moving to other X-points. Sometimes, particles escape upward into the erupting flux rope and propagate along the field line of the flux rope. Particles are slightly accelerated by the curvature drift acceleration in the erupting flux rope and finally precipitate to another X-point connected to the different pair of loop-foot points. We also compared this simulation result with radio spectrograph data observed in Ondrejov observatory in Czech Republic. The radio spectrograph data shows similar intermittent time variability of type III bursts, i.e. electron beams, and sometimes slowly drifting pulsating structures, i.e. trapped electron beams in a plasmoid.

In this talk, we mainly talk about the test particle acceleration in 3D MHD simulation of an erupting solar flare and the comparison with the radio observation data. We are also aiming at simulating the propagation of a flux rope eruption into the interplanetary space, i.e. coronal mass ejection, forming a shock at the propagation front and reconnecting with open field in the interplanetary space. We welcome discussion and collaboration in VarSITI.

Role of the Japanese SuperDARN network in the VarSITI Program

NISHITANI, Nozomu[1*] ; YUKIMATU, Akira sessai[2] ; NAGATSUMA, Tsutomu[3]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]National Institute of Polar Research, [3]National Institute of Information and Communications Technology

The Super Dual Auroral Radar Network (SuperDARN) is a network of HF radars operated under the international collaboration of 12 countries. At present, total of 33 radars have been operating in both hemispheres, monitoring important ionospheric parameters such as the global convection pattern and plasma density perturbations with high time (1 to 2 min) resolution. In addition to normal operaration modes, SuperDARN frequently operates special observation modes for conjunction studies with spacecraft programs, such as THEMIS, VAP and ERG missions. Japan has been operating total of 4 radars in Antarctica, Alaska and Hokkaido, contributing to the operation of the network. Judging from the characteristics of the network, it is expected to play important roles in several projects of the VartSITI programs, such as: ISEST (International Study of Earth-affecting Solar Transients/MiniMax24), SPeCIMEN (Specification and Prediction of the Coupled Inner-Magnetospheric Environment), and ROSMIC (Role Of the Sun and the Middle atmosphere/ thermosphere/ionosphere In Climate). Details of the SuperDARN network's role in the VarSITI program will be presented.

What determines the severity of space weather?

NANAN, Balan[5*] ; SKONG, R.[2] ; TULASI RAM, S.[3] ; RAJESH, P. K.[5] ; SHIOKAWA, Kazuo[1] ; HSU, R.[5] ; SU, T. H.[5] ; LIU, J. Y.[4]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Los Alamos National Laboratory, [3]Indian Institute of Geomagnetism, [4]National Central University, [5]National Cheng Kung University

Thanks to the works of a number of scientists it is known that severe space weather can cause extensive social and economic disruptions in the modern high-tech society. It is therefore important to understand what determines the severity of space weather, and whether it can be predicted. We present the results obtained from the analysis of solar-geophysical data during 30 space weather events that occurred since 1957 and produced geomagnetic storms of intensity less than -275 nT, and the Carrington event of 1859. The results seem to indicate that (1) space weather can become severe occasionally (7 since 1957) as experienced by satellite systems, Earth-based systems and Earth's environment. (2) It is the impulsive energy (or power) at the leading edge of the CMEs (coronal mass ejections) mainly due to impulsive leading edge velocity and partly due to density that determines the severity of space weather in the heliosphere; the higher the impulsive velocity (sudden increase by over 275 km s-1 over the background), the more severe the space weather. (3) Such CMEs with IMF Bz also southward from the leading edge cause severe space weather on Earth though the magnitude of southward Bz does not seem important, and the minimum impulsive velocity for severe space weather on Earth seems higher than that for severe space weather in heliosphere. (4) CMEs having northward IMF Bz at the leading edge do not seem to cause severe space weather on Earth though they can lead to geomagnetic storms of long duration main phase with intensity less than even -420 nT. Measurements of the rate of energy release during CME eruption (or measurements of the velocity and density of CMEs as close to the Sun as possible) and orientation of IMF Bz in CMEs may be used for predicting severe space weather.

Research and operatoinal activity of NICT space weather

ISHII, Mamoru[1*]

[1]NICT

ICT has been managing operational space weather forecast
since 1988 as a member of Inernational Space Environment Services (ISES). We provide the space weather forecast information every day including holidays with email and web site, and the number of subscribers is over 9,000.

In addition to these operational activity, we have research activities for improving the performance of space weather forecast.
We have three research projects, (1)sun and solar wind (2)magnetosphere, and (3)ionosphere with three approaches as follows: observation, simulation and informatics. These activities are progressing under the cooperation with domestic/international organizations which is suitable to the concept of VarSITI. Especially the connection to the operational users of space weather is important but very few institute only works for that including NICT. In this meaning we NICT can contribute to the activity of VarSITI.

Researches on solar eruptive phenomena and solar activities using chromospheric imaging data with the CHAIN

UENO, Satoru[1*] ; SHIBATA, Kazunari[1] ; ASAI, Ayumi[1] ; KITAI, Reizaburo[1] ; MORITA, Satoshi[2] ; OTSUJI, Kenichi[2] ; CABEZAS, Denis P.[3] ; G. ESCATE, Maria V.[3] ; ISHITSUKA I., Jose K.[4] ; YAMAGUCHI, Masashi[1] ; WATANABE, Hiroko[1] ; KIMURA, Goichi[1] ; ICHIMOTO, Kiyoshi[1] ; NAGATA, Shin'ichi[1] ; NAKATANI, Yoshikazu[1]

[1]Kyoto University, Japan, [2]NAOJ, [3]Presbiteriana Mackenzie University, Brazil, [4]Institute of Geophysics in Peru

In 2010, Kyoto University moved the Flare Monitoring Telescope (FMT) from Japan to Peru, and currently we are technically supporting two projects of building new solar telescopes in Saudi Arabia and Algeria under the Continuous H-Alpha Imaging Network (CHAIN) project. We also held international data analysis workshops three times during this four years to train foreign and domestic young researchers to analyze the data obtained by the FMT and Solar Magnetic Research Telescope (SMART) at Hida Observatory in Japan.

Current main scientific themes of the CHAIN project are

(1) 3D velocity field measurement of eruptive phenomena on the solar surface:
By applying "cloud model fitting" to multi-wavelength H-alpha chromospheric images, we can calculate physical parameters of moving features on the chromosphere. We especially focus on the 3D velocity field of erupting filaments to understand the process of growth and propagation of CMEs. Morimoto & Kurokawa (2003) statistically investigated time evolution of 3D velocity field of disappearing phenomena of chromospheric H-alpha filaments, and they observationally showed that if H-alpha filaments actually erupted, then CMEs necessary appears. On the other hand, however, when filaments are disappeared without eruption, sometimes CMEs occur. We have to know how to CMEs are generated in such a case, comparing with other observational data or MHD simulations. Moreover, we will statistically investigate relationship between characteristics of filament eruptions and geo-effectiveness of the CMEs .

(2) Detection of shock waves (Moreton wave) generated by solar explosive phenomena:
The FMT is quite effective to detect Moreton wave that was explained as the intersection of coronal shock wave on the solar chromosphere. Narukage et al. (2002) and Asai et al. (2012) observationally showed that Moreton waves detected in H-alpha chromospheric images actually correspond to foot-point of coronal shock waves observed with X-ray telescope or EUV telescope on satellites. On the other hand, even if flares that has almost the same intensity, sometimes they are accompanied by Moreton waves and sometimes they are not accompanied by them. We are investigating what are differences between flares "with" and "without" Moreton waves. According to our preliminary statistical study, the angle of filament eruption from the solar surface seems to be the most important parameter. We promote more investigation for more cases more accurately by combining with other satellite data or MHD simulations. Moreover, after that, we want to compare with characteristics of radio bursts and to investigate time evolution of various shock waves from solar surface to interstellar space.

(3) Estimation of solar UV radiation and comparison with ionospheric variation:
Solar radiation is also one of very important element for understanding the change of space weather. Especially solar UV around from 50 to 140 nm has strong influence for the ionosphere of the earth. One of good index of the change of ionosphere is the "geomagnetic solar daily quiet variation (Sq)". It basically changes well obeying the variation of solar UV radiation. When we investigate long-term variation of solar component and terrestrial component of Sq, currently we usually use F10.7 flux, sunspot number etc. as indexes of solar activity, because actual UV observations started just after around 1995. However, the indexes such as F10.7 do not accurately express variation of UV radiation and we cannot know accurate variation of terrestrial component of Sq. Therefore, we are currently trying to reproduce UV intensity from chromospheric images that have been obtained during longer-term than UV data. After this, by using estimated variation of solar UV radiation, we want to investigate relationship between solar activities and other physical parameters of ionosphere, too.

In this talk, we introduce our recent results and plans in VarSITI period on these themes.

The EISCAT (European Incoherent SCATter) Scientific Association is an international research organization, which operates incoherent scatter (IS) radars in northern Scandinavia and Svalbard for studies of physical and environmental processes in the middle/upper atmosphere and near-Earth space. Since 1996, National Institute of Polar Research, in collaboration with STEL, Nagoya University, has promoted EISCAT collaborations for the user community in Japan to utilize the EISCAT facility as well as EISCAT data for their scientific subjects. Japanese scientists have been studying several scientific topics such as 3-D ionospheric current system, aurora dynamics, ion upflow, neutral wind dynamics, using EISCAT data, and published 110 papers from1995 to 2013.

EISCAT_3D is the major upgrade of the existing EISCAT radars in northern Scandinavia. The EISCAT_3D radar is a new phased array IS radar using the center frequency 233 MHz. The idea was firstly presented as 'E-prime' in 2003. The EISCAT community has been doing large efforts to make it happen since then. The design study was conducted from 2005 to 2009, and the preparatory phase program has been conducting since 2009 (until September 2014). With a multi static phased array system composed of one central active (transmiter-receiver) site and four receiver sites, the EISCAT 3D system is expected to provide us 10 times higher temporal and spatial resolution and capabilities than the present EISCAT radars. Furthermore, continuous observations can be made, and will provide us with long-term data sets of the polar ionosphere, which can be used to investigate variations of the ionosphere as well as the neutral wind dynamics (in particular, studies of planetary waves and tidal waves). In this presentation, we will overview the EISCAT_3D project, and present our strategic plan of national funding for the EISCAT_3D as well as science targets.

ROSMIC (Role Of the Sun and the Middle atmosphere/thermosphere/ionosphere In Climate, co-leaders: F.-J. Luebken, A. Seppala, W. Ward) is one of the four projects in VarSITI started in 2014 as a five year project. The goal of the project is to understand the impact of the Sun on the terrestrial middle atmosphere/lower thermosphere /ionosphere (MALTI) and Earth's climate and its importance relative to anthropenic forcing over various time scales from minutes to centuries. ROSMIC project consists of four sub-projects: 1) Coupling through solar variability (radiative, electrodynamics, ionospheric and photochemical effects), 2) Coupling by dynamics, 3) Trends in Mesosphere and Lower Thermosphere, 4) Trends and solar cycle effects in the thermosphere (incl. technological aspects). The project will be conducted under close collaborations between observations and modelings. Observations include both usage of existing data records and new measurements from a wide range of ground based (lidars, radars, mappers), in-situ (rockets, balloons, aircraft), and satellite (e.g., AIM, TIMED) instruments. Dedicated models are used and developed for a better understanding of specific processes (e.g. gravity wave breaking, ice formation). Global scale models will be modified and applied from the ocean to the thermosphere. Through the five year projects, we expect better understanding of the impact of solar activity on the entire atmosphere, relative to anthrogenic forcing and natural long term variability. In the paper, we will introduce outline of ROSMIC project and discuss how Japanese activities contribute to the ROSMIC project.

Contribution of IUGONET to the VarSITI program

TANAKA, Yoshimasa[1*] ; YATAGAI, Akiyo[2] ; SHINBORI, Atsuki[3] ; KOYAMA, Yukinobu[4] ; ABE, Shuji[5] ; UMEMURA, Norio[2] ; SATO, Yuka[1] ; YAGI, Manabu[6] ; UENO, Satoru[7] ; HORI, Tomoaki[2]

[1]National Institute of Polar Research, [2]Solar-Terrestrial Environment Laboratory, Nagoya University, [3]Research Institute for Sustainable Humanosphere, Kyoto University, [4]World Data Center for Geomagnetism, Kyoto University, [5]International Center for Space Weather Science and Education, Kyushu University, [6]Planetary Plasma and Atmospheric Research Center, Tohoku University, [7]Kwasan and Hida Observatories, School of Science, Kyoto University

The Variability of the Sun and Its Terrestrial Impact (VarSITI) program aims at understanding the current extremely low solar activity and its influence on the Earth for various time scales and locations. In order to achieve these goals, it is necessary to conduct an interdisciplinary study that uses various types of data from multiple regions, such as solar interior, solar surface, heliosphere, magnetosphere, ionosphere, and atmosphere. The Inter-university Upper atmosphere Global Observation NETwork (IUGONET) project has developed the research infrastructure to promote such an interdisciplinary study. The IUGONET is an inter-university project by five Japanese institutes and universities (Tohoku University, Nagoya University, Kyoto University, Kyushu University, and the National Institute of Polar Research) that have been developing a worldwide ground-based observation network of the upper atmosphere, Sun and planets. The main tools developed by the IUGONET are metadata database and data analysis software.

The IUGONET metadata database (IUGONET-MDB) enables cross-searching of data distributed across the member institutes/universities of IUGONET. The metadata of various ground-based observational data have already been registered not only by the members of IUGONET but also by the other Japanese institutes, for example, the National Institute of Information and Communications Technology (NICT), the Solar Observatory of National Astronomical Observatory of Japan (NAOJ), and the Kakioka magnetometer observatory, Japan Meteorological Agency. We also consider including data from the satellites and the numerical simulation in the future. The iUgonet Data Analysis Software (UDAS) is a plug-in software of Space Physics Environment Data Analysis System (SPEDAS), which is an integrated analysis platform for visualizing and analyzing the ground-based and satellite observation data. The UDAS has provided many routines to load the ground-based observational data from various types of instruments, including solar telescope, solar radio telescope, ionosphere and atmosphere radars, imagers, magnetometers, and so on. The SPEDAS also includes a plug-in tool from a Japanese satellite mission, Energization and Radiation in Geospace (ERG), which will explore the dynamics of the radiation belts in the Earth's inner magnetosphere. Thus, they will be powerful tools for four projects of the VarSITI, in particular, Specification and Prediction of the Coupled Inner-Magnetospheric Environments (SPeCIMEN) and Role Of the Sun and Middle atmosphere thermosphere/ionosphere in Climate (ROSMIC). In the presentation we will show some examples of scientific researches that the IUGONET has done using the upper atmospheric data and discuss our possible contribution to the VarSITI program.

Characteristics of airglow and auroral emissions in the lower- and upper-thermosphere obtained with IMAP/VISI on ISS

SAKANOI, Takeshi[1*] ; PERWITASARI, Septi[1] ; SAKAMOTO, Daiki[1] ; SAITO, Akinori[2] ; OTSUKA, Yuichi[3] ; AKIYA, Yusuke[2] ; HOZUMI, Yuta[2] ; YAMAZAKI, Atsushi[4] ; SUZUKI, Shin[3]

[1]Grad. School of Science, Tohoku University, [2]Grad. School of Science, Kyoto University, [3]STEL, Nagoya University, [4]ISAS / JAXA

We report the recent highlights of results on airglow and auroral distribution in the lower- and upper-thermosphere based on IMAP/VISI measurement data, and also report the current status of the operation VISI. IMAP/VISI is a visible imaging spectrometer which aims to measures nightglow emissions from ISS (˜400 km altitude) covering the wide range from +51 deg. to ? 50 deg. in geographical latitude. VISI adopts two field-of-views (+/-45 deg. to nadir) to make a stereoscopic measurement of the airglow and aurora emission to subtract background contaminations from clouds and ground structures. Each field-of-view has 90 deg width faced perpendicular to the orbital plane, which is mapped to ˜600 km width at 100 km altitude and ˜300 km width at 250 km altitude. A continuous line-scanning for all emissions lines in the nightside hemisphere in the latitudinal range from +51 deg. to -51 deg. is carried out by VISI with the successive exposure cycle with a time interval of 1 - several sec, which corresponds to a spatial resolution of 10 km ? a few tens km. From VISI data, we obtain the global distribution of airglow emissions (O 630 nm at 250 km alt., OH Meinel band 730 nm at 87km alt., and O2 (0-0) atmospheric band 762 nm at 95 km alt.) and auroral emissions (O 630 nm at 250 km alt., N2 1P 730 nm at ˜110 km alt. and O2 762 nm at ˜120 km alt.).

Since the successful launch of IMAP on August 2012, we found that meso-scale (˜10 - 50 km) wave pattern is always seen in the airglow emission at O2 762 nm mainly at mid-latitudes. The typical O2 airglow intensity is several hundreds R to several kR. Most of O2 airglow shows straight-shaped pattern, which indicates plane atmospheric gravity waves. In addition, we found more than 30 events on the concentric gravity wave (CGW) pattern in O2 airglow emission, which suggests that the local generation source in the lower-atmosphere. 26 CGW events out of total 30 events happened in March and April in 2013, which suggests its seasonal effect.

VISI sometimes measured auroral emissions at high-latitudes during geomagnetically disturbed period. One of major purposes of auroral measurement with VISI is to understand the generation process of gravity wave by auroral activity. However, we could not obtain the gravity wave event caused by aurora so far. Another target of VISI high-latitude measurement is SAR arc in the sub-auroral region. Even though the solar activity is expected to be maximum in 2012 ? 2013, we could not obtain the SAR arc data so far. However, we still expect to measure the SAR arc event caused with a major storm during a solar declining phase.

In addition, in the low-latitude region around the magnetic equator, we frequently obtained the enhanced O630 nm emission associated with equatorial ionization anomaly (EIA) overlapped with small-scale dark filament pattern, i.e., plasma bubble. We found the seasonal dependence of O630 nm intensity in the EIA which is consistent with the vertical motion of ionospheirc plasma due to the dragged by thermospheric day-to night tidal winds. The O630 nm intensity associated with EIA significantly decreased during the main phase of magnetic storm when the Dst index is larger than 90 nT. This fact suggests that the westward electric field associated with Region-2 current system penetrates to the ionosphere in the lower latitude that reduce the upwelling of EIA. We also obtained the MSTID pattern in O 630 nm emission in the eastside of North America on August 1 2013 by comparing the O 630 nm emission and TEC map. We carried the special operation for the measurement of MSTID last winter, and will summarize the result.

The effect of Solar radiation on the Climate of Yakushima

MURAKI, Yasushi[1*] ; SHIBATA, Shoichi[2] ; SHIBATA, Takashi[3]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Department of Engeneering, Chubu University, [3]Graduate School of Environment Studies, Nagoya University

Yakushima (Yaku-island) is located to the south of Kyushu in Japan and is known as one of the world natural heritages of UNESCO. There are mountains on the island with heights of about 2,000m where cedar trees have lived for more than 2000 years. We analyzed meteorological data for the island from 1938 to 2013 and found several interesting results:

(1) Eleven and 20-30-year-periodicities are present in the data on daylight hours. Similar periodicities are, however, not seen in the data on temperature or water vapor pressure.
(2) The 11-year-periodicty appears strongly in June, the rainy season of the island, while the 20-30-year-periodicty is seen throughout the year except in April.
(3) An 11-year-periodicty can be also seen in the data for June and July at the other remote island Hachijyojima situated 300km to the south of Tokyo. Both islands are located on the Kuroshio warm current.
(4) The daylight hour data for January increased systematically around 1976. This may be related to the change of the North Hemisphere Temperature (NHT) in 1976.

In order to explain the observations, we examined the following hypothesis. Ocean waves produce large numbers of tiny salty droplets which contain plankton on the sea surface. These droplets (aerosols) are winded up and reach at the top of the mountain. They may act as cloud condensation nuclei (CCN).
It is known that the intensity of the UV light from the Sun is modulated by solar activity. It is also possible that the growth rate of CCN is affected by the solar UV radiation in the early stage of the aerosol formation process.
We speculate that this may be why solar activity is recognized in the daylight hour data. We have not accounted for the 20-30-year-periodicity in the data, but we speculate that this could be related to the Pacific Decadal Oscillation (PDO).
Details will be presented at the conference.

Sounding rocket observation of the thermosphere-ionosphere-magnetosphere coupling

ABE, Takumi[1*] ; SAITO, Yoshifumi[1]

[1]Japan Aerospace Exploration Agency

The polar ionosphere is an open window of the Earth atmosphere to the outside space such as the magnetosphere and the solar wind, because energy and/or mass tends to be injected along the magnetic fields via various physical processes. In this connection, there exist numerous unique and unrevealed phenomena in the polar ionosphere.

Sounding rocket is a powerful platform which provides opportunity to make a vertical sounding through the lower thermosphere, ionosphere and magnetosphere while satellite generally flies in a horizontal direction, and it has an advantage so that it can enable us to make a brief survey of the upper atmosphere in the vertical direction. The Institute of Space and Astronautical Science (ISAS) of Japan Aerospace Exploration Agency (JAXA) has conducted sounding rocket experiments in Norway to investigate the upper atmospheric dynamics and chemistry induced by the auroral energy input. The primary objectives of these experiments include various topics; pulsating aurora, ozone chemistry affected by the auroral activity, fine structure of the auroral arc, and the cusp ion outflow. These subjects arise from phenomena that is caused by interaction between the solar wind or magnetospheric plasma and the upper atmosphere. It is necessary to make a comprehensive observation of the energy input, the response and consequences for better understanding of the causal relationship.

There are several candidates of the sounding rocket experiment which should be conducted in the auroral region for a direct measurement of the energy input from higher altitudes and the ionospheric response. To obtain the high-time resolution data of the ionospheric ion outflow which is one of the most significant phenomena of the magnetosphere-ionosphere coupling, it is necessary for the sounding rocket equipped with plasma and field instruments to reach up to 1000 km altitude. For such an experiment, it will be a key to get information on the wave-particle interaction which may play an important role in accelerating ionospheric ions. It is well known that the polar lower thermosphere has a significant response to auroral energy input from higher altitudes. This indicates an existence of energy inputs from the magnetosphere probably in the form of electric fields or energetic particles. It is important to understand quantitatively the momentum transfer between the neutrals and plasma by observing the neutral wind and ion drift simultaneously. The sounding rocket experiment to elucidate such a neutral-plasma coupling is also under consideration.

Thus, we are considering several candidates of the sounding rocket experiments which should be conducted in the auroral region to investigate the upper atmospheric response against the energy input from higher altitudes. In this presentation, we will briefly introduce some of the promising experiments.

Trend of SST anomalies and Solar Activity

YAMASHIKI, Yosuke[1*]

[1]GSAIS, Kyoto University, [2]APL, JAMSTEC

The tendency of anomalies of SST during the fluctuation of Sunspot numbers are studied using composite SST and fluctuation of SSN.

In general, El Nino tendency is observed during Sunspot numbers (SSN) minimum, while La Nina tendency is observed in SSN maximum. It is generally accepted that the frequency of Solar Activity varies in 11 years, during those years there are SSN maximum and minimum. On the other hand, SST anomalies do not correspond well to the frequency of the solar activity. In addition, the thermal structure of sea surface temperature (SST) varies during El Nino and La Nina. Moreover, the impact of large-scale solar flare on the SST has not been clearly evident for the 4 days backward and forward comparison for the flare event on 2 April 2001 and 28 October 2003 on SST, wind velocity and OLR. Since the ocean has higher heat capacity, this might prevent the appearance of immediate SSN effect through the surge of any frequency in any band of electromagnetic waves from the SUN. The subtle impact might be confirmed either through cloud or wind. The long-term impact should also be considered by precise integration of the total energy on each wavelength. Numerical simulation is also expected to validate this issue.

Recent observations by Rayleigh/Raman lidar and developments of tunable resonance scattering lidar system in JARE

EJIRI, Mitsumu K.[1*] ; TSUDA, Takuo[1] ; NISHIYAMA, Takanori[1] ; ABO, Makoto[2] ; TOMIKAWA, Yoshihiro[1] ; SUZUKI, Hidehiko[3] ; KAWAHARA, Takuya[4] ; TSUTSUMI, Masaki[1] ; NAKAMURA, Takuji[1]

[1]National Institute of Polar Research, [2]Graduate School of System Design, Tokyo Metropolitan University, [3]College of Science, Rikkyo university, [4]Faculty of Engineering, Shinshu University

The National Institute of Polar Research (NIPR) is leading a six year prioritized project of the Antarctic research observations since 2010. One of the sub-project is entitled ”the global environmental change revealed through the Antarctic middle and upper atmosphere”. Profiling dynamical parameters such as temperature and wind, as well as minor constituents is the key component of observations in this project, together with a long term observations using existent various instruments in Syowa, Antarctica (69S, 39E). As a part of the sub-project, Rayleigh/Raman lidar was installed at Syowa Station in January, 2011 and has been operated at more than 350 nights ($>$3000 hours clear sky) by February, 2014. The Rayleigh/Raman lidar observes temperature and clouds in the mesosphere, the stratosphere and part of the troposphere, and providing seasonal and yearly variations of temperature profiles and data of gravity wave characteristics in the middle atmosphere, as well as high altitude clouds of PMC (polar mesospheric clouds) and PSC (polar stratospheric clouds). In order to extend the height coverage to include mesosphere and lower thermosphere region, and also to extend the parameters observed, a new resonance scattering lidar system with tunable wavelengths is developed at NIPR in Tachikawa (36N, 139E). The lidar transmitter is based on injection-seeded, pulsed alexandrite laser for 768-788 nm (fundamental wavelengths) and a second-harmonic generation (SHG) unit for 384-394 nm (second harmonic wavelengths). The laser wavelengths are tuned in to the resonance wavelengths by a wavemeter that is well calibrated using a wavelength-stabilized He-Ne laser. The new lidar has capabilities to measure density variations of minor constituents such as atomic iron (Fe, 386 nm), atomic potassium (K, 770 nm), calcium ion (Ca^+, 393 nm), and aurorally excited nitrogen ion ($N_2{}^+$, 390-391 nm) and temperature profiles in the mesosphere and lower thermosphere (MLT) region using resonance scatter of K. Currently, the fundamental laser pulses are transmitted with 120-160 mJ/pulse at approximately 25 Hz (i.e., $\sim$3-4 W) and the backscattered signal is received with a 35 cm diameter telescope. The new lidar system will be installed two years later at Syowa Station and provide information on the mesosphere and lower thermosphere as well as the ionosphere. This unique observation is expected to make important contribution to studies on the atmospheric vertical coupling process and the neutral and charged particle interaction. In this talk, current status of the research, observations, and system developments will be presented.

400 years interval of amplification in quasi bi-decadal climate variability: a case of summer precipitation in Japan

NAKATSUKA, Takeshi[1*]

[1]Research Institute for Humanity and Nature

Introduction

Quasi bi-decadal climate variability, often found in palaeoclimatological time series, should be not only attributed to internal climate variation such as ocean-atmosphere interaction, but also owing to astronomical climate forcing like 22 year cycle of solar activity. In long human history, the multi-decadal climate variations are sometimes enhanced to cause long abnormal meteorological conditions and result in numerous famines, wars and political regime shifts. Why does the amplitude of natural climate variation change? If we can understand mechanism of the amplitude modulation in climate variability and predict its future, it must be very helpful for improvement of our adaptability to climate change. In this presentation, I will discuss climatic mode of 400 year intervals of amplification in quasi bi-decadal climate variability found in last two millennial records of summer precipitation which were reconstructed annually by tree-ring cellulose isotope ratios.

Reconstruction of summer precipitation by tree-ring oxygen isotope ratio

Until recently, paleoclimatologists in Japan could not reconstruct precipitation before Edo era when weather descriptions in numerous diaries enable us to discuss climate change precisely. However, it is now possible to elucidate historical changes in summer precipitation with annual time resolution using tree-ring cellulose oxygen isotope ratios all over Asia monsoon area including Japan. Last two millennial summer precipitation variations have been reconstructed in central Japan using many wood samples of Japanese cypress from living trees, old architectures, archaeological remains and buried logs.

Amplification of quasi bi-decadal variability occurring at 400 years intervals.

By wavelet analysis of the two millennia length of summer precipitation record in central Japan, I have found that there are distinct periods of amplitude modulation for the multi-decadal variability, especially at quasi bi-decadal periodicity, in 2nd, 6th, 10th, 14th and 18th centuries when long lasting flood and drought occurred. In fact, 2nd, 6th and 14th centuries correspond to the end of Yayoi, Kofun eras and the medieval upheaval period (Namboku-cho, twin dynasty, era) in Japan, respectively. 10th and 18th centuries are also known as periods of the collapse of centralized political system and the occurrence of giant famines all over Japan, respectively. The amplitude modulation in quasi bi-decadal periodicity occurring at 400 years intervals always started with sudden decrease in tree ring d18O, accompanied with sudden increase and decrease in its d13C and 14C content, respectively. At present, I can propose the sudden enhancement of summer monsoon activity bringing tropical air mass to explain all signals of sudden changes in tree-ring isotope records. Especially, sudden increases in temperature during 14th century, which is corresponding to the precipitation increase in Japan, are found at low and middle latitudinal areas in both hemispheres, illustrating that they are actually owing to the summer monsoon enhancement originating from tropical areas. If the amplification in quasi bi-decadal variability at 400 year intervals is related to the periodical change in solar activity such as 800 year cycle, it must be very important to elucidate astronomical and climatic mechanisms combining cause (solar cycle) and effect (amplitude modulation) precisely.

Ionospheric studies using high-resolution GPS total electron content observations

TSUGAWA, Takuya[1*] ; NISHIOKA, Michi[1] ; SAITO, Akinori[2] ; OTSUKA, Yuichi[3] ; ISHII, Mamoru[1]

[1]National Institute of Information and Communications Technology, [2]Graduate School of Science, Kyoto University, [3]Solar-Terrestrial Environment Laboratory, Nagoya University

Two-dimensional total electron content (TEC) observations using dense GPS receiver networks have been applied to studies of various ionospheric disturbances since mid-1990s. For the purpose of monitoring and researching the ionospheric disturbances, we have developed high-resolution TEC maps using dense GPS receiver networks. We have been collecting all the available GNSS receiver data in the world to expand the TEC observation area. These GNSS data are provided by IGS, UNAVCO, SOPAC, and other regional data centers. Currently, we are providing global and regional maps of absolute TEC, detrended TEC, and rate of TEC change index (ROTI). These data and quick-look maps are archived and available in DRAWING-TEC website (http://seg-web.nict.go.jp/GPS/DRAWING-TEC/).

These high-resolution GPS-TEC maps have been applied to studies of various ionospheric disturbances. Sudden increase in TEC caused by solar flares were studied using global TEC observations. Regional TEC observations have revealed new characteristics of large- and medium-scale traveling ionospheric disturbances (LSTIDs and MSTIDs). Recently, clear concentric waves and short-period oscillations were observed after huge earthquakes/tsunamis and massive tornadoes, indicating that acoustic and/or gravity waves propagate upward from the lower atmosphere and reach the ionosphere.

These GPS-TEC observations will contribute the next SCOSTEP program VarSITI, particularly to the ROSMIC (Role Of the Sun and the Middle atmosphere/thermosphere/ionosphere In Climate) project.

Modulation of Greenland temperature through changes in solar activity

KOBASHI, Takuro[1*] ; KAWAMURA, Kenji[1] ; GOTO-AZUMA, Kumiko[1]

[1]National Institute of Polar Reseaerch

During the past decades, Greenland climate has undergone rapid warming and ice sheet ablation in coastal region with a nearly 1 mm/y sea level contribution. For sea level projection, it is critical to understand the mechanisms of Greenland temperature variability. Greenland temperature is known to be affected by the North Atlantic Oscillation (NAO), and it is also highly correlated with North Atlantic average temperature. Using the Greenland temperature reconstructed from argon and nitrogen isotopes in occluded air in GISP2 ice core (Kobashi et al., 2011), we found Greenland temperature deviated negatively (positively) from North Hemispheric (NH) temperature trend during stronger (weaker) solar activity over the past 800 years (Kobashi et al., 2013b). We also confirmed this effects continued over the past 4000 years (Kobashi et al., 2013a). Climate modeling suggests that the deviation was caused by solar induced atmospheric circulation changes (like NAO). The model also suggests that Atlantic meridional circulation weakens during the stronger sun by similar processes as enhanced greenhouse effect (Kobashi et al., 2013b). From the past relation between Greenland temperature anomaly and solar variability, it can be speculated that future gland solar minimum may induce additional 2 ^{0} C warming in Greenland with increased melting of the ice-sheet.

Study of equatorial atmosphere/ionosphere under RISH/LAPAN collaboration

YAMAMOTO, Mamoru[1*] ; YATINI, Clara[2] ; BUDIYONO, Afif[2] ; HERMAWAN, Eddy[2] ; HASHIGUCHI, Hiroyuki[1]

[1]RISH, Kyoto University, [2]National Institute of Aeronautics and Space (LAPAN)

The Earth's atmosphere is vertically coupled with atmospheric waves. Momentum/energy transfer from lower to upper atmosphere through wave propagation plays an big role of determining the dynamics of the atmosphere. The energy input from the sun is the maximum at the equator that leads to the intense convection, and then variety of atmospheric waves are generated in the region. The equatorial atmosphere could be regarded as an engine for dynamics of the whole atmosphere. RISH-LAPAN started collaboration for the study of equatorial atmosphere/ionosphere since mid 1980s, and conducted radiosonde observation campaigns, meteor and MF radars, etc. The Equatorial Atmosphere Radar (EAR) was installed over the geographic equator on Sumatra Island in 2001. We continued long-term experiment for more than 10 years, and have found that troposphere-stratosphere airmass exchange is controlled by the modulation of the tropopause by Kelvin waves. Turbulent structures of the tropopause region is also revealed by the EAR. In the ionosphere, spatial and temporal variability of the equatorial Spread-F are clearly observed by the multibeam experiment. With research collaboration with other Japanese university/institutes, the EAR site now became a complete observatory that consists of many instruments, i.e., a meteor radar, a boundary-layer radar, a meteorological radar, lidars, an ionosonode, GPS receivers, etc. The next big project of our own is to improve the EAR ability by building the Equatorial MU radar (EMU) aside of the EAR, which is now included in the Japanese Master Plan. RISH-LAPAN recently obtained a fund of "JSPS Bilateral Joint Research Projects" for FY2014-2016. We will have more chances to discuss collaborative research program for the equatorial atmosphere/ionosphere. In the presentation we summarize our collaboration, and discuss future direction of research including the new EMU.

Monitoring of molecular compositions in mesosphere with a network of ground-based millimeter-wave radiometers

NAGAHAMA, Tomoo[1*] ; MIZUNO, Akira[1] ; NAKAJIMA, Tac[1] ; OHYAMA, Hirofumi[1] ; ISONO, Yasuko[1] ; KOJIMA, Yasusuke[1] ; TSUTSUMI, Masaki[2] ; NAKAMURA, Takuji[2] ; MAEZAWA, Hiroyuki[3] ; OGAWA, Hideo[3]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]National Institute of Polar Research, [3]Osaka Prefecture University

Chemical composition in mesosphere and lower thermosphere (MLT) region is strongly affected by changes of solar-terrestrial environment; for example, energetic particle precipitation into the earth atmosphere induces composition change in the mesosphere and lower thermosphere. Changes of gravity-wave activities also make the composition changes caused by temperature variations in various timescales.

To investigate these changes related to environment changes in the altitude region, we have started a project of network measurements of the distribution of mesospheric minor constituents, such as ozone, by using ground-based millimeter-wave spectral radiometers with a high-sensitivity superconducting (SIS) mixer receiver. We have been operating three millimeter-wave radiometers in the southern hemisphere; Atacama highland in Chile (23S, 68W), Rio Gallegos in Argentina (52S, 69W), and Syowa station in Antarctica (69S, 39E), and one radiometer in Rikubetsu, Japan(44N, 144E). Especially, at Syowa station, we have been monitoring ozone and nitric oxide (NO) spectra in 250 GHz band, and we have clearly detected temporal variations of NO column density in the MLT region including sudden enhancements of NO suggested to be associated with the energetic electron precipitation events.

In the presentation, we report features of observed variations of mesospheric ozone and NO as well as details of instruments, data validation and future extensions.

Observations and modeling studies for understanding atmospheric responses to unusual solar activities

FUJIWARA, Hitoshi[1*] ; MIYOSHI, Yasunobu[2] ; JIN, Hidekatsu[3] ; SHINAGAWA, Hiroyuki[3] ; NOZAWA, Satonori[4] ; OGAWA, Yasunobu[5] ; KATAOKA, Ryuho[5]

[1]Faculty of Science and Technology, Seikei University, [2]Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University, [3]National Institute of Information and Communications Technology, [4]Solar Terrestrial Environment Laboratory, Nagoya University, [5]National Institute of Polar Research

As pointed out by many researchers, the recent solar activities are very unusual; the solar activity during the last minimum in 2008-2009 was extremely low and that during the next maximum of sunspot cycle 24 shows much lower activities compared with the previous two solar maximums in cycle 22 and 23. In order to understand the complex system of the Earth's middle and upper atmosphere, these solar activities will give us important information and/or good opportunities for searching the basic states of the system both from the observations and GCM simulations. Comprehensive studies by observations from space, ground-based ones, and numerical simulations will enable us to understand the polar mesosphere, thermosphere, and ionosphere quantitatively. In order to understand variations of the polar ionosphere from the solar minimum to maximum periods, we have made EISCAT experiments in January 2011, March, 2012, and March 2013. For example, ionospheric variations were observed during solar flare and CME events on March 12, 2012. These EISCAT data clearly show an example of the solar wind, magnetosphere, and ionosphere coupling. In addition to the EISCAT observations, we have also investigated variations of the polar thermosphere during periods of significant solar activities from GCM simulations. In this presentation, we will introduce our research activities mainly related to the "Role Of the Sun and the Middle atmosphere/thermosphere/ionosphere In Climate (ROSMIC)" project in VarSITI.

Enhancing our understanding of the atmosphere-ionosphere coupling with Low Earth Orbiting satellite missions

LIU, Huixin[1*] ; LUEHR, Hermann[2]

[1]Kyushu University, Japan, [2]GFZ, Germany

Low Earth Orbiting (LEO) satellites provide unique opportunities to observe the near-Earth space environment. Recent LEO satellite mission have been making rapid contribution to our understanding of the coupled atmosphere-ionosphere system by providing unprecedented observational evidences for the connection between ionospheric/thermosphric phenomena and their meteorological causes. This talk will briefly summarize the achievements of the decade-long CHAMP mission from the vertical coupling point of view, which is followed by a scientific perspective on the newly launched 3-satellite constellation SWARM mission.

Multipoint airglow imaging measurements of mesospheric gravity waves over Japan

SUZUKI, Shin[1*] ; SHIOKAWA, Kazuo[1] ; OTSUKA, Yuichi[1]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

Atmospheric gravity waves significantly contribute to the wind/thermal balances in the mesosphere and lower thermosphere (MLT) through their vertical transport of horizontal momentum. It has been reported that the gravity wave momentum flux preferentially associated with the scale of the waves; the momentum fluxes of the waves with a horizontal scale of 10-100 km are particularly significant. Airglow imaging is a useful technique to observe two-dimensional structure of small-scale (<100 km) gravity waves in the MLT region and has been used to investigate global behavior of the waves. The Solar-Terrestrial Environment Laboratory, Nagoya University, has made long-term airglow imaging observations with ground-based all-sky airglow imagers using the Optical Mesosphere and Thermosphere Imager (OMTI) system. Each airglow imager of OMTI has interference filters on rotating wheels to observe airglow emissions in the vicinity of the mesopause (OI 557.7-nm, emission height ∼96 km; OH Meinel-bands, ∼86 km) and the ionosphere (OI 630.0-nm, ∼250 km). Four airglow imagers, which each has the field-of-view with a size of 5 deg x 5 deg in longitude and latitude at the mesopause height, has been in operation in Japan and, as a whole system, they nearly cover all part of Japan. This multipoint network enables us to detect propagation signatures and the spatial extent of MLT waves over a much wide range than ever.

In the presentation, we will report recent results of the MLT gravity waves having a very large spatial extent based on the OMTI multipoint measurements, such as a coherent gravity wave ducting and large concentric gravity wave rings possibly induced by a typhoon; these results offer new insight into dynamical coupling process between the lower and upper atmosphere.

How has the atmosphere of terrestrial planets responded to the evolution of the sun, a center star of our solar system? In order to answer the question of the coevolution of our sun and the planetary environment " planetosphere ", planetary exploration missions have been promoted and related interdisciplinary researches are rapidly developing worldwide. It is scheduled that NASA ' s Mars mission MAVEN arrives at Mars in September 2014 and Venus weather explorer AKATSUKI arrives at Venus at the end of 2015. These missions will provide us new observations and insights in this field. Moreover, the solar evolution is included in one of the next emphasized problems in VarSITI program that starts in 2014, and the time of international collaborations is expected to come. On the other hand, the past researches in the solar-terrestrial sciences have had large emphasis on understanding of dynamic variations of the present sun and planetary environment. The interdisciplinary researches of understanding the coevolution of the sun and planetosphere over past four billion years or so are in the incunabula but start to develop rapidly. In this presentation, we will introduce an attempt to investigate the coevolution of the sun and planetosphere by combining large-scale numerical simulations and the latest observations based on international collaborations and cooperation of solar physics, solar-terrestrial physics, aeronomy, and meteorology.

