Coastal areas in the Kanto region have been damaged by large tsunamis in the past. The reported tsunami heights from the 1923 M7.9 Kanto earthquake show a great difference between in and around Tokyo Bay. Attenuation of tsunami heights was observed at the mouth of the bay. For example, tsunami heights were less than 1.0 m inside the bay at Shinagawa, Funabashi, and Chiba, although they were 3.0-10.0 m outside the bay (Hatori et al., 1973, ERI special publication).

On the other hand, the tsunams from the 2011 Mw 9.0 Tohoku earthquake did not experience such attenuation. For example, tsunami heights were 1.46 and 2.84 m inside the bay at Tokyo and Funabashi respectively, although they were 1.45 and 1.60 m outside the bay at Tateyama and Kyonan (Sasaki et al., 2012, CEJ).

It is important to know why this difference occurs, when estimating tsunami damage to the metropolitan area for future earthquakes. Therefore we conducted spectral analysis of tsunami waveform obtained by numerical simulations, and found that the dominant wave period in the bay is different for each earthquake. It is around 100 min for the Kanto earthquake tsunami and around 70 min for the Tohoku one. We inferred that the 100 min period may result from the normal mode of Tokyo bay (Aida, 1996, Zisin) and the 70 min period from the normal mode of Sagami Bay (Imai et al., 2011, SSJ meeting). In future, we will examine the relation between these different periods and tsunami behaviors.

Wave period dependence of the tsunami energy decay based on observation: In the case of the 2011 Tohoku-oki Earthquake

TANOBE, Atsushi[1*] ; IMAI, Kentaro[2] ; HAYASHI, Yutaka[3] ; IMAMURA, Fumihiko[2]

[1]Graduate School of Engineering, Tohoku University, [2]IRIDeS, Tohoku University, [3]Meteorological Research Institute

1. Introduction

2011 Tohoku-oki Earthquake caused serious damage. In the case of such a giant earthquake, transportation network suffer serious damage. Therefore ensuring sea route safety as the relief course is important for smooth relief and restoration activity. It is important that realize the decay process of tsunami to early ensure the security of the sea route. On the other hand, there is no clear and scientific standard to judge tsunami convergence (Hayashi et al., 2010).

In this study, we use the 2011 Tohoku-oki Earthquake tsunami wave form and show the characteristic of the tsunami decay process by the connection with time of the moving root mean square amplitude maximum onset and tsunami arrival time. And we paid attention to period, intended to clarify the characteristic of each decrement process.

2. Analysis

We targeted for analysis 20 points chose from observed tsunami wave form in the 2011 Tohoku-oki Earthquake that located in the Japanese Islands Pacific on shore and off shore station (observed by Japan Meteorological Agency, NOWPHAS, Geospatial Information Authority of Japan).

It is obvious that long sampling intervals can lead to a marked distortion of the wave properties (Rabinovich et al., 2011). We unified the sampling intervals for 30 sec and High-frequency filtering was used to remove sea level variations associated with synoptic atmospheric activity. We used the maximum of the moving root mean square amplitude to normalize the observed wave because of tsunami amplitude different from every observation point. After the Normalized process we analyzed that wave form.

Because the tsunami includes wave of various periods, and suggested decay process is different every period (Rabinovich et al., 2013). So we used band-pass 2-16 min, 16-32 min, 32-64 min, and 64-128 min filter to divide tsunami every periods. I calculated the moving root mean square amplitude and we analyzed it with a method of Hayashi et al. (2010) to define a decay coefficient.

In this study, t is the elapsed time from shock, M(t) is moving root mean square amplitude at t, Mmax is maximum of the M(t), Tm is time of onset Mmax, Tt is time of the first wave′s maximum observed, TL is differences between Tm and Tt, k is proportional constant every observation point, e is Napier's constant, τ is decay time. τ mean time required for the average amplitude being decay to 1/e .

As a result of analyzed, the tsunami decrement process of each observation point is characterized by the longer period wave that attenuate later and shorter period wave that maximum wave late for arrival.

3. Conclusion

In this study, we used the tsunami wave pattern at the 2011 Tohoku-oki Earthquake and analyzed it. I discussion a factor to characterize a decay process of the tsunami energy, and get the following result.

(1)Regardless of on shore or off shore, equilateral correlation has τ and Tt, and on shore points tends to get longer than τ.

(2)For a wider tendency, tsunamis indicates that shorter period waves attenuate much faster than longer period waves in a short period.

(3)Some observation point have a long TL about less than 32 min period.

Oscillations starting immediately after the 2011 Tohoku earthquake in Japan Sea

MUROTANI, Satoko[1*] ; IWAI, Maki[2] ; SATAKE, Kenji[1]

[1]ERI, the Univ. of Tokyo, [2]Yokohama City Univ.

The tsunamis from the March 11, 2011 Tohoku earthquake were recorded in the Japan Sea. At some tide gauge stations along the Japan Sea coast of Honshu and the Russian coast, sea surface disturbances were observed immediately after the earthquake, followed by tsunami propagated through the Tsugaru Strait between Honshu and Hokkaido. Using tsunami numerical computations from seafloor displacements including the effect of the horizontal displacement and seafloor slope, the oscillations starting immediately after the origin time were reproduced. We interpret that these tsunami forerunners were generated from horizontal motion of seafloor slopes in the Japan Sea.

The tsunami forerunners were particularly remarkable at Awashima (JCG), Sado, Noto Toyama and Fukaura (JMA) tide gauge stations along the Japan Sea coast of Honshu and at Rudnaya Pristan, Preobrazhenie, and Nakhodka stations along the Russian coast of Primorye (Shevchenko et al., 2013: Pageoph). The 2011 tsunami originated in the Pacific Ocean would pass the Tsugaru Strait 1.5 hours after the earthquake. It indicates that these forerunners were different from the tsunami originated in the Pacific Ocean.

We made the tsunami numerical computation to reproduce these forerunners from seafloor displacements in the Pacific Ocean and Japan Sea. We used the source model of Satake et al. (2013, BSSA). According to Tanioka and Satake (1996, GRL), if the ocean bottom contains steep slopes or steps, the effect of the horizontal displacement of ocean bottom cannot be neglected. Computation including this effect showed the oscillations starting immediately after the origin time. However, the short-period components about a few minutes are not well reproduced. Use of finer bathymetry grid than we used (30' and 5') may better reproduce the short-period components of the Japanese tide gauge stations. Seismograms at nearby stations suggest that some of the short-period components may be the seismic ground motion. When we applied low-pass filter to the observed waveforms, the agreement between the observed and synthetic waveforms on tide gauges became better.

Because the Russian stations are about 500 km away from the source area, we also computed the synthetic tsunami waveforms from seafloor displacements computed on the spherical Earth model (Sun et al., 2009: Geophys. J. Int.). However, the computed waveforms from the spherical models are not very different from those computed on Cartesian coordinate system. It is necessary to compute the tsunami waveforms using the finer grid including the shape of the bay.

The 24 September 2013 tsunami in the Makran region, northwestern Indian Ocean

HEIDARZADEH, Mohammad[1] ; SATAKE, Kenji[1*]

[1]Earthquake Research Institute (ERI), The University of Tokyo

Tsunami waves were observed in the northwestern Indian Ocean following the Mw 7.7 Pakistan inland earthquake on 24 September 2013. We analyze eleven tide gauge records as well as one DART record of this tsunami and perform numerical modeling of tsunami. The tsunami registered a maximum wave height of 109 cm in Qurayat tide gauge station (Oman). Spectral analysis showed that the most governing period of the tsunami waves was around 12 min though wavelet analysis showed that parts of the tsunami energy were partitioned into other period bands of 7 and 16 min. Distribution of aftershocks in the region showed that all of them were located inland indicating that the tsunami was generated by submarine geological phenomena triggered by the earthquake. Tsunami backward ray tracing showed that the tsunami source was possibly located at offshore Jiwani (Pakistan) and the tsunami was most likely generated immediately after the main shock. Tsunami modeling assuming a pile-up structure at the location of the new island was not successful in reproducing the observed sea level records. A landslide source with a length of about 15-20 km, a thickness of 100-150 m located at 61.72^{o}E and 24.60^{o}N seems capable of fairly reproducing the observed sea level records. This event was the second tsunami recorded in the Makran region since 1945, and may be evidence for hazards from landslide-generated waves following seismic activities.

Pre-computed Tsunami Database with Additional Slip Near to the Trench for Tsunami Early Warning in Southern Java

SUNENDAR, Haris[1*] ; TANIOKA, Yuichiro[1] ; GUSMAN, Aditya[1] ; LATIEF, Hamzah[2]

[1]Institute of Seismology and Volcanology, Hokkaido University, [2]Bandung Institute of Technology

We build tsunami database based on simple fault model scenarios for the Java trench subduction zone. We have 480 points along the subduction zone with distance between each other of 20 arc-min. This points are used as the center of simple fault model scenarios. Each point is the center of several fault models with different moment magnitudes.We used a magnitude to fault length and width scaling relationship for the fault model scenario. The moment magnitudes for the fault model scenarios are from Mw 6.3 to Mw 9.0 with interval of 0.3. The fault depth parameter is also a variable for the fault model scenario. We used depth between 10 km to 60 km with interval of 10 km.

From each fault model scenario we simulate tsunami propagation by solving the linear shallow water equations. We used bathymetry data based on Indonesian navy chart and GEBCO bathymetric dataset. The grid size for the tsunami simulation is 1 arc-min. The pre-computed maximum tsunami heights and tsunami arrival time at every point along the coast are stored in a database.

If a real earthquake occur at any location in the forecasting domain then the pre-computed tsunami heights from 16 scenarios are retrieved from the database. Theses 16 scenarios are those that are surrounding the actual hypocenter and each of the scenario has the closest higher or closest lower magnitude to the actual one. Then the tsunami heights from these scenarios are used in interpolation methods to get the tsunami height forecast. The tsunami heights from two scenarios with a same hypocenter and different moment magnitudes are interpolated by logarithmic interpolation. Then the tsunami heights with different depths and different epicenters are interpolated using linear interpolation and bilinear interpolation, respectively. The the interpolated tsunami heights is group into district administrative regions, then the maximum height for each administrative region is selected. The selected tsunami heights are categorized into three different warning levels. These levels are tsunami smaller than 0.5 m, between 0.5 m to 3 m, and larger than 3 m.

We apply this method to forecast the tsunami generated by the 1994 East Java earthquake. The 1994 earthquake is classify as a tsunami earthquake (Newman and Okal, 1998; Pollet and Kanamori, 2000). The earthquake moment magnitude was estimated to be Mw 7.6 (Abercrombie et al., 2001), Mw 7.8 (Bilek et al., 2006; USGS), Mw 7.9 (Pollet and Kanamori, 2000). Our result shows that the forecasted tsunami heights underestimate the actual tsunami heights. One of the main cause could be the fact that we used simple fault model scenarios which sizes were estimated from scaling relationship of magnitude to fault dimension of regular earthquake but not tsunami earthquake. Previous studies shows tsunami earthquake may generate large slip near the trench (Tanioka and Satake, 1996; Satake et al., 2013). Therefore to obtain a more accurate forecast, the fault model scenarios near the trench should represent fault model for tsunami earthquake event.