Role of global electric circuit in solar-climate connection

TAKAHASHI, Yukihiro[1*] ; SATO, Mitsuteru[1]

[1]Department of Cosmosciences, Hokkaido University

Global electric circuit model was proposed log time ago, in 1930s, in which thunderstorm plays a role of generator, and the ground and the ionosphere work as a spherical capacitor. We need to reconstruct this simple model, taking into account 3 aspects: 1) global-scale nonuniformities both of ionospheric conductivity and of the distribution of the generators, 2) connections between the troposphere and D-region, considering the effects of TLEs, such sprites and blue jets, 3) establishing the observational methodology for global electric field, excluding the effect of cloud existing just above the observation sites. Recently, the relationship between the global circuit and solar-climate connection was pointed out. Here we introduce an example, which indicates the roles of thunderstorm or its resultant electric circuit in solar-climate connection. Global relationship between thunderstorm/cloud activities and solar parameters are examined based on lightning measurement by Global ELF observation Network (GEON) operated by Hokkaido University and Outgoing Longwave Radiation (OLR) intensity. It was found that the number of lightning stokes in Asia Maritime Continent (AMC) varies with about month periodicity in the period from February to June 2004 and shows positive correlation (R= ˜0.8) with OLR in the Western Pacific Warm Pool (WPWP). On the other hand, OLRs in the central Africa and some other tropical areas show negative correlation with the number of lightning stokes in the AMC in that period. It is also found that the galactic cosmic rays or UV intensity associated with solar activity indicates good correlation with tropical OLR or lightning activity in AMC. One explanation to connect such global variations in thunderstorm / cloud amount with solar parameters would be the electrical circuit involving lower and upper atmospheres. If the ionospheric electric field modulates the potential gradient in the lower atmosphere, it could cause the re-distribution of ionized atmospheric particles, which may, in turn, change the generation / reduction speed of cloud particles.

A Realistic Whole Atmosphere-Ionosphere Modeling and Collaboration with Observations

JIN, Hidekatsu[1*] ; MIYOSHI, Yasunobu[2] ; FUJIWARA, Hitoshi[3] ; SHINAGAWA, Hiroyuki[1] ; MATSUO, Tomoko[4]

[1]National Institute of Information and Communications Technology, [2]Kyushu University, [3]Seikei University, [4]National Oceanic and Atmospheric Administration

There has been an increasing number of collaboration between modeling and observation for the study of upper atmospheric variability and its relation to the lower atmosphere. Observations are used as the forcing inputs to models as well as for their validation. Outputs from models can be useful for the interpretation of observed phenomena owing to their sufficient spatial and temporal coverage, especially for the analysis of phenomena whose effects extend beyond the several atmospheric layers. Recently, we have examined the effects of a prominent stratospheric sudden warming (SSW) in January 2009 on the upper atmospheric variability, by using a whole atmosphere-ionosphere coupled model called GAIA. The model used the meteorological reanalysis data as realistic lower atmospheric forcing, and we compared the model outputs with the satellite observations of upper atmosphere [Jin et al., 2012; Liu et al., 2012]. The comparison suggests that the model can reproduce the overall major features of the observed perturbed variations in the upper atmosphere during the SSW period, which ensures the usage of model output for the detail analysis of vertical coupling mechanism during the event.

In this study, we applied the same method for the inclusion of realistic lower atmospheric forcing and carried out a whole atmosphere-ionosphere simulation for longer period. We will show the relation of ionospheric variability to the climatological and irregular variations in the lower atmosphere including several SSW events. Initial results from data assimilation experiment will also be shown as an example of model-observation collaboration.

Contribution of the Optical Mesosphere Thermosphere Imagers (OMTIs) to VarSITI

OTSUKA, Yuichi[1*] ; SHIOKAWA, Kazuo[1]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

The Optical Mesosphere Thermosphere Imagers (OMTIs) consist of thirteen all-sky cooled-CCD imagers, five Fabry-Perot interferometers (FPIs), three meridian scanning photometers, and four airglow temperature photometers. They measure two-dimensional pattern, Doppler wind, and temperature through airglow emissions from oxygen (wavelength: 557.7 nm) and OH (near infrared band) in the mesopause region (80-100 km) and from oxygen (630.0 nm) in the thermosphere/ionosphere (200-300 km). They are in automatic operation at Australia, Indonesia, Thailand, far-east Russia, Japan, Canada, Hawaii, and Norway. Station information and quick look plots are available at http://stdb2.stelab.nagoya-u.ac.jp/omti/. We show recent results obtained by OMTIs particularly focusing on the penetration of short-period gravity wave from the lower atmosphere to the thermosphere and the ionosphere, which are often recognized as meridum-scale traveling ionospheric disturbances (MSTIDs) in the ionosphere. We also show some results obtained by the multi-point Fabry-Perot interferometers. These observations will contribute the next SCOSTEP program VarSITI, particularly to the ROSMIC Project.

Modeling Turbulence in Space Plasmas

CHO, Jungyeon[1*]

[1]Chungnam National University

Space plasmas are magnetized and in turbulent states. I will briefly introduce properties of turbulence in a strongly magnetized medium. Turbulence in space plasmas is involved with various length scales. In general, different descriptions should be used for different scales. On large scales, plasma turbulence can be described in the framework of magnetohydrodynamics (MHD). In the first par of the talk, I will focus on MHD turbulence in the presence of a strong mean field. I will discuss energy cascade and structure of turbulence in this regime. On the other hand, on small scales near the proton gyro-scale, we cannot use MHD. In the second part of the talk, I will discuss how we can treat magnetized turbulence on small scales. I will also discuss properties and scaling relations of waves and turbulence in this regime.

Nonlinear evolution of envelope-modulated Alfvenic turbulence in expanding accelerating solar wind plasmas

NARIYUKI, Yasuhiro[1*] ; HADA, Tohru[2] ; TSUBOUCHI, Ken[3]

[1]Faculty of Human Development, University of Toyama, [2]E.S.S.T., Kyushu University, [3]Tokyo Institute of Technology

It is well known that low-frequency Alfvenic turbulence is ubiquitously observed in solar wind plasmas. There is great interest in nonlinear evolution of the Alfvenic turbulence, since the observational studies clarified that the Alfvenic turbulence disappear with the increasing heliocentric distance and the fully-developed turbulence becomes dominant. Although most past studies on Alfvenic turbulence assumes uniform background plasmas and magnetic fields, the effects of the inhomogeneity may not be negligible in the inner-heliosphere, in which several future spacecraft missions are planned. It is important that even if the wave reflection due to the inhomogeneity is negligible, the inhomogeneity of background plasmas and magnetic field may affect the nonlinear interaction among waves through contraction and reflection of the waves and the radial dependence of the back ground parameters such as the Alfven velocity and the ion cyclotron frequency. In the present study, the nonlinear evolution of low-frequency, quasi-parallel propagating Alfvenic turbulence is studied by using the two-dimensional hybrid accelerating expanding box model. The dependence of the nonlinear evolution of Alfvenic turbulence on the effects of the inhomogeneity is discussed.

Development and Properties of Compressible MHD Turbulence in High-Beta Plasmas

JONES, Thomas[1*] ; RYU, Dongsu[2] ; PORTER, David[1] ; EMMERICK, Andrew[1] ; CHO, Jungyeon[3]

[1]University of Minnesota, [2]Ulsan National Institute of Science and Technology, [3]Chungnam National University

Many cosmic plasmas, including those in the solar wind and extra-galactic environments, are high beta = P_g/P_B>1, so that as turbulence develops, magnetic stresses are, at least initially, weak. As the turbulence evolves, magnetic stresses become increasingly important on scales below the driving scales. Depending on the initial field strength and topology this evolution can take many large-scale eddy times to reach saturation. Even in subsonic turbulence, shocks can form and influence turbulence evolution and properties. We have carried out an extensive set of high resolution compressible MHD simulations of the evolution of such turbulence for a range of initial magnetic field strengths and topologies. Here we report on their properties and the astrophysical implications of those properties. This work is supported at the University of Minnesota by the US National Science Foundation and the Minnesota Supercomputing Institute.

Instabilities and turbulence near the heliopause

POGORELOV, Nikolai[1*] ; BOROVIKOV, Sergey[2] ; ZANK, Gary[1] ; ZHANG, Ming[3]

[1]Department of Space Science, University of Alabama in Huntsville, [2]CSPAR, University of Alabama in Huntsville, [3]Department of Physics and Space Sciences, Florida Institute of Technology

Recent observations from the Voyager 1 spacecraft show that it is sampling the local interstellar medium (LISM). This is quite surprising because no realistic, steady-state model of the solar wind (SW) interaction with the LISM gives the inner heliosheath width as narrow as 30. This includes such models that assume a strong redistribution of the ion energy to the tails in the pickup ion distribution function. We show that the heliopause (HP), which separates the SW from the LISM, is not a smooth tangential discontinuity, but rather a surface subject to Rayleigh-Taylor-type instabilities which can result in the LISM material penetration deep inside the SW. We also show that the HP flanks are always subject to a Kelvin-Helmholtz instability. The instabilities are considerably suppressed near the HP nose by the heliospheric magnetic field in steady-state models, but reveal themselves in the presence of solar cycle effects. We argue that Voyager 1 may be in one of such instability regions and therefore observing plasma densities much higher than those in the pristine SW. These results may be an explanation of the Voyager 1 early penetration into the LISM. We also show that there is a possibility that the spacecraft may enter the SW again before it finally leaves the heliosphere.

We demonstrate a spontaneous transition to chaotic behavior in the heliosheath region covered by the heliospheric current sheet. Additionally, we analyze the behavior of the heliopause in the heliotail and show that it becomes violently unstable beyond 1000 AU, which results in the interpenetration of the solar and interstellar plasma.

Wave reflection-driven accretion in active solar-type star winds

SUZUKI, Takeru[1*] ; TERANISHI, Yasumasa[1]

[1]Nagoya University

In MHD simulations for winds from active solar-type stars by Suzuki et al.(2013), intermittent but long-time accretion phenomena were observed even though the Poynting flux associated with Alfven waves is directed outward. In this talk, we present the detailed mechanism how this counter-streaming accretion takes place. Alfven waves generated from a stellar surface are stochastically trapped in a transient density hole, and the magnetic pressure with the waves further dig the density hole. Eventually, this hole works as an efficient mirror against out-going Alfven waves. As a result, out-going waves are reflected and the reflected component excites counter streaming flow.

Physical Picture of 2-1/2D Driven Collisionless Magnetic Reconnection

CHENG, Chio[1*] ; INOUE, S.[2] ; ONO, Y.[3] ; HORIUCHI, R.[4]

[1]Plasma and Space Science Center, National Cheng Kung University, Taiwan, [2]Graduate School of Engineering, Universty of Tokyo, Japan, [3]Department of Advanced Energy, University of Tokyo, Japan, [4]National Institute of Fusion Science, Japan

The physical picture of how electrons and ions flow, how the electric and magnetic fields change, and how particles gain energy will be presented for the 2-1/2D collisionless driven magnetic reconnection. The 2-1/2 dimensional collisionless reconnection studies are performed using the particle simulation PASMO code [1] and theoretical analysis. In particular, we will provide the physical mechanism of how the poloidal current (including the Hall current in the downstream region) is generated and how the electrostatic potential is produced in the poloidal plane. The physical picture of how the quadrupole magnetic field and electrostatic potential are generated in the 2-dimensional (poloidal) plane is different from the one presented by Uzdensky and Kulsrud.[2]

Turbulence and shocks in high-beta plasmas

RYU, Dongsu[1*]

[1]Department of Physics, UNIST

High-beta plasmas are common in astrophysical environments, such as the intracluster medium (ICM) of galaxy clusters and the interplanetary medium (IPM) of the solar system. Observations and theoretical arguments suggest that the plasmas in such environments are in the state of turbulence, where highly nonlinear and complex physics is involved. Here we report high-resolution simulations to study the turbulence in high-beta plasmas. Along with the properties of the turbulence, we discuss the role of shocks and the energy dissipation.

Acceleration and Diffusion of Cosmic Rays in Supernova Remnants in a Multi-Phase interstellar Medium

ROH, Soonyoung[1*] ; INUTSUKA, Shu-ichiro[2] ; INOUE, Tsuyoshi[3]

[1]Graduate School of Science, Nagoya University, [2]Graduate School of Science, Nagoya University, [3]Department of Physics and Mathematics, Aoyama Gakuin University

Supernova remnants (SNRs) are one of the most powerful cosmic phenomena and are thought to be the dominant source of Galactic cosmic rays (CRs). A recent report by Funk et al. (2013) has shown an unequivocal signature of pion-decay in the gamma-ray spectra of SNRs. This provides strong evidence that high-energy protons are accelerated in SNRs. On the other hand, Fukui et al. (2012) showed that pion-decay from protons dominates in emission from SNR RX J1713 based on the spatial correlation of gamma-rays and molecular line emission. The actual gamma-ray emission from pion-decay should depend on the diffusion of CRs in a multi-phase interstellar medium with molecular clouds (Inoue et al. 2012). In order to quantitatively describe the diffusion of high energy CRs from acceleration sites, we have performed test particle numerical simulations using a three-dimensional magnetohydrodynamics (MHD) simulation data cube provided by Inoue et al. (2012). In this presentation, we analyze a realistic diffusion coefficient of cosmic rays in simulated SNRs, and discuss the possible implications for X-ray and gamma-ray observations.

Superdiffusion in turbulence and shock acceleration

YAN, Huirong[1*]

[1]Kavli Institute of Astronomy & Astrophysics, Peking U

Cosmic ray (CR) transport and acceleration are determined by the properties of turbulent magnetic field. We use the models of magnetohydrodynamic turbulence that were tested in numerical simulation, in which turbulence is injected at large scale and cascades to to small scales. I shall address, in particular, the cross field transport of CRs. I shall demonstrate both analytically and numerically that particles are superdiffusive on small scales. We consider both super- and sub-Alfvenic cases. In the sub-Alfvenic case, the transport in the perpendicular direction is proportional with M_Aˆ4, consistent with our earlier analytical prediction. Implication for shock acceleration is discussed and we show that the difference between acceleration at perpendicular shock and parallel shock is marginalized in the presence of superdiffusion.

We presents detailed features of micro-typeIII radio bursts and its relation to the outer corona, by using long-term observations made by the Geotail satellites. Micro-typeIII radio bursts are elements of the so-called type III storm, and are characterized by short-lived, continuous, and weak emissions. Their average power is estimated to be well below that of the largest type III burst by 6 orders of magnitude. The activity of micro-typeIII bursts with respect to the solar activity, lower frequency limit of the bursts and its relation to the solar activity, and the configuration of magnetic field line of which source electrons are trapped are investigated. The relationship between streamers and micro-typeIII bursts are discussed by using STEREO observations.

Keywords: micro-type-III burst, outer corona, solar radio burst, interplanetary space, inner-heliosphere

Coronal vector magnetic field and the plasma beta determined from the NoRH and multiple satellites observations

IWAI, Kazumasa[1*] ; SHIBASAKI, Kiyoto[1] ; NOZAWA, Satoshi[2] ; TAKAHASHI, Takuya[3] ; SAWADA, Shinpei[2] ; KITAGAWA, Jun[4] ; MIYAWAKI, Shun[2] ; KASHIWAGI, Hirotaka[5]

[1]Nobeyama Solar Radio Observatory, National Astronomical Observatory of Japan, [2]Department of Science, Ibaraki University, [3]Graduate School of Science, Kyoto University, [4]Solar-Terrestrial Environment Laboratory, Nagoya University, [5]Planetary Plasma and Atmospheric Research Center, Tohoku University

In the solar corona, there are various kinds of eruptive phenomena, such as flares and coronal mass ejections, which are caused by interactions between the coronal magnetic field and plasma. Hence, it is important to precisely measure the coronal plasma parameters, including the magnetic field, plasma density, and temperature, in order to understand the mechanisms that generate these eruptive coronal phenomena.

The solar coronal vector magnetic field, plasma density, and temperature is derived from coordinated observations of the radio thermal free-free emission using the Nobeyama Radioheliograph (NoRH) and multiple line-of-sight extreme ultraviolet observations using the Solar Dynamic Observatory (SDO) and the Solar Terrestrial Relations Observatory (STEREO). We observed a post-flare loop on the west limb on 2013 April 11. The line-of-sight magnetic field was derived from the circularly polarized free-free emission observed by NoRH, which was combined with the tilt angle toward the Earth observed with STEREO and converted to a vector magnetic field. The emission measure and temperature were derived from the Atmospheric Imaging Assembly (AIA) onboard SDO. The derived temperature was used to estimate the emission measure from the NoRH radio free-free emission observations. The derived density from NoRH was 40% larger than that determined using AIA, which is due to the fact that the low temperature plasma is not within the temperature coverage range of the AIA filters used in this study. The derived plasma parameters (vector magnetic field, plasma density, and temperature) were used to derive the plasma beta, which is a ratio between the magnetic pressure and the plasma pressure. The derived plasma beta is about 6.2×10^{-3} at the pool top region. The plasma parameters derived in this study were all based on observational results, and the calculated vector magnetic field presented herein is one of the least affected by assumptions or modeling ever derived.

Relationships among cosmic ray intensity, the photospheric magnetic field, and solar wind speed

HAKAMADA, Kazuyuki[1*] ; TOKUMARU, Munetoshi[2] ; FUJIKI, Ken'ichi[2] ; KOJIMA, Masayoshi[2]

[1]Chubu University, [2]Solar-Terrestrial Environment Laboratory

We visualize three-dimensional structure of the coronal magneic field by using the Radial-Field model for the coronal magnetic field devised by Hakamada with synoptic maps of photospheric magnetic field observed by the NSO/Kitt Peak, USA. As the rsults, we obtained the radial component of the photospheric magnetic field (Br_pho) and the one of the coronal magnetic field (Br_sou) on the source surface on the same field line in the coronal magnetic field. We estimate the solar wind speed (SWS) by using IPS technique divised by STE Lab, Nagoya Univiersity. According to our previous analysis on the Carrignton rotation bases, Log10|Br_pho|, Log10|Br_sou|show good correlations with the SWS for the data of [-1.0 <= Log10|Br_pho|<= 1.5, (0.1 G <= |Br_pho|<= 31.6 G), -1.5 <= Log10|Br_sou|<= 0.0, (0.0316 G <= |Br_sou|<= 1.0 G)]. In this study, we add the intensity of Oulu neutorn monitor (NM), and study relations among rotation averages of these NM, SWS, and Log10|Br_pho|. We found good simple correrations coefficients between Log10|Br_pho|-NM (r=-0.773), and SWS-NM (r=0.703), as well as, a good multiple correlaion (r = 0.785) among them by using the regression equation in the form of NM = a + b ∗SWS + c ∗log10|Br_pho|with a = 6363, b = 1.186, and c = -1400.0. However, Log10|Br_pho|-SWS also shows good simple correlation (r=-0.802). We calculated partial correlation coefficients between (a) Log10|Br_pho|-NM, (b) SWS-NM, (c) Log10|Br_pho|-SWS and obtained (a) r=-0.294, (b) r=0.130, (c) r=-0.364. These results suggest that, althogh the cosmic ray intensities shown by NM is determined by the intensity of photospheric magnetic fields on the open field lines and the solar wind speed occupied by these field lines, the dpendence of magnetic field is stronger than the one of wind speed.

Does a Plasma Tail of Comet ISON (C/2012 S1) Cause the Interplanetary Scintillation?

IJU, Tomoya[1*] ; ABE, Shinsuke[2] ; TOKUMARU, Munetoshi[3]

[1]Particle and Astrophysical Science, Nagoya-University, [2]Aerospace Engineering, CST, Nihon-University, [3]Solar-Terrestrial Environment Laboratory, Nagoya-University

C/2012 S1 (ISON) (referred to as Comet ISON) showed a well-developed plasma tail (longer than 0.1 AU) before its perihelion passage on November 28, 2013. A plasma tail consists of ionized gases emitted from a cometary nucleus and orients itself in the anti-solar direction by an interaction with the solar wind. In this study, we investigated the plasma tail of Comet ISON with interplanetary scintillation (IPS) data. The IPS is a scattering phenomenon of radio waves by density fluctuations of the solar wind, and it is well known that interplanetary disturbances such as coronal mass ejections (CMEs) cause an abrupt increase in IPS. A cometary plasma tail may also be a potential cause for the IPS enhancement, while observational studies for C/1972 E1 (Kohoutek), 1P/Halley and other are still controversial (*e.g.* Ananthakrishnan *et al.*, 1975, 1987; Slee *et al.*, 1987; Abe *et al.*, 1997; Roy *et al.*, 2007). We identified radio sources whose lines-of-sight approached to Comet ISON's plasma tail between November 1 and 28, and obtained their IPS data using the Solar Wind Imaging Facility (Tokumaru *et al.*, 2011) of the Solar-Terrestrial Environment Laboratory, Nagoya University. From examinations for them, we confirmed four IPS enhancement events, which is likely to be related to the plasma tail passage. In this session, we report this preliminary result for them and discuss an IPS of a cometary plasma tail origin.

Effects of phase and group velocities on wave spectra observed in the solar wind

TSUGAWA, Yasunori[1*] ; KATOH, Yuto[1] ; TERADA, Naoki[1]

[1]Department of Geophysics, Tohoku University

Waves propagating in a plasma medium which has a relative velocity to the observer are differently observed in the spectra from those in the plasma rest frame. As known in general, the observed frequency is Doppler shifted by the relative velocity between the medium and the observer, V_{rel}. The frequency shift is the result of the difference of the phase velocities of the waves in the medium rest frame and in the observer frame. When the wave vector has a finite angle with respect to V_{rel} and the component of V_{rel} parallel to the wave vector is considerable to the phase velocity, the difference of the phase velocities between the frames and the frequency shift become significant.

We note that the observed spectral density is also modified by V_{rel}. The modification of the spectral density is the result of the difference of the group velocities of the waves in the medium rest frame and in the observer frame. When the component of V_{rel} parallel to the group velocity vector is considerable to the group velocity, the difference of the group velocities between the frames and the modification of the spectral density become significant. In order to estimate the amount of the modification, we derive the analytical expression of the modified spectral density in the observer frame.

It is important to consider not only the frequency shift but also the modification of the spectral density of waves observed by spacecraft in a moving plasma, such as the solar wind. Indeed, the phase and group velocities of whistler-mode waves cause significant frequency shift and modification of the spectral density in the solar wind. By the modification of the spectral density, we can explain the characteristic properties of '1 Hz waves', which have been generally observed in the upstream regions of various bodies, and suggest that the broadband upstream whistlers are the same source waves. The understanding of the effects is necessary to reveal the true nature of waves propagating in a moving plasma and to discuss their generation processes.

Monochromatic whistler waves at 8 Hz observed by Kaguya above the terminator of the Moon

HASHIMOTO, Akira[1] ; NAKAGAWA, Tomoko[1*] ; TSUNAKAWA, Hideo[2] ; TAKAHASHI, Futoshi[2] ; SHIBUYA, Hidetoshi[3] ; SHIMIZU, Hisayoshi[4] ; MATSUSHIMA, Masaki[2]

[1]Information and Communication Engineering,Tohoku Institute of Technology, [2]Deparment of Earth and Planetary Sciences, Tokyo Institute of Technology, [3]Department of Earth and Environmental Sciences, Graduate School of Science and Technology, Kumamoto, [4]Earthquake Research Institute, University of Tokyo

Magnetic fluctuations around the moon are characterized with 2 major categories: (1) large amplitude monochromatic waves of 0.01 Hz and (2) monochromatic or non-monochromatic whistler waves, both observed on the dayside surface of the moon or above the terminator. Their generation is associated with (1) the solar wind ions or (2) electrons, respectively, reflected at the surface of the moon or the local crustal magnetic field. The monochromatic whistler waves are found at 1-2 Hz with left-handed polarization due to the Doppler shift caused by the solar wind flow. The frequency range is determined by the group velocity of the whistler waves that can overcome the solar wind speed.

Differently from the previously known characteristics, a new type of monochromatic waves was found at 8 Hz in the magnetic field data obtained by MAP/LMAG onboard Kaguya. They concentrated above the terminator. They propagated in the direction of the background magnetic field and showed right-hand polarization. They are thought to be whistler waves propagating down-stream, and the frequency was up-shifted due to the Doppler shift.

Measurement result of the neutron monitor onboard the Space Environment Data Acquisition Equipment(SEDA-AP)

KOGA, Kiyokazu[1*] ; MURAKI, Yasushi[2] ; SHIBATA, Shoichi[3] ; YAMAMOTO, Tokonatsu[4] ; MATSUMOTO, Haruhisa[1] ; OKUDAIRA, Osamu[1] ; KAWANO, Hideaki[5] ; YUMOTO, Kiyohumi[5]

[1]JAXA, [2]Nagoya University, [3]Chubu University, [4]Konan University, [5]Kyushu University

To support future space activities, it is crucial to acquire space environmental data related to the space-radiation degradation of space parts and materials, and spacecraft anomalies. Such data are useful for spacecraft design and manned space activity.
SEDA-AP was mounted on ”Kibo” of the ISS (International Space Station) to measure the space environment at a 400-kilometer altitude.

Neutrons are very harmful radiation, with electrical neutrality that makes them strongly permeable. SEDA-AP measures the energy of neutrons from thermal to 100 MeV in real time using a Bonner Ball Detector (BBND) and a Scintillation Fiber Detector (FIB). BBND detects neutrons using He-3 counters, which have high sensitivity to thermal neutrons. Neutron energy is derived using the relative response function of polyethylene moderators of 6 different thicknesses. FIB measures the tracks of recoil protons caused by neutrons within a cubic arrayed sensor of 512 scintillation fibers. The charged particles are excluded using an anti-scintillator which surrounds the cube sensor, and the neutron energy is obtained from the track length of a recoil proton.

There are three sources of neutrons in space;
1. Albedo Neutrons
Produced by reactions of galactic cosmic rays or radiation belt particles with the atmosphere
2. Local Neutrons
Produced by the reactions of galactic cosmic rays or radiation belt particles with spacecraft
3. Solar Neutrons
Produced by accelerated particles in solar flares
An accurate energy spectrum of the solar neutrons includes important information on high-energy particle generation mechanism in a solar flare, because neutrons are unaffected by interplanetary magnetic fields. These data will become useful to forecast solar energetic particles in future. Some candidate events involving solar neutrons were found as a result of analyzing data of the solar flare of M>2 since September 2009.

Moreover, it is important to measure albedo neutrons, since protons generated by neutron decays are thought to originate from the radiation belt. This theory is called CRAND (Cosmic Ray Albedo Neutron Decay). Our observation result is consistent with the CRAND theory prediction in the case of low-energy parts. Moreover, the flux and angular distribution of local neutrons were estimated using the nuclear simulation code ”PHITS” to evaluate the influence of local neutrons on the structure of SEDA-AP and ”Kibo”.

The results of our analyses on solar and albedo neutrons are reported in this paper.

The HISAKI (SPRINT-A) satellite, which was launched last summer, has been observing the extreme ultraviolet emission around planets, such as Venus and Jupiter. In addition to the main observational target of Venus and Jupiter, HISAKI has detected the emission from interplanetary space. In this presentation the HISAKI observation of interplanetary emission is shown and its potential on the interplanetary issue is argued.

The Behavior of Distributions for Magnetic Polarities on the Surface of the Sun and Solar Minimum

SEINO, Mitsuhiro[1*] ; SHIMABUKURO, Tomomi[1]

[1]Department of Physics and Earth Sciences, Faculty of Science, University of the Ryukyus

Time series of satellite image data for SOHO/MDI Continuum and Magnetogram from 1997 to 2010, and for SDO/HMI Continuum and Magnetogram from 2011 to 2013 are analyzed. The new time series data derived from fractal analysis of the time series images illustrated in 1200x1200 pixels from 1997 to 2013 are generated and fractal measures and packing exponents are analyzed by box-counting method. Then the occupancies of sunspot pixels in Continuum and of pixels for the positive and negative magnetic polarities in Magnetogram are calculated and packing exponents for sunspot pixels in Continuum and packing exponents for positive polarity pixels and negative polarity pixels in Magnetogram are evaluated. For packing exponents of Continuum and Magnetogram from 1997 to 2013, power spectra with peaks are calculated by using Fourier transform, respectively. A first peak which appears the power spectra is determined, and time intervals between nearest neighbor peaks are valued. The correlations between sunspot numbers and occupancies of the positive and negative magnetic polarities for 17 years are anatomized. As the correlation coefficients are calculated by using the least squares method, the correlation between sunspot number and occupancy of positive magnetic polarities has a very high correlational relationship because the correlation coefficient is 0.86 and it for negative magnetic polarities is low.

Furthermore, the behavior of occupancies of sunspot pixels in Continuum and of pixels for the positive and negative magnetic polarities in Magnetogram and the packing exponents represented with time series are described in detail and discussed. Fluctuations for occupancies of positive magnetic polarities are similar to it for Zurich number from 1997 to 2013. As observing the occupancies and packing exponents of positive and negative magnetic polarities, the two and three different fluctuations appear in (1) 1997-2005 and 2009 and (2) 2006-2008 including the time period that solar cycle 24 began on January 4, 2008, respectively. In addition, the occupancies and packing exponents of them have a single fluctuation in (3) 2010-2013. Therefore, the periods for characterizing solar activity from 1997 to 2013 are divided into three periods in (1), (2), and (3). Specially, for 2 years before solar minimum on 2008, the packing exponents start fluctuating suddenly and sharply in 2006 and the fluctuation disappear in the end of 2009.

Fine spectral structures of a solar radio type-II burst observed with AMATERAS

SATO, Shintaro[1] ; MISAWA, Hiroaki[1*] ; TSUCHIYA, Fuminori[1] ; OBARA, Takahiro[1] ; IWAI, Kazumasa[2] ; MASUDA, Satoshi[3] ; MIYOSHI, Yoshizumi[3]

[1]PPARC, Tohoku Univ., [2]Nobeyama Solar Radio Observatory, NAOJ, [3]STE Lab., Nagoya Univ.

Solar radio type-II bursts are metric to hectometric radio bursts that show frequency drifting spectral structures caused by the plasma emission from shock-accelerated electrons. The bursts are known to sometimes show rapidly drifting fine structures; for example, about 20% of type-II bursts are composed of both negative and positive rapidly drifting elements, which are called as ”herringbone” structure (hereafter HB) [Roberts, 1959]. Such the drifting fine structures are interpreted as the motion of non-thermal energetic electron beams accelerated by the shock. However, their particle acceleration mechanisms and regions have not been understood well. The purpose of this study is to extract characteristics of the fine spectral structures of type-II bursts from high-resolution observations and investigate their acceleration processes.

AMATERAS is a ground-based solar radio receiving system developed in 2010 by Tohoku University [Iwai et al., 2012]. This system enables us to observe radio phenomena in 150 - 500 MHz with the 10 ms accumulation time and 61 kHz bandwidth. So far some type-II bursts with fine spectral structures have been observed. Among them, a type-II burst observed on November 12, 2010 around 200MHz showed distinctive fine structures whose spectral characteristics were different from those of HB. The fine structures showed no core structure which were normally confirmed in HB, but showed various rapidly drifting nature and composed whole body of a slowly negative-drifting type-II burst. The statistical drift rate analysis showed that negative drift cases were dominant and some of them indicated more than 100MHz/s. The particle speed for the drift rate by assuming a general coronal plasma density model, for example the Newkirk model [Newkirk, 1961], is estimated to be unrealistically fast. This implies that the rapidly drifting fine structures were generated by energetic electron beams in an outward moving steep density gradient region such as a shock front.

In this presentation, we will show revealed statistical characteristics of the fine structures and discuss inferred generation processes of the type-II burst. We will also introduce characteristics of fine spectral structures of the other events of type-II burst.

Spectral fine structure of solar radio bursts observed with IPRT/AMATERAS: Characteristics of Zebra Pattern

KANEDA, Kazutaka[1*] ; MISAWA, Hiroaki[1] ; TSUCHIYA, Fuminori[1] ; OBARA, Takahiro[1] ; IWAI, Kazumasa[2]

[1]PPARC, Tohoku University, [2]NSRO/NAOJ

It is known that there are a variety of complex fine structures in solar radio bursts in the meter to decimeter wave bands such as broadband pulsations, narrowband spikes, fiber bursts and zebra patterns (hereafter ZP). Since they are thought to be caused by some inhomogeneities or modulations of wave generation and/or radio propagation processes, they have significant information about plasma parameters and dynamical plasma processes in the solar corona. Among the various fine structures, ZP has a particularly characteristic spectral pattern with parallel drifting narrow stripes of enhanced emission. Although several models for generating ZP have been proposed so far, the generation mechanisms have not been revealed well yet.

AMATERAS (the Assembly of Metric-band Aperture Telescope and Real-time Analysis System) is a radio spectro-polarimeter installed in a large radio telescope named IPRT in Fukushima, which was developed for solar radio observations in 2010 by Tohoku University (Iwai et al., 2012). The specifications of this system are time resolution of 10 ms, frequency resolution of 61 kHz and the minimum detectable flux of 0.7 s.f.u. in the frequency range of 150 MHz to 500 MHz, which are enough to observe fine structures of solar radio bursts and analyze their spectral characteristics. In this study we focus on an event on June 21, 2011 associated with C7.7 class flare. In this event enhanced ZP appeared around 200MHz with about 30 stripes in fast drifting envelopes like type III bursts or broadband pulsations. The emission was strongly polarized in right-handed and shows a distinctive time delay of the left-handed component relative to the right-handed component by several tens msec increasing with emission frequency. In the presentation, we will show the characteristics of ZP precisely and also discuss the expected generation processes.

Upgrade of the multi-station IPS system and solar wind observations at the cycle 24 maximum

TOKUMARU, Munetoshi[1*] ; FUJIKI, Ken'ichi[1] ; MARUYAMA, Kazuo[1] ; MARUYAMA, Yasushi[1] ; YAMASAKI, Takayuki[1] ; IJU, Tomoya[1]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

Since interplanetary scintillation (IPS) serves as a useful method to determine global distribution of the solar wind, IPS observations have been regularly conducted over more than 30 years using the multi-station system of the Solar-Terrestrial Environment Laboratory (STEL) of Nagoya University. Such long-term data collection is made possible by continuous maintenance and improvement of the system. The STEL has four antennas dedicated for IPS observations at Toyokawa, Fuji, Kiso, and Sugadaira. The system at Toyokawa was upgraded to a new antenna (called the Solar Wind Imaging Facility Telescope, SWIFT, Tokumaru et al., 2011) in 2008. After that, the observation control and data acquisition systems at Fuji and Kiso were upgraded in 2010 to enable 3-station IPS observations using Toyokawa, Fuji and Kiso antennas. However, the low-noise phased-array receivers of Fuji and Kiso antennas, which are a vital part to archive high sensitivity, remained unchanged, and some other parts such as reflectors, gears, motors, became superannuated. In order to improve these problems, we have performed extensive work for upgrading Fuji, Kiso and Sugadaira antennas since 2013.

The items for this upgrade are as follows; (1) installation of low-noise amplifiers using HEMTs (FE327-V5) and the phased-array control system, (2) development of the phase/gain calibration system using the loop method and the receiver temperature measurement system using a noise source for Fuji and Kiso antennas, (3) fabrication of reflector and replacement of gears and motors (for Kiso). The work at Fuji almost completed by the end of 2013, and that at Kiso will be made in this spring.

Owing to the upgrade project, IPS observations for 2013 was made for the period between April and August. Obtained IPS data clearly show that the fast wind reappears over the northern pole. This is not the case for the southern pole, and the slow wind is found to be dominant in the southern hemisphere. The disappearance and reappearance of the fast wind over the northern pole preceding that over the southern pole have been observed in solar maxima of two previous cycles, so that this is regarded as a common feature of the solar dynamo activity. While our IPS data for this cycle show good correlation between fast wind areas and polar fields, they reveal that the slope for this cycle differs from the ones for past cycle. This fact suggests that higher-order magnetic moments for this cycle may have more contribution for formation of fast winds than past cycles. The solar wind structure is expected to significantly change with declining solar activity toward the next minimum, and we intend to finish work for the upgrade project as soon as possible in order to miss observing this change.

MLT dependence in the response of ionospheric electric fields at mid-low latitude during geomagnetic sudden commencement

TAKAHASHI, Naoko[1*] ; KASABA, Yasumasa[1] ; SHINBORI, Atsuki[2] ; NISHIMURA, Yukitoshi[3] ; KIKUCHI, Takashi[4] ; NAGATSUMA, Tsutomu[5]

[1]Graduate School of Science, Tohoku University, [2]Research Institute for Sustainable Humanosphere (RISH), Kyoto University, [3]University of California, Los Angeles, [4]Solar-Terrestrial Environment Laboratory, Nagoya University, [5]National Institute of Information and Communications Technology

The geomagnetic sudden commencement (SC) is one of the geomagnetic disturbance phenomena triggered by an enhancement of the magnetopause current associated with the compression of the magnetosphere due to solar wind disturbances [e.g., Araki, 1994]. Detailed evolution and propagating processes of the electromagnetic field associated with SCs are observed three-dimensionally in the entire geospace. Unlike magnetic storms and substorms which involve complex plasma physical processes, SCs can be identified as distinct magnetic variations that sharply change on a global scale. However, the characteristics of SCs have been extensively investigated mainly by means of the magnetic field variations obtained by ground-based observations, which could be affected by conductivities when deducing electric fields. Thus, investigating the electric field variations is needed to understand the transport of electromagnetic energy (Poynting fluxes, E$\times$B/μ) associated with SCs. In this study, we examined two critical subjects about the ionospheric electric field associated with SCs using the in-situ electric field data.

The in-situ ionospheric electric field was derived from the drift velocity observed by the Ionospheric Plasma and Electrodynamics Instrument (IPEI) onboard ROCSAT-1, which orbited at an ionospheric altitude (about 600 km), with magnetic field from the IGRF-10 model. We also used the geomagnetic field data from ground stations at the subauroral region, mid and low latitudes, and dip equator with a high time resolution of 1 second.

The first subject is the transmission time of the ionospheric electric field from the subauroral region to the dip equator. We found the simultaneous SC onset between the ionospheric electric field by the ROCSAT-1 observations and geomagnetic fields by ground-based observations, and the time delay in the peak amplitudes of the preliminary impulse (PI) and main impulse (MI) occur irrespective of the magnetic local time (MLT). In statistical analyses, we showed that peak signatures of the ionospheric electric field at the low latitude appeared simultaneously with that of the geomagnetic field at the subauroral region. We also found that the peak signature at the equatorial region was observed with the time delay, and its value is about 20-40 seconds in the PI peak and 80-140 seconds in the MI peak. The instantaneous onset can be explained by means of the TM_0 mode waves propagating at the speed of light in the Earth-ionosphere waveguide, while the time delay in the peaks is interpreted as the difference of the time constant L/R of an equivalent circuit. From these results, we demonstrated the transmission of the electric field from the subauroral region and the common energy transport process for both the PI and MI.

The second subject is the global structure of the ionospheric field. Ground-based observations are limited to mid and low latitudes, and provide only the horizontal component (E_{phi}) of the electric field. Thus, it is difficult to estimate the global electric field variation, especially at the terminator sector where SC signatures tend to appear in the radial component (E_r) of the electric field. We found the MLT dependence of the SC amplitude both the PI and MI signatures in the E_r and E_{phi} electric fields. In addition, the dayside characteristics of the PI signature extended to the evening terminator sector (18-21 h MLT) with an enhancement around 20 h MLT. This tendency is consistent with previous results obtained by the ground-based observations and model calculations. We consider that enhancements associated with SCs are influenced by the non-uniform ionospheric conductivity.

In the present study, we revealed the global instant response of the ionospheric electric field during SCs based on the in-situ ionospheric electric field observations. Our results can serve as a basis for understanding energy transmission paths during rapid reconfigurations of ionospheric convection.