Simulation of tsunami inundation from future megathrust earthquake scenarios of Central Peru

MAS, Erick[1*] ; ADRIANO, Bruno[2] ; PULIDO, Nelson[3] ; KOSHIMURA, Shunichi[1]

[1]International Research Institute of Disaster Science, IRIDeS, Tohoku University, [2]Graduate School of Engineering, Tohoku University, [3]National Research Institute for Earth Science and Disaster Prevention, NIED

Great tsunami events like the 2011 Great East Japan Earthquake and Tsunami might occur around the world in the future. In particular at areas of the Pacific Rim or the Andaman Sea as history has confirmed. In this study we will focus on the central coast of Peru on the western Pacific. The earthquake history of Peru accounts for many devastating tsunami disasters in the past (1555, 1586, 1609, 1630, 1655, 1678, 1687, 1746). The potential damage to national infrastructure exposed in Callao and Lima could yield to a heavy economical breakdown in Peru. It is of great importance to assess and estimate the future tsunami inundation scenarios in order to grasp the extent of possible damage and the severity of it. Consequently, this study evaluates the tsunami hazard and the related features of inundation at the central coast areas of Peru based on possible megathrust earthquakes.

The source model we used in this study (Mw = 8.90) was obtained from results of the interseismic coupling distribution in subduction areas using GPS monitoring data as well as historical earthquake recurrence information (Pulido et al., 2011). This slip model was used to generate twelve additional slip scenarios for strong ground motion simulation, by adding spatially correlated short-wavelength slip heterogeneities (Pulido et al., 2012).

Here, we used these thirteen scenarios to evaluate the tsunami hazard of Callao area in Peru. From results of strong ground motion simulations Pulido et al. (2012) reported that the slip scenario with the deepest along strike slip average (Mw = 8.86) was the worst case scenario for strong ground motion in Lima-Callao area. On the other hand, in this study the slip model with the largest peak slip (Mw = 8.87) yielded the highest tsunami inundation and maximum velocity near shore. Such differences on maximum scenarios for peak ground acceleration and tsunami height reveals the importance of a comprehensive assessment of earthquake and tsunami hazard in order to provide plausible worst case scenarios of strong ground motion and tsunami inundation.

Acknowledgments

This study was carried out under the framework of the SATREPS project ”Enhancement of Earthquake and Tsunami Disaster Mitigation Technology in Peru, project sponsored by the Japan International Cooperation Agency (JICA) and the Japan Science and Technology Agency (JST). Our appreciation goes to the Ministry of Education, Culture, Sports, Science and Technology (MEXT), National Research Institute for Earth Science and Disaster Prevention (NIED) and the International Research Institute of Disaster Science (IRIDeS), Tohoku University for their support.

Identification of submarine landslide tsunami sources: A probabilistic approach for the Gulf of Mexico

SHIGIHARA, Yoshinori[1*] ; HORRILLO, Juan[2]

[1]National Defense Academy, [2]Texas A&M University at Galveston

The devastating consequences of recent tsunami events in Indonesia (2004), Japan (2011) have changed the perception about tsunami potential and have prompted a scientific response in assessing the tsunami hazard in regions even though an apparent low-risk or/and lack of complete historical tsunami record exists. Although a great uncertainty exists regarding the return period of large-scale tsunami events in the Gulf of Mexico (GOM), geological and historical evidences indicate that the most likely tsunami hazard could come from a submarine landslide triggered by a moderate earthquake. Under these circumstances, the assessment of the tsunami hazard in the region could be better accomplished by means of a probabilistic approach to include the uncertainty in the hazard analysis and thus to identify tsunami sources.

This study aims to customize for the GOM an existing probabilistic methodology to determine landslide-tsunami sources associated with return periods. The Monte Carlo Simulation (MCS) technique is employed to determine the uncertainty related to location/water-depth and landslide dimension based on normal/lognormal distributions obtained from observed data. Along fixed transects over the continental slope of the GOM, slide angle of failure, soil properties and seismic peak horizontal accelerations (PHA) are determined by publicly available data. These parameter values are used to perform slope stability analyses in randomly generated translational submarine mass failure (SMF) obtained from the MCS technique. Once the translational SMF is identified as tsunamigenic for a given recurrence rate, a preliminary tsunami amplitude can be estimated by using empirical formulations. Thus, the annual probability of a tsunamigenic SMF is determined by the joint probability with the annual PHA.

By using the probabilistic approach we identified tsunami sources associated with return periods from few thousands to 10,000 years for each fixed transects defined over the continental slope of the GOM.

A stochastic analysis and an uncertainty assessment of tsunami wave height using a random source parameter model

FUKUTANI, Yo[1*] ; SUPPASRI, Anawat[1] ; IMAMURA, Fumihiko[1]

[1]International Research Institute of Disaster Science, Tohoku University

In this paper, we conducted a stochastic tsunami hazard assessment including various uncertainties using a logic tree with targeting a region of the 3.11 Tohoku earthquake and investigated how heterogeneous slip faults generated by CRSP (Correlated Random Source Parameter) model influence the stochastic tsunami hazard assessment. In the assessment, observed tsunami wave height 6.7m in the 3.11 Tohoku Earthquake corresponded to 1112 year (0.50 fractile point), 1129 year (simple average) and 490 year (0.95 fractile point) for return period. Next, we investigated an influence that the number of slip patterns has on the results of the assessment. While the number of slip patterns had little impact on the results of the stochastic assessment in cases which a target wave height was comparatively low (2.0m), the return period at each fractile point was overestimated in case of 3 slip patterns and 5 patterns than 1 pattern when a target wave height was comparatively high (6.7m or 10.0m). We can conclude that the number of slip patterns had a great impact on the stochastic assessment depending on the target wave height. To clarify the uncertainties of tsunami wave height, we defined a 90 percent confidence interval and a coefficient of variation as indexes which can quantify the uncertainties of tsunami wave height. Basically, the 90 percent confidence interval had high value where the wave height at each fractile point was high. In addition, we confirmed that changing of maximum wave height due to changing of the asperity location in the assuming fault had a great impact on the coefficient of variations in the offshore point of the Ibaraki coast. The coefficient of variation in the offshore point of peninsula located in ria shoreline of the Iwate coast was comparatively higher than a result in closed-off section of bay located in ria coast. This result indicates an effect due to a characteristic topography in ria coast.