Evolution of convection vortices associated with sudden impulses observed by SuperDARN

HORI, Tomoaki[1*] ; SHINBORI, Atsuki[2] ; NISHITANI, Nozomu[1] ; FUJITA, Shigeru[3]

[1]STE lab, Nagoya Univ, [2]RISH, Kyoto Univ, [3]Meteorological College

Spatial evolution of transient ionospheric convection induced by sudden impulses (SIs) recorded by ground magnetometers is studied statistically by using SuperDARN (SD) data. An advantage of using SD data instead of ground magnetic fields is that ionospheric flows measured by the radars are not virtually biased by the spatially-varying ionospheric conductance or the magnetospheric currents. First we surveyed the Sym-H index for Jan., 2007 to Dec., 2012 to identify SI events with a peak amplitude |dSym-H|greater than 10 nT. Next we searched all SD data over the northern hemisphere during the SI events for ionospheric backscatters which give us the light-of-sight velocity of horizontal ionospheric flows. For each SI event, the collected ionospheric flow data were sorted into the four periods: the pre-SI period, the pre-Main Impulse (MI), middle-MI, and post-MI periods. In the present study, we examine the differences in flow velocity between the pre-SI period and the three MI periods to clarify how ionospheric flows change in association with SIs. As a result, the ionospheric flow shifts eastward on the dusk side and westward on the dawn side at the higher latitudes during positive SIs (SI+), while it shows a roughly westward/eastward shift on the dusk/dawn side, respectively, during negative SIs (SI-). These polarities of flow shifts are basically consistent with the higher latitude portions of the DP current for the MI phase as shown by Araki [1994] and Araki and Nagano [1988]. The high latitude flow shifts are basically larger for SI events with larger Sym-H variations, in the same fashion as ground magnetic field variations at high latitudes. In addition to the major dependence on SI amplitude, the flow shift magnitude shows a minor dawn-dusk asymmetry particularly under strong IMF-By conditions. We speculate that the interaction with pre-existing convection cells might cause the selective enhancement of either side of flow shifts.

To investigate temporal and spatial evolution of global geomagnetic field variations from high-latitude to the equator during geomagnetic storms, we analyzed ground geomagnetic field disturbances from high latitudes to the magnetic equator. The daytime ionospheric equivalent current during the storm main phase showed that twin-vortex ionospheric currents driven by the Region 1 field-aligned currents (R1 FACs) are intensified significantly and expand to the low-latitude region of ˜30 degrees magnetic latitude. Centers of the currents were located around 70 and 65 degrees in the morning and afternoon, respectively. Corresponding to intensification of the R1 FACs, an enhancement of the eastward/westward equatorial electrojet occurred at the daytime/nighttime dip equator. This signature suggests that the enhanced convection electric field penetrates to both the daytime and nighttime equator. During the recovery phase, the daytime equivalent current showed that two new pairs of twin vortices, which are different from two-cell ionospheric currents driven by the R1 FACs, appear in the polar cap and mid latitude. The former led to enhanced northward Bz (NBZ) FACs driven by lobe reconnection tailward of the cusps, owing to the northward interplanetary magnetic field (IMF). The latter was generated by enhanced Region 2 field-aligned currents (R2 FACs). Associated with these magnetic field variations in the mid-latitudes and polar cap, the equatorial magnetic field variation showed a strongly negative signature, produced by the westward equatorial electrojet current caused by the dusk-to-dawn electric field.

The forenoon-afternoon asymmetry of DP2 electric field penetrated to the dip equator

MATSUSHITA, Hiroki[1*] ; YOSHIKAWA, Akimasa[2] ; UOZUMI, Teiji[3] ; IKEDA, Akihiro[4] ; OHTANI, Shinichi[5]

[1]Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu university, [2]Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu university, [3]International Center for Space Weather Science and Education, Kyushu University, [4]Kagoshima National College of Technology, [5]The Johns Hopkins University Applied Physics Laboratory

DP2 oscillation is quasi-periodic disturbance whose period is from 30 min to a few hours, and it is well known that DP2 synchronize with IMF Bz oscillation [Nishida, 1968] and can be observed globally from polar to equator [Nishida, 1968], [Kikuchi et al., 1996]. These two characteristics indicate that the disturbance associated with solar wind comes into ionosphere at polar region and M-I coupled current system like penetrating to dip equator is produced, however, this mechanism of the inversion of electric field from polar to equator is not well understood.

The purposes of this study are to clarify how the electric field at polar region is penetrated to dip equator region and to identify the global distribution of DP2 current system. To attain these goals, we analyzed longitudinal and latitudinal distribution of DP2 oscillation observed at dip equator region that is the final destination of M-I coupling system. The electric field is calculated from magnetic field and electric conductivity based on Ohm ' s law, and magnetic field data used in this study are MAGDAS data [K. Yumoto et al., 2006 and 2007] and electric conductivity data are calculated using data of WDC for geomagnetism. We analyzed the real local time distribution of the electric field during DP2 event in 2007 and 2008 using these data. It is used the data Equatorial Magnetometer Network [T.-I. Kitamura, 1985] to derive latitudinal distribution of DP2 oscillation.

The result of this analysis shows that there is an asymmetry of electric field between forenoon and afternoon. It is difficult to explain this asymmetry from the view point of only the electric field at polar region on northern and southern hemisphere which makes global DP2 current system, so this result indicates that there is some mechanism to produce this asymmetry of electric field when the polar electric field is penetrated to equator. As this mechanism, we suggest that the polarization electric field along dip equator and the terminator line of day and night can change global potential structure by Cowling channel model [Yoshikawa et al., 2012, AGU], and the electrostatic potential distribution assumed from our observational result is consistent with the distribution derived from the calculation result based on this model.

Substorm electric fields at nightside low latitude

HASHIMOTO, Kumiko[1*] ; KIKUCHI, Takashi[2] ; TOMIZAWA, Ichiro[3] ; NAGATSUMA, Tsutomu[4]

[1]Kibi International University, [2]Nagoya University, [3]University of Electro-Communications, [4]National Institute of Information and Communications Technology

The convection electric field penetrates from the polar ionosphere to low latitude and drives the DP2 currents in the global ionosphere with an intensified equatorial electrojet (EEJ). The electric field often reverses its direction, that is, the overshielding occurs and causes the equatorial counterelectrojet (CEJ) during storm and substorms. In this paper we report that the overshielding electric field is detected by the HF Doppler sounders at low latitude on the nightside. We analyzed the Doppler frequency of the HF radio signals propagated over 120 km in Japan at frequencies of 5 and 8 MHz and compared with the equatorial EEJ/CEJ during the substorm expansion phase. We found that the overshielding electric field reaches around 2 mV/m during major substorms (AL <-1800 nT). Taking the geometrical attenuation into account, we estimate the equatorial electric field to be about 1.5 mV/m. We also found that the electric field drives the eastward electrojets in the equatorial ionosphere on the night side. It is to be noted that the overshielding electric field is observed on the nightside at low latitude during the major substorms, while the convection electric field is dominant during smaller size substorms, as the CEJ flows on the dayside. These results suggest that the overshielding electric field associated with the Region-2 field-aligned currents becomes dominant during substorms at low latitude on the nightside as well as on the dayside. On the other hand, we found strong seasonal dependence of the overshielding in the sub-auroral latitudes. Although the substorm CEJs at Huancayo do not depend on season, the overshielding frequently occurs at subauroral latitudes during the winter period from November to February. In contrast, the convection electric field is dominant at the subauroral and low-latitudes during the summer period from April to August. The strong seasonal dependence may suggest that the Region-1 field aligned currents (FACs) have a constant voltage source, while the Region-2 FACs have a constant current source, which results in the convection and overshielding electric fields being dominant in summer and winter, respectively.

We present a parameter study of simulated processes of the magnetosphere-ionosphere (M-I) coupling using the global MHD simulation code developed by *Tanaka* (2010).

The boundary conditions for the M-I coupling include some scaling factors. These factors are adjustable and are determined through trial and error. The main goal of this study is optimization of these scaling factors in the boundary condition by use of a data assimilation technique.

In this paper, we combine the MHD simulation and solar wind parameters derived from the ACE satellite, and compare the ionospheric E x B plasma drift obtained from the global MHD simulation and that obtained from the SuperDARN HF Radar Network.

Toward construction of comprehensive proton and electron auroral substorm model: Ground-based observation at Syowa

KADOKURA, Akira[1*] ; FUKUDA, Yoko[2] ; I, Tomofumi[3] ; MIYAJI, Kohei[4] ; MIYAOKA, Hiroshi[1] ; SATO, Natsuo[1]

[1]NIPR, [2]Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, [3]Kakioka Magnetic Observatory,Japan Meteorological Agency, [4]Graduate School of Science, Nagoya University

National Institute of Polar Research (NIPR) has been constructing an auroral optical observation system at Syowa Station during the 8th project term of 6 years of the Japanese Antarctic Research Expedition (JARE) program. Instruments categorized in the ”Monitoring observation” are (1) 4 sets of All-sky monochromatic digital CCD imagers (427.8, 557.7, 485.0, 481.0 nm) and (2) All-sky color digital camera, and those categorized in the ”Specific purpose observation” are (1) All-sky TV camera and (2) 8-color Scanning Photometer (SPM). Simultaneous observations with 2 electron and 2 proton CCD monochromatic imagers will be carried out in 2014. Interval of the 4 imagers are the same as each other, 15 sec, although the spatial resolution of the 2 proton imagers are reduced into 64x64, comparing with the full resolution of 512x512 of the electron imager.

Center (FWHM) wavelengths of the SPM are 482.5(0.6), 483.5(0.6), 484.5(0.6), 485.5(0.6), 486.5(0.6), 487.5(0.6),670.5(5.0), 844.6(0.6) nm.

Scanning speed and sampling rate are 180 deg/10 sec and 20 Hz, respectively.

Using these electron and proton auroral data observed with all-sky imager and scanning photometer, we would like to construct a comprehensive model of substorm including the information on energy characteristics of precipitating auroral electrons and protons.

We statistically investigate low-latitude Pi 2 pulsations observed around the dawn and dusk terminator. The main observational results of this study are: (1) Pi 2 pulsations tended to have east-west polarity in the sunlit side of the dawn terminator, while these in the sunlit side of the dusk terminator tended to have north-south polarity. (2) Phase reversals of D-component oscillations occurred near the dawn terminator and 2-3 hours before the dusk terminator. (3) Peaks of D/H (maximum amplitude ratio between D and H component) appear 3 hours after the dawn terminator and near the dusk terminator.

We suggest that there is the dawn-dusk asymmetry of meridional ionospheric currents connecting between equatorial Cowling current and oscillating nightside FACs; meridional currents around dawn is more intense than around dusk. This asymmetry current system can be qualitatively explained by the deformation of potential pattern caused by polarization charges at the terminator.

Automatic identification of Pc5 waves using RBSP mode data from the SuperDARN Hokkaido HF radar

MATSUSHITA, Toshinori[1*] ; SEKI, Kanako[1] ; NISHITANI, Nozomu[1] ; HORI, Tomoaki[1]

[1]STEL, Nagoya University

Ultra-low-frequency Pc5 waves have been observed by many methods such as ground-based magnetometers, HF radars and satellites. It has been demonstrated by numerical experiments that magnetospheric Pc5 waves are globally and directly generated on the dayside by solar wind dynamic pressure variations and/or on the dawn/dusk flank by Kelvin-Helmholtz surface waves. In addition, there are storm-time Pc5 waves on the dusk side magnetosphere that are associated with instabilities in the storm time ring current caused by the particle injection. The Pc5 waves can play an important role in mass and energy transport within the inner magnetosphere such as the radial diffusion of outer radiation belt electrons, as suggested by previous studies. Outstanding problems in Pc5 studies include clarification of their global characteristics and distribution, generation mechanisms, and especially their dependence on the solar wind parameters.

In this study, we try to develop a new automatic identification method of Pc5 waves using ˜20-sec time resolution data obtained by the SuperDARN Hokkaido HF radar operated in the RBSP mode. In this method, we use the Doppler velocity data and the power spectrum density calculated by the wavelet transformation. We set criteria which can detect Pc5 waves even when harmonic oscillations coexist. We show an example for the identification method using the Doppler velocity data obtained by the SuperDARN Hokkaido HF radar in details. Then, the candidates of Pc5 event are verified by inspection. From the rate of error identification, we evaluate the accuracy of the automatic identification method statistically. In the presentation we will also report on the preliminary results of mid-latitude Pc5 characteristics such as frequency distribution and MLT dependence.

A Simultaneous Observation of Pc 4 pulsation by Hokkaido HF Radar and Ground-Based Magnetometers

OBANA, Yuki[1*] ; NISHITANI, Nozomu[2] ; HORI, Tomoaki[2] ; TERAMOTO, Mariko[3] ; NOSE, Masahito[4] ; YOSHIKAWA, Akimasa[5]

[1]Department of Engineering Science, Osaka Electro-Communication University, [2]Solar-Terrestrial Environment Laboratory, Nagoya University, [3]Japan Aerospace Exploration Agency, [4]Graduate School of Science, Kyoto University, [5]Department of Earth and Planetary Sciences, Kyushu University

We studied a Pc 4 (6.7-22.2 mHz) oscillation of ionospheric Doppler plasma velocity observed around the dawn terminator on 16 Jul 2013 on an east-northeast pointing beam 14 of SuperDARN Hokkaido HF radar in Japan. We compared this ionospheric Pc 4 oscillation with magnetic field variation at St. Paratunka (PTK) in Russia, Kakioka (KAK) in Japan, Guam (GUA), Middlemarch (MDM) and Te Wharau (TEW) in New Zealand. PTK and conjugate points of MDM and TEW are located almost under the radar beam. The waveforms showed high similarity among the HF Doppler, the D (east-west) component of magnetic field at stations in the middle latitude of northern hemisphere (PTK and KAK). While, at the other stations (MDM, TEW, and GUA) the H (north-south) component of magnetic field showed high similarity to the HF Doppler. Using the value of the peak-to-peak amplitude of the HF Doppler velocity, we estimated amplitude of magnetic field variation with assuming a horizontal current sheet infinitely extended in the ionosphere. The estimated amplitude was comparable to the observed amplitude at PTK. We also studied longitudinal variation in amplitude using magnetic field data at Amsterdam Isl. (AMS) in South Indian Ocean and Fredericksburg (FRD) in the United States. The maximum amplitude was found at AMS which located around the midnight.

These results can be interpreted as follows. This event had its source from night side and the Doppler velocity oscillation was caused by an oscillating electric field in the east-west direction. In the northern hemisphere (PTK and KAK), the ionosphere above the observatory was sunlit, thus the ionospheric Hall current induced by the electric field makes D component of magnetic filed oscillation on the ground. On the other hand, in the southern hemisphere (MDM and TEW) and GUA, the ionosphere above the stations was still in the darkness, thus effective ionospheric current could not be induced due to low conductivity. The H component of magnetic field oscillation may reflect direct incidence of magnetic field oscillation from the magnetosphere to the ground.

Solar zenith angle dependence of relationships between energy inputs to the ionosphere and O+ and H+ ion outflows

KITAMURA, Naritoshi[1*] ; SEKI, Kanako[1] ; KEIKA, Kunihiro[1] ; NISHIMURA, Yukitoshi[2] ; HORI, Tomoaki[1] ; STRANGEWAY, Robert J.[3] ; MCFADDEN, James P.[4] ; LUND, Eric J.[5]

[1]STEL, Nagoya University, [2]Dept. of Atmos. and Oceanic Science, UCLA, [3]Inst. of Geophys. and Planetary Phys.,UCLA, [4]Space Science Laboratory, UCBerkeley, [5]SSC, Univ. of New Hampshire

Recent satellite observations and simulations have clarified that plasma outflows play an important role in abrupt changes in the ion composition in the plasmasheet and ring current during geomagnetic storms. Statistical studies by Strangeway et al. [2005] and Brambles et al. [2011] indicated that the flux of ion outflows is correlated well with soft electron precipitation (precipitating electron density and electron density in the loss cone), and DC and Alfvenic Poynting fluxes using the data obtained by the FAST satellite near the cusp region in the dayside during the 24-25 September 1998 geomagnetic storm. To distinguish between O^+ and H^+ ion outflows, we performed statistical studies using the ion composition data in addition to the ion and electron data obtained by the FAST satellite at 3000-4150 km altitude during January 1998 and January 1999. The long-term dataset enables us to identify empirical formulas between the outflowing O^+ and H^+ ion fluxes and the precipitating electron density, the electron density in the loss cone, the net electron number flux, and the DC and Alfvenic Poynting fluxes in a wide solar zenith angle (SZA) range (for dayside, 50-110 degree; and for nightside, 90-150 degree). In the SZA range of 90-110 degrees, the above formulas in the dayside are almost similar to those in the nightside. While SZA dependence of the relationshps between the outflowing O^+ and H^+ ion fluxes and the DC and Alfvenic Poynting fluxes are weak, the empirical formulas between the outflowing O^+ and H^+ ion fluxes and soft electron precipitation, especially the precipitating electron density and the electron density in the loss cone, depend on SZA. Although the precipitating electron density and the electron density in the loss cone that correspond to the outflowing O^+ ion flux of about 10^7 /cm^2/s increase with decreasing SZA, the outflowing O^+ and H^+ ion fluxes become more sensitive to an increase in soft electron precipitation with decreasing SZA.

Inversion method for estimating the helium ion density distribution in the plasmasphere based on IMAGE/EUV data

NAKANO, Shin'ya[1*] ; FOK, Mei-ching[2] ; BRANDT, Pontus C.[3] ; HIGUCHI, Tomoyuki[1]

[1]The Institute of Statistical Mathematics, [2]NASA Goddard Space Flight Center, [3]The Johns Hopkins University Applied Physics Laboratory

The plasmasphere exhibits a variety of shapes as a result of the variation in the electric field in the inner magnetosphere due to the coupling processes between the solar wind, the magnetosphere, and the ionosphere. Global imaging observations from outside the plasmasphere provide striking evidence of the variability of the plasmasphere. In particular, the EUV imager on board the IMAGE satellite obtained global EUV images of the plasmasphere, which have provided important insights into the variation of the plasmasphere. Our aim is to obtain the information on the ion density distribution for individual events rather than simply the averaged distribution from IMAGE/EUV data. For this purpose, we propose a linear inversion technique by which to estimate the helium ion density distribution. We applied this technique to a synthetic EUV image generated from a numerical model. This technique was confirmed to successfully reproduce the helium ion density that generated the synthetic EUV data. We also demonstrate how the proposed technique works for real data using real EUV images.

Current availability and utilization prospect of data obtained by AKEBONO for the research on lightning whistler

OIKE, Yuta[1*] ; KASAHARA, Yoshiya[1] ; GOTO, Yoshitaka[1]

[1]Kanazawa University

The AKEBONO spacecraft (EXOS-D) was launched in 1989 to observe particles and plasma waves in the auroral region and the plasmasphere of the Earth. It covers the altitude region from 300 km to about 10,000 km with an orbital inclination of 75 degree, and has been operated for more than 25 years which exceed 2 cycles of solar activity or 1 cycle of solar magnetic polarity reversal. Therefore analyses of the data obtained by AKEBONO enable us to study how the magnetosphere varies comprehensively.

The WBA (Wide Band Analyzer) is one of subsystems of the VLF instruments onboard AKEBONO. It measures 1 component of electric or magnetic analogue waveform in the frequency band of 50 Hz - 15 kHz. Typical waves such as chorus, hiss and whistler were frequently observed by the WBA. Huge amounts of data obtained by the WBA for more than 25 years are originally recorded as analogue waveform format in the magnetic audio tapes. Data conversion from analogue to digital is now carried out and the converted data are stored in our computer storage as digital WAVE format. Total number of the data files of digital WAVE format is more than 6,000, the total file size exceeds 10 terabytes and the processable data amount corresponds to more than 5,000 hours observation.

An automatic detection system to detect lightning whistlers from spectrograms of the WBA was developed. The spectrum intensity is automatically calibrated inside the system referring to the status of automatic gain controller of the receiver before detecting lightning whistlers. The system can output observed time, frequency band and dispersion of each detected lightning whistler. Some statistics of the lightning whistlers such as spatial and local time dependence of the occurrence frequency were already performed and the comparison with lightning activities are now under study. Because the dispersion of lightning whistler strongly depends on the electron density profile along the propagation path of the wave so that global electron density profile can be estimated using trend of dispersions of lightning whistlers. It is also pointed out that the propagation behavior of lightning whistlers is important clue to understand the wave-particle interaction. Thus these data and statistics have potential to achieve more valuable knowledge of the plasma physics in the magnetosphere.

In this presentation, we introduce the current status of data availability of the WBA and the derived results so far. We also discuss prospect of the data utilization.

Simultaneous ground-based and satellite observations of MF/HF auroral radio emissions

SATO, Yuka[1*] ; KUMAMOTO, Atsushi[2] ; KATOH, Yuto[2] ; SHINBORI, Atsuki[3] ; KADOKURA, Akira[1] ; OGAWA, Yasunobu[1]

[1]National Institute of Polar Research, [2]Department of Geophysics, Graduate School of Science, Tohoku University, [3]Research Institute for Sustainable Humanosphere, Kyoto University

Ground-based and satellite observations have revealed that the Earth is a distinct radio source. The terrestrial auroral ionosphere emits electromagnetic waves in the MF/HF ranges (about 1-6 MHz) as well as well-known intense auroral kilometric radiation (AKR) and auroral hiss in the VLF/LF ranges. Terrestrial Hectometric Radiation (THR) is observed by satellite observations in a frequency range of 1-4.5 MHz at high latitudes during geomagnetic disturbances and is regarded as a counterpart of auroral roar which is one type of MF/HF auroral radio emissions observable from the ground. Both THR and auroral roar are attributed to mode conversions of upper hybrid waves favorably generated under the matching condition, $f_{UH} \sim nf_{ce}$, where previous studies confirmed n = 2,3,4 and 5 for auroral roar, and n = 2 for THR. However, no previous studies have tested the simultaneous appearance. In this study, we survey long-term observation data obtained by the ground-based passive receivers installed at the Husafell station, Iceland (after September 2005, latitude 64.67^{o}N, longitude -21.03^{o}E, 65.3^o magnetic latitude) and the Kjell Henriksen Observatory (KHO), Svalbard (after August 2008, latitude 78.15^{o}N, longitude 16.04^{o}E, 75.2^o magnetic latitude) and by the Plasma Waves and Sounder experiment (PWS) mounted on the Akebono satellite. This data set includes several simultaneous appearance events, while the frequency of aurora roar is different from that of THR observed by the Akebono satellite passing over the ground-based stations. This frequency difference supports the previously proposed idea that auroral roar and THR are generated at different altitudes near 250 km and 1000 km, respectively. There is hardly any possibility that simultaneous observations indicate the identical generation region of auroral roar and THR. We also find that auroral roar appearing during the time when the Akebono satellite passes over the ground-based stations tends to be accompanied by THR. However, when the Akebono satellite passing over the stations detects THR, auroral roar does not always appear. This tendency is explained in terms of the fact that the Akebono satellite can detect THR emissions coming from a wider region, and a considerable portion of auroral roar emissions generated in the F region is absorbed in the D/E regions.

Spatiotemporal distribution of auroral brightening in the cusp

TAGUCHI, Satoshi[1*] ; HOSOKAWA, Keisuke[1] ; OGAWA, Yasunobu[2]

[1]University of Electro-Communications, [2]National Institute of Polar Research

Previous studies have shown that mesoscale auroral forms occur near the equatorward edge of the background, stable cusp aurora, and that they move in a direction that is consistent with the motion of the magnetic field line after reconnection on the dayside magnetopause. In this study we pay attention to its initial brightening using data from a high-sensitivity all-sky imager at Longyearbyen, Svalbard. The imager has a field-of-view that spans more than 4 hours in MLT, and can observe auroral brightenings that are widely separated in MLT. We determined the position of dayside auroral brightening using the 630-nm auroral images, and examined how these positions are distributed in the cusp, focusing on intervals when IMF was extremely stable. Results of analyses show that brightening occurs over a wide dayside MLT range. We show detailed spatiotemporal patterns for successive brightening events, and discuss the patterns in terms of the formation of intermittent reconnection on the dayside magnetopause.

Height measurement from stereo imaging of aurora

KATAOKA, Ryuho[1*] ; SHIGEMATSU, Kai[2] ; MIYOSHI, Yoshizumi[2] ; MIYAHARA, Hiroko[3] ; ITOYA, Satoru[4]

[1]NIPR, [2]Nagoya University, [3]MAU, [4]JSF

A new stereoscopic measurement technique is developed (Kataoka+2013) to obtain an all-sky altitude map of aurora using two ground-based digital single-lens reflex (DSLR) cameras. Two identical full-color all-sky cameras were set with an 8 km separation across the Chatanika area in Alaska (Poker Flat Research Range and Aurora Borealis Lodge) to find localized emission height with the maximum correlation of the apparent patterns in the localized pixels applying a method of the geographical coordinate transform. It is successfully estimated that a typical ray structure of discrete aurora shows the broad altitude distribution above 100 km, while a typical patchy structure of pulsating aurora shows the narrow altitude distribution of less than 100 km. Recent new findings about the time variation of the emission height and further new challenges of February/March 2014 will also be reported.

Statistical analysis of auroral structures related to the plasma instability based on ground optical observations

HASHIMOTO, Ayumi[1*] ; SHIOKAWA, Kazuo[1] ; OTSUKA, Yuichi[1] ; OYAMA, Shin-ichiro[1] ; NOZAWA, Satonori[1]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, Nagoya, Japan

Auroral complex shapes are formed due to the connection of the ionosphere and magnetosphere by geomagnetic field lines which project disturbance of the magnetosphere onto the ionosphere through auroral particles. Thus, study of the auroral dynamics is important in considering the disturbance of the magnetosphere. Shiokawa et al. [JGR, 2010] reported observations of small-scale finger-like auroral structures which appeared on the west side of auroral patches, using a high-resolution narrow field-of-view CCD camera at Gillam (geomagnetic latitude: 65.5 N), Canada. At the recovery phase of substorm in the night side, these structures appeared when the speed of the patches moving to the east was slowed down, due to the macroscopic Rayleigh-Taylor type instability in the magnetosphere. However, statistical characteristics of this phenomenon have not been investigated yet. In this study, based on observations by an all-sky imager at Tromso (magnetic latitude: 67.1 N), Norway from January 2009 to November 2012, we made statistical analysis of the occurrence conditions of 19 events of auroral structures that seem to be driven by pressure-driven plasma instability. We found fourteen large-scale finger-like structures which developed from auroral arcs and six small-scale finger-like structures which appeared in auroral patches. We investigated MLT dependence of the start time of these finger-like structures, their relationship with auroral substorms, scale sizes, eastward drift speeds, development speeds, and so on. The large- scale structures were seen from midnight to dawn and small-scale structures were seen at dawn mainly. Large-scale structures tend to appear at the beginning of substorms' recovery phase and small-scale structures tend to occur at the late recovery phase of substorms. The scale sizes of these large and small structures are larger than the gyro radius of the ions in the magnetospheric equatorial plane, indicating that the finger-like structures are caused by MHD instabilities. The eastward propagation speeds are slower than the typical midnight auroral drift speed. This fact indicates that the low-energy plasma may be source of the structures. However, this consideration may contradict with the idea that the high-energy particles lead to the pressure-driven instability.

Auroral vortex street formation and cavity trapping of Alfven waves

HIRAKI, Yasutaka[1*]

[1]National Institute of Polar Research

The structuring of auroral arc has been studied to be understood in the context of magnetohydrodynamic (MHD) instabilities and their nonlinear evolution in the magnetosphere-ionosphere (MI) coupling system. It was demonstrated that feedback instability of field-line resonant and ionospheric Alfven resonant modes occurs, by means of linear analysis with non-uniformity of the Alfven velocity (v_A) in the dipole magnetic field and the convection electric field [Hiraki and Watanabe, 2011; 2012, Hiraki, 2013]. We performed 3D reduced-MHD simulations in the MI coupling system to examine nonlinear behavior of the initially assumed arc structure, where v_A is constant along the field line. Results show that i) the initial arc splits, intensifies, and just after that deforming into a vortex street, and ii) the transition of the growth pattern exists at the convection electric field of 20-40 mV/m. We also performed 3D simulations with non-uniformity of v_A, though without the initial arc, to examine changes in auroral structure and properties of Alfven waves due to the magnetospheric and ionospheric cavities. It was found that, if the ionospheric cavity becomes deep, the secondary instability in the magnetic equator side [Watanabe, 2010] is suppressed, alternatively, large-amplitude waves are trapped in the ionospheric cavity. In this talk, we report the initial results of the above two simulations. Furthermore, we would discuss on auroral electron acceleration in the cavity region, by means of extended analyses with two-fluid effects and parallel electric field.

Relative timing of substorm-associated magnetic reconnection in the magnetotail and formation of auroral onset arc

MIYASHITA, Yukinaga[1*] ; IEDA, Akimasa[1] ; MACHIDA, Shinobu[1] ; HIRAKI, Yasutaka[2] ; ANGELOPOULOS, Vassilis[3] ; MCFADDEN, James P.[4] ; AUSTER, H. uli[5] ; MENDE, Stephen B.[4] ; DONOVAN, Eric[6] ; LARSON, Davin[4]

[1]STEL, Nagoya Univ., [2]NIPR, [3]Univ. of California, Los Angeles, [4]SSL, Univ. of California, Berkeley, [5]Technischen Universitat Braunschweig, [6]Univ. of Calgary

We have studied the relative timing of magnetic reconnection in the near-Earth magnetotail and formation of auroral onset arc, based on substorm events observed by the THEMIS spacecraft and ground-based all-sky imagers. The THEMIS all-sky imagers can observe auroras over a wide area with temporal and spacial resolutions higher than spacecraft-borne cameras. This enables us to investigate the timing of auroral development in more detail than before. A few min after the appearance and intensification of an auroral onset arc, it begins to form wave-like structure. Then auroral poleward expansion begins another few min later. Based on observations of plasmoids in the near-Earth magnetotail, we clearly show that magnetic reconnection is initiated at X∼-20 Re at least 1-3 min before the appearance of the auroral onset arc. This result suggests that magnetic reconnection plays some role in the formation of auroral onset arc.

Characteristics of eastward propagating aurora vortices obtained by aurora tomography

TANAKA, Yoshimasa[1*] ; OGAWA, Yasunobu[1] ; KADOKURA, Akira[1] ; MIYAOKA, Hiroshi[1] ; GUSTAVSSON, Bjorn[3] ; PARTAMIES, Noora[2] ; BRANDSTROM, Urban[4] ; WHITER, Daniel[2] ; ENELL, Carl-fredrik[5]

[1]National Institute of Polar Research, [2]Finnish Meteorological Institute, [3]University of Tromso, [4]Swedish Institute of Space Physics, [5]EISCAT Scientific Association

We investigate characteristics of three mesoscale aurora vortices observed in the Northern Scandinavia by aurora campaign observation in March, 2013, which was conducted in collaboration with the Swedish Institute of Space Physics (IRF) and the Finnish Meteorological Institute (FMI). The aurora vortices propagated eastward intermittently at about 15-minute intervals in the post-midnight sector (0:00-0:40 UT; 2:30-3:10 magnetic local time) after the substorm onset. They were simultaneously observed by three monochromatic (427.8nm wave length) all-sky EMCCD imagers at Tromso (69.6N, 19.2E), Norway, Kilpisjarvi (69.0N, 20.9E), Finland, and Abisko (68.4N, 18.8E), Sweden, with an exposure time of about 2 seconds and a sampling rate of about 10 seconds. In addition to these optical data, geomagnetic field data from the IMAGE magnetometer chain were also available.

The propagation speed of these vortices was approximately 3 to 10 km/s at 100 km altitude. The ionospheric equivalent current system accompanied by the aurora vortices indicated a two-vortex structure. By applying tomographic inversion analysis to the events, we also obtained 3D distributions of volume emission rate and ionospheric electron density, as well as horizontal distribution of auroral precipitating electrons. It is also possible to estimate horizontal distribution of the ionospheric conductivity from the electron density distribution at every 10-second interval. In the presentation we will discuss the magnetosphere - ionosphere coupling process of the aurora vortices and the relationship with the omega bands that are generally observed in the post-midnight sector.

Observation of 630 nm auroral polarization with a newly-developed imaging spectrograph

TAKASAKI, Shimpei[1*] ; SAKANOI, Takeshi[1] ; KAGITANI, Masato[1]

[1]PPARC, Tohoku University

From the recent result of observation of OI 630nm auroral emission related to polar rain at high-latitudes using a polarization photometer, linear polarization parallel to geomagnetic field with 2-7% was reported [Lilensten et al., 2013]. From a theoretical approach, OI 630nm emission can be polarized up to 17% [Bommier et al., 2011]. However, these past measurements were limited in the polar cap region and its polarimetry characteristics is not clear. Therefore, we developed an imaging spectrograph which can measure auroral polarization in the wide field-of-view of 130 deg. from 420 nm to 680 nm with a accuracy of 1% polarization degree, which enable us to obtain polarization degrees at 557.7 nm aurora and 630 nm auroral emission simultaneously at various geomagnetic angle configuration. Here we consider that 557.7nm aurora is useful as a standard light source because a theory predicts 557.7nm emission does not produce polarization. We installed it in the middle of auroral region at Poker Flat Research range in November 2013and carried out precise calibration to extract artificial polarization which may be produce inside the optical system using an LED light source with a linear polarizer. From the calibration, we found the acrylic dome does not produce serious artificial polarization. Since then, automatic operation is continuously going on till the beginning of April 2014.

From the result on January 1st 2014, we obtain the polarization of 630 nm aurora with degree of 10%. Then, there was elevation angle dependence in both degree and direction. But, we also observed the polarization of no polarized 557.7nm emission. It has same elevation angle dependence as former. So, it is indicated that they are polarized by same processes like atmospheric scattering on the path from emission region to instrument. In this presentation, we report these results.

Development of polarization photometer and observation of OI 630 nm auroral polarization

MONJI, Hiroyuki[1*] ; KAGITANI, Masato[1] ; SAKANOI, Takeshi[1]

[1]PPARC, TOHOKU Univ.

Auroral O630 nm emission is theoretically expected to be polarized due to the velocity anisotropy of precipitating electrons. On the other hand, auroral O557.7 nm emission should not be polarized because it is quadrupole transition [Lilensten et al., 2006].

Recent ground-based measurement data showed that auroral emission at OI 630 nm probably polarized with a degree of 1-4%, and the polarization is maximized in the magnetic perpendicular direction [Lilensten et al., 2008, Barthelemy et al., 2011]. This fact suggest that it would be possible to investigate auroral physical processes, like electron anisotropy, by remote-sensing the auroral polarization.

In this study, we aim to establish the procedures of polarimetry observation of aurora, and obtain its polarization degree by developing a new polarization photometer.

We developed the polarization photometer which measures the polarization parameters (Stokes vector) using a quartz waveplate mounted on rotation stage and a polarization beam splitter. We adopt a narrow band 630 nm for wavelength selection. The field-of-view of this photometer is 3 deg. Observation of OI 630 nm auroral polarimetry was performed at Poker Flat Research Range in Alaska for three weeks in January 2013. We rotated the waveplate and took data at nine positions in one rotation. The time resolution for one rotation is 30 s. In addition, we carried out the calibration at Polar Flat with a linear polarizer and LED lamp. Using the auroral polarization data set and calibration data, we estimated the linear polarization degree and circular polarization simultaneously for the world first time.

On January 17, aurora appeared in the whole sky around 14:00 UT. During this period, we estimated the auroral polarization degree at various points along geomagnetic meridian. The estimated polarization degree maximized at the point parallel to the local geomagnetic field, which is inconsistent with the past result. On January 18, the auroral linear polarization degree increased correlated with auroral enhancement at 11:30 UT. This fact suggest that auroral polarization may increase due to the change in anisotropy in precipitating electrons.

Approximate formula of daytime ionospheric conductance ratio

IEDA, Akimasa[1*] ; OYAMA, Shin-ichiro[1] ; FUJII, Ryoichi[1] ; NAKAMIZO, Aoi[2] ; HORI, Tomoaki[1] ; YOSHIKAWA, Akimasa[3] ; NISHITANI, Nozomu[1]

[1]STEL, Nagoya University, [2]Finish meteological institute, [3]Kyushu University

Solar zenith angle (SZA) dependences of daytime ionospheric conductances are studied. In particular, we developed a simple theoretical form for the Hall to Pedersen conductance ratio against SZA. The European incoherent scatter (EISCAT) radar observations located at Tromso (67 MLAT) on 30 March 2012 were used to calculate conductances.

Daytime electric conductances in the ionosphere are associated with plasmas created by Solar extreme ultraviolet radiation into the neutral atmosphere of Earth. Previous conductance models have been either consistent or not with the ideal Chapman theory of such plasma productions.

Our results indicate that the SZA dependence of the Pedersen conductance can be consistent with the Chapman theory after modifications. Such modifications include an approximation of vertically-uniform plasma densities in the topside E region, and taking atmospheric temperature upward gradient into account. The Hall conductance decreases with increasing SZA more rapidly than the Pedersen conductance does. This is because that the Hall conductivity layer thins from noon toward night.

Temporal variation of electron density in the vicinity of the ionospheric trough

ISHIDA, Tetsuro[1*] ; OGAWA, Yasunobu[2] ; KADOKURA, Akira[2] ; HOSOKAWA, Keisuke[3] ; OTSUKA, Yuichi[4]

[1]The Graduate University for Advanced Studies, [2]National Institute of Polar Research, [3]The University of Electro-Communications, [4]Nagoya University

The purpose of this study is to examine temporal variation of electron density in the vicinity of the ionospheric trough, and to understand its physical mechanisms on different geomagnetic activities.

Basu et al. [2008] showed that Subauroal Polarization Stream (SAPS) enhances in the south of the trough during storm main phase. At the same time, GPS-TEC map showed that the trough also extends longitudinally throughout the Northern American continent. In addition, they pointed out that the plasma density irregularities in the trough/SAPS region impact the GPS-based navigation systems.

So far, it remains unclear how the trough and such irregularities develop in a shorter time scale and what determines their spatial structure because adequate observation with sufficient temporal resolution has not been operated. Therefore, we had conducted EISCAT SP experiment (high speed meridional scans which take only 60-80 seconds to scan elevation angles from 25 to 89 degrees) in duskside-nightside (1630-2030 MLT) on Oct. 2013 - Dec. 2013, and obtained totally 9 events including 7 quiet-moderate events and 2 disturbed events.

We have been investigating on the following topics: (1) the difference of temporal variation of electron density between inside and outside the trough, (2) the characteristic of temporal variation of electron density in the vicinity of the trough. We have obtained the following results so far.

1. The quasi-periodic variations in electron density, on the time scale of 5-40 minutes, have been found outside the trough, which varies with time and altitude. Oh the other hand, such structures less occurs within the trough. This tendency is independent on geomagnetic activity.

2. The quasi-periodic variations in electron density, on the time scale of 5-10 minutes, have been found within the trough boundary, which is nearly consistent toward altitude in magnetically quiet-moderate condition. However, this cyclic pattern is inconsistent toward altitude in magnetically disturbed condition.

Classification and occurrence characteristics of subauroral rapid plasma flows observed by SuperDARN Hokkaido HF radar

NAGANO, Hiroki[1*] ; NISHITANI, Nozomu[1] ; HORI, Tomoaki[1]

[1]STEL, Nagoya Univ.

The rapid ionospheric plasma flows equatorward of the auroral zone are called Sub-Auroral Polarization Stream (SAPS). As a result of the past studies of SAPS, Kataoka et al. [2009] reported that positions of SAPS shift toward lower latitude with developing Dst index using the SuperDARN Hokkaido HF radar.

In this study we investigate the occurrence characteristics of SAPS, with focus on the relationship between SAPS occurrence and solar wind / geomagnetic parameters, using the SuperDARN Hokkaido HF radar with the field of view covering the Far East region, which began its operation in 2006. In order to discuss characteristics of SAPS extensively, we take a wider range of velocity (>10 m/s) and MLAT (>40 deg) than the previous studies. As a result of the statistical analysis we identified two kinds of flows with a threshold of 150 - 200 m/s. MLAT of faster flows has correlation with SYM-H and AL index, whereas the slower ones have no such correlation. We will report on the details of correlation between flow characteristics of solar wind and geomagnetic parameters, including substorm and storm phases.

Magnetic latitude and MLT dependence of the bandwidth of MF/HF auroral radio emissions in the topside ionosphere

SAKAI, Masataka[1*] ; KUMAMOTO, Atsushi[1] ; KATOH, Yuto[1] ; SATO, Yuka[2]

[1]Department of Geophysics, Tohoku University, [2]National Institute of Polar Research

In the ionosphere, auroral radio emissions are generated by precipitating auroral particles. Previous studies reported that the MF/HF auroral radio emissions emitted from the bottomside ionosphere were observed on the ground. The narrowband emissions are called auroral roar, and the broadband emissions are called MF burst. On the other hand, Sato et al. [2010] showed the spectrum and polarization of two events of MF/HF radio emissions observed in the topside ionosphere by the Akebono satellite. Based on the event studies, they suggested that the observed narrowband emissions are generated by the mode conversion of UHR waves enhanced in the auroral ionosphere where the upper hybrid frequency matches the harmonics of the electron cyclotron frequency as suggested for generation mechanism of the auroral roar observed on the ground [Weatherwax et al., 1995; Yoon et al., 1998; Weatherwax et al., 2002].