Seismic and tsunami fragility of industries, revealed by the 2011 Tohoku-oki earthquake

KUWAHARA, Yasuto[1*] ; HASEGAWA, Isao[1] ; YOSHIMI, Masayuki[1] ; NAMEGAYA, Yuichi[1] ; HORIKAWA, Haruo[1] ; NAKAI, Misato[1] ; MASUDA, Satoru[2]

[1]AIST, GSJ, [2]Graduate school of Economics and Management, Tohoku University.

We have developed seismic and tsunami fragility curves of industries by using damage data of industrial companies, estimated strong motions and estimated tsunami heights of the 2011 Tohoku-oki earthquake. The damage data were obtained from 7,019 industrial companies through inquiry surveys by the Regional Innovation Research Center of Tohoku University. As a damage level indicator for each company, we introduced a ratio of an economical damage of physical fixed assets excluding lands to previous balance of the physical fixed assets. The estimated strong motions of the 2011 Tohoku-oki earthquake at all the sites of the companies were from the database of the so-called QuiQuake system (Quick estimation system for shaking maps triggered by observation records) operated by the National Institute of Advanced Industrial Science and Technology (AIST). It is noted that the estimated data were obtained by taking account of seismic local site effects and the actually observed ones. The tsunami height data at each site of the company were obtained by interpolating the confirmed data compiled by the 2011 Tohoku Earthquake Tsunami Joint Survey Group (2013). It is found that a frequency-damage level distribution for each seismic intensity is well correlated with a binominal distribution where the only parameter characterizing the distribution is an average value of the damage levels in each seismic intensity. The tsunami fragilities are also obtained as a function of the tsunami height in the same way. These fragility curves can be useful not only to estimate economic damages for future huge earthquakes, but also to rapidly assess the damage just after earthquakes.

Compiling the source area data of large earthquakes occurred in Pacific Rim

ISHIKAWA, Yuzo[1*]

[1]Y. Ishikawa

The locations of hypocenters were usually plotted by some symbols. This way leads to misunderstand that the earthquake source is the point source. It was caused by the earthquake catalog of which location data were given as a point.

Now, the earthquake source are given by the area obtained by the one month aftershock distributions. Events of which magnitude are larger than 8.0 from 1970, using PDE earthquake catalog. Some large events were added in 20 century. The source areas of large earthquakes occurred in Pacific Rim were digitized.

A set of characterized earthquake fault models for the probabilistic tsunami hazard assessment in Japan

TOYAMA, Nobuhiko[1*] ; HIRATA, Kenji[1] ; FUJIWARA, Hiroyuki[1] ; NAKAMURA, Hiromitsu[1] ; MORIKAWA, Nobuyuki[1] ; OSADA, Masaki[1] ; MATSUYAMA, Hisanori[2] ; KITO, Tadashi[2]

[1]NIED, [2]OYO CORPORATION

A set of characterized earthquake fault models are necessary for nation-wide probabilistic tsunami hazard assessment in Japan (Fujiwara et al., 2013; Hirata et al., 2014). It should include all possible earthquakes in future and should take into account various types of uncertainty.

In general, origins of tsunamis include a volcano, a landslide as well as an earthquake, but as the first step we focus on tsunamis that are caused by only earthquakes occurring near Japanese Islands. We introduce our strategy to construct a set of earthquake fault models for tsunami hazard assessment in Japan, showing examples of earthquake fault models along the Japan Trench.

The ”Long-term Evaluation of earthquakes from Sanriku-oki to Boso-oki region (2nd edition)” (2011/11/25) by the Headquarters for Earthquake Research Promotion(HERP), Japanese government, defined 8 seismogenic segments along the Japan Trench. Based on these segmentations, we classify tsunamigenic earthquakes into 7 categories as follows; 1)”March 11, 2011 Tohoku earthquake-type” earthquakes, 2) maximum-sized class earthquakes, 3) other large-sized earthquakes, 4) earthquakes occurring in any single segment which HERP assessed its possible magnitude and/or location with recurrence interval, 5) tsunami earthquakes, 6) intra-plate earthquakes with normal faulting, and 7) moderated-sized earthquakes (HERP called this type ”earthquakes which we cannot expect its magnitude and size”). HERP assessed earthquake potentials only in categories 1), 4), 5), and 6). To enhance the entirety of tsunami hazard assessment, we newly add the categories 2), 3) and 7), though no previous earthquakes in categories 2), 3), and 7) are known yet. We place earthquake fault on the upper boundary of the subducting Pacific Plate except earthquakes of the category 6).

Seismic moment, Mo, to a characterized earthquake fault model, is determined by an empirical scaling relation between Mo and fault area, S. To determine the empirical relation we first make a list of tsunamigenic earthquakes from the data base of ”Size of tsunamis around Japan for 1498-2006” (http://wwweic.eri.u-tokyo.ac.jp/tsunamiMt.html) by Abe. Next we assign Mo and S to listed tsunamigenic earthquakes, referring in previous studies (Sato et al.,1989) and then derive an empirical Mo-S scaling relation for tsunamigenic earthquakes occurred in the area of the Pacific ocean side. There are some previous studies suggesting that rigidity is depth dependent, but we use a constant value of $5*10^{10}$(N/m^2) as rigidity.

We introduce inhomogeneity in earthquake fault slip to define ”large slip area (LSA)” and ”extremely large slip area (ELSA)” by following a characterized ratio of high-slip area to entire fault area (Korenaga et al., 2014). For great earthquakes of Mw $>$˜8.4, LSA is allowed to be located 3 patterns for along-trench direction and 3 patterns for trench-normal direction, thus total of 9 basic configurations, for each characterized earthquake fault model. ELSA can be allowed to be located along the upper edge in a LSA when the LSA is located adjoined the trench axis. For large earthquakes with the magnitudes less than ˜8.3, that is the category 7), we consider only a LSA at the center of the entire fault area. In this case, variability of possible LSA location is taken into account by introducing an uncertainty value of possible LSA location in process of tsunami hazard curve calculation.

A set of characterized earthquake fault models that we place along the Japan Trench, spans from Mw 7.0 to 9.4 at every 0.1 or 0.2 magnitude intervals. Total number of the models along the Japan Trench reaches more than 1800. It takes whole three months to complete non-linear tsunami simulations for all characterized earthquake fault models.

This study was done as a part of ”Tsunami hazard assessment project for Japan”in NIED.

Tsunami hazard assessment (THA) is the most important information to take effective measures against possible tsunami attacks in future. After the national tragedy caused by the 11st March 2011 Tohoku earthquake (Mw9.0), NIED started a research project regarding TSA in Japan to support various kind of measures by sectors such as local governments, life-line companies, etc (Fujiwara et al., 2013, JpGU). Our research project consists of two components; (A) a research of probabilistic tsunami hazard assessments (PTHA) in which we consider all of possible tsunamis that may affect coastal regions in future and (B) a research to forecast coastal tsunami heights and inundation flow depths based on specified earthquake scenarios.

In the research (A) of PTHA, we began working on subjects of (1) nation-wide probabilistic tsunami hazard assessment (NW-PTHA) and (2) detailed probabilistic tsunami hazard assessment for a specific region (DPTHASR). Outlines of (1) NWPTHA are as follows; (i) we consider all of possible earthquakes in future including earthquakes that the Headquarters for Earthquake Research Promotion (HERP), Japanese Government, already assed. (ii) We construct a set of simplified earthquake fault models, called ″ characterized earthquake fault models (CEFMs) ″ , for all of the earthquakes mentioned above by following prescribed rules (Toyama et al., 2014, JpGU; Korenaga et al., 2014, JpGU). (iii) We solve a non-linear long wave equation, using staggered leap-flog, finite difference method (FDM), including inundation calculation as coastal boundary condition, over a nesting grid system with the minimum grid size of 50 meters, to calculate tsunamis for each of initial water surface distributions (under research for initial water surface calculation by Akiyama et al., 2014, JpGU) generated from a large number of the CEFMs. (iv) Finally we integrate information about coastal tsunami heights from the numerous CEFMs to get nation-wide tsunami hazard curves, defining excess probability, for coastal tsunami heights, incorporating uncertainties inherent in tsunami forward calculation and earthquake fault slip heterogeneity (Abe et al., 2014, JpGU). In the present step we are revising a prototype of NWPTHA in the case where possible tsunami sources are located along the Japan Trench as well as we are constructing a set of CEFMs in the case where possible tsunami sources are located along the Nankai Trough.

As for the research of (2) DPTHASR, we are going to develop new methods to assess inundation probability and inundation time, etc., through tsunami inundation simulations for a set of CEFMs using the same FDM over a nesting grid system with the minimum grid size of 10 meters including information of seawalls and breakwaters. Some of results from DPTHASR will be represented in a similar format of ″ Karte ″ (medical chart) to help understandings of tsunami hazard information by residents. In the present step, we are constructing a new method to assess probabilistic inundation depth distribution along with calculation of hazard curves for inundation depth at specified points on land (Saito et al., 2014, JpGU).

In the research (B), we are planning to construct a deterministic method to forecast coastal tsunami heights, inundation area and depth, etc. in specified sites in the scenarios that possible maximum-sized tsunamis strike there. These deterministic forecasts should be examined through comparisons with tsunami deposits distribution, historical materials, and instrument records.

Also, we are making a lot of effort to utilize probabilistic and deterministic tsunami hazard information by investigating actual usages of domestic/oversea tsunami hazard information (Osada et al.,2014, JpGU) and by investigating opinions and ideas from persons-in-charge of measures by local governments for tsunami disasters thorough questionnaire surveys with direct interviews (Ohsumi et al., 2014, JpGU).

This work partially functions to support activities of HERP.

G-EVER Earthquake and Volcanic Eruption Risk Management Activities and Asia-Pacific Region Hazard Mapping Project

TAKARADA, Shinji[1*] ; ISHIKAWA, Yuzo[1] ; BANDIBAS, Joel[1] ; G-EVER, Promotion team[1]

[1]Geological Survey of Japan, AIST

The Asia-Pacific Region Global Earthquake and Volcanic Eruption Risk Management (G-EVER) Consortium among the geo-hazard research institutes in the Asia-Pacific region was established in 2012. G-EVER aims to formulate strategies to reduce the risks caused by earthquakes, tsunamis and volcanic eruptions worldwide. The First Workshop on Asia-Pacific Region Global Earthquake and Volcanic Eruption Risk Management (G-EVER1) was held in Tsukuba, Japan from February 22 to 24, 2012. During the workshop, the G-EVER1 accord was approved by the participants. The Accord consists of 10 recommendations such as; enhancing collaboration, sharing of resources, and making information of the risks of earthquakes and volcanic eruptions freely available and understandable. The G-EVER Hub website was setup to promote the exchange of information and knowledge about volcanic and seismic hazards among Asia-Pacific countries. Establishing or endorsing standards on data sharing and analytical methods is important to promote data and analyses results sharing. The major activities of G-EVER include participation in global risk reduction efforts such as the Integrated Research on Disaster Risk (IRDR) Program, Global Earthquake Model (GEM) and Global Volcanic Model (GVM). The 2nd G-EVER International Symposium and the 1st IUGS&SCJ International Workshop on Natural Hazards was held in Sendai, Tohoku Japan on October 19-20, 2013. We endorsed Sendai Agreement during the symposium (http://g-ever.org/en/sendai/). Several G-EVER Working Groups and projects were proposed such as; (1) Risk mitigation of large-scale earthquakes WG, (2) Risk mitigation of large-scale volcanic eruptions WG, (3) Next-generation volcanic hazard assessment WG, and (4) Asia-Pacific region earthquake and volcanic hazard mapping project.