In this study, we have focused on broadband emissions observed in the topside ionosphere which are similar with broadband MF burst observed on the ground. We analyzed MF/HF broadband emissions (with wider bandwidth of $>$0.5 kHz) observed by the Akebono satellite. Because it is difficult to observe broadband emissions on the ground and in the topside ionosphere at the same time, we have performed statistical analysis. We found that the bandwidth of the MF/HF emissions was larger in the high latitude and in the dusk side. The bandwidth of the MF/HF emissions was greater than 1 MHz in higher geomagnetic latitude than 70 degree in the sector from 12 to 24 MLT. Previous studies suggested that the MF bursts observed on the ground were generated by the mode conversion of upper hybrid waves stimulated by the energetic auroral electrons [e.g. Sato et al., 2008]. Therefore, we can expect that the bandwidth of MF bursts depend on the generation processes of upper hybrid waves, mode conversion processes of upper hybrid waves, and propagation processes of converted electromagnetic waves in the auroral ionosphere.

Time Variability of Characteristics of Pc5 during Passage of CIRs

KITAMURA, Kentarou[1*] ; SAITA, Satoko[2] ; TANAKA, Yoshimasa[3] ; KADOKURA, Akira[3] ; YAMAGISHI, Hisao[3]

[1]Tokuyma college of Technology, [2]The Institute of Statistical Mathematics, [3]National Institute of Polar Research

In this study, we analyzed the magnetic data observed at the high-latitude magnetic stations in Antarctica, H057 (-66.42, L=6.25), and Skallen (-66.42) to compare with the >2Mev electron flux observed by GOES 10 satellite. The pair of stations is located at the same latitude and within 1.7 degrees in longitude, which are quite suitable to estimate the azimuthal wave number.

We statistically analyzed the wave characteristics of the Pc5 pulsations by the superposed epoch (SPE) analysis for 14 magnetic storm events caused by the passage of CIRs (Corotating Interaction Region). The epoch time is defined as days from the passage of the stream interface (SI) of the CIR. The Pc5 power suddenly increases at 3-6 MLT sector from 0 day which is much stronger than that at dusk sectors. During 1-2 days, which is correspond to the recovery phase of the storms, the Pc5 power at the afternoon sectors (12-21 MLT) increases with the peak frequency of 2.5-3 mHz, whereas the Pc5 power at the morning sector does not become stronger.

On the other hand, the phase delay between the Pc5s at H057 and SKAL also shows the local time dependence especially during the epoch time of 1-2 day. At the noon and afternoon sectors, the Pc5 shows the eastward propagation and the phase lags between H057 and SKAL are less than 5 seconds. In contrast, at the morning sector, the Pc5 shows westward propagation with small azimuthal wave numbers.

These features indicate that the sources and generation mechanisms of Pc5 in the two periods (0-1 day and 1-2 day) are quite different. The premiere intensification of the Pc5 corresponds to the main phase of the moderate magnetic storm and can thought to be the forced oscillation caused by the strong disturbance of the solarwind dynamic pressure. In this case, the local time dependence of the phase structure does not show the obvious regularities. In the latter intensification of the Pc5 corresponds to the recovery phase of the storm (1-2 days). The westward (eastward) propagation at the morning (afternoon) sector and local time distribution of the Pc5 power could well correspond with the previous perception which could explain the Pc5 pulsations caused by the KH instability on the magnetopause.

The present result implies that the difference of the wave characteristics of Pc5s closely related the drift bounce resonance with the relativistic electrons. The drift bounce resonance might occur at the afternoon sector during the recovery phase of the moderate magnetic storm by the KH instability due to the passage of the high speed solar wind.

Spontaneous excitation of Alfven waves and their interactions with high-energy ions in a magnetic mirror configuration

ICHIMURA, Makoto[1*] ; IKEZOE, Ryuya[1]

[1]Plasma Research Center, Univ. of Tsukuba

In laboratory fusion plasmas, high-energy ions are produced with DD and DT fusion reactions and are also created with high-energy neutral beam injection and electromagnetic waves for plasma heating. Special emphasis is given to plasma waves excited by such high-energy ions and their interactions with particles. For example, energetic alpha particles produced with DT fusion process can interact resonantly with shear Alfven waves during slowing-down process, and excite plasma instabilities, that is, so-called Alfven eigenmodes (AEs). Recently, enhancement of energetic ion transport caused by these instabilities has been remarked on its deleterious effects. When a small fraction of alpha particles is transported to the first wall in burning plasma devices, plasma facing materials can be damaged seriously. Many kinds of the experimental observations related to such wave-particle interactions are reported. In this report, spontaneously excited waves in Ion Cyclotron Range of Frequency (ICRF) and their interactions with high-energy ions in a mirror magnetic field configuration are presented.

The ICRF waves are frequently used for the plasma heating in laboratory fusion devices with the mirror magnetic field configuration. When the ICRF power and consequent wave energy levels are increased, it will become important to understand the detailed physics of wave-wave and wave-particle interactions. It is required to consider both linear and nonlinear processes for deposition of ICRF powers. In the ICRF heating experiments on the GAMMA 10 tandem mirror, the maximum ion temperature in the perpendicular direction has reached 10 keV and the temperature anisotropy (which is defined as the temperature ratio of perpendicular to parallel to the magnetic field line) becomes more than 10 in the central cell. Alfven-ion- cyclotron (AIC) waves are spontaneously excited owing to such the strong temperature anisotropy. The excitation of the AIC wave is one of the common physical phenomena in space plasmas with an anisotropic velocity distribution. High energy ions, of which energy is more than 50 keV, have been observed along the magnetic field line at the open end of the mirror magnetic field configuration. The transport of high-energy ions along the magnetic field line owing to the loss processes other than the classical Coulomb scattering has been suggested. The existence of considerable energy transport along the magnetic field line owing to the AIC waves is discussed theoretically. The AIC waves in GAMMA 10, which has several discrete peaks in the frequency spectrum, are excited as eigenmodes. Their spatial structures are measured with a microwave reflectometer inside the plasma and magnetic probes in the peripheral region. Low-frequency fluctuations around 0.1 MHz, which is a differential frequency between discrete peaks of the AIC waves, are observed in the central cell. These fluctuations are also observed in the high-energy ion signal detected by a semiconductor detector installed at the end for measuring ions along the magnetic field line. Pitch angle scattering in the velocity space owing to the spontaneously excited Alfven waves are indicated. The radial transport of high-energy ions owing to the low-frequency MHD instability has been observed, however, the transport across the magnetic field line owing to the AIC waves has not yet been detected.

Observations of spontaneously excited waves in ICRF in the large tokamak experiments are also reported as Ion Cyclotron Emissions (ICE). The fluctuations in ICRF are driven by the presence of non-thermal ion distribution in magnetically confined plasmas and plasmas with the strong anisotropy. Waves owing to fusion products of ^{3}He and T ions are clearly detected in D-plasma and alpha particles in DT-plasma experiments.

Nonlinear wave particle interaction of electromagnetic ion cyclotron wave

SHOJI, Masafumi[1*] ; OMURA, Yoshiharu[2]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Research Institute for Sustainable Humanosphere, Kyoto University

Spacecraft observations and simulations show generation of coherent electromagnetic ion cyclotron (EMIC) triggered emissions with rising-tone frequencies. In the inner magnetosphere, the spontaneously triggered EMIC waves are generated by the energetic protons with large temperature anisotropy. We reproduced EMIC triggered emissions in the Earth's magnetosphere by real scale hybrid simulations with cylindrical magnetic geometry. We perform parametric analyses of electromagnetic ion cyclotron (EMIC) triggered emissions on the gradient of the non-uniform ambient magnetic field using a hybrid simulation. According to nonlinear wave growth theory, as the gradient of the ambient magnetic field becomes larger, the theoretical threshold of the wave amplitude becomes larger although the optimum wave amplitude for nonlinear wave growth does not change. With a larger magnetic field gradient, we obtain coherent rising tone spectra because the triggering process of the EMIC triggered emission takes place only under the limited condition of the wave amplitude. On the other hand, with a smaller magnetic field gradient, triggering of the emissions can be caused with various wave amplitudes, and then the sub-packets are generated at various locations at the same time. The concurrent triggerings of emissions result in incoherent waves, observed as "broadband" EMIC bursts. Broadband emissions induce rapid precipitation of the energetic protons into the loss cone since the scattering by the concurrent triggering takes place faster than that of the coherent emissions. The coherent triggered emission causes efficient proton acceleration around the equator because of the stable particle trapping by the coherent rising tone emission.

Solar energetic particle spectrum at the Sun and the Earth

KUBO, Yuki[1*]

[1]National Institute of Information and Communications Technology

It is well accepted that high-energy solar energetic particles are accelerated at reconnection regions in a solar flare and coronal shock waves driven by a coronal mass ejection. The coronal shock waves accelerate particles through the first-order Fermi process. The original Fermi acceleration theory predicts a power law particle distribution in momentum with index depending on shock compression ratio. Solar energetic particle spectra have been well investigated and it is found that the observed spectra are represented by almost power law (with high energy rollover). This looks like natural results at first glance. However, the observed spectrum is the spectrum at the observation location not at the acceleration site, and it is not trivial if the observed spectrum is as same as the source spectrum. There are some evidences that typical observed power law index will be about 6 in ground level enhancement (GLE). If the source spectrum of accelerated particle at a coronal shock is assumed to be as same as observed one, a compression ratio of the coronal shock accelerating particles should be about 1.6 according to the Fermi acceleration theory. This shock strength may not be enough to accelerate particles to GeV energy range in a short time. This implies that the spectrum at the source may not be as same as one at the observation location. While a power law spectrum predicted by Fermi process is a steady state solution, a lot of study show that a shock accelerated particle spectrum is time dependent manner. This fact may also imply a different spectrum between at the Sun and at the Earth. In this study, we investigate an energetic particle spectrum difference between at the source region and at the observation location by the interplanetary particle transport simulations.

Coupling between ULF waves and high-energy particles in the inner geomagnetosphere based on a drift-kinetic simulation

SEKI, Kanako[1*] ; AMANO, Takanobu[2] ; SAITO, Shinji[3] ; MIYOSHI, Yoshizumi[1] ; KEIKA, Kunihiro[1] ; MIYASHITA, Yukinaga[1] ; MATSUMOTO, Yosuke[4] ; UMEDA, Takayuki[1] ; EBIHARA, Yusuke[5]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University, [2]Graduate School of Science, University of Tokyo, [3]Graduate School of Science, Nagoya University, [4]Graduate School of Science, Chiba University, [5]Research Institute for Sustainable Humanosphere, Kyoto University

Understanding of acceleration mechanisms of electrons to cause drastic variation of the Earth's outer radiation belt is one of outstanding issues of the geospace researches. While the radial diffusion of the electrons driven by ULF waves has been considered as one of the candidate mechanisms, efficiency of the mechanism under realistic ULF characteristics and distribution is far from understood. GEMSIS (Geospace Environment Modeling System for Integrated Studies) of STEL, Nagoya University, is the observation-based modeling project for understanding energy and mass transportation from the Sun to the Earth in the geospace environment. The GEMSIS-Magnetosphere working team has developed a new physics-based model for the global dynamics of the ring current (GEMSIS-RC model). The GEMSIS-RC model is a self-consistent and kinetic numerical simulation code solving the five-dimensional collisionless drift-kinetic equation for the ring-current ions in the inner-magnetosphere coupled with Maxwell equations. In contrast to previous ring current models assuming a force-balanced equilibrium, the new model allows the force-imbalance to exist, which generates induced electric field through the polarization current. The most prominent advantage of the new model is the capability of describing fast time scale phenomena such as injections during substorms and MHD-time scale (ULF) waves.

We applied the GEMSIS-RC model for simulation of global distribution of ULF waves. Comparison between runs with/without ring current ions show that the existence of hot ring current ions can deform and amplify the original sinusoidal waveforms. The deformation causes the energy cascade to higher frequency range (Pc4 and Pc3 ranges). The cascade is more pronounced in the high beta case. It is also shown that the existence of plasmapause strengthens ULFs outside the plasmapause and widens the MLT region where the E_r (toroidal) component is excited from initially-given E_phi (poloidal) component. We also report the basic characteristics of the ring current driven ULF waves and its effects on the electron transport in the inner magnetosphere.

Radiation spectra from relativistic electrons moving in a Langmuir turbulence

TERAKI, Yuto[1*]

[1]Osaka University / RIKEN

We examine the radiation spectra from relativistic electrons moving in a Langmuir turbulence expected to exist in high energy astrophysical objects by using numerical method. The spectral shape is characterized by the spatial scale λ, field strength σ, and frequency of the Langmuir waves, and in term of frequency they are represented by {s:0188$_0$ $2\pi c/\lambda$, ω_{st} = eσ/mc, and ω_p, respectively. We normalize ω_{st} and ω_p by ω_0 as a $\equiv \omega_{st}/\omega_0$ and b $\equiv \omega_p/\omega_0$, and examine the spectral shape in the a ? b plane. An earlier study based on Diffusive Radiation in Lang- muir turbulence (DRL) theory by Fleishman & Toptygin showed that the typical frequency is $\gamma^2\omega_p$ and that the low frequency spectrum behaves as F$\omega\overline{\Gamma}\omega^1$ for b $>$1 irrespective of a. Here, we adopt the first principle numerical approach to obtain the radiation spectra in more detail. We generate Langmuir turbulence by superposing Fourier modes, inject monoenergetic electrons, solve the equation of motion, and calculate the radiation spectra using Lienard-Wiechert potential. We find different features from the DRL theory for a $>$b $>$1. The peak fre- quency turns out to be $\gamma^2\omega_{st}$ which is higher than $\gamma^2\omega_p$ predicted in the DRL theory, and the spectral index of low frequency region is not 1 but 1/3. It is because the typical deflection angle of electrons is larger than the angle of the beaming cone $\approx$ 1/γ. We call the radiation for this case " Wiggler Radiation in Langmuir turbulence " (WRL).

Fine Spectral Structures and Their Generation Mechanisms for Solar Radio Bursts Observed by AMATERAS

IWAI, Kazumasa[1*] ; MIYOSHI, Yoshizumi[2] ; MASUDA, Satoshi[2] ; TSUCHIYA, Fuminori[3] ; MORIOKA, Akira[3] ; MISAWA, Hiroaki[3]

[1]Nobeyama Solar Radio Observatory, NAOJ, [2]STEL, Nagoya University, [3]PPARC, Tohoku University

The solar corona contains many particle acceleration phenomena that are caused by the interactions between the coronal magnetic field and plasma. Non-thermal electrons accelerated in the corona emit radio waves in the metric range. As a result, many types of solar radio bursts are observed. There are many types of complex fine spectral structures in the solar radio bursts. They are thought to be caused by some inhomogeneity of particle acceleration, wave generation, radio emission, and radio propagation processes. Hence, metric solar radio bursts are very important to understand coronal plasma processes such as the particle acceleration and wave-particle interaction.

The fine spectral structures of solar radio type-I bursts were observed by the solar radio telescope AMATERAS. The spectral characteristics, such as the peak flux, duration, and bandwidth, of the individual burst elements were satisfactorily detected by the highly resolved spectral data of AMATEAS with the burst detection algorithm that is improved in this study. The peak flux of the type-I bursts followed a power-law distribution with a spectral index of 2.9?3.3, whereas their duration and bandwidth were distributed more exponentially. There were almost no correlations between the peak flux, duration, and bandwidth. That means there were no similarity shapes in the burst spectral structures. We defined the growth rate of a burst as the ratio between its peak flux and duration. There was a strong correlation between the growth rate and peak flux. These results suggest that the free energy of type-I bursts that is originally generated by non-thermal electrons is modulated in the subsequent stages of the generation of non-thermal electrons, such as plasma wave generation, radio wave emissions, and propagation. The variation of the time scale of the growth rate is significantly larger than that of the coronal environments. These results can be explained by the situation that the source region may have the inhomogeneity of an ambient plasma environment, such as the boundary of open and closed field lines, and the superposition of entire emitted bursts was observed by the spectrometer.

Co-evolution of upstream waves and accelerated particles around parallel shocks

SUGIYAMA, Tooru[1*] ; FUJIMOTO, Masaki[2]

[1]JAMSTEC, [2]JAXA

We have investigated the co-evolution of upstream waves and the accelerated particles around the parallel shock. Hybrid particle simulations are performed in the exactly parallel shock configuration with Mach number of ˜10. The upstream waves convecting into the shock surface contribute the particles acceleration as reported in Sugiyama et al. (2001). The appropriate wave-length exists for the particle energization, that is, the longer wave-length wave leads the higher energy particles. Simultaneously, the higher energized particles excite the longer wave-length waves in the upstream region. Here we report that the higher energy particles and longer wave-length waves are observed as the time elapses later in the simulation runs. Therefore, the present process is ”co-evolution” of the upstream waves and accelerated particles.

Colliding Two Oblique Shocks: Shock Structures and Particle Acceleration

NAKANOTANI, Masaru[1*] ; MATSUKIYO, Shuichi[1] ; HADA, Tohru[1]

[1]ESST, Kyushu univ.

Mechanisms of the particle acceleration at a collisionless shock have been intensively studied analytically, numerically, and observationally. Most of the previous studies assume that energetic particles interact with a single shock. However, shock waves are ubiquitous in space, and two shocks frequently come close to or even collide with each other. For instance, it is observed that a CME (coronal mass ejection) driven shock collides with the earth's bow shock [H. Hietala et al., 2011], or interplanetary shocks pass through the heliospheric termination shock [J. Y. Lu et al., 1999]. The detailed structures of such colliding shocks and the accompanied particle heating/acceleration processes have not been understood.

Cargill et al. [1986] performed one dimensional hybrid simulations to discuss the dynamic structure of colliding shocks and the accompanied ion acceleration. They showed that some ions are efficiently accelerated at the time of the collision of two supercritical shocks. However, since electron dynamics are neglected in a hybrid simulation, the microstructures of the colliding shocks, which may affect the early stage processes of particle acceleration, cannot be resolved.

Here, we perform full Particle-in-Cell (PIC) simulations to examine colliding two shocks. In particular, the following three points interacting with two colliding oblique shocks is discussed in detail.

1. Energetic electrons are observed upstream of the two shocks before their collision. These energetic electrons are efficiently accelerated through multiple reflections at the two shocks (Fermi acceleration). Moreover, a part of the accelerated electrons are farther energized by interacting with increasing magnetic field during the collision and/or one of the shocks after the collision.

2. Before two shocks collide, there is a large amplitude wave excited by electrons flowing out to the upstream. We discuss the excitation mechanism and the influence on particle propagation or shock structures.

3. After two shocks collide, we find that a plasma density and pressure in the downstream is lower than the value calculated by MHD. The reason is that energetic electrons run away to the upstream. In addition to this, we discuss kinetic influences by comparing PIC simulation's results with the value after two shocks collide (magnetic fields, the shock velocity and etc.) calculated by MHD.

Particle acceleration in high Mach number quasi-parallel shocks

KATO, Tsunehiko[1*]

[1]Hiroshima University

We study particle acceleration process of electrons and protons in high Mach number (M_A~30) quasi-parallel collisionless shocks by particle-in-cell (PIC) simulation. We found that a fraction of protons which consist of the plasma are injected into acceleration mechanisms and efficiently accelerated around the shock. The energy spectrum of the accelerated protons becomes power-law like distribution. A part of electrons are also accelerated around the shock although they are roughly two orders of magnitude fewer than the accelerated protons. For both protons and electrons, the acceleration processes are often not diffusive and their time-scales are even shorter than the respective gyration times. We also found that protons reflected at the shock generate circularly polarized Alfven waves with very large amplitude in the upstream region of the shock and that, because of the strong perpendicular magnetic field of these waves, the structure of the collisionless shock itself is in fact similar to that of quasi-perpendicular shocks.

Particle simulations on electron acceleration at Quasi-Perpendicular Shocks

SHINOHARA, Iku[1*] ; FUJIMOTO, Masaki[1] ; NAKAMURA, Takuma[2]

[1]Institute of Space and Astronautical Science / Japan Aerospace Exploration Agency, [2]Los Alamos National Laboratory

We found efficient production of non-thermal electrons up to $\gamma\sim20$ in results of three-dimensional full kinetic simulations of quasi-perpendicular shocks. The seed acceleration occurs in large-amplitude electromagnetic wave excited in the most front region of the shock foot. A small portion of electrons keeps staying in the foot region due to the scattering by the large-amplitude electromagnetic wave, and these electrons can get energy from the motional electric field in the shock rest frame. Since the large-amplitude electromagnetic wave is only possible in 3-D simulations, no electron acceleration is observed in previous 1-D and 2-D simulations. After the seed acceleration, these electrons can be further accelerated at the shock lamp region by the shock drift acceleration. The acceleration process occurs during the steepen phase of the self-reformation, and the acceleration efficiency depends on the phase of the shock self-reformation. In contrast to the standard Fermi acceleration at quasi-parallel shocks, the electron acceleration process at quasi-perpendicular shocks is much quicker (order of the ion cyclotron period); however, electrons cannot experience effective acceleration again and again so that there would be an energy limitation of the acceleration. In this presentation, we will discuss the energy limit of electron acceleration at quasi-perpendicular shocks by using simulation results obtained from the K computer.

The fast acceleration of particles scattered by MHD wave in parallel shock

MURAKI, Koudai[1*] ; AMANO, Takanobu[2] ; HOSHINO, Masahiro[2]

[1]EPS. Univ. of Tokyo, [2]University of Tokyo

The origin of the galactic cosmic ray is believed to be generated around the supernova remnant shocks (SNR), and the first-order Fermi acceleration is widely recognized as the standard theory of cosmic ray acceleration. Yet this acceleration mechanism is not always efficient enough to explain high energy cosmic ray particles extending to the knee. The maximum attainable energy expected by the first-order Fermi acceleration is less than the observations. To overcome this problem, additional acceleration and/or other efficient acceleration processes are needed.

Scattering process is important to investigate diffusive shock acceleration(DSA). In the previous numerical simulations, scattering is often treated as just numerical way like Monte-Carlo methods or electromagnetic perturbation. Among these researches, a special attention is paid to the particle acceleration for the particles scattered by magnetohydrodynamic (MHD) waves around the shock wave front. In the uniform system, when the wave phases are strongly correlated spatially localized traveling wave packets can efficiently large angle scatter charged particles (*Kuramitsu & Hada, 2000*). The scattering process through monochromatic large amplitude MHD waves around the parallel shock (*Sugiyama et al. 2001*) is regarded as a possible pre-acceleration process injecting the thermal particles into the Fermi acceleration process and the subsequent fast Fermi acceleration process.By extending the previous researches, we study a fast particle acceleration process for MHD turbulence around the parallel shock. By using the test particle simulation, we argue about the particle acceleration in the quasi-linear regime and also about the case of strongly coherent waves and large amplitude waves.

On statistics of a plasma in a nonuniform flow

HADA, Tohru[1*]

[1]IGSES, Kyushu University

It is well known that energetic particles such as cosmic rays can efficiently be accelerated by scatterers convected by a compressional flow (Fermi acceleration). Scatterers convected by an expanding flow decelerate the particles, but this is not the reverse process of the acceleration. Plasma in space is never uniform, but is rather composed of different plasmas with different propagation speeds. We analyze statistics of energetic particles in such nonuniform plasma flow analytically and numerically. Results will be compared with non-equilibrium plasma distributions in the solar wind.

Helicon wave propagation, mode conversion, and plasma heating

ISAYAMA, Shogo[1*] ; HADA, Tohru[1] ; TANIKAWA, Takao[2] ; SHINOHARA, Shunjiro[3]

[1]Graduate School of Engineering Sciences, Kyushu University, [2]Research Institute of Science and Technology Tokai University, [3]Tokyo University of Agriculture and Technology, Institute of Engineering

Helicon plasma is a high-density (number density ˜10^{19} /m^3) and low-temperature (electron temperature ˜a few eV) plasma generated by the helicon wave, i.e., electromagnetic whistler wave in a bounded plasma. Helicon plasma is thought to be useful for various applications including plasma processing and electric thrusters. On the other hand, there remain a number of unsolved fundamental issues regarding how the plasma is generated. Some of the key processes involved are the wave propagation (dispersion relation), mode conversion, collisional and non-collisional damping and resultant plasma heating, ionization and re-combination of neutral particles due to electrons accelerated by the wave, and modification of the dispersion relation due to addition of newly produced plasma.

In this presentation, as a first step to understand the helicon plasma production mechanism, we study the helicon wave propagation, mode conversion, and the plasma heating. According to Shamrai (1996), the helicon wave is linearly mode converted to an electrostatic Trivelpiece-Gould (TG) wave, which can accelerate electrons efficiently. However, the mode conversion and the production of the TG wave strongly depend on the dissipation included in the plasma. Using fluid and particle-in-cell (PIC) simulations, we discuss the mode conversion efficiency, wave damping, and plasma heating due to wave-particle interactions. We show that direct damping of the helicon waves can play major roles in the plasma heating under circumstances relevant to actual laboratory experiments.

Hamilton-Jacobi equation based on exterior derivative

NAKAMURA, Tadas[1*]

[1]Fukui Prefectural University

Analytical Mechanics of fields usually singles out the temporal coordinate as an independent parameter and calculates the time evolution regarding fields as dynamical parameters with infinite degree of freedom. Spatial coordinates are treated as infinit number of indexes of dynamical parameters. This approach has a disadvantage when applied to electromagnetism: the resulting equations are not manifestly covariant. Moreover, when applied to gauge fields, the canonical theory with this approach has extra degree of freedom, which need to be eliminated with some constraints. One must fix the gauge at the price of loosing manifest covariance, or introduce some
complicated technique such as Dirac brackets.

The author reported the way to treat four (time 1 + space 3) parameters equally to construct analytical mechanics at the fall SGEPPS meeting. The expression obtained is manifestly covariant, and there is no need for gauge fixing when applied to gauge fields. The present study is to extend it to Hamilton-Jacobi theory. Also, possible application to the fluid dynamics will be discussed at the presentation.

The name of Hamilton-Jacobi equation is well known by name, however, not many researchers try to understand its detail because it is not quite useful to solve actual problems. However, it is conceptually important for the deep understanding of analytical mechanics. Also, it is essential to introduce quantum mechanics based on the knowledge of classical mechanics.

Several attempts have been made to establish classical mechanics of relativistic fluid dynamics, but fully covariant expressions are yet to come. Kambe (2010) has reported the Euler equation can be cast into the form of Maxwell equation with appropriate definitions of variables. The present study has been successfully applied to the analytical mechanics of electromagnetism, therefore, it may be applicable to fluid dynamics based on Hasimoto's representation.

Study of the slowly drifting narrowband structure in type-IV solar radio bursts observed by AMATERAS

KATOH, Yuto[1*] ; IWAI, Kazumasa[2] ; NISHIMURA, Yukio[1] ; KUMAMOTO, Atsushi[1] ; MISAWA, Hiroaki[3] ; TSUCHIYA, Fuminori[3] ; ONO, Takayuki[1]

[1]Department of Geophysics, Graduate School of Science, Tohoku University, [2]Nobeyama Solar Radio Observatory, National Astronomical Observatory of Japan, [3]Planetary Plasma and Atmospheric Research Center, Graduate School of Science, Tohoku University

We show the type-IV burst event observed by AMATERAS on June 7, 2011, and reveal that the main component of the burst was emitted from the plasmoid eruption identified by the EUV images of SDO. The slowly drifting narrowband structure (SDNS) appear in the spectra of the burst. By a statistical analysis, we reveal that SDNS appeared with the duration of tens to hundreds of millisecond and with the typical bandwidth of 3 MHz. For the generation mechanism of SDNS, we propose the wave-wave coupling between Langmuir waves and whistler-mode chorus emissions generated in a post-flare loop, inferred from the similarities of the plasma environments between a post-flare loop and the equatorial region of the Earth's inner magnetosphere. We assume that a chorus element with a rising tone is generated at the loop-top of a post-flare loop. By referring to the propagation properties of chorus in the magnetosphere, we assume that the chorus element propagates downward along the magnetic field line and then propagates away from the central region of the flare-loop toward the outer edge of the loop where the plasma density is relatively small. By the magnetic field and plasma density models, we quantitatively estimate the expected duration of radio emissions generated through the coupling between Langmuir waves and chorus during its propagation in the post-flare loop and find that the observation properties of duration and bandwidth of SDNS are consistently explained by the proposed generation mechanism. The characteristics of SDNS are its intermittency in time and the negative frequency drift in the limited frequency band. While observation in the terrestrial magnetosphere shows that chorus is a group of large amplitude wave elements naturally generated intermittently, the mechanism proposed in the present study can explain both intermittency and slowly drifting narrowband structure in the observed spectra.

Numerical simulation of magnetic field generation by relativistic effect in high intensity laser experiments

KAWAZURA, Yohei[1*] ; YOSHIDA, Zensho[1]

[1]Graduate School of Frontier Sciences, The University of Tokyo

It has been a big mystery how the seed (primordial) magnetic field is generated in the universe. In fluid description of plasma, a magnetic filed is coupled with a mechanical vorticity then represented as curl of canonical vorticity. Recently, Mahajan and Yoshida proposed a novel mechanism of vorticity generation by relativistic effect [1, 2]. The relativistic plasma have two vorticity generating terms, one is so-called baroclinic term(S_T). The baroclinic term is known to be weak except for strongly thermal nonequilibrium state (e.g. shock front). Mahajan and Yoshdia proposed that, even if the system is barotropic, there appears another term available to generate vorticity due to the relativistic effect (S_R).

Recent progress in high intensity laser experiment enables us to obtain relativistic electron plasma, and some of the workers established high accuracy measurement of the generated magnetic field [3]. The relativistic vorticity generation (RG) is expected to be verified in such high intensity laser experiments.

In this study, we conducted numerical simulation for the proposal of the experimental verification. We have following objectives; is RG sufficiently working in actual experiment? If not, in what parameters will RG effectively work? What is the characteristics of the magnetic field given by RG? We calculated for parameters relevant to the experiment in Ref. 3. Observing the ratio of relativistic baroclinicity to thermodynamic baroclinicity, we can state that thermal baroclinic effect is governing and RG is not sufficiently working. By raising the hot electron temperature or decreasing the ratio of skin depth to scale length, the ratio is improving (Fig).

It is a still controversial matter whether the production efficiency of cosmic rays (CRs) is relatively efficient or inefficient (e.g. Helder et al. 2009; Hughes et al. 2000; Fukui 2013). In upstream region of SNR shocks (the interstellar medium), the energy density of CRs is comparable to a substantial fraction of that of the thermal plasma (e.g. Ferriere 2001). In such a situation, CRs can possibly exert a back-reaction to the shocks and modify the global shock structure. These shocks are called cosmic ray modified shocks (CRMSs). In CRMSs, as a result of the nonlinear feedback, there are almost always up to three steady-state solutions for given upstream parameters, which are characterized by CR production efficiencies (efficient, intermediate and inefficient branch).

We evaluate qualitatively the efficiency of the CR production in SNR shocks by considering the stability of CRMS, under the effects of i)magnetic fields and ii)injection, which play significant roles in efficiency of acceleration.

By adopting two-fluid model (Drury & Völk, 1981), we investigate the stability of CRMSs by means of time-dependent numerical simulations. As a result, we show explicitly the bi-stable feature of these multiple solutions, i.e., the efficient and inefficient branches are stable and the intermediate branch is unstable, and the intermediate branch transit to the inefficient one. This feature is independent of the effects of i) shock angles and ii) injection.

Furthermore, we investigate the evolution from a hydrodynamic shock to CRMS in a self-consistent manner. From the results, we suggest qualitatively that the CR production efficiency at SNR shocks may be the least efficient.

2D Full Particle-In-Cell Simulation on a High Beta Collisionless Shock and Particle Acceleration

MATSUKIYO, Shuichi[1*] ; MATSUMOTO, Yosuke[2]

[1]Kyushu University, [2]Chiba University

High beta and relatively low Mach number shocks are commonly present in a vriety of space and astrophysical environments, like the earth's bow shock, the heliospheric termination shock (effective beta is rather high due to the presense of pickup ions), galaxy cluster merger shocks, etc. Even such high beta shocks show some evidences that high energy particles are possibly accelerated there. Voyager 2 spacecraft revealed that the fluxes of non-thermal electrons and ions (the latter are called as termination shock particles) are enhanced at the crossings of the termination shock. Radio synchrotron emissions from relics of galaxy cluster mergers imply the presence of relativistic electrons accelerated in the merger shocks. In this study we perform two-dimensional full particle-in-cell simulation to discuss structure of the shock as well as the acceleration process of electrons. The one-dimensional simulations performed in the past showed that under the high beta and relatively low Mach number conditions the shock is more or less laminar and time stationary and electron acceleration occurs through the so-called shock drift mechanism. Here, we reveal that two-dimensional structure of the shock is highly complex even for such a high beta and a low Mach number and further that some electrons are accelerated to high energy but their acceleration mechanism appears not to be so simple as that reproduced in one-dimensional simulations.

Kelvin-Helmholtz turbulence in space and astrophysical plasmas

MATSUMOTO, Yosuke[1*]

[1]Graduate School of Science, Chiba University

Solar wind interactions with magnetized or un-magnetized planets destabilize planetary boundaries such as the magnetopause of the Earth magnetosphere and the ionopause of Mars and Venus. The Kelvin-Helmholtz (K-H) instability arising at a velocity shear layer has been considered to be important for momentum transport of the solar wind across the boundary layers, and been a universal nature of the planetary interactions. Linear and nonlinear growths of the instability depend on background plasma and magnetic field configurations. At the Martian ionopause, where the ionospheric ion escape is expected by the K-H instability, a fast (˜400 km/s), delute (˜1 /cc) plasma flow directly interacts with a high density (10^4-10^5 /cc), low temperature (a few thousand K) plasma. The situation can be found similarly at the terrestrial magnetopause, where in-situ observations have often indicated growth of the instability and resultant transport of the solar wind plasma into the magnetosphere, in the sense that the K-H instability grows in a strongly inhomogeneous plasma.

In this presentation, we review nonlinear evolutions of the K-H instability in strongly inhomogeneous plasmas. The evolutions are characterized by the secondary instabilities such as the Rayleigh-Taylor instability and the magnetic reconnection, by which a coherent eddy structure are destroyed and the energy is transported to smaller scales. Recent kinetic plasma simulations have shown that electron-scale structures are spontaneously generated as a consequence of the secondary instabilitties (Karimabadi et al., 2013). The micro-scale structure accompanied with the MHD-scale evolution enhanced mixing of collisionless plasmas. It was also found that the spatial size of the turbulent area was quickly broaden when coupled with a coalescence of large scale K-H modes, that is, the inverse energy cascade (Matsumoto & Seki, 2010). When nonlinear mode coupling was considered the time scale of the inverse energy cascade can be even faster than the fastest growing mode of the K-H instability. These nonlinear features in micro and macro scales have large impact on plasma transport process in the solar wind - planetary interactions as well as in astrophysical plasmas.

Experimental Study on Turbulent Transport using ElectroHydroDynamics Convection Turbulence

NAGAOKA, Kenichi[1*] ; YOSHIMURA, Shinji[1] ; HIDAKA, Yoshiki[2] ; TERASAKA, Kenichiro[2] ; YOKOI, Nobumitsu[3] ; MASADA, Yohei[4] ; MIURA, Hideaki[1] ; TSUNETA, Saku[5] ; KUBO, Masahito[6] ; ISHIKAWA, Ryoko[6]

[1]National Institute for Fusion Science, [2]Kyushu Univ., [3]Tokyo Univ., [4]Kobe Univ., [5]ISAS, [6]NAOJ

Turbulent transport is a very general subject in a wide area of physics research. The phenomena that we are interested in are very complex ones associated with structure formations in turbulence. It is well known that the Kolmogorov scaling appears in three-dimensional isotropic turbulence. However, it is less interested because nothing happens. In many cases of our interest, some structures appear in turbulence due to symmetry breaking such as temperature gradient, density gradient, intensity gradient of turbulence, rotation, velocity shear, magnetic field, etc. We have proposed a new experimental approach to turbulent transport using ElectroHydrodynamic Convection (EHC).

The EHC is a convection motion driven by the electric field in a liquid crystal, where the gravity and the temperature gradient in a Rayleigh Bernard convection (RBC) system can be replaced by the electric field alone. When the electric field is increased, the EHC becomes turbulent, which is the same feature as RBC with stronger buoyant force. Non-dimensional parameters characterizing EHC turbulence can be easily controlled with the biased voltage. The Rayleigh number is proportional to voltage squared and the Prandtl number is inversely proportional to the frequency of biased ac voltage, respectively. When the EHC turbulence experiment on a rotating table becomes possible in future, the Rossby number can be also controllable.

In the first step of the EHC turbulence experiment, particle transport in homogeneous EHC turbulence without rotation (symmetric case) was evaluated with a particle tracing technique. The small particles put in the liquid crystal can visualize local flow velocity in the EHC turbulence and the particle transport can be evaluated by the orbit tracing of particles. The diffusive nature (random walk process, the Hurst number ˜0.5) of particle transport was observed in the EHC turbulence. The effective diffusivity increases with the Rayleigh number with the power index of ˜0.85. These results are very similar to turbulent transport properties in viscos fluids (Navier-Stokes system).

The details of EHC turbulence experiment in laboratory frame without symmetry breaking and three experimental plans will be discussed. One is an investigation of non-uniformity effects on turbulent transport with inhomogeneity of turbulence intensity (spatial gradient of the Rayleigh number). Second one is an investigation of rotation effect on turbulent transport. These experiments on turbulent transport may reveal some general effects of symmetry breaking of scalar field and vector field, respectively. The last one is a laboratory simulation of the convection zone in stars and/or planet atmosphere with three-dimensional geometry identical to the real geometry (rotating spherical shell with radially driven convection). The radially-driven turbulence in rotating spherical shell have never realized in laboratory. Using ECH turbulence, turbulence can be driven in the radial direction with radial electric field. The convective zone in the Sun is the first target because of relatively large Rossby number˜0.1-1.

Investigation of magnetic flux transport on the solar surface based on satellite data and auto-tracking technique

IIDA, Yusuke[1*]

[1]ISAS/JAXA

Spatial displacement of patch structure on the solar surface is investigated based on satellite data and auto-tracking technique.

Magento-convection system on the solar surface is thought to be important not only as a cause of various solar activities but also as an actual observable magneto-convection on the stellar surface. One important issue is how magnetic flux is transported there. In global scale, the transport of magnetic field is treated as a diffusion now. However it is not clear that diffusion treatment is appropriate in magneto-convection system. The aim of this study is to understand if the diffusion treatment of magnetic field transport in global scale is good or not.

I investigate the dependence of mean-square displacement on elapsed time by using auto-tracking technique, which is thought to be one of the critical characteristics for global-scale description of transport.

The longest magnetogram data obtained by Hinode/FG is used. In that data, number of tracked patches is enough for statistical study, more than 40000. The obtained dependence show a different character above and below the point of L˜10^4 km. Below that scale, it has a power-law dependence with an index of ˜-1.4, namely super-diffusion scheme. However, in the larger scale, the power-law dependence becomes ˜-0.6, namely sub-diffusion scheme. These characters can be explained by the network flow pattern qualitatively. Below the network scale, patch is transported by constant flow (˜0.3km s^{-1}) from center of network cell to edge of the cell addition to the large (˜1km s^{-1}) perturbing flow of granulation. On the other hand, above the network scale, patches experience the trapping around stagnation point of network flow, which makes displacement of patch shorter than that only by diffusion motion.

Dynamic structure of convective motion depending on the height with line profile originating at solar photosphere

OBA, Takayoshi[1*] ; IIDA, Yusuke[2] ; SHIMIZU, Toshifumi[2]

[1]The Graduate University for Advanced Studies, [2]ISAS/JAXA

On the solar surface, there are bright cellular patterns which are called granules, separated by narrow dark regions named intergranular lanes. These spatial patterns result from surface convection. The surface convection induces the magnetic field dynamics and it is considered as an energy source of corona heating problem. Therefore, it is important to understand a convective motion in revealing the mechanism of corona heating problem. However, the smallness of its spatial structure prohibits us from resolving granular patterns in the observation. Furthermore, though the vertical structure is important in convection mechanism, it is difficult to observe it because there are few methods for a direct observation of solar interior. In this study, we investigate the height dependence of the vertical velocity and its spatial correlation with granular pattern based on the analysis of spectrum obtained by Solar Optical Telescope (SOT) on board the Hinode satellite. SOT/Spectropolarimeter (SP) obtains the spectrum including the Fe I 630.13/630.25nm lines, which corresponds the solar photosphere. The high spatial resolution of SP enables us to obtain spectra in granule and intergranular lanes separately. In addition, the seeing free condition in space observation enables the long time observation with high resolution, in this study, which is difficult for ground base observation. Consequently, we can remove the 5-min oscillation, which affects the radiative intensity and Doppler velocity, and then reduce errors of the analysis.

In this study, we focus on line profile of Stokes I originating in quiet region. Vertical velocity of convection is obtained from the Doppler shift of the line profile. We also analyze the wavelength structure of the line profile. Because of the dependence of absorption coefficient on wavelength, the intensity at different wavelength position reflects the structure at different height. The intensity at the line center reflects the structure in the higher layer, while the intensity at the line wings reflects the structure in the lower layer. We found that the difference of convective velocity between upper and lower level are typically 300 m s-1. At some locations, it exceeds 1km s-1. Taking into account that the speed of sound is approximately 7km s-1, it means that there are remarkable acceleration or deceleration around the solar surface. Further, there is a tendency between convective motion and acceleration, that granular region has upward motion with deceleration and intergranular region has downward motion with acceleration. In the presentation, we will discuss about the description of typical convective structure on the solar surface and what happens where has the different structure.