The Asia-Pacific region earthquake and volcanic hazard mapping project aims to make an advanced online information system that provides past and recent earthquake and volcanic eruption information (e.g. age, location, scale, affected areas and fatalities) and risk assessment tools for earthquake and volcanic eruption hazards. A printed map will also be published as the new version of the Eastern Asia Geological Hazard Map of the Commission for the Geological Map of the World (CGMW). The online hazard mapping system will provide useful information about earthquake and volcanic hazards in an interactive and user-friendly interface. Past and recent large-scale earthquakes and volcanic eruptions, tsunami inundation areas, and active faults distributions will be shown on the map. Links to major earthquakes and volcanic eruptions databases will be available in the system. The earthquake and volcanic eruption hazard mapping project will be implemented with the cooperation of major research institutes and organization in the Asia-Pacific region such as PHIVOLCS, CVGHM, GNS Science, EOS, USGS and CCOP.

Observing Schumann Resonance by demodulating High Frequency Waves

CAO, Bingxia[1*] ; ZHOU, Hongjuan[1]

[1]Harbin Institute of Technology at Weihai

The limited dimensions of the Earth cause the waveguide between the surface of the Earth and the conductive ionosphere to act as a resonant cavity for electromagnetic waves in the ELF band so that Schumann Resonance (SR)occurs there. It has been suggested that SR may be used to monitor global temperature variations. SR has been used to study the lower ionosphere on Earth and suggested as one way to explore the lower ionosphere on celestial bodies. A new field of interest using SR is related to short-term earthquake prediction. The manmade noises in the ELF band was a problem for observing. A new way to observe SR based on cross-modulation in the low ionosphere is discussed.

The effect of cross-modulation was established by Yampolski et al. between SR and HF signals experimentally. The HF signals called Round-the-world signals (RWS) and large antenna arrays of the radio telescope UTR-2 were used. But the problem is whether the SR can be seen only with a simple antenna. If the answer is yes, we have a new measurement method for SR.

The HF-SR multiple mode nonlinear interaction theory is researched based on the basic theory model established. In the multiple interaction mode theory, the modulation depth is affected by electromagnetic wave phase in the nonlinear effect. Before the experiment, a lot of simulation experiments and theoretical research are carried out , including Schumann Resonance global distribution simulation and multi-mode interaction of HF-SR theory etc.. One simpler half wave cross dipole antenna is used to receive the time service signal of China called BPM. And in the demodulation spectrum of BPM, the first 4 order resonance peaks of the SR are obtained successfully, respectively on 7.5Hz, 14Hz, 20Hz and 26Hz.

The electric field distributions and phase variations of the firse 3 order peaks of Schumann Resonance in the earth ionosphere cavity are obtained through a series of SR distributed simulation experiments. The result shows that in the same phase region, the phase of SR only depends on time. At the same time all the points have the same vibration phase. Two points have 180 degree difference phase after a phase mutation point.

The actual multi interaction mode effect between RWS and SR is uncertain. It may change with the propagation conditions. The modulation depth can not be increased significantly in the multiple interaction effects of HF wave and SR propagate around the globe. The main reason is the high frequency wave goes through the the phase jump points of Schumann Resonance. The final depth of modulation in the Yampolski experiment is about 07-3.5 times to the modulation depth of single interaction.

RWS goes through around the earth. But the modulation depth of of RWS and SR nonlinear effect is not significantly far greater than that of 1 jump value because of the path length growth.

Using the RWS signal, greater modulation than short reception, for example, 1 hop, can be obtained. But due to the SR wave distribution in the earth ionosphere cavity, the value is less than the direct summation of each modulation results. That is to say, high frequency electromagnetic wave propagates around the earth for nearly a circle. It is modulation result with SR dose not significantly increase compared with that of the obtained by ionospheric reflection arrive at the receiving station.

According to the new theory of HF-SR interaction, a receiving station was established. The system receives the BPM time service signals from the National Time Service Center in PuCheng, 1160 km away from the receiver. The carrier frequency is 10 MHz. By demodulating the BPM signal, the first 4 order peaks of SR are obtained. Maybe it is a new way for SR observing.

Influence of mircotopography in lowland to tsunami disaster of 2011 Tohoku Earthquake

IKARI, Kazuya[1*] ; NARAMA, Chiyuki[2]

[1]Graduate School of Science & Technology, Niigata University, [2]Faculty of Science, Niigata University

The earthquake (magnitude 9.0) on Mar 11, 2011 in Tohoku, Japan triggered the terrible destructive tsunami, striking the eastern coastal region of Japan. Although residents in valley bottom plain of the Sanriku Coast (ria coast) have a refuge area around hills, residents in Sendai Plain (meander plain of lowland) had to go to inland in order to escape tsunami. The lowland such as Sendai Plain is very vulnerable to tsunami. However, Building damages differed among the Sendai Plain. This study evaluated the influence of landform in lowland of Sendai Plain to tsunami disaster.

The Sendai plain is meander plain of lowland (0-3m asl.), including beach ridges and inter-ridge march of ridged beach plain, and natural levees along present and mender scars.Three beach ridges are developed along the coast. Relative height of present beach ridge is 3-5m, and inner two beach ridges are 1-2m.

We classified three damage-categories (flow out, destroy, and remain) to individual buildings in tsunami inundation area of the Sendai Plain, based on interpretation of aerial-photographs on 2011 and Google Earth satellite image 2012.In addition, we made a GIS data of utility pole, flattened tide protection forest, driftwood, tsunami scratch in Sendai Plain, to know flow directions of tsunami and distribution of woods.