Particle acceleration and magnetic field generation in the relativistic jet-plasma interactions

ARDANEH, Kazem[1*] ; CAI, Dongsheng[1]

[1]Department of Computer Science, University of Tsukuba, Ibaraki 305-8573, Japan

The aim of the current work is to analyze particle acceleration and magnetic field generation related to propagation of a relativistic electron-ion jet front into an unmagnetized ambient electron-ion plasma. We have focused on the earliest evolution in shock formation. The analysis is on the basis of a three-dimensional relativistic electromagnetic particle-in-cell (PIC) code. The results demonstrate that the Weibel instability is responsible for generation of strong small-scale magnetic fields and subsequent particles acceleration. In agreement with previous studies the majority of the particles acceleration occurs behind the jet front. Initially, the incoming electrons respond to field fluctuations growing as a result of the Weibel instability. Therefore, the electron channels are generated and the total magnetic energy grows linearly due to the mutual attraction between the channels, and downstream advection of the magnetic field fluctuations. When the magnetic fields become strong enough to deflect the much heavier ions, the linear growth rate of instability decreases as a result of oppositely directed electron-ion currents and topological change in the structure of magnetic fields. The Ion channels are then merged and magnetic energy increases more slowly at the expense of the energy stored in ion stream. It has been clearly illustrated that the ion channels develop through a larger scale in the longitudinal direction, while extension of the electron filaments is limited. Hence, the ions channels are the sources of deeply penetrating magnetic fields. Our results are in valid agreement with those reported in the literature.

Magnetohydrodynamic evolutions of the Richtmyer-Meshkov instability in astrophysical and laboratory plasmas

SANO, Takayoshi[1*]

[1]Institute of Laser Engineering, Osaka University

The Richtmyer-Meshkov instability (RMI) in magnetohydrodynamics is of great interest in many fields such as astrophysical phenomena, laboratory experiments, and inertial confinement fusion. The RMI occurs when an incident shock strikes a corrugated contact discontinuity. A strong shock wave traveling through the density inhomogeneity of magnetized interstellar medium is a promising site of the RMI. This astrophysically common event plays a key role in determining the dynamics of supernova remnants and gamma ray bursts. Recent laboratory experiments are designed to test the magnetic field amplification due to the RMI by the use of laser-induced shock waves. In inertial confinement fusion, the RMI excited at several capsule interfaces amplifies the perturbations that seed the Rayleigh-Taylor instability. For the fast ignition approach, the utilization of an external magnetic field to guide the fast electrons is discussed proactively and sheds light on the impact of magnetohydrodynamic (MHD) instabilities during the implosion.

The inclusion of a magnetic field brings two important consequences into the RMI, which are the amplification of an ambient field and the suppression of the unstable motions. The magnetic field can be amplified by the stretching motions at the interface associated with the RMI. A strong magnetic field inhibits the nonlinear turbulent motions of the RMI. The vorticity generated by the interaction between a shock front and a corrugated contact discontinuity is the driving mechanism for the RMI. For the cases of MHD parallel shocks, the role of the magnetic field is to prevent the deposition of the vorticity on the interface, and stabilize the RMI.

We have investigated that the critical strength of a magnetic field required for the suppression of the RMI numerically by using a two-dimensional single-mode analysis. For the cases of magnetohydrodynamic parallel shocks, the RMI can be stabilized as a result of the extraction of vorticity from the interface. A useful formula describing a critical condition for magnetohydrodynamic RMI is introduced and is successfully confirmed by direct numerical simulations. The critical field strength is found to be largely dependent on the Mach number of the incident shock. If the shock is strong enough, even low-beta plasmas can be subject to the growth of the RMI.

Gyrokinetic simulation of multi-scale plasma turbulence

WATANABE, Tomo-hiko[1*]

[1]Graduate School of Science, Nagoya University

As is well known, spatio-temporal scales of plasma phenomena are characterized by multiple scale-lengths. As the scale-separation may not necessarily hold, multi-scale phenomena have been regarded as a common subject in the space and laboratory plasma studies. Magnetic reconnection is discussed as one of the examples. On the other hand, turbulence involves macro- and micro-scale structures simultaneously, and shows the fluctuation spectrum in a wide wavenumber range. Here, we discuss plasma turbulence with multiple scale-lengths, focussing on turbulent transport in magnetic fusion plasma.

By means of the gyrokinetic simulation, we have investigated transport phenomena in case with the electron temperature gradient (ETG) turbulence and the trapped electron mode (TEM) driven by a density gradient, where two scale-lengths characterizing the turbulence are involved. If both the two modes are unstable, after development of the ETG turbulence with a short spatio-temporal scale, the TEM instability grows with a long spatio-temporal scale. We have found an interesting case where the TEM drives a shear (zonal) flow with a longer spatio-temporal scale by which ETG and TEM fluctuations are regulated. The obtained result implies a possibility of turbulent transport reduction with a different driving source with a help of cross-scale interaction through zonal flows.

Furthermore, we have carried out a large-scale gyrokinetic simulation of multi-scale turbulence including the ion temperature gradient mode, where a turbulence spectrum from ion to electron scales as well as its dynamical evolution is studies. In the presentation, we will discuss characteristics of the multi-scale plasma turbulence and related transport.

∗This work is based on collaboration studies with Y. Aasahi (TiTech), S. Maeyama, M. Nakata, Y. Idomura (JAEA), A. Ishizawa, M. Nunami, and H. Sugama (NIFS). Plasma heating by nonlinear development of a finite amplitude whistler wave

SAITO, Shinji[1*] ; NARIYUKI, Yasuhiro[2] ; UMEDA, Takayuki[3]

[1]Graduate School of Science, Nagoya University, [2]Faculty of Human Development, University of Toyama, [3]Solar-Terrestrial Environment Laboratory, Nagoya University

A two-dimensional, three-velocity (2D3V) particle-in-cell simulation has been done in order to study nonlinear development of a finite amplitude and long wavelength R-mode wave propagating parallel to the mean magnetic field, where the fluctuation energy is 10% of the mean magnetic field and the wavelength is about the ion inertial length. The simulation has shown that the bulk motion associated with the finite amplitude wave triggers the modified-two-stream instability that generates electrostatic field in the quasi-perpendicular direction. The electrostatic field scatters ions in the perpendicular direction and electrons in the parallel direction. About 70% of fluctuation energy of the initially imposed R-mode decreases in one gyro-period of ion. The dissipation through the modified-two-stream instability in the two-dimensional system is more effective than the parametric instability in the one-dimensional system. Further the simulation found that quasi-perpendicular-propagating electromagnetic fluctuations are enhanced through the nonlinear development of the R-mode. Discussion will focus on both the plasma heating and the nonlinearly enhanced fluctuations propagating quasi-perpendicular directions.

A theoretical model of nonlinear Alfven waves in expanding accelerating solar wind plasmas

NARIYUKI, Yasuhiro[1*]

[1]Faculty of Human Development, University of Toyama

During about forty years, a lot of studies have discussed the linear and nonlinear dynamics of Alfven waves in solar wind plasmas. Although the uniform plasmas are assumed in most past studies, the effects of the inhomogeneity of background plasmas cannot be negligible in the inner heliosphere, in which several future spacecraft missions are planned. In the present study, a nonlinear evolution equation of envelope-modulated Alfven waves is derived from the magnetohydrodynamic accelerating expanding box model by using the reductive perturbation method. The effects of the acceleration of solar wind to nonlinear evolution are discussed in detail.

Alfven wave resonance in density profile structure and the effect for nonlinear phenomenon

TSUTSUMI, Akihiro[1*] ; SUZUKI, Takeru[1]

[1]Nagoya University

Wave transport in plasma (e.g. Alfven wave) is a universal phenomenon for astrophysical fluid which is effected by electromagnetic force. Presence of

density structure in plasma causes these wave reflection, and prevents smooth transport for one direction. However, it is known that if the density structure is like square well form, Alfven wave is trapped in the structure and wave reflection does not occur. It seems that this wave trapping is a ordinary case and concerns with physical phenomenon, because density valley usual exist in plasma. For example, it is pointed out that Alfven wave energy is dissipated at low-density area which is located in surface of the sun, and this mechanism is relate to coronal heating.

At linear phase, we can understand analytically the property of Alfven wave transport on square well density profile. Therefore, we can also understand the condition that wave trapping and no reflection occurs. At this phase, the flow is well-regulated and steady state, and compressibility effect (e.g. pressure or density vary) doesn't appear because Alfven wave is essentially transverse wave. However, as the wave injection continues, the amplitude increases and nonlinear effect turns important. At this phase, the flow is complicated due to trapped wave's collision, and square well density profile can not keep the form. As a result, the resonance condition will change voluntarily. This density profile is universal in the plasma gas, so above physical mechanism is important for understanding plasma phenomenon.

In our numerical simulation, we pay attention voluntarily structural change due to linear phase shift to nonlinear phase. Consequently, the linear phase resonance condition directly affects the time evolution in nonlinear phase. We will introduce the result.

The effect of the ion gyro motion to nonlinear processes of the Kelvin-Helmholtz instability

UENO, Satoshi[1*] ; UMEDA, Takayuki[1] ; NAKAMURA, Takuma[2] ; MACHIDA, Shinobu[1]

[1]Solar-Terrestrial Environment Laboratory, [2]Los Alamos National Laboratory

Nonlinear evolution of the Kelvin-Helmholtz instability (KHI) at a transverse velocity shear layer in an inhomogeneous space plasma is investigated by means of a four-dimensional (two spatial and two velocity dimensions) electromagnetic Vlasov simulation. When the rotation direction of the primary KH vortex and the direction of ion gyro motion are same, there exists a strong ion cyclotron damping. In this case, spatial inhomogeneity inside the primary KH vortex is smoothed and the secondary Rayleigh-Taylor instability is suppressed. The ion gyro motion also suppresses the formation of secondary vortices in the spatial scale smaller than the ion gyro radius, when the rotation direction of the vortex and the direction of ion gyro motion are same. As a result, the secondary instabilities take place at different locations in the primary KH vortex, where the rotation direction of the secondary vortex and the direction of ion gyro motion are opposite. These results indicate that secondary instabilities occurring in the nonlinear stage of the primary KHI at the Earth's magnetospheric boundaries might show dawn-dusk asymmetries.

Magnetohydrodynamic and Radiation Hydrodynamic Simulations of Tidal Disruption Events by a Supermassive Black Hole

KAWASHIMA, Tomohisa[1] ; OHSUGA, Ken[2] ; MATSUMOTO, Ryoji[3*]

[1]Shanghai Astronomical Observatory, [2]NAOJ, [3]Chiba University

Gas clouds or a star approaching a supermassive black hole can be disrupted by its tidal force. Such tidal disruption events enable us to observe the luminosity variations and state transitions triggered by the increase of the accretion rate, and give us hints to understand the transitions between different types of active galactic nuclei. Furthermore, the interval between the state transitions restricts the angular momentum transport rate, which determines the time scale of viscous evolution of an accretion disk. In 2014, tidal disruption flares are expected in two objects. One is the Galactic center supermassive black hole Sgr A$*$. A gas cloud named G2, whose mass is three times of the Earth mass is now approaching Sgr A$*$, and its pericenter passage will be in March, 2014. Since the distance from the black hole is well inside the radius of the accretion disk around Sgr A$*$, the tidally disrupted gas cloud will interact with the accretion disk. We carried out three-dimensional magnetohydrodynamic simulations of this interaction by applying a MHD code CANS+ based on the HLLD scheme. We found that the accretion rate increases more than 10 times during this outburst, and that magnetically driven jets are ejected. Increase of the X-ray and radio luminosity takes place within 1 month after the passage. The second object we expect an outburst is Swift J1644+57, which showed extremely high energy outburst in March 2011. This object locates at the center of a galaxy at redshift z=0.35. The energy released in this outburst indicates that the outburst was triggered by a disruption of a star. The luminosity of this source exceeded the Eddington luminosity for a 1-million solar mass black hole for period longer than a year but the X-ray luminosity decreased 100 times in August 2012. This darkening can be interpreted as the transition from a supercritically accreting slim disk state to a sub-critically accreting standard disk state. We carried out radiation hydrodynamic simulations of this event and showed that mass of the stellar debris is accumulating in the outer disk. When the surface density of the outer disk exceeds the threshold for the transition from a standard disk to a slim disk, the disk mass will accrete supercritically onto the black hole. Numerical results indicate that the luminosity of Swift J1644+57 may exceed the Eddington luminosity again in 1-2 years from the darkening.

Physics of weakly ionized dusty plasmas in planet formation

OKUZUMI, Satoshi[1*]

[1]Graduate School of Science and Engineering, Tokyo Institute of Technology

Planets form in gas disks around young stars. These protoplanetary disks are a typical example of weakly ionized plasmas in space: they are cool (∼10-1000 K) but are nonthermally ionized by galactic cosmic rays and stellar X-rays. The disks can also viewed as dusty plasmas as they contain micron-size dust particles from which planets form.

In this talk, we highlight interesting aspects of protoplanetary disks as weakly ionized dusty plasmas, and discuss their importance in planet formation as well as the MHD of the disks themselves. In particular, we focus on the interplay between charged dust particles and disk's MHD turbulence. Ionized accretion disks are prone to become turbulent because of the magnetorotational instability (MRI; Balbus & Hawley 1991). In protoplanetary disks, the activity of MRI strongly depends on how much dust has grown to larger solid bodies, as small dust particles determine the ionization degree of the disk gas. Meanwhile, turbulence, if present, drives the relative velocity of solid particles, which in turn affects how far the particles can grow by collisions. We briefly review recent developments in the numerical study of MRI-driven turbulence, and then discuss possible coevolution of MRI turbulence and dust particles as predicted by our latest self-consistent simulation (Okuzumi & Hirose 2012).

We will also highlight the importance of plasma heating by turbulent electric fields. A simple order-of-magnitude estimate shows that electric fields in MRI turbulence can significantly heat up electrons in the gas. This implies that Ohm's law can become *nonlinear* in the field strength. To study the nonlinearity of Ohm's law, we construct a gas-dust charge reaction model that takes into account the heating of ionized gas particles as well as impact ionization by hot electrons (Okuzumi & Inutsuka, in prep.). We find that the heating gives rise to negative differential resistivity at a high electric field strength. This occurs because heated electrons more frequently adsorb onto dust particles. The reduced conductivity will lead to suppressed MHD turbulence. Our ionization balance calculations predict that this effect become important in realistic protoplanetary disks (Mori & Okuzumi, in prep.).

The Global Positioning System (GPS) is a worldwide precise radio-navigation system formed from a constellation of at least 24 satellites at 20,200 km altitude, 4.2 R_E from the center of the Earth. GPS orbit configuration ensures that 5-10 satellites are visible from any single point on the Earth. The dual-frequency signals from the GPS satellites pass through the ionosphere to reach ground-based GPS stations. The phase and group velocities of radio waves vary in the ionosphere depending on the integrated electron density, that is total electron content (TEC), along the ray path and on the frequency of the radio waves. Using these characteristics, the TEC integrated along the ray path between a GPS satellite and a receiver can be accurately measured using two GPS signals in different frequencies. The TEC strongly reflects variations in the ionosphere at an altitude of about 300 km, where is the peak height of ionospheric electron density.

We have developed high-resolution TEC maps using dense GPS receiver networks. We have been collecting all the available GNSS receiver data in the world to expand the TEC observation area. These GNSS data are provided by IGS, UNAVCO, SOPAC, and other regional data centers. Currently, we are providing global and regional maps of absolute TEC, detrended TEC, and rate of TEC change index (ROTI). These data and quick-look maps are archived and available in DRAWING-TEC website (http://seg-web.nict.go.jp/GPS/DRAWING-TEC/).

These high-resolution GPS-TEC maps have been applied to studies of various ionospheric disturbances. Sudden increase in TEC caused by solar flares were studied using global TEC observations. Regional TEC observations have revealed new characteristics of large- and medium-scale traveling ionospheric disturbances (LSTIDs and MSTIDs). Recently, clear concentric waves and short-period oscillations were observed after huge earthquakes/tsunamis and massive tornadoes, indicating that acoustic and/or gravity waves propagate upward from the lower atmosphere and reach the ionosphere.

In this presentation, we will introduce recent studies of ionospheric disturbances using high-resolution GPS-TEC observations.

Observation of Lightning in Protoplanetary Disks by Ion Lines

MURANUSHI, Takayuki[1*] ; AKIYAMA, Eiji[2] ; INUTSUKA, Shu-ichiro[3] ; NOMURA, Hideko[4] ; OKUZUMI, Satoshi[4]

[1]Kyoto University, [2]The National Astronomical Observatory of Japan, [3]Nagoya university, [4]Tokyo Institute of Technology

Lightning in protoplanetary disks is an important elementary process in protoplanetary disk science. It has been studied as a candidate mechanism for chondrule formation, and it provides unique window to probe the electromagnetic state of the protoplanetary disks. As a consequence, multiple lightning models has proposed for protoplanetary disks, and it is important for protoplanetary disk astrophysics to observationally distinguish which model is correct. Here we study the possibility of observationally distinguishing lightning models in protoplanetary disks.

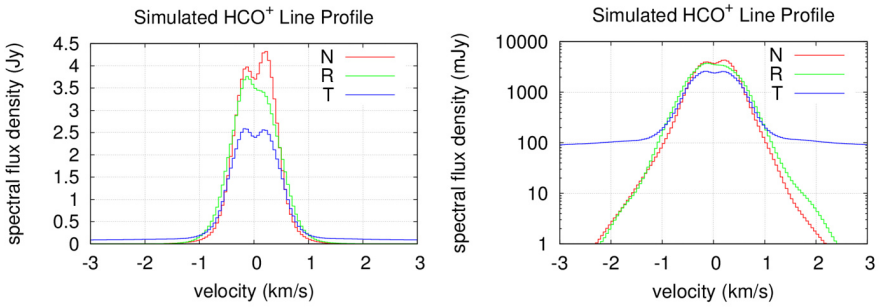
Lightning on Earth is discharge phenomenon in the air, and the gas discharge physics in air has been studied for centuries and is well understood process. But it has been observed that lightning takes place under electric field amplitude well below the dielectric strength of the air, the fact that has been a long standing mystery. Here, dielectric strength of an insulating material is the maximum amplitude of the electric field the subject material does not cause the electric breakdown. It is physical property of central importance for discharge physics.

In attempt to solve the mystery, traditional Townsend breakdown model has been challenged by new discharge models such as Druyversteyn-Penning breakdown model and runaway breakdown model. The values of the dielectric strength according to the latter two model are much smaller than it by Townsend breakdown model.

We can distinguish the breakdown models by their dielectric strength. Dielectric strength is the point where the electrons accelerated by the electric field reaches certain ionization energy. The electric field also accelerates the positively-charged ion species to the energy comparable to the electrons. Because the ionization energy is a universal constant, the accelerated ion energies are also constant. Observationally, this means that we will observe ion velocities much faster than the thermal velocity, and the observed velocities will be independent of the local density nor temperature among the lightning regions. This will be unique observational feature to detect and distinguish breakdown models in protoplanetary disks. For example, under disk gas that consists of 92% H_2 and 8% He, the characteristic ion speed of HCO^+ is 7.1km/s, 2.9km/s and 0.49km/s, respectively, for Townsend breakdown model, Druyversteyn-Penning breakdown model, and runaway breakdown model.

We have calculated the velocity distribution of the three ion species HCO^+, DCO^+ and N_2H^+, taking the lightning models into consideration. We have simulated the line profile and two-dimensional position-velocity images. We found lightning features of 10-100mJy appear in line profile. Recent ALMA observations e.g. by Mathews et al. (2013) and Qi et al. (2013) achives ˜10mJy sensitivity. Therefore we can reject some of the lightning models based on ALMA archive data, and distinguish lightning models by future ALMA observations.

Keywords: Protoplanetary disks, Discharge phenomena, Lightning, Weakly-ionized plasma, astrophysical plasma



Simulated HCO^+ line profile of an MMSN disk located at distance d=56pc, inclination i = 7(deg). The three curves indicate disk without lightning (N), disk with runaway breakdown model (R), and with Townsend breakdown model (T), respectively.

Investigation of attractive forces associated with overlapping Debye spheres using N-body simulations

ITOU, Hotaka[1*] ; AMANO, Takanobu[1] ; HOSHINO, Masahiro[1]

[1]Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo

Dust grains are quite common in space. They are thought to exist in, e.g., molecular clouds, protoplanetary disks, Earth's magnetosphere, and planetary rings. In addition, also in laboratories, the lattice formation of dust grains is the well-known phenomena and called Coulomb crystallization. Dust grains immersed in plasmas usually acquire large amount of charges due to several charging processes such as collisions with plasma partilcles and photoemission. Then the charged grains and the ambient plasma are strongly coupled with each other, and such plasmas are called dusty plasmas or complex plasmas. Since in situ observations in the solar system or Ikezi's prediction of Coulomb crystallization, dusty plasmas have been studied for not only astrophysical applications but also industrial applications.

When collisions between dust grains and plasma particles dominate charging processes, the dust grains are nagatively charged because generally the flux of electrons is larger than that of ions. Thus we expect that they repel each other. However, in realty, the force on dust grains is quite complex due to the interaction with the ambient plasma and several types of forces have been proposed (e.g., Shukla and Eliasson [2009]). Interestingly, some attractive forces may also exist and play important roles in aggregation or crystallization of dusty plsamas.

One of proposed attractive forces is that of due to the overlapping of Debye spheres (ODS). Resendes et al. [1998] showed that the potential between two dust grains is similar to Lennard-Jones potentials, which is repulsive at short distance and weakly attractive at longer distance. Moreover, Hou et al. [2009] showed that this type of attractive interaction has, if indeed it exists, the drastic aggregation and crystallization effect in dusty plasmas. On the other hand, it was suggested that the ODS attractive force does not exist when particles electrically trapped by grains are negligible ,i.e., the orbital motion limited (OML) theory is valid (Lampe et al. [2000]), and it has not been confirmed experimentally.

The aim of our study is to investigate the possibility of the ODS potential, by using direct N-body simulations, which allow us to investigate the electrostatic potential structure around the dust grains with minimun assumptions. By using a newly developed N-body simulation code implementing Ewald's sum algorithm, in which the short-range part of the potential is calculated in real space and the long-range part is calculated in wavenumber space, we have shown that in plasmas with a low plasma parameter there does not exist the ODS attractive force. In this study, we introduce the mesh and extend the code to implement the PM (particle-mesh) or PPPM (particle-particle particle-mesh) method allowing us to perform simulations with a much more particles to attempt the investigation of plasmas with the large plasma palameter.

Test-particle simulation of electron-H2O elastic collision along the magnetic field line around Enceladus

TADOKORO, Hiroyasu[1*] ; KATOH, Yuto[2]

[1]Tokyo University of Technology, [2]Department of Geophysics, Graduate School of Science, Tohoku University

Saturn's inner magnetosphere is dominated by water group neutrals originated from Enceladus' water plume [e.g., Shemansky et al., 1993; Richardson et al., 1998; Esposito et al., 2005]. The neutrals in the inner magnetosphere contribute to one of the important loss processes of plasma through plasma-neutral collisions. However, little has been reported on a quantitative study of the electron loss process due to electron-neutral collisions. In this paper, we will focus on the collisional loss process with neutrals.

We examine the variation of equatorial electron pitch angle distribution and loss rate of precipitated electrons into Saturn's atmosphere through pitch angle scattering due to elastic collisions with neutral H_2O along Saturn's magnetic field line around Enceladus. We focus on 1 keV electrons as a typical energy in the present study. To examine the variation of those, we perform one-dimensional test-particle simulation when the co-rotating electron flux tube passes the dense H_2O region in the vicinity of Enceladus (˜6.4 minutes). Results show that the equatorial electron pitch angle distribution near the loss cone ($<$20 degrees and $>$160 degrees) decreases with time through pitch angle scattering due to elastic collisions. It is found that the electrons of ˜19 % to the total number of equatorial electrons at the initial condition are lost in ˜380 seconds. The calculated loss time is twice faster than the loss time under the strong diffusion.

MHD wave-driven mass loss from gas giants and effects on atmospheric structure

TANAKA, Yuki[1*] ; SUZUKI, Takeru[1] ; INUTSUKA, Shu-ichiro[1]

[1]Department of Physics, Nagoya University

Recently a number of exoplanets have been found, and some of them are close-in gaseous planets. Such planets are called hot Jupiters, and their surface temperatures are ˜1000K due to strong irradiation from central stars.

Information of radius and orbital period of exoplanet can be observed by transit method which is the one of method to detect exoplanets. Additionally, atmospheric composition can be estimated by variation of spectrum between transiting and non-transiting, and atmospheric structure can be estimated by multi-wavelength transit observation. From these observations, inflated hydrogen atmosphere of hot Jupiters and atmospheric escape are suggested. It is observed that escaping atmospheric flow is very fast, and mass loss rate is also estimated. However, detailed mechanism of mass loss from hot Jupiters are still unknown.

We propose a new mechanism of mass loss, which is mass loss driven by magneto-hydrodynamic wave, same as solar wind. Atmosphere is weakly ionized because surface temperatures of hot Jupiters are about 1000K, but it is good to treat as ideal MHD at upper atmosphere. If gas giant have magnetic field and turbulence exist on the surface of planet, magneto-hydrodynamic wave will be generated. The wave propagates upward and dissipates in upper atmosphere, then gas flow is accelerated. In this work, we apply numerical calculation of solar wind to mass loss from hot Jupiters. In consequence, mass loss by this magnetically driven wind is comparable to observed mass loss rate, therefore magnetically driven wind can be important role in mass loss from hot Jupiters.

We also derive an analytical solution for radius and mass dependence of mass loss rate, and it shows a good agreement with numerical results. Dissipation of MHD wave in the atmosphere also affects on atmospheric structure. The gas flow is accelerated to supersonic at upper atmosphere, and temperature become several tens of thousand kelvin. In this talk, we will discuss the possibility of mass loss from general gaseous planet and effects on atmospheric structure.

Group motion of heteromorphic fine particles in HF discharge plasma

MIENO, Tetsu[1*] ; MASUDA, Risa[2] ; MORIBAYASHI, Takashi[2] ; HAYASHI, Yasuaki[3]

[1]Grad. School Sci. Technol, Shizuoka Univ., [2]Dept. Phys., Shizuoka Univ., [3]Grad. School Eng., Kyoto Inst. Technol.

Related with complex systems, fine-particle plasmas have much attention to scientists and engineers [1, 2]. Hence, we are trying to make fine-particle plasmas with heteromorphic particle distributions by using a high-frequency (HF) Ar plasma. And the motions of charged particles are observed. In a stainless steel chamber (150 mm in diam, 150 mmh), 100 mm in diam disk electrodes and a 80 mm in diam metal ring are set. In this experiment, HF argon discharge is produced at 10˜13 Pa by applying HF voltage of about 270˜290 V_{rms} to the lower disk-electrode with respect to the upper grounded disk-electrode. And a ring is added on the lower electrode to confine fine-particles. The particles used are silicon carbide, which has diameter of about 8 um, or silicon-nitride (about 8 um), or short hemp (about 25 um diam. 10 ? 1500 um long). They are injected from a dust dropper. A digital microscope camera (SELMIC LWD100) and a CCD video camera are used to investigate the particle behaviors. Under a condition of discharge voltage V_d= 280 V_{rms}, discharge current I_d= 0.2 A_{rms} and pressure p(Ar)= 13 Pa, a disk-shaped cloud is generated as shown in Fig. 1. Each particle motion and the particle-group motion are recorded by the cameras. We could observe planet-like motions like Fig. 2 (track of a SiC particle). In case of the short hemp, there are spin motions and planet-like motions. We conjecture that these motions are activated by the dust-acoustic perturbation.

A new instability along toroidal magnetic field in differentially rotating plasmas

HIRABAYASHI, Kota[1*] ; HOSHINO, Masahiro[1]

[1]Department of Earth and Planetary Science, The University of Tokyo

We discuss a new type of instability expected to take place in an accretion disk, which has a differentially rotating plasma threaded by a weak magnetic field, by performing linear eigenvalue analysis. We study the linear stability of a disk with a localized, toroidal magnetic field in the radial direction, which can be expected in an accretion disk during the nonlinear evolution of the magneto-rotational-instabilities (MRI).

The MRI is believed to be a strong source of magneto-hydro-dynamic (MHD) turbulence and the resultant angular momentum transport in the accretion disk, which is required for the gas to accrete onto the central object. Once the MRI grows, the system is chiefly governed by the toroidal and radial magnetic field newly generated by the dynamo action of MRI. Such a configuration allows the Alfven waves to propagate along toroidal direction.

In this talk, we study the linear stability of the Alfven wave in the local Cartesian coordinate, the so-called shearing periodic box, and show that the toroidally propagating Alfven wave can become unstable if its wavelength is larger than the length scale of the localized magnetic field gradient. We investigate our results of the linear eigenvalue analysis by changing the structure of the localized magnetic field, and discuss some properties of the instability with examining the eigenvectors and eigenvalues. It is revealed that this type of instability may also appear in non-rotating plasma, but it is highly suppressed in a rigid body rotating plasma. In addition to the linear analysis, the corresponding nonlinear behavior will also be discussed by using MHD numerical simulations. This instability plays an important role in the plasma transport because it probably couples with the magnetic reconnection occurring in the equatorial plane and then to contributes to the saturation mechanism of the MRI.

Particle acceleration and angular momentum transport during magnetorotational instability in kinetic accretion disks

HOSHINO, Masahiro[1*]

[1]The University of Tokyo

Magneto-rotational instability (MRI) in a gravitational rotating system is known to play an important role on the formation of the astrophysical accretion disk and the angular momentum transport, and the nonlinear time evolution of magneto-rotational instability has been extensively investigated by using MHD simulations so far. The mean free path of plasma, however, is not necessarily smaller than the characteristic scale length for some classes of astrophysical accretion disks, and the collisionless behavior of MRI beyond the MHD approximation needs to be understood. In this talk, we study momentum transport and particle acceleration of the kinetic (collisionless) MRI by focusing on magnetic reconnection. We discuss that a strong pressure anisotropy is associated with the formation of the channel flow, and the anisotropic channel flow can lead to a rapid magnetic reconnection, that can occurs sporadically in three-dimensional system. As a result of the reconnection, non-thermal power law distribution with a hard spectral index p=1-1.5 is quickly formed. We also discuss that the so-called alpha parameter in the standard accretion disk model, which is numerically measured from the Reynolds and Maxwell stresses, can be dramatically enhanced during the nonlinear time evolution of MRI. The kinetic MRI is one of plausible mechanisms to explain much more efficient angular momentum transport and high-energy particle emissions observed from massive black holes such as Sgr A$*$.

Numerical Simulation of Kinetic Magnetorotational Instability using a new Hybrid Technique

SHIRAKAWA, Keisuke[1*] ; AMANO, Takanobu[1] ; HOSHINO, Masahiro[1]

[1]Faculty of Science, University of Tokyo

The evolution of Magnetorotational instability (MRI) is considered to be important in the context of efficient angular momentum transport in the accretion disks in our universe. Conventionally, the nonlinear evolution of MRI is studied under the MHD approximation which assumes the mean free path of the plasma is sufficiently small compared to the actual size of the disk. However some classes of the accretion disks, for example the disk around SgrA∗, are found to be constituted with a collision less plasma and therefore the kinetic effect of the plasma, such as generation and relaxation of the pressure anisotropy, should be taken into account.

For the inclusion of the kinetic plasma effects, hybrid code, which treats ions as particles and electrons as massless charge neutralizing fluid, may provide a robust approach resolving the ion scale physics and integrating over the Keplerian time scale. However in the 2 dimensional simulation of the MRI, it is well known that the system eventually grows to a set of channel flows. In this state, the density of the plasma is found to be extremely low in the region where the magnetic field is enhanced as a result of a strong dynamo effect of the differential rotation of the disk. In this low density, strong magnetic field region, the CFL condition determined by the R-mode wave is found to be severe. Moreover, since the extremely low density region is generated in the channel flow, the division-by-density operation in the conventional hybrid code leads to an unexpected termination of the calculation.

In this study we adopted a new approach of hybrid simulation to a differentially rotating system. In this approach, the finite electron inertia is taken into account which gives a upper bound in the phase velocity of the R-mode wave, providing a reduced CFL condition. In addition, the new approach is almost free from the division-by-density operation and the extremely low density region generated in the channel flow can then be calculated appropriately. With this new code we would like to discuss the nonlinear evolution of the 2 dimensional kinetic MRI.

Self-organization and flow in high-beta magnetized plasmas

NAGATA, Masayoshi[1*]

[1]University of Hyogo, Graduate School of Engineering

The self-organized plasmas with high-beta such as spheromaks have the common features as magnetic reconnection, kinking behavior, particle acceleration and shock wave which are observed in space phenomena. Dynamical process of explosive plasmoid ejection, magnetic field's twisting and reconnection could account for the various phenomena called astrophysical jets, solar coronal loops and Jupiter's zonal flow driven by thermal convection. As for fusion plasmas, to control externally plasma flow or rotation plays an important role on maintaining high-beta confinements with an optimized pressure gradient. It is well known that for example, the H-mode transition in tokamak plasmas is created by inward radial electric field and poloidal shear flow. The diamagnetic configuration like Field Reversed Confinement (FRC) with super high beta, in which ion flows generate currents, is normally analyzed based on two-fluid MHD relaxation model. In helicity-driven system, non-axisymmetric dynamic processes create current due to the dynamo action in the plasmas and relax them toward certain minimum energy equilibria. The non-axisymmetric behavior, which arises from a helical kink instability on the open flux, could be responsible for the formation and sustainment of the configurations by helicity injection [1]. In this conference, we will present recent topics about dynamics and relaxed states relevant to MHD relaxations, plasmoid ejection, dynamo and kinking behavior which are recognized as analogical phenomena in astrophysical and fusion plasmas.

It is possible to replicate astrophysical plasma phenomena in the laboratory because MHD has no intrinsic scale. The governing MHD equations can be expressed in a dimensionless form that is equally applicable to systems having scale lengths with many orders of range. Now, a point is how to produce flexibly plasmoid eruptions like solar flares by taking critical issues of geometry and topology into consideration. We will introduce the magnetized coaxial plasma gun (MCPG) to make it possible to investigate such a bubble burst-like behavior. The MCPG is often used to produce spheromaks with poloidal and toroidal magnetic fields generated by internal current. Historically the spheromak was for the first time produced by Alfven et al. by using the MCPG.

The driven-relaxed configurations with open field lines, as well as closed systems, are described by the force-free equilibrium (Jensen-Chu) equation, $\nabla \times B = \lambda B$, where λ is the force-free parameter. The nature of the relaxed states in helicity-driven systems is characterized by the strength of the external toroidal field and the value of λ determined by coupling to the MCPG. Note that in the doubly connected helicity-driven system, the flipped spherical torus (ST) state appears in the regime of $\lambda < \lambda e$, where λe is the lowest eigenvalue, so that it could be observed in laboratory experiments. The structural formation of the flipped field configuration incorporates the self-reversal process of the toroidal and poloidal fields. This self-organizing phenomenon may have some analogy to reversal of the dipole field of Earth generated by a dynamo action. It is fundamentally important to elucidate a current-reversal phenomenon occurring in space and laboratory plasmas. We have observed this novel current-reversal phenomenon in our HIST experiment [2, 3]. The most important discovery of this experiment is that spherical torus plasmas tend to self-organize to the flipped states while reversing the direction of the external toroidal field [2, 3]. This experimental finding provides, for the first time, evidence for the existence of the relaxed states which were theoretically predicted.

Observations of Alfvenic waves in the solar atmosphere

OKAMOTO, Joten[1*]

[1]ISAS/JAXA

Coronal heating and the acceleration of the solar wind are unsolved problems in solar physics. The propagation of Alfven waves along magnetic field lines is one of the candidate mechanisms to carry energy to large distances from the surface and heat the coronal plasma. However, such waves had not been observed for years.

The solar physics satellite, Hinode, was launched in 2006, and it opened the door to the world of coronal waves. Hinode observations have directly resolved small-scale transverse oscillations of field lines as a result of Alfven/Alfvenic waves in prominences (Okamoto et al. 2007) and spicules (De Pontieu et al. 2007) which are typical chromospheric features embedded in the corona. These waves had a period of 2-5 minutes (low frequency) and the velocity amplitudes are up to 20 km/s. If we assume these are propagating waves, the waves have enough power to heat the corona. However, since the wavelength of these waves is as long as or longer than the observed structures, it is difficult to resolve the phase difference along the field lines. This means we cannot know whether they are propagating or standing waves.

More recently, we had a challenge to detect ”propagating” waves (Okamoto and De Pontieu 2011). In this study, we developed an algorithm to detect spicules and phase difference of waves along them automatically. As a result, upward- and downward-propagating waves as well as standing waves were successfully detected. With statistical analyses, it is found that the behaviour of waves depends on the evolution of spicules, and numerous waves are reflected at the top of spicules. These waves detected in this study are high-frequency ones, and the energy is not larger than that of low-frequency ones. Hence, it is suggested that low-frequency waves are more important for coronal heating.

Finally, oscillations/waves shown here are ubiquitous in the solar atmosphere and ”wave hunting” is getting more active after the Hinode launch. In addition, investigation of coronal waves is important for the derivation of physical parameters such as coronal magnetic field strength, which it is difficult to measure in observations. In this talk, I will show these studies with Hinode and introduce a new result with a new satellite ”IRIS”.

2.5D MHD Simulations of Solar Filament Formation by Condensation

KANEKO, Takafumi[1*] ; YOKOYAMA, Takaaki[1]

[1]Department of Earth and Planetary Science, The University of Tokyo

We investigate the formation mechanism of solar filaments by two-dimensional magnetohydrodynamic (MHD) simulations. Solar filaments are cool dense plasma clouds in the hot tenuous corona. Filaments abruptly erupt with flares, hence, they are the important objects to comprehend the explosive events in the solar atmosphere. On the other hand, their formation mechanism is still unclear as well as the mechanism for eruptions.

Filaments always appear inside the coronal arcade fields, and the cool dense plasma is sustained by the magnetic forces. Observations show that filaments are categorized as normal polarity filaments or inverse polarity filaments. The normal polarity filaments have the same polarity with the surrounding coronal magnetic fields, while the inverse polarity filaments have opposite polarity. One candidate to explain the origin of the cool dense plasma is condensation by the radiative cooling in the corona. The current condensation model can reproduce the normal polarity filaments, but not the inverse polarity filaments. We propose a new condensation model to reproduce the inverse polarity filaments, and demonstrate it by two-dimensional MHD simulations including radiative cooling, thermal conduction along the magnetic field and gravity. Our model starts from the formation of the magnetic flux rope. The relatively dense plasma at the lower corona is trapped inside the flux rope and lifted up to the upper corona. The dense plasma causes imbalance between the radiative cooling and the background heating, while the thermal conduction along the closed field line of the flux rope does not suppress the thermal imbalance. Consequently, the condensation process is triggered and the cool dense plasma is formed. We test two types of heating term (one depends on magnetic pressure and the other depends on density) and two types of formation mechanisms of the flux rope (one is the conversing motion at the footpoints of the coronal arcade field and the other is the interaction between the emerging flux and the coronal arcade field). As a result, the cool dense plasma is formed inside the flux rope in every case. We also show that our model has a possibility to reproduce the density of solar filaments, which is 10 -100 times larger than that of the surrounding corona, qualitatively.

Comparative study of Observation and Calculation of Hot Fast Flow above a Solar Flare Arcade

IMADA, Shinsuke[1*]

[1]Nagoya Univ. STEL

Solar flares are one of the main forces behind space weather events. However, the mechanism that drives such energetic phenomena is not fully understood. The standard eruptive flare model predicts that magnetic reconnection occurs high in the corona where hot fast flows are created. However, there is not enough observational knowledge of the physical parameters in the reconnection region. The inflow into the reconnection region, the temperature of the plasma in the reconnection region, and the temperatures and densities of the plasma jets predicted by reconnection, have not been quantitatively measured in sufficient. First, we will show a flare that occurred on the west solar limb on 2012 January 27 observed by the Hinode EUV Imaging Spectrometer (EIS) and found that the hot (?30MK) fast (>500 km s?1) component was located above the flare loop and discuss how extent we understand the key-region of solar flare. Second, it is important to answer why the most observation cannot detect the predicted flow or temperature in the reconnection region. One of the reasons why we cannot observe inside the magnetic reconnection region is due to its darkness. Generally we can see the bright cusp-like structure during solar flare, although the reconnection region is faint/blind. One may think that the temperature in the reconnection region is enough higher than that of cusp-like flare loops. Thus the wavelength of emission from reconnection region is different from flare loops. However, this is not entirely true. Magnetic reconnection causes rapid heating. Thus ionization cannot reach to the equilibrium stage. We have calculated the ionization process in the down stream of Petschek type magnetic reconnection. From our result, we can clearly see that plasma cannot reach the ionization equilibrium in the down stream of slow-mode shock. The typical emissions from magnetic reconnection region are FeIXX or FeXX, although the plasma temperature is equal to 40MK. The typical temperature and density of post flare loops are 10 MK and 10ˆ11 /cc, and the dominant emissions from post flare loops are from FeIXX to FeXXIII. Thus the wavelength of emission from reconnection region is not so much different from post flare loops. We will discuss how the emissions from reconnection region looks like by using several ionization calculations of magnetic reconnection.

Magnetic Evolutions at Extremely High Latitude Region during Polarity Reversal Observed with Hinode

SHIOTA, Daikou[1*] ; SHIMOJO, Masumi[2] ; SAKO, Nobuharu[3] ; KAITHAKKAL, Anjali john[3] ; TSUNETA, Saku[4]

[1]STEL, Nagoya University, [2]National Astronomical Observatory of Japan, [3]The Graduate University for Advanced Studies, [4]ISAS, JAXA

The magnetic field in the Sun's polar region is a key ingredient of the solar dynamo mechanism because the polar field strength at a solar minimum has a correlation with solar activity of the following cycle. The evolution processes of the polar field (its polarity reversal and its build-up after the reversal) are thought to be caused by magnetic flux transport due to meridional flow and diffusion by turbulent convection. Nevertheless, our understanding of the meridional flow and diffusion in the polar region is still poor because of many difficulties in magnetic observation near the limb.

We recorded time evolution of magnetic polarity distribution within the whole of both polar regions derived from the high-accuracy spectropolarimetric observation with Solar Optical Telescope aboard Hinode. In the north polar region, the latitudinal polarity inversion line (PIL) between the preexisting negative polarity region and transported positive polarity region migrates from 60 degrees latitude at January 2012 to 68 degrees latitude at September 2012. Then the whole of the north polar region becomes positive at September 2013. The migration speed of the PIL is 5 m s^{-1} (January - September 2012) and then becomes 8.5 m s^{-1} (September 2012 - September 2013). According to a flux transport model, the speed-up is understood as a result of a diffusion process. In contrast, the whole of the south polar region observed in March 2013 has still ample positive field. The PIL locates out of the observed region (over 67 degrees latitude).

We examined a few parameter sets of the meridional flow pattern and the diffusion coefficient with an advection-diffusion model. The observed PIL migration in the north polar region can be explained well if there is slightly strong diffusion without the meridional flow.

Properties of small-scale jets in a sunspot chromosphere revealed through spectroscopic observations

KATSUKAWA, Yukio[1*] ; OI, Akihito[2] ; REARDON, Kevin[3] ; TRITSCHLER, Alexandra[3]

[1]National Astronomical Observatory of Japan, [2]Kyoto University, [3]National Solar Observatory

High-resolution observations with HINODE Solar Optical Telescope (SOT) revealed that small-scale jets frequently occur in a sunspot chromosphere though their driving mechanism is not well understood yet because of lack of spectroscopic information, such as temperatures and Doppler velocities, in the chromospheric observations with Hinode SOT. Spectroscopic observations of the small-scale jets were attempted using an Interferometric BIdimensional Spectrometer (IBIS) at the National Soar Observatory (NSO), and suggested that temperature enhancements associated with the jets happened in the lower chromosphere though their upward flows were not clearly detected (Reardon, Tritschler, Katsukawa 2013). We've tried obtaining another spectroscopic data set of a sunspot chromosphere with better spectral resolution with IBIS, and carried out careful analysis of spectral profiles and their temporal evolution. The study shows majority of the heated plasma in the lower chromosphere has a bulk flow slower than the sound speed in the chromosphere. The spectral profiles indicate enhancements in the blue wing, which suggests a part of the heated plasma has a supersonic upflow. In addition, small temperature enhancements are also found in the upper chromosphere near the end of the duration of the jets. The supersonic upflows are possibly responsible for heating in the upper chromosphere. This study provides an important observational support for slow-mode waves as acceleration and heating mechanism in the chromospheric jets. We are going to present a new spectroscopic observation of chromospheric jets made by the Interface Regiong Imaging Spectrograph (IRIS) spacecraft that has just started observations since 2013.

Fast magnetic reconnection with a moving X-point in resistive MHD

MIYOSHI, Takahiro[1*] ; KUSANO, Kanya[2]

[1]Graduate School of Science, Hiroshima University, [2]STEL, Nagoya University

Fast magnetic reconnection in high magnetic Reynolds number plasmas is one of the most important physical process of explosive phenomena in space and astrophysical plasmas. In recent years, using high-resolution MHD simulations with high magnetic Reynolds numbers, it has been indicated that fast magnetic reconnection may be triggered by the plasmoid instability in a thin current sheet [1]. Moreover, a state-of-the-art high-resolution MHD simulation revealed that some of multiple secondary reconnection are developed as Petschek-like reconnection [2]. However, the detailed structure and dynamics of individual secondary reconnection is not clarified yet.

The objective of this study is to reveal the structure and dynamics of resistive magnetic reconnection with a moving X-point paying attention to the motion of the secondary reconnection. Particularly, we propose an asymmetric reconnection model where a local anomalous resistivity including a shifting motion is added to the two-dimensional Harris equilibrium. A high-resolution MHD simulation for the asymmetric resistive reconnection was performed using the HLLD approximate Riemann solver and analyzed with respect to the structure in detail. Besides, we discussed the possibility of a self-sustaining mechanism of the asymmetric reconnection due to the flow driven by the reconnection itself.

Dynamical Petscheck Reconnection

KUSANO, Kanya[1*] ; NAKABOU, Takashi[1] ; MIYOSHI, Takahiro[2] ; VEKSTEIN, Grigory[3]

[1]STEL, Nagoya University, [2]Graduate School of Science, Hiroshima University, [3]Manchester University

Magnetic reconnection is the major mechanism for explosive energy liberation in various plasmas. However, the mechanism of fast reconnection in high magnetic Reynolds number (S) plasmas like the solar corona, in which $S>10^{10}$, is still unclear. The observations suggested that the reconnection rate in solar flares is as large as 10^{-2}, although the classical theory by Sweet (1958) and Parker (1963) predicted that the reconnection rate is limited by $S^{-1/2}$. While Petscheck (1964) proposed the fast reconnection model driven by slow mode shock, the previous simulation study suggested that the Petscheck-type reconnection is not stable in uniform resistivity and some anomalous resistivity or non-MHD effects are needed for fast reconnection.

In this paper, we developed the high-resolution magnetohydrodynamics (MHD) simulation of magnetic reconnection for the high-S (S~10^4-10^6) regime aiming at revealing the acceleration mechanism of magnetic reconnection in the MHD regime of uniform resistivity. We applied the HLLD Riemann solver developed by Miyoshi and Kusano (2005) to the high resolution two-dimensional MHD simulation of current sheet dynamics. The initial state is given by the Harris sheet equilibrium plus perturbation, and the uniform and constant resistivity model is adopted.

As a result, we found a new type of fast reconnection. When S is larger than 10^4, multiple X-line reconnection appears as a result of the secondary tearing instability and magnetic reconnection is accelerated through the formation of multiple plasmoids. Furthermore, we found that the electric current sheets between some particular magnetic island bifurcate to V-shape current layers and that the reconnection at the apex of bifurcated current layers is preferentially accelerated. The bifurcated current layers create slow mode shocks which more increase the reconnection rate up to about 0.05. The slow mode shocks are repeatedly created and dissolved corresponding to the formation and transportation of plasmoids. These results indicate that, even though resistivity is uniform, when the magnetic Reynolds number is high enough, the multiple X-line reconnection of Sweet-Parker current sheets (plasmoid reconnection) is switched to a new regime called ”dynamical Petschek reconnection”. The mechanism of transition from the conventional plasmoid reconnection to the dynamical Petscheck reconnection will be discussed.

Thermal conduction effect on the Petschek magnetic reconnection

KONO, Shunya[1*] ; YOKOYAMA, Takaaki[1]

[1]University of Tokyo

We simulated the magnetic reconnection including the nonlinear thermal conduction effect with two-dimensional MHD equations. Magnetic reconnection is considered to be the basic process of the solar explosive phenomena. In the atmosphere with high temperature and low density like solar corona, time-scale of the nonlinear heat conduction becomes shorter and can become comparable to the Alfven time-scale. Thermal conduction effect should be considered. Previous studies have showed that, in the model of magnetic reconnection produced by Petschek, adiabatic slow mode shock wave generated from the localized diffusion region is dissociated into isothermal shock wave and conduction front due to the thermal conduction. However, the effect of the thermal conduction on the energy release rate in the magnetic reconnection is not explained enough in the past.

Here we investigated how the thermal conduction influences the energy conversion rate. We calculated the energy release rate in different magnitude of the magnetic diffusivity to see the dependence on the Lundquist number. As a result, due to the thermal conduction effect, adiabatic shock wave is dissociated into isothermal shock wave and conduction front and this makes temperature in the reconnection outflow jet smaller. In the outflow region with small temperature, density becomes larger. Considering mass conservation between the mass flux in the reconnection inflow and that in the outflow, inflow velocity is accelerated because of larger density in the outflow region. This causes increase of the energy release rate in the magnetic reconnection. That increase rate tends to become larger as the magnitude of magnetic diffusivity becomes smaller. Smaller magnetic diffusivity correponds to the larger Lundquist number. In the real solar atmosphere, plasma gas has larger Lundquist number than that in this numerical simulation. This means that thermal conduction effect on the energy release rate in magnetic reconnection might become more effective in the real solar atmosphere.

Analysis on turbulent reconnection of three-dimensional resistive MHD simulation

WANG, Shuoyang[1*] ; YOKOYAMA, Takaaki[1] ; ISOBE, Hiroaki[2]

[1]The University of Tokyo, [2]Kyoto University

This study starts from a three-dimensional current sheet with random perturbation on velocity, in order to understand more on the 3D reconnection in a more general way.

Due to the periodic boundary condition, the core of current sheet quickly develops a resonance netlike pattern under tearing instability. Small reconnection site mainly form two chains on either side of the current sheet center and constitute a zigzag arrangement. The outflow from one reconnection site is fed into the counterpart on the other side thus composes a positive feedback system resembles even double tearing mode. As the inflow being enhanced, slow-mode shocks are identified along the current sheet. The conversion of the magnetic energy is further raised. Total kinetic energy of the current sheet presents 4 steps of development while first 3 exhibit linear growing tendency. At the same time, reconnection rate increases by 5 times compared with the early phase. Thus we have achieved faster reconnection without localized resistivity in a more universal idea.

Ion Acceleration Mechanisms in the Exhaust Region of Magnetic Reconnection

TAKAMOTO, Makoto[1*] ; FUJIMOTO, Keizo[2]

[1]Max-Planck-Institute for Nuclear Physics, [2]National Astronomical Observatory of Japan

Magnetic reconnection is considered to be a key mechanism to convert magnetic field energy into plasma kinetic and thermal energy in various plasma phenomena, in particular, in many astrophysical systems. In collisional plasma, many works assuming magnetohydrodynamic approximation have revealed that plasma jets can be accelerated up to the upstream Alfven velocity. However, in the case of the collisionless plasma, which is common in many astrophysical phenomena, there is still no conclusive theory of the ion acceleration mechanism and the maximum plasma jet velocity because of the complexities of plasma phenomena and the associated high numerical cost.

In this study, we performed a large-scale 2D particle-in-cell simulations with adaptive mesh refinement under an open boundary condition. The simulation was performed until the MHD condition is well-satisfied in the exhausts,
which allows us to study a long-time dynamical evolution of the structure of the diffusion region and exhausts.
To analyze the detailed mechanisms of the ion acceleration in the exhausts, we also performed test particle simulations on the dynamical background plasma. We found that the ions are accelerated mainly by the electric field perpendicular to the reconnection plane. However, effects from other electric field components are not negligible;
in particular, the contribution from the electric field along the exhausts becomes significant as the ions are accelerated. We also compared the results with the velocity distribution functions inside of the exhausts.

In this talk, we present our numerical results of the particle-in-cell simulation, and discussed its physical interpretations of the structure. We also discuss the ion kinetic mechanisms leading to the formation of reconnection jets.

Waves and particle acceleration around the separatrices of magnetic reconnection

FUJIMOTO, Keizo[1*]

[1]National Astronomical Observatory of Japan

Understanding the properties of waves in magnetic reconnection is very important in collisionless plasmas. The waves can transport the momentum and energy between the different species in plasmas, which results in the anomalous magnetic dissipation, particle heating, and formation of non-thermal particles. Therefore, the wave activities relevant to the kinetic interactions can have a significant impact on the dynamical behaviour of magnetic reconnection. Theoretical modeling of waves in the reconnection region is also beneficial to reveal the reconnection dynamics using in-situ satellite observations where wave properties are obtained in much higher time resolution than plasma distribution functions.

Recent satellite observations in the Earth's magnetotail have shown that the wave activities are significantly enhanced in a broad range of frequency around the separatrices of anti-parallel magnetic reconnection. The waves were recognized as lower hybrid waves, Langmuir waves, electrostatic solitary waves (ESWs), and whistler waves. In most cases, they were associated with cold electron beams and density cavity. However, because of the limited space-time resolutions of the observations, it has been difficult to identify the generation mechanisms of the waves and their roles in magnetic reconnection.

In this study, large-scale 2D particle-in-cell simulations with adaptive mesh refinement have been performed under an open boundary condition. The simulations use a set of more realistic parameters than those in most other simulations, achieving lower plasma beta in the upstream region that leads to stronger electron beams in the reconnection region. The wave activities are dominant in the inflow side of the separatrices. The waves are generated mainly due to the electron beams that constitute the Hall current. The relatively weak beams before strong acceleration trigger the Buneman instability which results in the waves with a frequency of the lower hybrid range. The strong acceleration occurs along the field line due to a localized potential hump and causes the density cavity. The intense electron beams excite the electron two-stream instability and the beam driven whistler instability. The former mode gives the Langmuir waves and the flat-top electron distributions in the parallel direction, both of which have been observed frequently in the Earth's magnetotail. The latter mode, on the other hand, scatters the electrons in the perpendicular direction, forming isotropic distribution with non-thermal high-energy tail. Both the Buneman and electron two-stream instabilities evolve the ESWs in the nonlinear phases.

In this talk, we present the generation mechanisms of the waves around the separatrices and their roles in magnetic reconnection. The mechanism of the intense electron acceleration along the field line will be discussed.

Minimum spatial scale for maintaining vigorous magnetic reconnection

SHIMIZU, Kenya[1*] ; FUJIMOTO, Masaki[2] ; SHINOHARA, Iku[2]

[1]University of Tokyo, [2]Institite of Space and Astronautical Science, Japan Aerospace Exploration Agency

Magnetic reconnection drives the fast release of magnetic energy in explosive events such as magnetic substorms in the Earth's magnetosphere and flares in the solar corona. On the large scale, reconnection is an MHD-scale process but its rate is controlled by the compact electron diffusion region (EDR), where electrons are not magnetized. Recent kinetic simulations have revealed the structure of EDR in a quasi-steady reconnection rate. In some works, it is suggested that an elongated electron jet in the outflow region does not affect the reconnection rate. However, it is not clear the spatial scale for determining the rate. We find that the minimum spatial scale for maintaining magnetic reconnection by using kinetic simulations on periodic and reflective wall boundary conditions. On the periodic condition, an outflow jet extends a large distance downstream from the X-line with the fast rate of reconnection. However, the influence of periodicity shortens the jet to a narrow structure though the rate of reconnection is still fast. This structure is the minimum spatial scale for maintaining magnetic reconnection. On the other hand, asymmetric reconnection is performed on the reflective wall condition to lead a slow motion of the diffusion region away from the wall, the so called 'X-line retreat.' During the retreat motion an outflow jet is blocked by the wall though the rate of reconnection is maintained. The structure of the blocked jet is very similar to the minimum spatial scale on the periodic condition. We quantitatively show the minimum structure for maintaining magnetic reconnection by comparing the result on these periodic and reflective conditions. We also find the minimum structure is independent of domain sizes but gets smaller with decreasing electron mass.

Magnetothermal instability in the solar outer corona

YOKOYAMA, Takaaki[1*]

[1]The University of Tokyo

We discussed an application of the magnetothermal instability (MTI) to the solar atmosphere. This instability proposed by Balbus (2000) occurs in weakly collisionless plasmas where non-isotropic thermal conduction plays a role in a magnetized atmosphere. The time scale of the maximum growth is given as approximately sqrt(H/g) where H is the scale height, and g is the gravity. The magnetic field must be weak enough since its tension force contributes as a restoring force.

The solar corona is a dilute hot atmosphere where the thermal conduction is non-isotropic. The MTI is possible to work in the upper corona around a few solar radii above the photosphere where the temperature is decreasing outward and the scale height is about one solar radius. The condition for weak horizontal magnetic field might be satisfied above a closed loop in the lower corona. If the MTI is effective in such regions, it might contribute to generate the waves or perturbations in the solar wind.

We found that the MTI is unlikely to work in the upper corona because of its strong magnetic field that suppress the growth of the geometrically possible wavelength modes. It is found that when the field strength is 0.1 times the real corona, the wavelength for the maximum growth is comparable with the geometrical radius. The growth time for this setup can be consistent with the low frequency fluctuations in the solar wind.

Cosmic-ray Parker Instability and Galactic Plane Symmetry

KUDOH, Takahiro[1*] ; YOKOYAMA, Takaaki[2] ; KUDOH, Yuki[3] ; MATSUMOTO, Ryoji[3]

[1]National Astronomical Observatory of Japan, [2]University of Tokyo, [3]Chiba University

We study two-dimensional MHD numerical simulations of the Parker instability with the cosmic-ray pressure under the circumstance of the galactic disk. Instead of the symmetric boundary conditions on the galactic plane as often used, we solve the entire region of the disk. Numerical simulations show that the symmetric mode on the disk also grows when the cosmic-ray pressure is relatively large, while the glide reflection symmetric mode dominates on the disk when the cosmic-ray pressure is small. We confirm that the results are consistent with those of the liner analyses: the growth rate of the symmetric mode approaches that of the glide reflection symmetric mode as the cosmic-ray pressure becomes relatively large.

In the nonlinear stage, some loop structures of the magnetic field lines expand rapidly and grow into large structure when the cosmic-ray pressure is relatively large. Other loops, which start to grow a little later, are suppressed by faster growing loops located nearby and do not reach the nonlinear expansions. Eventually, the loop structure at the nonlinear stage is larger than that is expected form the linear analysis when the cosmic-ray pressure is relatively large.

When the nonlinear fast growing loops collide with another loops, the high density thin gas layers are formed by the compression between the loops. The figure shows the logarithmic density at that stage. Some of the high density gas shows filament structures and some of them look like high density loops. Similarities of these structures with some observational features and the relation of star formation activities can be studied further.

Formation of Dense, Cold Loops by Parker Instability in Galactic Gas Disks

PENG, Chih-han[1*] ; KUDOH, Yuki[1] ; ASAHINA, Yuta[1] ; MATSUMOTO, Ryoji[1]

[1]Faculty of Science, Chiba University

We performaced two dimensional numerical simulations of Parker instability taking into account the cooling and heating functions of the interstellar medium (Inoue et al. 2006). Our numerical experiment is based on the simulation code ”CANS+” in which the HLLD Riemann solver (Miyoshi & Kusano 2005) is used to solve the MHD equations. We found that the cold, dense filaments formed at the valley of magnetic field lines by Parker instability coupled with the cooling instability are deformed into loops of dense, cold gas when the Ram pressure at the left- and right-hand side of the filament is different. The maximum number density and the lowest temperature of cold, dense filament at 100Myrs is about 200 per cubic cm and 50K, respectively. These results support the model in which thermal instability triggered in the dense region formed by Parker instability is responsible for the formation of molecular loops found in the Galactic center region (e.g., Fukui et al. 2006).

Effects of cosmological infall of galaxies: its discovery, plasma physical implications, and verification with ASTRO-H

MAKISHIMA, Kazuo[1*]

[1]Department of Physics, University of Tokyo

Clusters of galaxies are a system consisting of hundreds of galaxies that are gravitationally bound together. About 10% of the mass of each cluster is in the form of X-ray emitting hot plasmas, called Intra-Cluster Medium (ICM), that constitute the most dominant form of known baryonic components in the universe. The ICM is tenuous, hot, and magnetized, and is hence considered as the most ideal classical plasma ever known.

At central regions of many clusters, the ICM was considered to cool over the Hubble time by emitting X-rays, and lose its pressure. Then, the ICM would flow from outer to inner regions, and enhance the radiative cooling by raising the density. This catastrophy, called cooling flows, were long thought to be actually taking place, as X-ray observations kept discovering its evidence.(3) the energy is then transported to the cool ICM phase via Alfven waves and reconnection, (4) the two ICM phases are kept thermally stable by a mechanism known in Solar corona; and (5) the moving galaxies will gradually fall to the potential center as they transfer their dynamical energies to the ICM (Makishima et al., Publ. Astro. Soc. J. 53, 401, 2001). We have been striving to observationally enhance this novel scenario.

At central regions of many clusters, the ICM was considered to cool over the Hubble time by emitting X-rays, and lose its pressure. Then, the ICM would flow from outer to inner regions, and enhance the radiative cooling by raising the density. This catastrophy, called cooling flows, were long thought to be actually taking place, as X-ray observations kept discovering its evidence.

Through observations of clusters of galaxies with the 4th Japanese X-ray satellite ASCA launched in 1993, we found that the cooling flows are not taking place anywhere, even though the ICM ubiquitously shows mild temperature decrease towards the cluster center: there must be some unknown plasma heating source. We have hence proposed a novel plasma physical scenario; (1) the central galaxy has a magnetosphere, where the cooler plasma is confined and insulated from the surrounding hot ICM; (2) other galaxies, all moving in the cluster space, will receive resistance from the ICM and excite MHD turbulence therein; (3) the energy is then transported to the cool ICM phase via Alfven waves and reconnection, (4) the two ICM phases are kept thermally stable by a mechanism known in Solar corona; and (5) the moving galaxies will gradually fall to the potential center as they transfer their dynamical energies to the ICM (Makishima et al., Publ. Astro. Soc. J. 53, 401, 2001). We have been striving to observationally enhance this novel scenario.

Recently, we have obtained crucial evidence supporting (5). That is, we studied 34 clusters with various redshifts (0.1-0.9) with X-ray and optical wavelength. Then, galaxies in nearby clusters were confirmed to be much concentrated than the ICM, while these two components are nearly co-spatial at distant clusters (Gu et al., Astrophys. J. 767, id 157, 2013). That is, galaxies in each luster have been falling, on the Hubble time scale, to the center. This result not only provides the long-sought heating mechanism of the ICM and strengthen our hypothetical view, but means the discovery of a very large energy flow that has not been known. Furthermore, it can explain many other puzzles with clusters of galaxies.

We are now developing, under an extensive international collaboration, the innovative X-ray satellite ASTRO-H, to be launched in 2015. With ASTRO-H, we will be able to detect X-ray Doppler effects which is caused when moving galaxies drag the ICM around them, and study possible particle acceleration phenomena as a consequence of energy loss by galaxies.

Direct measurement of the plasma momentum in a magnetic nozzle helicon plasma for electric propulsion

TAKAHASHI, Kazunori[1*] ; CHARLES, Christine[2] ; BOSWELL, Rod[2] ; CHIBA, Aiki[1] ; ANDO, Akira[1]

[1]Department of Electrical Engineering, Tohoku University, [2]Space Plasma, Power and Propulsion Laboratory, The Australian National University

The ion and electron energy distribution functions of a low-pressure, current-free helicon plasma in a magnetic nozzle configuration are experimentally investigated by electrostatic Langmuir probes including a radiofrequency compensated probe and a retarding field energy analyzer; the ions are electrostatically accelerated by a spontaneous potential drop of a double layer and/or ambipolar electric field, and only the energetic electrons can overcome the potential structure. The results indicate that the accelerated ions are spontaneously neutralized by the energetic electrons. These findings propose that the source system is applicable to an electrodeless and neutralizer-free plasma thruster.

Momentum of the plasma flow is one of essential physical parameters dominating the particle acceleration in both laboratory and space. Especially their interaction with magnetic fields have been significant subject associated with natural plasmas (astrophysical jets, magnetospheric physics, solar dynamics, aurora dynamics, etc.) and artificial plasmas (thermonuclear fusion devices, electric propulsion systems, plasma devices for material processing, etc.). The plasma momentum is equal in magnitude and opposite in direction to a thrust imparted from a plasma thruster for the electric propulsion device. The direct measurement of the thrust imparted from a magnetic nozzle helicon plasma thruster is successfully measured by using a pendulum thrust balance immersed in vacuum, where the thrust components arising from the presence of the physical boundaries and magnetic nozzle are also independently measured by attaching each component to the thrust balance. Further a laboratory experiment of a helicon plasma thruster is established to control only a plasma cross-field diffusion in a rapidly-divergent magnetic nozzle while maintaining a constant plasma injection into a magnetic nozzle. The thrust component due to a plasma pressure force inside the source cavity is constant and that due to the magnetic nozzle increases when inhibiting the cross-field diffusion in the nozzle. The latter force is well explained by an electron-diamagnetic-induced plasma momentum derived from two-dimensional momentum equations and approaches the theoretical limit derived from a one-dimensional model assuming an ideal magnetic nozzle with no plasma loss. Further a new source system approaching the ideal magnetic nozzle and the recent progress of the thruster performance will also be shown. It is noted that the above-described phenomena are occuring in current-free source system. These insights into the plasma thruster dynamics might include a common physics relating to the plasma acceleration in a non-uniform magnetic field in both the laboratory and space.

Wave-particle interactions are thought to play important roles to generate MeV electrons in the radiation belt. “ Wave-Particle Interaction Analyzer (WPIA) ” , which derives energy flaxes between wave and particle from simultaneous measurements of an electric field and particle velocity vector, has been developed to observe the interaction between wave and particle in space plasma. We have been conducting laboratory in-situ experiments of plasma wave-particle interaction.

We have carried out the laboratory simulation using the Q_T-Upgrade Machine in Tohoku University, which is linear magnetized plasma machine. The Q_T-Upgrade Machine consists of a vacuum chamber of 0.2 m in diameter and 4.5 m in length, and plasma sources, which generates high-temperature electrons using electron cyclotron resonance (ECR) and low-temperature thermal electrons. Thus, an electron temperature gradient (ETG) is formed in the apparatus by superimposing low temperature thermal electrons on the high temperature electrons of the ECR plasma. Moon et al. [Rev. Sci. Instrum., 2010] reported that low-frequency fluctuations of drift-wave mode with a frequency of 7 kHz were excited with ETG mode of 0.5 MHz. We focus on the low-frequency fluctuations and simultaneously measures an electric field vector (**E**) and current vector (**J**). Energy flaxes between wave and particle can be calculated from inner products of **E** and **J** vectors. For the simultaneous measurements, we have developed a combination probe, which is a combination of Mach probe for ion flow measurements and Twin probe for electric field measurements. Three-dimensional vector are measured by turning and moving the probe in the chamber.

In this presentation, we will report the performance of the combination probe, the phase relationship between the electric field fluctuation and the current fluctuation, and transient response of fluctuation growth in detail.

Collisionless shocks are considered to be sources of high-energy particles or cosmic rays, and occur when a coulomb mean-free-path is longer than the shock-front thickness. In such plasmas wave-particle interactions and collective effects play an essential role in the shock formation. In addition to local observations of spaces plasmas by spacecraft and global emission measurements of astrophysical plasmas, a laboratory experiment can be an alternative approach to study the formation of collisionless shocks.

In this paper, we investigate the formation of Weibel-instability mediated collisionless shocks in counter-streaming plasmas produced by large-scale laser systems. Kato and Takabe investigated the collisionless Weibel shock in two-dimensional PIC simulation using the injection method [1]. A scaling-law derived in simulation revealed that high-density (electron density $\sim 10^{20}$ cm^{-3}), high-flow velocity ($\sim$1000 km/s) plasmas are required to produce the collisionless Weibel shock. In order to achieve these plasma parameters, a MJ-class high-power laser system or the word largest laser, the NIF laser (LLNL, USA), is required. Before starting the NIF experiment, we conducted OMEGA laser (LLE, USA) experiment and measured plasma parameters such as electron and ion temperatures, electron density, and flow velocity of counter-streaming plasmas using collective Thomson scattering, and current filaments produced by the Weibel instability using proton-radiography.

Collisionless shocks play significant roles in particle acceleration, for example, in Earth’s bow shock and Supernova remnant shocks. In collisionless shocks, collisions between particles can not account for the formation mechanism and particle?field interactions are essential. Therefore, the shock thickness is much smaller than ion-ion mean free path and a large electromagnetic field exists at the vicinity of the shock. Laboratory experiments with high-power laser systems can be alternative to observations or in-situ measurements by satellites. Collisionless shocks have been produced and investigated in counter-streaming laser-produced plasmas. To investigate collisionless shocks, the measurements of an electric or magnetic field and of fundamental plasma parameters are required. Shocks have been measured by optical diagnostics such as interferometry, shadowgraphy, optical pyrometry, and Thomson scattering to obtain the fundamental plasma parameters: density, temperature, charge state, and flow velocity. We will present recent results from series of our experiments on collisionless shocks with Gekko-XII laser system.

Collisionless shocks are ubiquitous in various space and astrophysical environments like a termination shock of a stellar wind, planetary bow shocks, supernova remnant shocks, etc. Recently, collisionless shocks have been able to be experimentally generated by using high power laser facilities. One of the advantages in an experimental study is that both the global and the local structures of the phenomenon are simultaneously accessible in principle, which is inherently difficult in-situ or remote sensing observations in space. However, the shocks produced in the laser experiments and the method for measuring them are quite different from those in space. A majority of the shocks produced in laser experiments are unmagnetized shocks. The methodology for measuring their local quantities in the transition region has not been established.

On the other hand, basic structures and dissipation mechanisms in an unmagnetized shock have not been well understood theoretically. So far high Mach number electrostatic shocks are thought to be generated by the counter streams of two non-identical plasmas. In this study microstructures of such electrostatic shocks are studied by using a full particle-in-cell simulation. In addition, characteristics and issues of currently adopted method of measuring local quantities in shock transition region, known as Thomson scattering measurement, are also discussed.

Electromagnetic Field Excitation in Magnetized Plasmas by External Electrodes: 1D PIC Simulation Studies

OTSUKA, Fumiko[1*] ; HADA, Tohru[1] ; SHINOHARA, Shunjirou[2] ; TANIKAWA, Takao[3]

[1]Interdis. Grad. Sch. Eng. Sci., Kyushu Univ., [2]Inst. Eng.,TUAT, [3]RIST, Tokai Univ.

We perform one-dimensional particle-in-cell (PIC) simulation of external electromagnetic field excitation into magnetized plasmas. We consider two models for the electromagnetic field excitation: electrostatic excitation by electrodes and electromagnetic excitation by current antenna. Here, the external electrodes are placed outside plasma region, background magnetic field is perpendicular to the one-dimensional direction, and the externally applied field frequency is chosen in a range below the lower-hybrid frequency. For both models, we will discuss the electromagnetic field excitation processes by varying the externally applied field frequency and the plasma radius.

It is known that a satellite is charged by plasma in space.

Satellite charging on surface is a cause of discharge and malfunction electric equipment, and affect plasma diagnostics by the satellite potential accelerate ambient plasma, therefore a satellite is designed to mitigate surface charging. However, a perfect mitigation of satellite charging is difficult.

Thereby, a charging mitigation technique using electron emitter and ion emitter is often adopted. Satellite charging will be caused due to collisions with charged particles in plasma. In general, surface potential is determined by the balance of inflow current and outflow current. It becomes a positive value in the sunshine, and a negative value in the shade. The potential balance point can be controlled using charged particle beam emission.

We investigate a feasibility of satellite potential control under various environments using numerical simulation.

New solar radio telescope in NICT - II

KUBO, Yuki[1*] ; WATARI, Shinichi[1] ; ISHII, Mamoru[1] ; ISHIBASHI, Hiromitsu[1] ; IWAI, Kazumasa[2]

[1]National Institute of Information and Communications Technology, [2]Nobeyama Solar Radio Observatory, National Astronomical Observatory of Japan

Solar radio burst is one of the most important events for not only space weather forecasting but also investigating high-energy phenomena in solar corona. The GHz solar radio waves are synchrotron radiation emitted by high energy electrons at lower corona. On the other hand, the MHz solar radio bursts, especially type II and III bursts, are radiated via mode conversion of Langmuir waves excited by high energy electrons. These high energy electrons are accelerated at reconnection regions in solar flare and shock waves in solar corona. Therefore, MHz and GHz solar radio waves are closely related each other through the accelerated high energy electrons. So, wide frequency range (MHz to GHz) radio wave observations with high time resolution are required to comprehensively understand high energy phenomena in solar corona. We have been operating solar radio spectrograph called HiRAS for over twenty years in Hiraiso Solar Observatory, National Institute of Information and Communications Technology (NICT), but the system has been decrepit and radio wave environment in Hiraiso is getting worse. So, we have developed a new solar radio telescope in Yamagawa radio observation facility, NICT. The frequency range and time resolution in the system is 70MHz to 9.0GHz and 8 msec. In this presentation, we introduce situation in progress for our new solar radio telescope.

Frontier of space plasma observations expanding from interplanetary space to interstellar medium

TOKUMARU, Munetoshi[1*]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

The Sun emits the super-sonic plasma flow, called the solar wind, to form the heliosphere in the ambient interstellar medium. The spatial scale of the heliosphere is about 100 AU. Since interesting physical phenomena such as the solar wind formation, excitation and propagation of shocks, acceleration of energetic particles arises through interaction between plasma and fields in the heliosphere, it is used as an experiment site to make various observational studies of the space plasma. Remote sensing measurements of the solar wind with the interplanetary scintillation (IPS) method are one of those studies. The obtained IPS data revealed the global distribution of the solar wind drastically changes its global distribution over short- and long-timescales being closely associated with the solar activities (Tokumaru, 2013).

At present, marked progress occurs in the heliospheric sciences, being driven by new observational facts. One of progress has been brought about by exploration of heliospheric boundary region by Voyager-1, 2 (V1,V2) and IBEX spacecraft (Gurnett et al., 2013, McComas et al., 2009). The V1 encountered the termination shock (TS) at 94 AU in 2004, and reached the heliopause at 120 AU in 2012, then entered the interstellar medium. The V2 encountered the TS at 87 AU in 2007, being expected to reach the heliopause in a few years. The IBEX revealed the large-scale ribbon structure surrounding the heliosphere from imaging observations of energetic neutral atoms (ENAs). In order to interpret those observations, information on 3-diminensional (3D) structure of the heliospheric boundary region is needed. Since IPS observations mentioned above give global distribution of the solar wind in the inner heliosphere, 3D structure of the heliospheric boundary region can be determined precisely by MHD simulation based on the IPS data. The IPS-based MHD simulation data are provided to both Voyager and IBEX teams to make collaborative studies of the heliospheric boundary region.

Another driver for progress in the heliospheric science is arrival of the peculiar solar activity. The level of the current solar cycle is 100 years low, and IPS observations revealed that significant changes including marked drop of the solar wind density and different distribution of fast and slow solar winds occurs in this cycle (Tokumaru et al., 2009, 2010, 2012). These facts are important not only for studies of the heliospheric boundary region and influence on the planetary magnetospheres (i.e. the space weather), but also for elucidating enigma of the solar wind acceleration mechanism. Besides, observations during the current peculiar activity provide a clue to understand a hidden process for cooling of the Earth's climate during the Maunder minimum in the 17th century.

The V2 encounter for the interstellar medium which is expected to occur within a few years will enable detailed investigation of plasma environment in the local interstellar cloud surrounding the heliosphere. Furthermore, the heliopshere is immersed in the low-density (but high-beta) region called the local bubble, whose plasma properties have been investigated from radio observations using pulsars (Spangler, 2009). In the future, space plasma study for the integrated region ranging from the heliosphere to the local bubble will significantly advance by using in situ and remote sensing observations.

Scale hierarchy and self-organization in magnetospheric plasma

YOSHIDA, Zensho[1*]

[1]Graduate School of Frontier Sciences, University of Tokyo

Inhomogeneous magnetic field gives rise to interesting properties of plasmas which are degenerate in homogeneous (or zero) magnetic fields. Magnetospheric plasmas, as observed commonly in the Universe, are the most simple, natural realization of strongly inhomogeneous structures created spontaneously in the vicinity of magnetic dipoles. In this talk, we describe the experimental results form a ”laboratory magnetosphere” RT-1, and theoretical modeling of its spontaneous confinement.

The RT-1 device produces a magnetospheric plasma by a levitated superconducting magnet. Stable confinement (particle and energy confinement time = 0.5 s) of high-beta (local electron beta $>$0.7); electron temperature $>$10 keV) plasma has been demonstrated (which are promising characteristics for an innovative concept of advanced fusion; it is also applicable as a particle trap for experimental particle physics or atomic physics). The radial profile of the electron density n(r) is highly peaked. Fitting the data by a function $n(r) = n_0\ r^{-p}$,we estimate p=2.8$\pm$0.4 for a wide range of operating parameters. Multiplying n(r) by the magnetic flux tube volume, we can estimate the particle number N(r) in a unit magnetic-flux tube. While n(r) is a steep increasing function towards the center of the dipole magnetic field, N(r) is a decreasing function, hence interchange modes are stable. Whereas the simple kinetic model predicts a flat distribution of N(r) [1], the model of grand-canonical equilibrium explains the observed equilibrium state [2].

Theoretically, we can describe the self-organized confinement of the magnetospheric plasma as a grand-canonical equilibrium in a ”foliated phase space” of magnetized particles [3]. What makes the distribution function fundamentally different from the conventional Boltzmann distribution is the topological constraints on the phase space which limits the actual domain where the particles can occupy; the adiabatic invariants pose such constraints. Taking into account the constancy of the magnetic moment and the parallel action, we obtain a foliated phase space of coarse-grained variables, on with the invariant measure is distorted by the inhomogeneous magnetic field. The grand-canonical equilibrium has an inhomogeneous density when it is immersed in the laboratory flat space. Hence, the creation of a steep-density clump is a natural consequence of equipartition in the magnetic-coordinate phase space.

Solar wind plasma entry into the wake behind an unmagnetized obstacle

NAKAGAWA, Tomoko[1*]

[1]Information and Communication Engineering, Tohoku Institute of Technology

Plasma entry into a wake downstream of a non-magnetized obstacle in the supersonic flow of the solar wind is studied by using a two-dimensional, electromagnetic particle-in-cell simulation. Importance of negative charging of the downstream-side surface of the obstacle is examined by comparing the simulation results of 3 different ratios 8, 16, 32 of the obstacle size to the Debye length.

Global Vlasov simulation of a small body with a magnetic anomaly with the K-computer

UMEDA, Takayuki[1*]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

The interaction between a plasma flow and a small dielectric body with a weak intrinsic global magnetic field is studied by means of a five-dimensional (5D) full electromagnetic Vlasov simulation with two configuration spaces and three velocity spaces. In the present study, entry processes of ions into the nightside wake tail are examined. The simulation result shows that the bow shock and the magnetopause are formed on the dayside. However, most of solar-wind ions are reflected at the dayside magnetopause and are picked up by the interplanetary magnetic field. Then, a small part of the reflected ions are taken into the deep wake tail near the body by the E cross B cycloid motion. The present result, in which the spatial resolution is low and the Debye-scale charge separation on the dayside surface is not solved, is obtained by using a recent cluster computer system. Currently we are performing a 5D high-resolution global Vlasov simulation by using the K-computer. The direct comparison between the low- and high-resolution runs would show importance of fully kinetic global simulations.

Dependence of Jovian Magnetopause Location on Solar Wind Dynamic Pressure

KITAGAWA, Hirotaka[1*] ; KASAHARA, Satoshi[2] ; TAO, Chihiro[3] ; KIMURA, Tomoki[2] ; FUJIMOTO, Masaki[2]

[1]Earth and Planetary Science, School of Science, University of Tokyo, [2]Institute of Space and Astronautical Science, Japan Aerospace Exploration Agency, [3]Research Institute in Astrophysics and Planetology

Past observations revealed that the probability density distribution of Jovian magnetopause stand-off distance has double-peak. The probability between two peaks is very low. Thus the stand-off distance of Jovian magnetopause changes from the peak distance to the other peak by solar wind dynamic pressure. However, the scatter plot of stand-off distance versus solar wind dynamic pressure was nearly on one line. But the solar wind dynamic pressure was considered by magnetic pressure in the Jovian magnetosphere, due to the absence of the solar wind monitor at the Jovian orbit. We approached the double-peaked distribution by using the calculated solar wind parameters via MHD equations whose input parameters are based on the observation at Earth's orbit. Referring the propagated solar wind parameters, we investigated the location of Jovian magnetopause observed by the Galileo spacecraft. We found that the peaks of the distribution seem to be a result of probability density distribution of solar wind dynamic pressure. The very low probability stand-off distance between the peaks seemed to be caused by unusual distribution of solar wind dynamic pressure.