Building damages in the Sendai plain show >80% of buildings flowed out within 1km area from the coast. Remaining buildings are located on ridged beaches with 1-2m high. Driftwood and rubble had stopped on the near side of beach ridges and highway embankment. Tsunami flow was concentrated in the inter-ridge march or small stream channels. Around the Abukuma River, buildings under cut slope received tsunami damage, and slip-off slope side was safety. In lowland plain, we clarified microtopography with 1-2m relative height reduced tsunami damages around inland side area (>1km) from the coast.

Eruptive Sequence of Rinjani Caldera, 13th Century, Lombok, Indonesia

FURUKAWA, Ryuta[1*] ; TAKADA, Akira[1] ; NASUTION, Asnawir[2] ; TAUFIQURROHMAN, Roni[3]

[1]Geological Survey of Japan, AIST, [2]Institute Technology of Bandung, [3]Center for Volcanology and Geological Hazard Mitigation

Rinjani Volcanic Complex located at northern part Lombok Island is centered by a large stratovolcano, Rinjani volcano, which is the volume of 100 km^3 and 3726m high (Nasution et al., 2003). A caldera of 6x8 km in diameter lies western side of the summit formed at mid-13th century (Nasution et al., 2010; Lavigne et al., 2013). Sequence of the caldera forming eruption is reconstructed from original stratigraphy of eruptive deposits and consists of 6 phases with no prominent time interval between them. Phase 1 is a small phreatic eruption produced thin ash fall bed only occurrs proximal of the summit. Phase 2 is large plinian eruption dipersed pumice lapilli to western side and extending to adjacent islands. Pumice lapilli become finer and lithic fragments increase upward in the fall bed. Phase 3 is defined by widely extending pyroclastic flow deposit consists of vaguely bedded unsorted ash with subordinating rounded pumice lapilli. Its thickness varies from several to 50 cm especially thickens local topographic depression and eroding underlying pumice fall bed. This deposit extends more than 50 km from the probable source and reached Gili Island isolated by ocean suggesting extremely dilute pyroclastic flow possibly caused by plinian eruption column collapse from high altitude. Phase 4 is unstable plinian eruption implied by graded pumice lapilli bed intercalated by multiple thin ash beds. Phase 5 is characterized by enormous pyroclastic flow effusion resulting thick and massive pumiceous lapilli tuffs extending more than 30 km from the source. Proximally fines depleted lithic breccia including andesite lavas and minor amount of granodiorite are interbedded with massive pumiceous lapilli tuff. Thickly stratified lapilli tuff beds exposes along the coastline suggest the pyroclastic flow caused the secondary explosions and formed littral cone at the ocean entry. Phase 6 is last plinian eruption dispersed pumice fall of limited extent which is smaller than preceding plinian phases 2 and 4. Petrological analysis shows magma composition changes between phase 3 and 4 suggesting formation of new vent or widening pre-existing vent eventually causes the caldera formation.

Holocene rock avalanche phenomena from the upper Okumatashirodani Basin, Kamikochi Valley, northern Japanese Alps

KARIYA, Yoshihiko[1*] ; MATSUSHI, Yuki[2] ; HARAYAMA, Satoru[3] ; MATSUZAKI, Hiroyuki[4]

[1]Senshu University, [2]Kyoto University, [3]Shinshu University, [4]University of Tokyo

Hummocks and a minor ridge both of which have been considered to be moraines are present on alluvial fans near the Shinmurabashi Bridge, Tokusawa Area of Kamikochi Valley in the Hida Mountains. A series of geomorphological, lithological, and chronological studies of these landforms and their forming materials revealed that hummocks and a minor ridge were formed by two different rock avalanches that occurred on the steep east face of Kitahotaka-dake north ridge about 3000 m ASL and ran into valley floor near the Shinmurabashi Bridge. A terrestrial cosmogenic nuclide dating method of igneous rocks comprising hummocks and a minor ridge showed that hummocks were formed during 6.0-7.9 ^{10}Be ka and a ridge was during 0.8-1.1 ^{10}Be ka.

Rock failure of welded tuff in Sounkyo valley, Hokkaido, on September 2013

ISHIMARU, Satoshi[1*] ; TAJIKA, Jun[1] ; WATANABE, Tatsuya[1] ; ISHIKAWA, Isao[2] ; SHIMURA, Kazuo[3]

[1]Geological Survey of Hokkaido, [2]Hokkaido Government, [3]Shin Engineering Consultants

A rock failure occurred at the left valley side of the Ishikari River in Sounkyo, Hokkaido, on 8th September 2013. Although Route 39 runs along the Ishikari River, rocks did not reach on the road, because the road is 170m distance from the collapse slope in the other side of the Ishikari River. However, the rock debris buried a part of the river, and formed a 200m-long flooding area at the upper reach. The type of this rock failure is a rock slide to a debris avalanche with high velocity flow.

Paleogene shale of the Hidaka Supergroup is overlain by Sounkyo welded tuff at the valley wall. Sounkyo welded tuff consists of two facies. The lower is a soft non-welded part, and the upper is a welded part with developed columnar or platy joints. Sounkyo valley has been formed by erosion of the pyroclastic flow deposits (30Ka), Sounkyo welded tuff, from Ohachidaira Caldera by the Ishikari River. In consequence, steep cliffs have developed in the valley. At the collapse point, only the uppermost 30m of the slope is steep cliff, but the lower 140m is about 40 degree. According to air photo interpretation, the surface with gently roughness profile develops on the 40 degree slope. This shows talus deposits as past collapse debris overlie the slope.