Pickup ion acceleration via multiple reflection between two successive CIRs

TSUBOUCHI, Ken[1*]

[1]Tokyo Institute of Technology

Interstellar neutral particles, during their propagation inside the heliosphere, become ionized by the charge exchange with the solar wind (SW) plasma. The interplanetary magnetic field picks up these newborn ions, called ”pickup ions” (PUIs), and carries them away into the outer heliosphere with SW. The gyrating velocity of PUIs around the magnetic field is equivalent to the SW flow speed, hundreds of km/s, which is much faster than the SW thermal velocity. This property enables PUIs to be accelerated more efficiently at the shock than the thermal SW particles. Thus PUIs are considered to be the dominant source of anomalous cosmic rays (ACRs) generated at the heliospheric termination shock.

However, the well-known diffusive shock acceleration (DSA) process alone is insufficient to raise the PUI energy up to the ACR range, typically in the order of MeV. This is because the primary PUI energy (10 keV at most) is still too low to be injected into DSA, where at least hundreds of keV is necessary. Therefore, some preacceleration should take place inside the heliosphere before SW and PUI reach the termination shock. Interplanetary shocks are the most possible source for it. In the present study, we focus on the shocks driven by the interaction of the fast SW with the ahead-flowing slow SW. The regions bounded by these shocks are called corotating interaction regions (CIRs); forward shock in the slow SW side and reverse shock in the fast SW side.

We demonstrate how particles are accelerated at this CIR system by performing hybrid simulations. The simulation results show that more efficient acceleration is identified in the PUI reflected at the shock than in those transmitted through the shock. The acceleration takes place while the PUI stays close to the shock surface. This situation is similar to the shock-drift or surfing acceleration mechanism. However, our results indicate that the acceleration is not dominant in the component transverse to the magnetic field, i.e., the direction of motional electric field. Rather, the net acceleration is confirmed in the field-aligned component. The mechanism will be discussed in terms of the characteristic of the Lorentz force balance acting on PUIs.

The periodic boundary condition applied in the present simulation virtually allows the successive appearance of two CIRs. After the reflected PUI travels the ”inter-CIR” space, it encounters the shock of another CIR, where the reflection again takes place. While one reflection increases the PUI energy only a few times, this multiple reflection process yields the most energetic PUI with its maximum energy up to 100 keV, probably enough for the injection into DSA. Recent CIR observations have confirmed the presence of the energetic PUI in the solar wind between two CIRs, which may prove the present results.

Study on The Difference Between Proper-Motion of Balmer hydrogen line emission and Non-Thermal X-Ray emission in SNRs

SHIMODA, Jiro[1*] ; INOUE, Tsuyoshi[2] ; OHIRA, Yutaka[1] ; YAMAZAKI, Ryo[1] ; SOEDA, Masanobu[1]

[1]Aoyama Gakuin University, [2]National Astronomical Observatory of Japan

Balmer line emission (Hα) by neutral hydrogen and X-ray synchrotron emission by accelerated electrons are observed from some supernova remnants (SNRs), which are thought as accelerators of galactic cosmic rays (CRs). From these observations, the cosmic ray acceleration eciency is estimated. According to the theory of diusive shock acceleration (DSA), electrons are accelerated around the shock front, and emit the synchrotron radiation. Measurement of proper motion of the synchrotron X-rays gives the shock velocity. At the same time, we can estimate the post shock temperature from the line width of Hα emission, because neutral hydrogen collide with downstream hot protons and exchange their charge, so that the hot neutral component arises.

In the specific case of a SNR RCW86, measured expansion speed of Hα filament is about 1200km/s(Helder et al. 2013), while 6000km/s in X-rays (Helder et al. 2009). It is expected that the emission regions of the Hα and the synchrotron X-rays are dierent. However, they are overlaid in the same line of sight.

In this study, using three dimensional magnetohydrodynamics (MHD) simulations, we consider propagation of super

nova blast wave shock in realistic inhomogeneous interstellar medium. Interaction between the upstream density inhomogeneity and the shock wave causes rippled shock structure and uctuation of local shock velocity. We show that our synthetic observations of the MHD simulation data are consistent with actual observation results for RCW86.

Magnetohydrodynamic Simulations of the Interaction of a Jet with Interstellar Neutral Hydrogen Clumps

ASAHINA, Yuta[1*] ; OGAWA, Takayuki[1] ; MATSUMOTO, Ryoji[1]

[1]Graduate School of Science, Chiba University

An astrophysical jet transfers the energy released near the gravitating object and interact with the interstellar medium. When the jet propagates in the interstellar medium interacting with its environment. We carried out magnetohydrodynamic simulations of the jet propagation in neutral hydrogen (HI) clumps taking into account the interstellar cooling. At the initial state, HI clumps are assumed to be in thermal equilibrium. As the clumps are compressed by the bow shock ahead of the jet, the shocked cloud is heated up but since the density enhancement increases cooling rate, the cloud is subsequently cooled down. As a result, cold, dense sheath is formed around the jet. The enhanced density triggers the cooling instability and prompts the formation of the cold, dense gas.

We studied the dependence of numerical results on the volume filling factor of the HI clumps. We found that when the volume filling factor is large, the propagation speed of the jet is slow and arc-shaped cold dense region is formed. When the volume filling factor is small, propagation speed does not decrease so much and dense cloud distribution is more elongated. The distribution of the cold, dense gas and the length of the jet propagation speed depend on the filling factor.

We report the application of this model to molecular clouds toward the stellar cluster Westlund 2 and TeV γ-ray source HESS J1023-575 observed by NANTEN2 and Mopra telescope. HESS J1023-575 is located between these molecular clouds. The shape of molecular cloud on the right of HESS J1023-575 is like an arc and molecular clouds on the other hand distribute linearly. The difference of the filling factor can explain the difference of the shape of these molecular clouds.

High beta plasma production and their diagnostics in magnetosphere RT-1 device

NISHIURA, Masaki[1*] ; YOSHIDA, Zensho[1] ; SAITOH, Haruhiko[1] ; YANO, Yoshihisa[1] ; KAWAZURA, Yohei[1] ; NOGAMI, Tomoaki[1] ; YAMASAKI, Miyuri[1]

[1]Graduate school of frontier sciences, The Univeristy of Tokyo

The magnetosphere plasma device is one of new concepts for nuclear fusion devices. A ring trap 1(RT-1) realizes the concept as a laboratory magnetosphere using a superconducting magnet levitated in a vacuum vessel, which produces a dipole magnetic field. We study the characteristics of confined plasmas in RT-1. In recent experiments, the RT-1 experiment has demonstrated the self-organization of a plasma clump with a steep density gradient; a peaked density distribution is spontaneously created through ”up-hill diffusion”.

The operation regime of RT-1 is extended into the electron density from 10^{17} to 10^{18} m^{-3} by optimizing the electron cyclotron heating (ECH) system. The line integrated density measured by an interferometer achieved 6.2x$10^{17}m^{-3}$ and diamagnetic flux 5.6 mWb. It is considered that the beta value (the ratio of plasma pressure to magnetic pressure) exceeds 100%. In such situation, a millimeter wave reflectometer is implemented to measure the density peaking and spatial structure. We observed the initial results and started the analysis of acquired signals.

When we use the electron heating by ECH system, the ion remains cold due to a collisionless situation. Therefore we installed three turn antenna into RT-1 to heat ions by a slow wave (ion cyclotron heating: ICH) in a MHz range. In the case of ˜$10^{18}m^{-3}$ as a target plasma of ICH by only use of ECH, the heating efficiency of ICH increases, and then leads to the increase of ion temperature. The effect has been observed by an electrostatic energy analyzer, which located at the plasma edge of RT-1.

We designed an ion probe to diagnose energies and pitch angles of ions in ICH experiments of RT-1. The principle of the ion probe is the same as that of fast ion loss measurement in a fusion machine, and is applied to the ion diagnostic in RT-1 plasmas. A scintillator is mounted inside the probe head with a pin hole. Ions with gyro motion enter into the probe head, and then hit the scintillator. We can know the energies and pitch angle simultaneously from the scintillation image.

We report the extension of plasma parameters by ECH optimization, progress on the installation of ion probe, and future perspective.

Hybrid simulations of the interaction between the solar wind and the ion scale magnetosphere

NAKAMURA, Masao[1*]

[1]Osaka Prefecture University

The interaction between the solar wind and the ion scale magnetosphere with a dipole magnetic field is investigated by a three-dimensional hybrid simulation. In the present study, the ion scale magnetosphere has a dayside stand-off distance which is several to a hundred times larger than the ion Larmor radius of the solar wind proton in the magnetic field strength at the dayside magnetopause boundary. The hybrid simulation treats the ions as kinetic super particles via particle-in-cell method and the electrons as a massless fluid. In the interaction between the solar wind and the magnetosphere, the interplanetary magnetic field (IMF) condition controls not only the reconnection regions but also the subsolar sheath flow due to the ion kinetic effects. Those influence the structures of the bow shock and the magnetopause boundary layer. We will also discuss the momentum transfer process from the solar wind into the magnetosphere and to the magnetized object.

Full PIC simulations on plasma electromagnetic disturbance in the vicinity of spacecraft

USUI, Hideyuki[1*] ; MIYAKE, Yohei[1]

[1]Graduate School of System Informatics, Kobe University

Space exploration has been rapidly increasing, and a strong demand arises regarding comprehensive understanding of spacecraft-plasma (SP) interactions [1]. This is clearly required to ensure survivability and proper operations of space-based systems, and also for correct interpretation of measurements and other information collected in situ by scientific spacecraft.

In space environments, spacecraft are electrically charged due to plasma contact to spacecraft surface and its floating potential is basically determined by the current balance at spacecraft surface. The current consists of incident background plasma, emission of photoelectrons/secondary electrons from spacecraft surface as well as active emission of plasma beam in electric propulsion system such as ion engine. Due to the spacecraft charging, plasma environment near spacecraft is influenced. Non-uniform plasma distributions such as sheath and wake structures are formed near spacecraft surface and in the downstream region with respect to the solar wind, respectively. Field components near spacecraft can be also disturbed by the plasma response to spacecraft. Understanding of the SP interactions is important from a view point of spacecraft observation of plasma environment as well as its data analysis. To discriminate plasma phenomena artificially disturbed by spacecraft from observational data, quantitative understanding of SP interactions is necessary. In designing science instruments such as electric field sensor, plasma disturbance near spacecraft has to be minimized as much as possible to obtain reliable and valuable data. To obtain self-consistent solution of these plasma disturbances near spacecraft, we perform plasma simulations including spacecraft body in a simulation domain.

For solving SP problems, we have developed the EMSES plasma particle simulation code [2]. EMSES is based on the standard electromagnetic PIC method, and also has the capability to include the conducting bodies of a spacecraft, based on the capacitance matrix method. In addition, a number of crucial physics such as the photoelectron emission and the secondary emission are modeled numerically in the latest version of EMSES. The code has been applied so far to some specific spacecraft, e.g., Geotail, Cluster, BepiColombo/MMO, and Solar Probe Plus.

In this talk, first we will briefly explain the numerical treatment of spacecraft in EMSES. Then we will show a few examples of EMSES applications to scientific spacecraft. One of such applications is an enhanced wake formed behind the Cluster satellite in tenuous streaming plasma [3]. In the simulation we have included the conducting surfaces of very thin (in an order of mm) wire booms by using the fictitious surface technique. We found that even the extremely thin wire booms can contribute substantially to the formation of an electrostatic wake because of highly positive spacecraft charging in the tenuous plasma environment. We will also show a recent research topic on the SP interactions in the near-Sun environment. Large photoelectron emission current caused by an intense solar flux forms a negative potential barrier on the spacecraft surface, leading to negative charging of the spacecraft. Electromagnetic environments around these specific spacecraft will be presented in the talk.

General relativistic simulations of magnetized binary neutron star merger on K

KIUCHI, Kenta[1*] ; KYUTOKU, Koutarou[2] ; SEKIGUCHI, Yuichiro[1] ; SHIBATA, Masaru[1]

[1]Yukawa Institute for Theoretical Physics, [2]University of Wisconsin-Milwaukee

Binary neutron stars are a binary which is composed of two neutron stars and nine binaries have been observed so far. They gradually lose the orbital energy and angular momentum due to gravitation wave emission and merge in the end. Within the observed binaries, six of them will merger within the Hubble time. Gravitational waves emitted during the merger would be detectable with the ground-based gravitational wave detectors such as KAGRA, advanced LIGO, and advanced VIRGO at a frequency of about ten times per year. If we could observe the gravitational waves, they would tell us the validity of General Relativity in a strong gravitational field and the equation of state of neutron star matter which is poorly known to date as well.

This situation facilitates a theoretical study of binary neutron star mergers. During the merger, the density is as high as 10^{15} g/cc and the temperature rises as high as 10^{10} degrees. Therefore, any analytical approaches break down and we need a numerical modeling. Our group is approaching this problem in the framework of Numerical Relativity. It is a research field whose aim is figuring out phenomena in a strong gravitational field by solving the Einstein equation as well as the hydrodynamical equation and neutron radiation transfer.

The observations of the pulsars have revealed that the neutron stars are magnetized with about 10^{12} Gauss in general. Moreover, some of them could have 10^{14} Gauss. However, it is still unknown what the role of magnetic field during binary neutron star mergers is. There are several hydrodynamical instabilities which amplify the magnetic field and a short wavelength mode is essential in all cases. Therefore, it is mandatory to perform a high-resolution simulation. In the previous studies of this subject, it is hard to say that enough resolution is assigned to resolve these instabilities. Our group is performing a numerical simulation with the highest resolution on the supercomputer K and figuring out the role of the magnetic field during the merger of binary neutron stars. We summarize the result as follows.

When the two stars come into contact, the shear layer between the stellar surface becomes unstable against the Kelvin-Helmholts instability. The vortices are produce by this instability and the shorter the wavelength is, the larger the growth rate of the instability is. If there exists magnetic field lines, they are curled by these vortices and are expected to be amplified exponentially. By performing the convergence study against the numerical resolution, we have found the maximum magnetic field is amplified by the factor of about thirty at least at the merger.

After the merger, a hypermassive (HMNS) neutron star is transiently formed, which is supported by a rapid and strong differential rotation in addition to the thermal pressure. Although this star is unstable against the magnetorotational instability (MRI), it is difficult to resolve the MRI because the wavelength of the unstable mode is quite short due to the high density and high angular velocity of the HMNS neutron star. In our simulation, we have resolved this unstable mode and we have shown that the HMNS neutron star has the magnetic field as large as 10^{16}-10^{17} Gauss as a result.

In the HMNS neutron star, the angular momentum transport due to the non-axisymmetric structure as well as due to the MRI works. In addition, the star loses a significant amount of the angular momentum due to the gravitational wave emission. Then, the star collapses to a black hole which is surrounded by the accretion disk. Inside the accretion disk, the magnetohydrodynamical turbulence transports the angular momentum and its surface is unstable against the Kelvin-Helmoholts instability. Vortices produced by these two mechanisms transport the energy outwardly and the disk wind activates as a result. In this talk we will introduce the simulation result in details.

Electromagnetic Vlasov simulations of magnetized plasma with a finite-volume multi-moment advection scheme

MINOSHIMA, Takashi[1*] ; MATSUMOTO, Yosuke[2] ; AMANO, Takanobu[3]

[1]Institute for Research on Earth Evolution, Japan Agency for Marine-Earth Science and Technology, [2]Graduate School of Science, Chiba University, [3]Department of Earth and Planetary Science, University of Tokyo

The Vlasov simulation, which directly discretizes the Vlasov equation on grid points in phase space, has been proposed as an alternative method to the common Particle-In-Cell simulation, to improve the accuracy of kinetic plasma simulations. Although the electrostatic Vlasov simulations have been successfully carried out thus far, the electromagnetic Vlasov simulation of magnetized plasma is still limited, owing to numerical difficulty in solving the distribution function in velocity space.

To overcome the difficulty, we develop a new numerical scheme, specifically designed to solve the Vlasov equation in magnetized plasma. The scheme advances multiple piecewise moments of a physical profile based on their governing equations, to preserve the profile with high accuracy. The scheme allows us to perform a long-time calculation of the distribution function of magnetized plasma with small numerical diffusion.

In this talk, we first present the scheme and its performance. Then, we report the application of the scheme to two-dimensional (2D3V) electromagnetic Vlasov simulations. Long-time simulations of the linear wave propagation in magnetized plasma are conducted with quite small numerical errors. We also conduct the simulation of collisionless magnetic reconnection. The simulation resolves macroscopic structure without numerical noise, and is in good agreement with previous studies. Furthermore, the simulation resolves microscopic structure of the non-Maxwellian plasma velocity distribution around the reconnection site, e.g., acceleration by the reconnection electric field at the X-point, high energy beams around the boundary layer, and heating by the magnetic compression at the downstream. Since the simulations have been successfully carried out with the grid size much larger than the Debye length, the Vlasov simulation is a powerful technique to treat global-scale kinetic plasma phenomena.

Generalization of Plasma Hybrid Simulation Model

AMANO, Takanobu[1*] ; HIGASHIMORI, Katsuaki[1] ; SHIRAKAWA, Keisuke[1]

[1]Department of Earth and Planetary Science, University of Tokyo

The hybrid simulation model has been widely used as one of the self-consistent simulation methods in investigating nonlinear space plasma phenomena, which treats ions as kinetic macro-particles whereas electrons are assumed to be an inertialess fluid. It can correctly simulate from magnetohydrodynamic to the ion inertia length scale. However, the assumption of the inertialess electron makes it sometimes numerically difficult to handle high-frequency whistler waves. We have recently shown that the problem may be resolved by appropriately including finite electron inertia effect, which also makes it possible to handle vacuum regions in a hybrid code. In this report, we discuss extension of the model which may be able to incorporate electron kinetic effect. Ignoring the displacement current and assuming charge neutrality, we adopt the Vlasov-Ampere system of equations. An equation to determine the electric field is derived from the basic equation without any approximations. We demonstrate that by using the equation, the electron cyclotron resonance can be properly included.

Optimization of Magnetohydrodynamic Simulation Code for Planetary Magnetosphere to Xeon Phi

FUKAZAWA, Keiichiro[1*]

[1]Research Institute for Information Technology, Kyushu University

For investigating the global structures of plasma, such as the planetary magnetospheres, the Magnetohydrodynamic (MHD) equations are often used, in which full kinetics of plasma are neglected by taking the moments of the Vlasov equations. The MHD equations are highly nonlinear and are very complex to solve by hand calculations. Thus computer simulations play essential roles in studies of global magnetosphere.

The numerical MHD code for the magnetosphere has been optimized for vector-type supercomputers for a long time because the MHD code is a kind of fluid code and most of supercomputers with vector processors have high performance to solve the fluid codes in 1990's. These codes often have achieved a very high computational efficiency (the ratio of the effective performance to the theoretical performance). However, almost 100% of the "Top 500" supercomputer systems in the world adopt the massively parallel scalar type processors and more than 85% of systems consist of the x86 processor architecture in these days. The other scalar type computers are POWER and SPARC architectures. Recently the new coprocessor Xeon Phi which has many cores (˜60 cores) of X86 architecture is introduced to the supercomputer system and achieved good performance of the Linpack benchmark.

In this study I evaluate the performance of MHD code for the planetary magnetosphere on the single Xeon Phi coprocessor. For the performance evaluation, I use the three-dimensional domain decomposition method and a cache-hit type of three-dimensional domain decomposition method with the flat MPI and hybrid MPI. As the results, I found that normal three-dimensional decomposition of the MHD model with the hybrid MPI is suitable for Xeon Phi coprocessor and achieved computing performance efficiency of ˜7%. Furthermore, I add the optimization to the MHD code based on the Xeon Phi architecture and obtained the computing performance efficiency of almost 10% which is the double performance of FX10 single node.

The NICT Science Cloud is a cloud system designed for scientific researches, and expected as a new infrastructure for big data sciences. Not only parallelization of CPU as in super-computers, but I/O and network throughput parallelization are crucial for the big data science. A high-performance visualization system is constructed on the NICT Science Cloud using Gfarm/Pwrake middleware. We examined performance of this parallel visualization environment for a set of computer simulation with 1000 files (2.3TB in all). After setting higher priority to access to local file on local disk, we finally achieved 124 times higher visualization using 192 core cpu.

Development of magnetic field tracking module for analyzing a decaying sunspot

KATO, Shota[1*] ; IMADA, Shinsuke[1] ; MACHIDA, Shinobu[1]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

In order to analyze the structures of magnetic fields using the data from Solar Optical Telescope (SOT) on board the Hinode satellite, we have developed the automatic tracking module, which detects the magnetic region and tracks the time variation of each region.

The module, based on three thresholds, intensity, size, and distance, has main three functions: (1) detect the magnetic fields based on the intensity threshold, (2) remove the micro region by the size threshold, (3) based on move distance by time variation, detect the same regions and track them.

We made simple sample data for test and checked on the accuracy of our tracking module.

We applied the module to sunspot and analyzed the time variation of decaying sunspot which is one of the sources of magnetic element in the solar surface.

We have use the magnetograph data which was observed by Hinode/SOT from 29 Dec 2009 to 2 Jan 2010. We also discuss the north-south/east-west asymmetry of the decaying process in the active region.

Application of feature recognition technique in the investigation of magneto-convection on the solar surface

IIDA, Yusuke[1*] ; HOTTA, Hideyuki[2]

[1]ISAS/JAXA, [2]High Altitude Observatory/JSPS

We show the recent feature recognition technique and its benefits in the investigation of magneto-convection on the solar surface using observational and numerical approaches.

The magneto-convection on the solar surface is important not only as a trigger of many surface energetic events, e.g. solar flare, jet, and X-ray bright point, but also as an actual example of the most detailedly observed and numerically simulated magneto-convection on the stellar surface owing to its closeness to the earth. However, the elements of magneto-convection (<1,000km), the basic convective cells and magnetic patches formed by convective motion, are much smaller than solar global scale(~70,0000km). It means that we need large field of view to catch up enough number of structures simultaneously with high spatial resolution to capture such small scale structures. Thanks to the improvement of engineering technique for satellite observation and computers for numerical calculation, we are now able to catch such a large scale structure at the same time. However, the new difficulty, how to investigate statistical characters of convective cells and magnetic structures in such huge data sets, has just shown up in the analysis.

Because of this situation, feature recognition and tracking technique is now focussed on. In this presentation, we want to introduce the auto-recognition and tracking code of magnetic patches and convective cells on the solar surface. Further it is shown that the statistical characters obtained through the analysis of observational data and numerical calculation data based on the auto-recognition and tracking code. We want to note that the feature tracking technique drastically improve statistics of the analysis drastically. We also want to discuss about the applicants of feature tracking technique with the scientists in the other fields though this collaborative session.

On stability properties of the numerical Cherenkov instability in relativistic plasma flows

IKEYA, Naoki[1*] ; MATSUMOTO, Yosuke[1]

[1]Graduate School of Science, Chiba University

We examined stability properties of the numerical Cherenkov instability in relativistic plasma flows. Particle-in-cell simulation code package, pCANS, was used for the numerical analysis. With the implicit FDTD method for Maxwell equations, we found that the instability was greatly inhibited with the CFL number of 1.0. Numerical tests with various CFL numbers ranging from 0.5 to 1.0 showed that the growth rate remarkably decreased at CFL = 1.0 following a gradual decrease from the value at CFL=0.5. The implicitness factor (alpha=0.5 for Clank-Nicolson method) was also found to control the width of the dip. The present result contrasts with the recently reported results (Vay et al., 2011, Godfrey & Vay, 2013) in which the magical CFL number were 0.5 and 0.7 respectively for their different explicit field solvers. We present the result with the detailed dispersion relation of the implicit field solver and its application to relativistic collisionless shock simulations.

Electron hybrid code simulations with OhHelp load balancer

KATOH, Yuto[1*] ; MIYAKE, Yohei[2] ; NAKASHIMA, Hiroshi[3] ; USUI, Hideyuki[2] ; OMURA, Yoshiharu[4]

[1]Department of Geophysics, Graduate School of Science, Tohoku University, [2]Graduate School of System Informatics, Kobe University, [3]Academic Center for Computing and Media Studies, Kyoto University, [4]Research Institute for Sustainable Humanosphere, Kyoto University

A spatially one-dimensional electron hybrid code has been developed for the study of the generation process of whistler-mode chorus emissions and relativistic electron acceleration in the Earth's inner magnetosphere [1-3]. In the electron hybrid code, we treat cold electrons as a fluid and energetic electrons as particles by the Particle-in-Cell (PIC) method. Since we assume an inhomogeneous background magnetic field in the simulation system so as to treat the bounce motion of energetic electrons along a magnetic field line, the distribution of energetic electrons in the system is non-uniform and energetic electrons move around the magnetic equator assumed at the center of the simulation system. While the electron hybrid code has been parallelized through the particle decomposition method, we need to improve the scalability of the electron hybrid code so as to use a large simulation system and billions of particles for simulations under initial conditions corresponding to the real magnetosphere.

In the present study, we have developed a spatially one-dimensional electron hybrid code domain-decomposed by OhHelp [4]. The OhHelp is a library which enables us to conduct PIC simulations by achieving both dynamic load balancing and scalability. The efficiency and scalability of OhHelp have been confirmed by a 3D full PIC simulations [5]. We show the efficiency and scalability of the developed code tested on the system A (Cray XE6) of Academic Center for Computing and Media Studies, Kyoto University. We compare the performance of the developed code and those of the code with the particle decomposition.

Effect of Surface BRDF on the Geostationary and Low Orbit Observations of Tropospheric NO_2

NOGUCHI, Katsuyuki[1*] ; RICHTER, Andreas[2] ; ROZANOV, Vladimir[2] ; ROZANOV, Alexei[2] ; BURROWS, John[2] ; IRIE, Hitoshi[3] ; KITA, Kazuyuki[4]

[1]Nara Women's University, [2]University of Bremen, [3]Chiba University, [4]Ibaragi University

We investigated the effect of surface reflectance anisotropy, Bidirectional Reflectance Distribution Function (BRDF), on geostationary and low orbit satellites' retrievals of tropospheric NO_2. We first develop an empirical model of the three BRDF coefficients for each land cover type over Tokyo, and then apply the model to the calculation of land cover type dependent AMFs and BAMFs. Results show that the variability of AMF among the land types is up to several tens percent, and if we neglect the reflectance anisotropy, the difference from BRDF's AMF reaches 10% or more. The evaluation of the BAMFs calculated shows that not to consider variations in BRDF will cause large errors if the concentration of NO_2 is high close to the surface, although the importance of BRDF for AMFs decreases for large AOD.

R&D of passive radar -Water vapor estimation with digital terrestrial broadcasting wave-

KAWAMURA, Seiji[1*] ; OHTA, Hiroki[1] ; HANADO, Hiroshi[1]

[1]National Institute of Information and Communications Technology

In general, radars retrieve some information by transmitting radio waves and by receiving their scatted echoes. On the other hand, passive radars never transmit radio waves. They retrieve some information by receiving radio waves which are transmitted by others for other purposes. Passive radars do not need new radio wave frequencies, and just consist of rather simple and low cost receivers because they do not transmit radio waves. We, National Institute of Information and Communications Technology (NICT), are developing passive radar measurement systems whose targets are environmental monitoring.

In this study, we are developing a water vapor measurement system using digital terrestrial broadcasting wave as one of passive radars. Localized heavy rain in the urban area is a social issue in these days. Water vapor is an essential parameter for weather forecast because it is a state before rain drop. And it is one of the most difficult physical quantity to measure with remote sensing technique. If we can monitor water vapor around the ground surface with precise time and spacial resolutions, the weather forecast might be able to predict the localized heavy rain.

Radio waves are delayed due to water vapor through propagation. If we can measure this time delay, water vapor can be retrieved from it. Since delay doe to water vapor is quite small, very precise (sub-nano second order) measurements are needed. Radio waves used for digital terrestrial broadcasting are modulated with OFDM, and known signals are embedded. Complex delay profiles are calculated using these known signals. Using the phase of delay profile, we can measure propagation delay with precise accuracy (pico-second order).

When we consider the accuracy with order of sub-nano seconds, phase fluctuations of local oscillators at radio tower and receivers are essential error factors. We have developed a real-time delay (phase of delay profiles) measurement system with software-defined radio technique. Using this system, we can also measure phase fluctuations of local oscillator at each TV station by just receiving radio waves. With these systems at two receiving points on the same line including the radio tower, and with synchronization between their local oscillators, we can measure water vapor between two receiving points. After proving test of estimation of water vapor, we will distribute many small receivers and develop water vapor monitoring system in collaboration with many observations and data assimilations.

Observation of local circulation in north area of Fukui prefecture by using two adjoining 1.3-GHz wind profiler radars

NAKAJO, Tomoyuki[1*] ; YAMAMOTO, Masayuki[2] ; AOYAMA, Takashi[1] ; HASHIGUCHI, Hiroyuki[2] ; UJIHASHI, Yasuyuki[3]

[1]Department of Electrical, Electronic and Computer Engineering, Fukui University of Technology, [2]Research Institute for Sustainable Humanosphere, Kyoto University, [3]Department of Architecture and Environmental Engineering, Fukui University of Technology

Global impact of our lifestyle to our own has been pointed out previously. In the field of atmospheric environment, it has been considered that heavy rainfall, of which occurrence and damages are increasing in recent years, to be related with global warming. In addition to influence of yellow dust and PM 2.5 on our health, it has been known that photochemical oxidant tends to increase again since 1980's. Furthermore, the severe accident of Fukushima Daiichi Nuclear Power Station has caused us the interest about diffusion of radioactivity.

Above atmospheric problems are not only global but also local because they are strongly affected by local circulation. Local circulation occurs in atmospheric boundary layer (ABL) which has different characteristics in each local area, therefore, it is essential to reveal the detailed characteristics of ABL for resolution of the atmospheric problems.

Under such a situation, Fukui University of Technology started a project named as "Formation of research base for measurement and conservation of environment in Hokuriku area" (H23 - H27) supported by MEXT. In the project, a 1.3-GHz wind profiler radar (FUT-WPR), which is same type atmospheric radar as that of JMA WINDAS network, was installed in the coastal area of northern part of Fukui prefecture in 2012. In Fukui prefecture, a WPR of WINDAS has worked at Fukui local meteorological observatory (WINDAS-FUKUI), and the distance between FUT-WPR and WINDAS-FUKUI is only 24 km. There is no area in Japan where two WPRs are located within such a short distance, which enables more detailed study of the local circulation in Fukui plain than previous studies.

The observation results of FUT-WPR have revealed the detailed characteristics of see and land breeze (SLB) which is well known local circulation in coastal areas; its temporal variation, structure in altitude, relation with ABL, occurrence probability, and effect on generating area of clouds. Especially, the comparison with WINDAS-FUKUI not only confirms the observation results by FUT-WPR but also shows the SLB reaches from the seashore to a few 10 km inland. Although the observation results are fundamental in meteorology, this is the first time that the real picture of SLB in Fukui plain was revealed in detail so far. The comparison with WINDAS-FUKUI also shows the horizontal winds under about 1 km in altitude often differs between FUT-WPR and WINDAS-FUKUI, which indicates the importance of measurement of ABL.

We also carried out the data analyses in the case of heavy rain. On September 3 in 2013, passage of the stationary front accompanying the typhoon No. 17 brought about the heavy rain reaching to 10 mm/10min in Fukui prefecture from 14:00 to 16:00 (JST). FUT-WPR observed not only a typical structure and temporal variation of horizontal wind followed by the passage of stationary front but also intermittent upward flow, of which velocity reaches 1 m/s in the altitude from 200 m to about 4 km, from 7 hours before the passage of front. Especially, a strong upward flow with the velocity of 4 m/s was observed around 12:00 in the altitude from 3.5 to 5 km although the duration was relatively short. The observations of MTSAT from 10:00 to 14:00 have shown that optically thick clouds, of which top altitude was estimated to reach about 10 km, had arrived over Fukui prefecture. Therefore, the upward flows observed by FUT-WPR should be a part of cumulonimbi system which brought about the heavy rain. On the other hand, upward flows observed by WINDAS-FUKUI was weaker than that of FUT-WPR, which indicates the horizontal scale of upward flow accompanying the cumulonimbi system was under 24 km at least.

The results of observations and data analyses obtained so far indicates the observation of ABL by adjoining WPRs will be useful in early detection of arriving cumulonimbi system or local weather prediction.

Relationship between solar activity and disturbance in the middle atmosphere during Arctic winter

SAKANOI, Kazuyo[1*] ; KINOSHITA, Takenari[2] ; MURAYAMA, Yasuhiro[2]

[1]Komazawa Univ., [2]National Institude of Information and Communications Technology

Purpose of this research is to clarify relationship between solar activity and disturbance in the middle atmosphere during Arctic winter. In this research we consider stratospheric sudden warming (SSW), which is typical phenomenon in Arctic winter, as disturbance in the middle atmosphere including the mesosphere. Previous research reported effect of 11-year solar cycle on thermal structure only in the Stratosphere.

To get thing started, we selected daily bottom altitude of easterly wind area, which corresponds to SSW, in the zonal mean horizontal wind. Averaged value of those during one SSW event is used for quantitative comparison with solar activity and QBO index. No clear relationship was found between the selected new value (ZEW index) and two indexes. However we confirm that the ZEW index represents well the degree of disturbance. Next, we calculate AO index in the altitude range from 1000 hPa to 0.1 hPa (65km alt). AO index also represents the degree of disturbance.

In this presentation, we will examine and discuss in more detail about ZEW and AO index as those which indicate the degree of disturbance in the middle atmosphere for quantitative comparison with solar activity.

Temporal variations of O3 and NO in the middle atmosphere above Syowa Station observed by a millimeter-wave radiometer

OHYAMA, Hirofumi[1*] ; ISONO, Yasuko[1] ; UEMURA, Miku[1] ; NAGAHAMA, Tomoo[1] ; MIZUNO, Akira[1] ; TSUTSUMI, Masaki[2] ; EJIRI, Mitsumu[2] ; NAKAMURA, Takuji[2]

[1]Solar-Terrestrial Environmental Laboratory, Nagoya University, [2]National Institute of Polar Research

Precipitation of energetic particle into the atmosphere impacts abundances of atmospheric constituents in the middle atmosphere. Highly energetic solar protons, which directly enter the middle atmosphere, cause increase of HOx and NOx species. Energetic electrons also increase NOx in the thermosphere, and the downward transport in the polar vortex moves the produced NOx to lower altitudes. These NOx species cause a decrease of O_3 in the middle atmosphere through catalytic reactions [Seppälä et al. 2006; Daae et al., 2012]. To investigate the effect of NOx on O_3 variation in the polar region, a ground-based millimeter-wave spectroscopic radiometer was installed at Syowa Station, Antarctica in March 2011. The instrument has recorded brightness temperature spectra of rotational emission from the atmospheric O_3 and NO molecules. From the NO spectra, both multiple short-term enhancements and seasonal variation of NO column are observed [Isono et al., 2014]. The short-term enhancements are correlated with the energetic particle precipitation. In the present study, O_3 profiles are retrieved from the brightness temperature spectra between 238.94-239.24 GHz, whose spectral range has sensitivity to the O_3 abundance between 20 and 70 km. The optimal estimation scheme is used for the O_3 profile retrieval, along with radiative transfer calculation through the use of the NCEP reanalysis data and spectroscopic parameters. Since the O_3 spectra are integrated over 1 hour every 6 hours, we usually derive four O_3 profiles in a day. We present the result of O_3 retrieval and discuss how the O_3 mixing ratios at given altitudes response to the short-term NO column enhancement.

Current status of Syowa lidar project in the prioritized observation project for VIII-th term JARE

EJIRI, Mitsumu K.[1*] ; TSUDA, Takuo[1] ; NISHIYAMA, Takanori[1] ; ABO, Makoto[2] ; TOMIKAWA, Yoshihiro[1] ; SUZUKI, Hidehiko[3] ; KAWAHARA, Takuya[4] ; TSUTSUMI, Masaki[1] ; NAKAMURA, Takuji[1]

[1]National Institute of Polar Research, [2]Graduate School of System Design, Tokyo Metropolitan University, [3]College of Science, Rikkyo university, [4]Faculty of Engineering, Shinshu University

The National Institute of Polar Research (NIPR) is leading a six year prioritized project of the Antarctic research observations since 2010. One of the sub-project is entitled ”the global environmental change revealed through the Antarctic middle and upper atmosphere”. Profiling dynamical parameters such as temperature and wind, as well as minor constituents is the key component of observations in this project, together with a long term observations using existent various instruments in Syowa, Antarctica (69S, 39E). As a part of the sub-project, Rayleigh/Raman lidar was installed at Syowa Station in January, 2011 and has been operated at more than 350 nights (>3000 hours clear sky) by February, 2014. The Rayleigh/Raman lidar observes temperature and clouds in the mesosphere, the stratosphere and part of the troposphere, and providing seasonal and yearly variations of temperature profiles and data of gravity wave characteristics in the middle atmosphere, as well as high altitude clouds of PMC (polar mesospheric clouds) and PSC (polar stratospheric clouds). In order to extend the height coverage to include mesosphere and lower thermosphere region, and also to extend the parameters observed, a new resonance scattering lidar system with tunable wavelengths is developed at NIPR in Tachikawa (36N, 139E). The lidar transmitter is based on injection-seeded, pulsed alexandrite laser for 768-788 nm (fundamental wavelengths) and a second-harmonic generation (SHG) unit for 384-394 nm (second harmonic wavelengths). The laser wavelengths are tuned in to the resonance wavelengths by a wavemeter that is well calibrated using a wavelength-stabilized He-Ne laser. The new lidar has capabilities to measure density variations of minor constituents such as atomic iron (Fe, 386 nm), atomic potassium (K, 770 nm), calcium ion (Ca^+, 393 nm), and aurorally excited nitrogen ion ($N_2{}^+$, 390-391 nm) and temperature profiles in the mesosphere and lower thermosphere (MLT) region using resonance scatter of K. Currently, the fundamental laser pulses are transmitted with 120-160 mJ/pulse at approximately 25 Hz (i.e., $\sim$3-4 W) and the backscattered signal is received with a 35 cm diameter telescope. The new lidar system will be installed two years later at Syowa Station and provide information on the mesosphere and lower thermosphere as well as the ionosphere. This unique observation is expected to make important contribution to studies on the atmospheric vertical coupling process and the neutral and charged particle interaction. In this talk, current status of the research, observations, and system developments, as well as future plans will be presented.

A Rayleigh/Raman lidar system has been operated by the Japanese Antarctic Research Expedition (JARE) since February, 2011 (JARE 52nd) in Syowa Station Antarctica (69.0S, 39.5E). Polar Mesospheric Cloud (PMC) was detected by the lidar at 22:30UT (+3hr for LT) on Feb 4th, 2011, the first day of a routine operation. This event is the first time to detect PMC over Syowa Station by a lidar [Suzuki et al., 2013]. However, signal to noise ratio (SNR) of the PMC event was not so good due to a large shot noise from a daytime background signal. Moreover, a receiver system was mainly designed for nighttime observations. Therefore, observation of PMC during the midnight Sun, which also corresponds to PMC most active period, was difficult. Thus, to improve SNR of the PMC observation with Syowa Rayleigh/Raman lidar during daytime, a narrow bandpass Fabry-Perot etalon system has been developed and installed in the receiver system on Dec 2013 by JARE 55th. In this paper, Prompt report of a PMC observation with Syowa Rayleigh Raman lidar system equipped with the new etalon unit is presented.

Study on generation and sustaining mechanism for an SSL during a night of high auroral activity above Tromsoe

TAKAHASHI, Toru[1*] ; NOZAWA, Satonori[1] ; TSUDA, Takuo[2] ; OYAMA, Shin-ichiro[1] ; FUJIWARA, Hitoshi[3] ; TSUTSUMI, Masaki[2] ; KAWAHARA, Takuya[4] ; SAITO, Norihito[5] ; WADA, Satoshi[5] ; KAWABATA, Tetsuya[1] ; MATUURA, Nobuo[1] ; HALL, Chris[6]

[1]STEL, Nagoya Univ., [2]NIPR, [3]Faculty of Science and Technology, Seikei Univ., [4]Faculty of Engineering, Shinshu Univ., [5]RIKEN, [6]Univ. of Tromso

We will report observational results about an SSL (Sporadic Sodium Layer) that appeared on 22 January 2012 above Tromso, Norway (69.6deg N, 19.2deg E). An SSL is sudden formation (more precisely, from observer's viewpoint) of a dense thin sodium layer superposed on a normal sodium layer. Characteristic of an SSL is suitable for investigating, in particular, fine structures in the atmosphere such as small scale waves and turbulences. For example, Tsuda et al., GRL, 2011GL048685 [2011] found out a short-period wavelike structure on an SSL with sodium lidar operated Tromso, Norway.

Some generation mechanisms for SSLs have been proposed and discussed. A high correlation between an SSL and a sporadic E (Es) layer occurrences has been reported, and several authors proposed mechanisms how SSLs are generated by association of the Es layers [e.g., von Zahn and Hansen, JATP, 50, 93-104, 1988]. Kirkwood and von Zahn, JAP, 53, 389-407 [1991] have suggested that a strong electric field that generates an Es layer plays an important role for generation of an SSL as well in the auroral region. Recently, Matuura et al. JGR, 118, 1-12, jgra.50414 [2013] have proposed another mechanism that an electric current loop plays an important role for the convergence of positive ions including metallic ions.

Altitudinal temperature gradients have been also discussed as a candidate for an SSL generation. Clemesha et al., JASTP, j.jastp.2010.03.017 [2010] showed that an SSL tended to be located in the region where the temperature gradient is negative. A sodium lidar measurement exhibited a 40 K temperature increase on the topside of the SSL [Gardner et al., JGR, 98, 16,865-16,873, 1993].

We like to point out two concerns to be improved for the previous studies. First, although an SSL is complex phenomenon resulting from the confluence of various mechanisms, most studies focused on one mechanism alone. Second is a temporal resolution to calculate the neural temperature and sodium density. Since the sodium density inside an SSL varies largely and quickly in an order of seconds, data with insufficient resolution mislead our understanding. The temporal resolutions of five minutes used in previous studies are insufficient. In this study, we have derived neutral temperature and sodium density with a 15 second. Furthermore, we have used data obtained with the EISCAT UHF radar, meteor radar and photometer together with the sodium LIDAR at Tromso.

On 22 January 2012, an SSL was observed by the sodium lidar at about 94 km about 19 minutes after hard auroral precipitations. From 2118 UT to 2142 UT, the sodium density inside the SSL was from 2 and 6 times greater than the background sodium density. After 2142 UT the peak of the SSL went up to 96 km and the SSL became thinner than it was. The peak sodium density decreased, but it was still a few times higher than the background sodium density from 2142 UT to 2400 UT. We have calculated the temperature with a 15 second resolution, and have found that there are no remarkable enhancements in temperature profiles inside the SSL from 2118 to 2142 UT. It would be worth to point out that from 2200 to 2400 UT the SSL stayed in the local temperature minimum of the background atmosphere. Gardner et al. JGR. 2004JD005670 [2005] argued that the sodium density has a negative correlation with temperature at topside of the sodium layer. Therefore, our result is likely to indicate that the temperature profile contributes sustention of the SSL in this event. To investigate other candidate mechanisms for the SSL generation, we have analyzed the EISCAT radar data. The EISCAT radar detected an Es layer simultaneously with the SSL. The Es layer was located on about 94 km altitude where the SSL was located from 2118 UT to 2200 UT. However, after 2200 UT the Es layer was located on 2 km below the SSL. This result is likely to indicate that the Es layer contributes the SSL generation.

Seasonal variation of Polar Mesosphere Winter Echo (PMWE) observed by PANSY radar

NISHIYAMA, Takanori[1*] ; SATO, Kaoru[2] ; TSUTSUMI, Masaki[1] ; SATO, Toru[3] ; NAKAMURA, Takuji[1] ; NISHIMURA, Koji[1] ; KOHMA, Masashi[2] ; TOMIKAWA, Yoshihiro[1] ; EJIRI, Mitsumu[1] ; TSUDA, Takuo[1]

[1]National Institute of Polar Research, [2]Department of Earth and Planet Science, Graduate School of Science, The University of Tokyo, [3]Graduate School of Informatics, Kyoto University

In the lower thermosphere at the altitude of around 100 km, both neutral turbulence and ionization of atmosphere due to solar radiations cause irregularities of reflective index, and as a result back scatter echoes from that altitude are frequently observed by radars on the ground. In the mesosphere, Polar Mesosphere Summer Echo (PMSE) is reported to be a strong echo associated with ice particles, which are produced around the coldest mesopause region in the polar summer, by a number of past radar observations [*Cho and Rottger*, 1997; *Rapp and Lūbken*, 2004]. It should be also noted that occurrence rate of PMSE is very high (80-90%) [*Bremer et al*., 2003]. On the other hand, Polar Mesosphere Winter Echo (PMWE) is also known as back scatter echo from 55 to 85 km in the mesosphere, and it has been observed by MST and IS radar in polar region during winter [e.g., *Ecklund and Balsley*, 1981; *Czechowsky et al*., 1989; *Lūbken et al*., 2006; *Strelnikova and Rapp*, 2013]. Due to the lack of of free electrons and ice particles in the dark and warm mesosphere during winter, it is suggested that PMWE requires strong ionization of neutral atmosphere associated with precipitations of Solar Energetic Particles (SEPs) during geomagnetically disturbed periods [*Kirkwood et al*., 2002; *Zeller et al*., 2006]. However, the detailed generation process of PMWE has not been identified yet, partly because the reported PMWE occurrence rate was quite low (2.9%) [*Zeller et al*., 2006].

In the Ⅷ-th six-year project of the Japanese Antarctic Research Expedition (JARE) from 2010, the middle and upper atmosphere research is one of the sub-projects of the prioritized research project entitled 'Global warming revealed from the Antarctic', and comprehensive ground based observations with various remote sensing instruments for the middle and upper atmosphere have been operating continuously in Syowa station. We analyzed data obtained by PANSY (Program of the Antarctic Syowa MST/IS) radar, which is the core instrument of the project, focusing on PMWE in the context of neutral-plasma atmospheric coupling process between the middle and upper atmosphere. PANSY radar is a 47 MHz VHF radar with 125 kW (full system 500 kW) output power, and it is the largest MST radar composed 5,000 m^2 (full system 20,000 m^2) antenna array in Antarctica at the moment. PANSY has already identified a number of PMWE near local noon since operation of mesosphere observation mode was started in June 2012.

We would like to show seasonal variations of occurrence characteristics of PMWE between June 2012 and July 2013. Taking full advantage of PANSY radar's detectability, we calculated monthly-averaged height-time section of backscatter echo power in austral winter between 2012 and 2013. The result demonstrated that durations of PMWE strongly depended on hours of sunlight, although occurrence heights of PMWE, which range from 60 to 80 km, were fixed on every month and year. These statistical characteristics of PMWE were consistent with previous studies suggesting ionization at the PMWE height due to solar radiation play a dominant role in generation of PMWE [*Zeller et al*., 2006; *Lūbken et al*., 2006]. However, the mean occurrence rate of PMWE estimated by our study was 20-30%, which was considerably higher than that of previous studies. It implies that atmospheric turbulence in the mesosphere would be driven by breakings of atmospheric gravity waves more frequently than past observations, especially in Antarctica, and the role of atmospheric gravity waves cannot be ignored when considering the long-termed climate changes.

Analysis of atmospheric gravity waves observed by airglow imaging at Syowa Station (69S,39E), Antarctica

MATSUDA, Takashi S.[1*] ; NAKAMURA, Takuji[2] ; EJIRI, Mitsumu K.[2] ; TSUTSUMI, Masaki[2] ; SHIOKAWA, Kazuo[3] ; TAGUCHI, Makoto[4] ; SUZUKI, Hidehiko[4]

[1]Graduate University for Advanced Studies, [2]National Institute of Polar Research, [3]Solar-Terrestrial Environment Laboratory, Nagoya University, [4]Rikkyo University

Atmospheric gravity waves (AGWs), which are generated in the lower atmosphere, transport significant amount of energy and momentum into the mesosphere and lower thermosphere and cause the mean wind accelerations in the mesosphere. This momentum deposit drives the general circulation and affects the temperature structure. Among many parameters to characterize AGWs, horizontal phase velocity is very important to discuss the vertical propagation. Airglow imaging is a useful technique for investigating the horizontal structures of AGWs at around 90 km altitude. Recently, there are many reports about statistical characteristics of AGWs observed by airglow imaging. However, it is difficult to compare these results obtained at various locations because each research group uses its own method for extracting and analyzing AGW events. In order to deal with huge amounts of imaging data obtained on different years and at various observation sites, without bias caused by different event extraction criteria for the observer, we have developed a new statistical analysis method for obtaining the power spectrum in the horizontal phase velocity domain from airglow image data. This method was applied to the data obtained at Syowa Station, Antarctica, in 2011 and compared with a conventional event analysis in which the phase fronts were traced manually in order to estimate horizontal characteristics. This comparison shows that our new method is suitable for deriving the horizontal phase velocity characteristics of AGWs observed by airglow imaging technique.

We plan to apply this method to airglow imaging data observed at Syowa Station in 2002 and between 2008 and 2013, and also to the data observed at other stations in Antarctica (e.g. Rothera Station (67S, 68W) and Halley Station (75S, 26W)), in order to investigate the behavior of AGWs propagation direction and source distribution in the MLT region over Antarctica. In this presentation, we will report interim analysis result of the data at Syowa Station.

First detection of daytime tweek atmospherics observed at Moshiri and Kagoshima, Japan

OHYA, Hiroyo[1*] ; SHIOKAWA, Kazuo[2] ; MIYOSHI, Yoshizumi[2]

[1]Graduate School of Engineering, Chiba University, [2]Solar-Terrestrial Environment Laboratory, Nagoya University

It is well known that tweek atmospherics can be observed only at night except for solar eclipse days, because daytime attenuation rate of the tweeks is much larger (˜70 dB/1000 km) than that in nighttime (˜3 dB/1000 km). In this presentation, we firstly report detection of daytime tweeks at Moshiri (Geographic coordinate: 44.37^{o}N, 142.27^{o}E) and Kagoshima (31.48^{o}N, 130.72^{o}E), Japan, on non-solar eclipse days in December, 1980. The daytime tweeks were observed both before and during a large magnetic storm during 16-20 December, 1980. The minimum Dst value was -240 nT at 04:00 UT on 20 December. The average occurrence numbers of the daytime tweeks at Moshiri and Kagoshima were 2.7 and 0.3 tweeks per minute, respectively. The local times (LT) when the daytime tweeks occurred were through 07:00 - 17:00 LT at Moshiri, while they were 07:00 - 09:00 LT and 15:00 - 17:00 LT at Kagoshima. All the daytime tweeks show clear frequency dispersion. The average duration was 18.94 ms, while that of nighttime tweeks is ˜50 ms. The average reflection heights of daytime tweeks at Moshiri and Kagoshima were 86.2 km and 94.7 km, respectively. The average reflection heights of nighttime tweeks at Moshiri and Kagoshima in same period were 87.1 km and 92.1 km, respectively. The variation of the daytime tweek reflection height was higher than that of nighttime tweeks. The horizontal propagation distance in daytime cannot be estimated from the dispersion, because the duration was too short to estimate the distance.

We found through a theoretical consideration that the VLF/ELF attenuation on the D-region ionosphere depends not only on the ionospheric height, but also the sharpness of electron density profiles, β. The β is a conventional parameter proposed by Wait and Spies [1964]. When the β increases, the attenuation decreases. Even daytime, when the β is occasionally large, the attenuation would become less down to be able to observe the tweeks. In this talk, we will show the results of the daytime tweeks and discuss their occurrence mechanism.

Long term variation of geomagnetic Sq field over 100 years

TAKEDA, Masahiko[1*]

[1]Data Analysis Center for Geomag. and Space Magnetism, Kyoto Univ

The long-term variation of the geomagnetic Sq field over 100 years at several observatories was studied in the Y-component as well as the ionospheric conductivity estimated by the IRI model. The amplitude of the geomagnetic Y-component (Sq(Y)) depended strongly on solar activity, and showed features similar to those in the solar activity even when 11-years running averages were employed. The solar activity dependence of Sq(Y) can be fully explained by that of the ionospheric electrical conductivity, and wind velocity tends to be large for low solar activity; and slower in the middle of the 1900s in response to higher long-term solar activity. On the other hand, other long-term variations were not clear in the wind velocity. Although the dynamo theory predicts that the Sq current is enhanced when geomagnetic main field intensity decreases, the result of the present analysis does not necessarily support this prediction.

Long-term variation in the upper atmosphere as seen in the geomagnetic solar quiet (Sq) daily variation

SHINBORI, Atsuki[1*] ; KOYAMA, Yukinobu[2] ; NOSE, Masahito[2] ; HORI, Tomoaki[3] ; OTSUKA, Yuichi[4] ; YATAGAI, Akiyo[4]

[1]Research Institute for Sustainable Humanosphere (RISH), Kyoto University, [2]Data Analysis Center for Geomagnetism and Space Magnetism Graduate School of Science, Kyoto Universi, [3]Nagoya University Solar Terrestrial Environment Laboratory Geospace Research Center, [4]Solar-Terrestrial Environment Laboratory, Nagoya University

It has been well-known that the geomagnetic field on the ground shows a regular variation with a fundamental period of 24 hours during a solar quiet day. This daily variation depends on local time, latitude, season and solar cycle and has been called solar quiet (Sq) geomagnetic field daily variation. The Sq variation is mainly produced by magnetic effects due to ionospheric currents flowing in the E region of the ionosphere around 105 km. The global pattern of the Sq variation of the H-component shows positive and negative changes in the equatorial and middle-latitude regions around noon, respectively. The Sq current system expected from the geomagnetic field perturbations consists of two large current vortices: one is an anticlockwise current in the northern hemisphere and the other is a clockwise current in the southern hemisphere. The Sq current is dominant in the daytime ionosphere where ionospheric conductivity is relatively large, and is driven by electric fields originating from the ionospheric dynamo via the interaction between ionized and neutral particles. According to the Ohm's law, the main variables in the Sq amplitude are the ionospheric conductivity, the polarization electric field, the solar diurnal tide, and the intensity of the ambient magnetic field at the E-region height. Then, to investigate the long-term variation in the Sq amplitude is important for understanding the physical mechanism of long-term variation in the upper atmosphere related to solar activity and lower atmospheric change such as global warming. In this study, we investigated long-term variation in the Sq amplitude using 1-hour geomagnetic field data obtained from 184 geomagnetic observation stations within a period of 1947-2012 in order to clarify the physical mechanism of long-term variation in the upper atmosphere. For the analysis of long-term observation data obtained from a lot of geomagnetic stations, we took advantage of the IUGONET data analysis system (metadata database search system and data analysis software). The Sq amplitude is defined as a difference of the H-component of geomagnetic field between the maximum and minimum values each solar quiet day. We identified the solar quiet day as the day when the maximum Kp value is less than 4 for each day. As a result, the Sq amplitude observed at all the geomagnetic stations showed a clear dependence on the 11-year solar activity and it tended to be enhanced significantly during solar maximum. The Sq amplitude became the smallest around the minimum of 23/24 solar cycle in 2008-2009. The relationship between the Sq amplitude and F10.7 solar activity index was not linear but nonlinear. This nonlinearity could be interpreted as the decrease of production rate of electrons and ions in the ionosphere for the strong extreme ultraviolet (EUV) and ultraviolet (UV) fluxes. In order to minimize an effect of solar activity including the long-term variation in the Sq amplitude, we calculated second orders of fitting curve between the F10.7 solar index and Sq amplitude during 1947-2012, and examined the residual Sq amplitude defined as the deviation from the fitting curve. As a result, majority of the residual Sq trends passed through the trend test showed a negative value without dependence on geographical latitude and longitude. The tendency was strong in India, the southern part of Africa, and the northern part of America and Europe. In a region of northern part of America and Europe, the secular variation of magnetic inclination becomes relatively large, compared with other regions. Therefore, the long-term trend in the residual Sq amplitude could be linked to a change in the ionospheric conductivities associated with the secular variation of the ambient magnetic field and the upper atmosphere and electro motive force (UxB) via the interaction between ionized and neutral particles.

Temporal increases of horizontal speed of frontal Es observed by HFD

TOMIZAWA, Ichiro[1*] ; MIYAWAKI, Masami[1]

[1]Center for Space Science and Radio Engineering, The University of Electro-Commnunications

In the yearly analysis of the horizontal speed of frontal Es by using the HFD observation data of the year 2012, we found some events which showed temporal increase and then decrease within the time scale from 40 to 270 minutes. The rate of the temporal speed enhancements were only 2.4 % in all frontal Es events in 2012, and the enhances were mainly observed aroun 21h JST in summer. The rate of the speed enhancement were less than 30 %, but some peak speeds increased up to more than 200 m/s. The duration times varied from 40 to 300 min, but most of the events terminated within 150 min. The average leading and trailing times were 35 and 50 min, respectively, so the trailing part took long time. The cause of temporal speed variation can be related to time variation of horizontal electric field or of horizontal wind speed of neutral atmosphere in the E layer. The former should show coincidence over the wide area but the latter would show some time difference. Analyzing pair data over 100 km separation, we obtained time delay less than 20 min. It is therefore interpreted that the temporal speed increase is caused by the change of the horizontal wind speed. Because the distance between successive Es front shows the minimum of less than 50 km around the speed peak, and increases upto 200 km both to the start and to the end, it can be attributed to the inequally spaced Es front. Combining all separation distances for each event, we get the outer size of the temporal variation as 400 km for 65 %, and as the maximum of 1400 km. On the otherhand, it can be related to a non-isotropic structure because the peak speed did show different values for the separate stations. Based on those observational results, it is concluded that the temporal speed increase may be introdued by a spiral-like, instead of linear, structure.

Medium-scale traveling ionospheric disturbance (MSTID) is an interesting phenomenon in the F-region. The MSTID is frequent in summer nighttime over Japan, showing wave structures with wavelengths of 100-200 km, periodicity of about 1 hour, and propagation toward the southwest. The phenomena are observed by the total electron content (TEC) from GEONET, Japanese dense network of GPS receivers, and 630 nm airglow imagers as horizontal pattern. It was also measured as Spread-F events of ionograms or as field-aligned echoes of the MU radar. MSTID was, in the past, explained by Perkins instability (Perkins, 1973) while its low growth rate was a problem. Recently 3D simulation study by Yokoyama et al (2009) hypothesized a generation mechanism of the MSTID, which stands on electromagnetic E/F-region coupling of the ionosphere. The hypothesis is that the MSTID first grows with polarization electric fields from sporadic-E, then show spatial structures resembling to the Perkins instability. We recently conducted a observation campaign to check this hypothesis. We launched JASA ISAS sounding rockets S-310-42 and S-520-27 at 23:00 JST and 23:57JST on July 20, 2013 while an MSTID event was monitored in real-time by the GPS-TEC from GEONET. We found 1-5mV/m northeastward/eastward electric fields during the flight. Variation of electric fileds were associated with horizontal distribution of plasma density. Wind velocity was measured by the TME and Lithium releases from S-310-42 and S-520-27 rockets, respectively, showing southward wind near the sporadic-E layer heights. These results are consistent to the expected generation mechanism shown above. In the presentation we will discuss electric-field results and its relationship with plasma density variability together with preliminary results from the neutral-wind observations.

Characteristics of O630nm emission associated with equatorial ionization anomaly obtained with IMAP/VISI

SAKAMOTO, Daiki[1] ; SAKANOI, Takeshi[1*] ; PERWITASARI, Septi[1] ; OTSUKA, Yuichi[2] ; SAITO, Akinori[3] ; AKIYA, Yusuke[3] ; HOZUMI, Yuta[3] ; YAMAZAKI, Atsushi[4]

[1]Grad. School of Science, Tohoku University, [2]STEL, Nagoya University, [3]Grad. School of Science, Kyoto University, [4]ISAS / JAXA

The Equatorial Ionization Anomaly (EIA) is occurred by plasma upwelling due to eastward electric field in the dayside magnetic equator, and descends to both northern and southern hemispheres along the field line. Density maximum appears around geomagnetic latitudes of +/-15 degree at both hemispheres. Since most of the past studies carried out with ground experiments, it is difficult to observe a wide area and study the variability of the northern and southern O630nm emission associated with EIA.

IMAP/VISI on the International Space Station(ISS) measures O630 nm airglow emission in the nightside hemisphere at an altitude of 400km. It covers the latitudinal range between +/-52 degrees with a typical spatial resolution of 1x14 km. Because of the wide observation coverage, it is possible to observe the variability of O630nm airglow associated with the EIA.

In this study, we carried out a statistical analysis using IMAP/VISI data from September 2012 to December 2013 to understand the variability of O630nm airglow associated with the EIA, particularly on its local time dependence, seasonal variation and geomagnetic activity. We derived the integrated intensity of O630nm emission along latitude with the four criteria as follows: (1) The O630nm emission in the EIA is greater than the background airglow that was determined by emission intensity in the middle latitude. (2) Latitudinal distribution of O630nm emission in the EIA is fully measured. (3) The northern and southern O630nm emission in the EIA is clearly separated. (4) The moon phase is smaller than 0.5. In case that the moon phase is bigger than 0.5 then we used the data when the moon did not appear.

We find that the time dependence of O630nm emission which is decreased from the evening toward the post mid-night. But there is a large variance in the intensity at the same local time. This fact suggests that other process, such as the longitude and/or seasonal variation, may affect the O630nm emission associated with the EIA in addition to the local time dependence.

On the seasonal dependence, we find that O630nm emission in the EIA in the winter hemisphere is greater than that in the summer hemisphere. This is consistent with the model that the thermospheric tidal wind affects the 630 nm intensity, namely, the tidal wind decreases the altitude of O630 nm emission layer and finally gain the O630 nm intensity.

To examine the longitudinal dependence, we used the data in equinox (September and October, 2013) and find that O630nm emission in the EIA in the northern hemisphere is greater than that in the southern hemisphere where the dip equator is the south of geographic equator (longitude is between 200 degree ? 310 degree). This is also consistent with the model that the thermospheric tidal wind controls the O630 nm intensity by making a vertical motion of emission layer.

Finally, we investigate the magnetic storm dependence on O630 nm intensity and find that significant decrease of O630nm intensity in the EIA happens during the period when the Dst index is larger than 90. From this fact, it is plausible that westward electric field in Region 2 current system penetrates to the low latitude region during the main phase of magnetic storm and reduce the formation of EIA.

Analysis of the airglow structures using the simultaneous observations by ISS-IMAP and all-sky imagers

YUKINO, Hideko[1*] ; SAITO, Akinori[1] ; OTSUKA, Yuichi[2] ; SAKANOI, Takeshi[3]

[1]Dept. of Geophysics, Kyoto Univ., [2]STEL, Nagoya Univ., [3]Grad. School of Science, Tohoku Univ.

The spatial structure of the atmospheric gravity waves in the mesosphere was analyzed using the simultaneous observational data of ISS-IMAP and the all-sky imager at Hawaii. There are a plenty of ground-based observations of the atmospheric gravity waves in the mesosphere and the thermosphere. The problem of the ground-based observation is that it cannot distinguish spatial variations from temporal variations for the structures whose scale size is larger than its field-of-view. ISS-IMAP was launched on July 21, 2012 to observe the atmospheric gravity waves whose scale size is larger than 100 km. The altitude of the International Space Station (ISS) flies around 400 km altitude, and its orbital inclination angle is 51.6 degrees. ISS-IMAP/VISI (Visible-light and infrared Spectrum Imager) observes the airglow in the mesosphere and the ionosphere. The spatial resolution of the VISI imaging observation is from 10 km to 25 km. The airglow wavelengths observed by VISI are 630 nm, 730 nm, and 762 nm and by the ground-based all-sky image of Hawaii (20.48 N, 156.2 W) are 630 nm and 557.7-nm with 5.5 minutes interval. The observational data of ISS-IMAP/VISI and an all-sky imager in Hawaii were investigated for the nights when VISI made the observation over Hawaii, and the sky over the imager was clear. The night when the plasma bubble was detected by the ground-based all-sky imager, the plasma bubble was detected by the 630nm airglow observation of ISS-IMAP/VISI. The spatial and vertical structures of the airglow that were observed by the ground-based imager and the ISS-IMAP/VISI were analyzed. The sensitivity of the observation of ISS-IMAP/VISI will also be discussed in the comparison of the ground-based observation.

Horizontal structures of ionized Helium in the topside ionosphere of dusk side were obtained with the Extreme Ultra Violet Imager (EUVI) of the ISS-IMAP (Ionosphere, Mesosphere, upper Atmosphere and Plasmasphere mapping) mission. EUVI has taken image of He He II radiation (30.4 nm) from the International Space Station (ISS) since October 2012. In this work, images taken in 2013 were analyzed. North-south asymmetry and longitudinal structure of ionized Helium were found. Seasonal dependence of these horizontal structures will be discussed.

Study of ionospheric disturbance characteristics during solar flare events using the SuperDARN Hokkaido radar

WATANABE, Daiki[1] ; NISHITANI, Nozomu[1*]

[1]Solar-Terrestrial Environment Laboratory, Nagoya University

Ionospheric disturbances during solar flare events have been studied by various kinds of observation instrument in the last few decades. Kikuchi et al. (1985) reported on the positive Doppler shift in the HF Doppler system data during solar flare events, and indicated that there are two possible factors of Doppler shift, i.e., (1) apparent ray path decrease by changing refraction index due to increasing electron densities in the D-region ionosphere, and (2) ray path decrease due to descending reflection point associated with increasing electron density in the F-region ionosphere.

In this study, we use the SuperDARN Hokkaido Radar to investigate the detailed characteristics of solar flare effects on ionospheric disturbances. We focus on the positive Doppler shift of ground / sea scatter echoes just before sudden fade-out of echoes. Davies et al. (1962) showed that if the factor (1) is dominant, the Doppler shift should have positive correlation with slant range and negative correlation with elevation angle and frequency. On the other hand, if the factor (2) is dominant, the Doppler shift should have negative correlation with slant range and positive correlation with elevation angle and frequency. While Kikuchi et al. (1985) studied solar flare events and mainly discussed frequency dependence of Doppler shift, we study mainly slant range and elevation angle dependence, for the first time to the best of our knowledge. We found that the factor (1), in other words, increase of electron densities at D-region ionosphere, is dominant during solar flare events. This result is consistent with that of Kikuchi et al. (1985). In order to study characteristics of ionospheric disturbance in more detail, we are studying relationship between timing / amplitude of ionospheric disturbance and that of the solar irradiation changes, by comparing the HF radar data with high wavelength resolution irradiation data for X-ray and EUV from RHESSI and SDO satellites. Generally, X-ray radiation becomes more important for the changes in the D-region during solar flare events. Therefore we investigate relationship between X-ray flux changes and electron density variation in the D-region ionosphere intensively. Furthermore, we estimated electron density changes in the ionsosphere by analyzing elevation angle dependence of Doppler shift in radar echoes quantitatively. We are estimating electron density by considering chemical reaction and photoreaction caused by solar radiation. We will compare the two electron density changes deduced from different two ways and evaluate the amplitude of ionospheric disturbance observed by the HF radar. More detailed analysis result will be reported.

Thermospheric tidal effects on the ionospheric midlatitude summer nighttime anomaly

CHEN, Chia-hung[1*] ; LIN, Charles[1] ; CHANG, Loren[2] ; HUBA, J. D.[3] ; SAITO, Akinori[4] ; LIU, Jann-yenq[2]

[1]Department of Earth Science, National Cheng Kung University, Tainan, Taiwan, [2]Institute of Space Science, National Central University, Chung-Li, Taiwan, [3]Plasma Physics Division, Naval Research Laboratory, Washington, D. C., USA, [4]Department of Geophysics, Kyoto University, Kyoto, Japan

This study use a 3D physics-based ionospheric model, SAMI3, coupled with the National Center for Atmospheric Research Thermosphere Ionosphere Electrodynamics General Circulation Model (TIEGCM) and Global Scale Wave Model (GSWM) to simulate the mesospheric and lower thermosphreic tidal effects on the development of midlatitude summer nighttime anomaly (MSNA). Using this coupled model, the diurnal variation of MSNA electron densities at 300 km altitude is simulated on both June solstice (day of year (DOY) 167) and December solstice (DOY 350) in 2007. Simulation results show successful reproduction of the southern hemisphere MSNA structure including the eastward drift feature of the southern MSNA, which is not reproduced by the default SAMI3 runs using the neutral winds provided by the empirical Horizontal Wind Model 93 (HWM93) neutral wind model. A linear least squares algorithm for extracting tidal components is utilized to examine the major tidal component affecting the variation of southern MSNA. Results show that the standing diurnal oscillation component dominates the vertical neutral wind manifesting as a diurnal eastward wave-1 drift of the southern MSNA in the local time frame. We also find that the stationary planetary wave-1 component of vertical neutral wind can cause diurnal variation of the summer nighttime electron density enhancement around the midlatitude ionosphere.

Horizontal ion drag effect on the thermospheric mass density anomaly in the cusp

MATSUMURA, Mitsuru[1*] ; TAGUCHI, Satoshi[2]

[1]Center for Space Science and Radio Engineering, University of Electro-Communications, [2]Graduate School of Informatics and Engineering, University of Electro-Communications

CHAMP satellite observations have revealed that the thermospheric mass density in the cusp region is statistically larger by a factor of about 1.3 than that in its adjacent region. Many studies have pointed out that the upward mass transport due to heating is important for the generation of the mass density anomaly, but what confines the heating rate to the cusp is controversial. We have paid attention to the effect of the horizontal mass transport. Our reasoning on this point is as follows. Ionospheric convection gives momentum to the neutral air through ion drag, and the ion drag can modify the distribution of the neutral mass density. Our recent results from numerical simulations have indicated that the ion drag enhances the neutral mass density in the cusp that the terminator overlaps. In this paper, we report on the result about more general situations including cases when the terminator is located away from the cusp. Our results show that the mass density anomaly is confined to the cusp by ion drag, irrespective of the location of the terminator. We show detailed relations between the ion drag distribution and the mass density enhancement or depletion.

Edge of polar cap patches

HOSOKAWA, Keisuke[1*] ; TAGUCHI, Satoshi[1] ; OGAWA, Yasunobu[2]

[1]University of Electro-Communications, [2]National Institute of Polar Research

A highly sensitive all-sky EMCCD airglow imager (ASI) has been operative in Longyearbyen, Norway (78.1N, 15.5E) since October 2011. One of the primary targets of this optical observation is a polar cap patch which is defined as an island of enhanced plasma density in the F region drifting anti-sunward across the central polar cap. Since the electron density within patches is often increased by a factor of 2?10 above that in the surrounding region, all-sky airglow measurements at 630.0 nm wavelength are capable of visualizing their spatial distribution in 2D fashion.

During a 4-h interval on the night of December 4, 2013, a series of polar cap patches was observed by the ASI in Longyearbyen. By using the high-quality ASI images, we estimated the gradients in the leading/trailing edges of the patches and found that the gradient in the leading edge is 2-3 times steeper than that in the trailing edge. We also identified finger-like undulating structures growing along the trailing edge of the patches. Generation of these fingers is probably governed by a structuring through the gradient-drift instability which is known to occur only along one side of patches.

From these observations, we suggest that such a structuring process can transport and mix the patch plasma across their trailing edges so that the scale size of the edges get extended. This means that the structuring through the plasma instability can strongly influence the large-scale shape of patches. Such a knowledge is of particular importance for better understanding the space weather effects of patches on the trans-ionospheric satellite communications in the polar cap region.

Correlation analysis between equatorial electrojet,pre-reversal enhancement and equatorial spread F in Southeast Asia

KUNITAKE, Manabu[1*] ; TSUGAWA, Takuya[1] ; YOKOYAMA, Tatsuhiro[1] ; NISHIOKA, Michi[1] ; YAMAMOTO, Kazunori[1] ; ISHIBASHI, Hiromitsu[1] ; NAGATSUMA, Tsutomu[1] ; MARUYAMA, Takashi[1] ; ISHII, Mamoru[1] ; SHIOKAWA, Kazuo[2]

[1]NICT, [2]STE Lab., Nagoya Univ.

At the equatorial latitudes, the reversal of dayside eastward electric field to westward around sunset is often accompanied by a strengthened eastward electric field. The strengthened eastward electric field is called as the pre-reversal enhancement (PRE). PRE is considered to be the primary process acting on the equatorial spread F (ESF) onsets. Relationships between PRE strength, ESF onsets, and equatorial electrojet (EEJ) strength have been investigated by using ionosonde observation and magnetometer observation. Uemoto et al. (2010) found that PRE strength and ESF onsets are suppressed when pre-sunset integrated EEJ from 2 hours to 1 hour prior to sunset is negative owing to the evening counter electrojet, by statistical analysis of observations in the Southeast Asia low-latitude ionospheric network (SEALION). Their analyzing period is from November 2007 to October 2008. The period is in solar minimum phase.

We use SEALION data from 2007 to 2013. Therefore, our analyzing period covers not only solar minimum phase but also solar maximum phase. Statistical analyses for each year are conducted. Further, detailed case study is conducted. Significant day-to-day variations of EEJ strength, PRE strength, and ESF onsets are picked up from these seven years data. Then, we investigate how and to what extent day-to-day variations of EEJ strength relate to the day-to-day variations of PRE strength and ESF onsets. The magnetometer data in our study were obtained at Phuket (geographic lat. 8.09N, geographic long. 98.32E, dip lat. -0.2) and Kototabang (0.20S, 100.32E, dip lat. -10.1). The ionosonde data in our study were obtained at Chumphon (10.72N, 99.37E, dip lat. 3.0), Chiang Mai (18.76N, 98.93E, dip lat. 12.7), and Kototabang (0.20S, 100.32E, dip lat. -10.1).

Low-latitude ionosphere dynamics as deduced from meridional ionosonde chain: Ionospheric ceiling

MARUYAMA, Takashi[1*] ; UEMOTO, Jyunpei[1] ; ISHII, Mamoru[1] ; TSUGAWA, Takuya[1] ; SUPNITHI, Pornchai[2] ; KOMOLMIS, Tharadol[3]

[1]National Institute of Information and Communications Technology, [2]King Mongkut's Institute of Technology Ladkrabang, [3]Chiang Mai University

Peculiar ionospheric features at low latitudes originate in the earth's magnetic field configuration that has a shape of arch. Near the magnetic equator, the daytime eastward electric field raises the ionosphere to high altitudes where the ion-neutral collision frequency reduces. The ionospheric plasma slips down over off-equatorial latitudes along the arch-shaped magnetic field line by the earth's gravity acceleration and the reduced ion-neutral drag, which is called the fountain effect. As a consequence, the latitudinal distribution of ionospheric critical frequency (foF2) forms two crests at low latitudes and a trough above the magnetic equator, which is well-known equatorial anomaly in foF2 distribution. As for the diurnal variation of the ionosphere above the magnetic equator, foF2 once increases in the morning and decreases before noon along with the development of the equatorial anomaly, which is called noon bite-out. Another feature at the magnetic equator, associated with the fountain effect, is the relatively steady ionospheric peak height (hmF2) around noon, even though the EXB drift is upward throughout the daytime. However, not much attention has been paid to hmF2 except for the time rate of change of it in connection with the vertical plasma drift velocity.

Interest in the equatorial anomaly has been focused mostly on foF2 (or NmF2), and there have been a few studies on hmF2 variations associated with equatorial anomaly development. In this paper, we revisit the equatorial anomaly in terms of height variations. For this purpose, we analyzed scaled ionogram parameters from three stations located along the magnetic meridian that is a primary component of Southeast Asia low-latitude ionospheric network (SEALION); one at the magnetic equator and the others at conjugate off-equatorial latitudes near 10 degrees magnetic latitude.

The daytime hmF2 was investigated for each season during the solar minimum period, 2006-2007 and 2009. The peak height increased for approximately 3 hr after sunrise at all locations, as expected from the daytime upward EXB drift. The apparent upward drift ceased before noon at the magnetic equator, while the layer continued to increase at the off-equatorial latitudes, reaching altitudes higher than the equatorial height around noon. The noon time restricted layer height at the magnetic equator did not depend on the season, while the maximum peak height at the off-equatorial latitudes largely varied with season. The daytime specific limiting height of the equatorial ionosphere was termed ionospheric ceiling. Numerical modeling using the SAMI2 code reproduced the features of the ionospheric ceiling quite well. Dynamic parameters provided by the SAMI2 modeling were investigated and it was shown that the ionospheric ceiling is another aspect of the fountain effect, in which increased diffusion of plasma at higher altitudes has a leading role.

Three-dimensional high-resolution plasma bubble modeling

YOKOYAMA, Tatsuhiro[1*] ; SHINAGAWA, Hiroyuki[1] ; JIN, Hidekatsu[1]

[1]National Institute of Information and Communications Technology

Equatorial plasma bubble (EPB) is a well-known phenomenon in the equatorial ionospheric F region. As it causes severe scintillation in the amplitude and phase of radio signals, it is important to understand and forecast the occurrence of EPB from a space weather point of view. The development of EPB is known as a evolution of the generalized Rayleigh-Taylor instability. Numerical modelings of the instability on the equatorial two-dimensional plane have been conducted since the late 1970's, and the nonlinear evolution of the instability has been clearly presented. Recently, three-dimensional (3D) modelings became popular tools for further understanding of the development of EPB such as 3D structure of EPB, meridional wind effects and gravity wave seeding. One of the biggest advantages of the 3D model is that the off-equatorial E region which is coupled with the equatorial F region can be included in the model. It is known from observations that the conductance of the off-equatorial E region controls the growth rate of the Rayleigh-Taylor instability, that is, sudden decrease of the E-region conductance around the sunset accelerates the evolution of the instability. We have developed a new 3D high-resolution model for EPB, and studied internal structure of EPB and the contribution of the off-equatorial E region. As it is necessary to use high-order numerical schemes to capture sharp plasma density gradient of EPB, we adopted the CIP scheme which can keep the third-order accuracy in time and space. The simulated EPB has asymmetrical density gradients at east and west walls, and the growth rate changes significantly depending on the condition of the off-equatorial E region. In the future, we will integrate the high-resolution model into whole atmosphere-ionosphere coupled model (GAIA) to study the growth of EPB under the realistic background conditions.

1. Introduction

In Japan, the high altitude balloon for scientific observation has been continuously launched by JAXA. The balloon has a possibility to reach 50 km altitude without severe environmental condition for onboard equipments, being operated with lower cost than sounding rockets, however, development of such large-scale scientific observating balloons by university laboratories is still difficult. Being coupled with rapid improvement of tiny semiconductor sensors recently, laboratory-basis balloon experiments using small weather balloons have been becoming easily in these years (e.g. Near Space Ventures, Inc., 2013).

Although the balloon is very small as its diameter of 6 feets, excluding its extra buoyancy and the weight of the balloon itself, it is expected that loading mass capacity of about 2 kg is remained for payloads to send it up to about 35 km. However, operation of such small balloons in Japan is not in general because precise prediction of a landing area of the payload is difficult, thus high-risk situation for balloon releases is still remained. In this study, we aim to achieve practical engineering experiments of weather balloons in Japan in order to operate laboratory level scientific observation within a university. Here we report an approach of developing many devices currently in progress.

2. Equipments development

We have been developing devices onboard a small tethered balloon for the future weather balloon release experiments. That is, one is a small-size and light-weight telemeter system of about 250 g that can be mounted on a commercially available balloon, while another is a ground station device that receives data from the telemeter. A combination of a wireless module, a GPS receiver, a barometer, a temperature and humidity meter, a camera, an accelerometer, an electronic compass, a power monitor sensor is mounted on the telemeter, and the measured values by each sensors can be transmitted in real time to the ground station device. Newly developed software for balloon operation can be run on a PC connected with the ground station device, it is possible to provide the operator the sensor information visualized in real time based on the position coordinates set on the ground station device using the software before the launch.

Real-time mapping of the balloon coordinates can be realized to rewrite a KML file to be input into the Google Earth continuously. In addition, azimuth and elevation of the balloon can be calculated by spherical trigonometry from obtained the GPS position. Providing these angles to a newly developed rotater to be mounted on a camera tripod, it is possible to track a small antenna automatically to the balloon direction continuously.

3. Result of the experiment

A tethered balloon experiment was performed for evaluating the developed telemeter system, however, there occurred unexpected issue in the communication distance. As a result, in the telemeter line, operating limit of the distance between the ground station and the telemeter is significantly shortened to approximately 110 m. It was almost different from our pre-experiment confirmation of a packet loss rate of 0% at 270 m distance in a preliminary experiment on ground.

Therefore, evaluation of the antenna rotator was carried out only at close range, i.e., in severe condition. It is because maximum elevation of the rotator was limited physically at 50 degrees or less, and there exists about 5 to 10 m error in the GPS positioning operated in the single receiver mode.

Nevertheless, it was possible to track the balloon continuously in a stable situation even in the shortened communication distance. In addition, the software and telemeter system worked as expected, the problem was not found in particular.

In this presentation, the data obtained by the tethered balloon experiment and detail of the developed equipments will be shown.

Impacts of stratospheric sudden warming (SSW) events on the middle and upper atmosphere have been widely recognized. However, due to an insufficient number of global observations, SSW's effects on the general circulation in the mesosphere and lower thermosphere (MLT) are not well known. In this study, we investigate the short term variation of the temperature, zonal wind and meridional wind in the MLT region during SSW events using a general circulation model that contains the region from the troposphere to the thermosphere. We conducted GCM simulation with meteorological reanalysis data during the period from November 1, 2008 to March 31, 2010. Our results show that the temperature drop occurs in the Southern hemisphere, during SSW events. This means that SSW influences the general circulation in the summer hemisphere. Furthermore, it is found that the temperature in winter polar region in the lower thermosphere increases during SSW events. This is related to upward propagation of the planetary wave excited in the mesosphere.