The area of the slope failure, erosional and depositional area, is 190m in height, 90-100m in width, and 365m in length. The equivalent coefficient of friction is 0.52. The volume of the collapse is more than 33,000m^3. Sounkyou welded tuff is exposed on the upper slope with 90m height, and the debris of the collapse covers on the lower slope with 95m height. A debris slump, 45m height and 20m width, is locates on the lower center part of the debris slope. A part of the past talus deposits is exposed by this debris slump. The Hidaka Supergroup shale is covered with talus deposits. Springs from the piping halls eroded the gullies in talus, and the talus deposits were wet state at the investigation of two days after the failure.

The debris from the collapse slope was spread in lobe-shapes over the valley flat. Arcuate ridges and troughs, 1-2m high, shaped concentric half circles in the center axes of the main lobe. This suggests flow-type mass movement. The debris is distributed on 130m in length and 120m in width of the valley flat. The most of the debris is grayish white welded tuff, and the pale reddish welded tuff originated from the uppermost slope is distributed around the ridges. Shale of the Hidaka super group is rare. The squeeze of the mixture of the soil deposits, composed of woods and organic matters, and volcanic ash is distributed in front of the ridges and in gaps in the troughs. This was dragged from the base of the moving body of the collapse, and played a role in a flow layer, matrix facies, of debris avalanche. The talus deposits would be fluidized. The debris would run with high velocity at the front part of the depositional area. According to the estimating equation (Sceidegger, 1973), using the equivalent coefficient of friction, the velocity is estimated by 38m/s at the foot of the slope.

The rock failure was occurred by the bellow mechanism. Rock slide was occurred near the boundary, the Hidaka Soupergroup shale and the non-welded part of the tuff, and the upper slope broke down. Ground water concentrates in the permeable layer of the non-welded tuff on the impermeable layer of the shale. Because the pyroclastic flow, the Sounkyo Welded Tuff, buried the former valley slope of the Hidaka Soupergroup shale in 30,000 years ago, the boundary is incline toward the river, and also the structure of the tuff is incline. This rock failure was occurred at the instability slope, which consisted of soft non-welded tuff with concentrated groundwater beneath heavy welded tuff. The columnar joints, the collapse surface, at the uppermost of the slope have opened before the rock failure, because moss grows on the joint surface.

Geologic causes of Akatani rockslide induced by heavy rain with typhoon Talas (1112)

NAGATA, Hidehisa[1*] ; YOKOYAMA, Shunji[2] ; INOKUCHI, Takashi[3] ; KATO, Hironori[4] ; KIMURA, Katsumi[5]

[1]Fu Sui Do co. ltd., [2]Kochi Univ., [3]NIED, [4]Aratani Civil Eng. Consultants, [5]AIST

Heavy rain by the Typhoon Talas in 2011 triggered many landslides at Kii Peninsula. The Akatani rockslide in Gojo City, Nara Prefecture is one of the largest landslides, which has dimensions of 500 m wide, 1100 m long, about 80-100 m deep, and 10 million cubic meters in volume. Geologic causes of the rockslide were investigated.

Geology of the Akatani rockslide is composed of mudstone and sandstone of the Miyama Complex of the Shimanto Belt. Not only bedding plane, but also fault planes and joint planes formed in various stages are weak planes related to the rockslide. The average attitude of the bedding planes tends to dip steeply northward while varying. However, there are low-angle dip slip faults nearly parallel or daylight to the slope surface. These are considered to be out-of-sequence thrusts, because they obliquely intersect bedding plane and some of them subdivided the Miyama Complex into several tectonic units. The rupture surface is not smooth curved but rough. This was the combined fragile planes including faults subparallel to the slope. It is similar to the other landslides in the Shimanto Belt that simple slide along bedding planes did not occur.

Development history of sagging around Kanmuriyama Pass, Gifu-Fukui prefecture boundary

KOJIMA, Satoru[1*] ; NIWA, Ryota[1] ; KANEDA, Heitaro[2] ; IKEDA, Akiko[3] ; NAKAMURA, Toshio[3] ; OHTANI, Tomoyuki[1]

[1]Department of Civil Engineering, Gifu University, [2]Department of Earth Sciences, Chiba University, [3]Center for Chronological Research, Nagoya University

Recently sagging landforms like double ridges and uphill-facing scarps attract attention as precursors of large-scale landslides. Many types of large- and small-scale saggings have been ubiquitously found in the Japanese mountainous regions by the analyses of detailed topographic maps made by LiDAR survey. Their development histories and processes, however, are unclear. We report the results of field and chronological researches on saggings in the Kanmuriyama Pass area, Gifu-Fukui prefecture boundary. Since the lithology and age of sediments accumulated in the linear depression between the double ridges east of the Kanmuriyama Pass were reported in the last meeting, those on the uphill-facing scarps west of the pass will be presented in the meeting this year.

Four rows of uphill-facing scarps parallel to the slope are recognized on the south side of the prefecture boundary ridge about 2 km west of the Kanmuriyama Pass. The sediments accumulated in the linear depressions were collected and analyzed by the hand-auger boring and pit survey. Lithological characteristics of these sediments are common and they are composed of, in descending order, 1) carbonaceous mud/leaf litter mixture, 2) dark gray mud, 3) light gray mud, and 4) orange-color conglomeratic mud. This lithology is also similar to that of the sediments between the double ridges east of the Kanmuriyama Pass. The sediments in the first, second and third depressions from the top include Kikai-Akahoya tephra (K-Ah) about 7.3 ka or have peaks of volcanic glass contents of this tephra. The horizons of the tephra, however, are recognized in the different lithologies; the sedimentary environment about 7.3 ka varied with the depression. The ages of the tephra and the AMS-^{14}C ages of wood fragments embedded in the sediments indicate that the sedimentation rates of the dark and light gray mud members are about 0.08 mm/year, and several times slower than those of the upper carbonaceous mud/leaf litter mixture member. The depressions and uphill-facing scarps formed about several tens of thousand years ago on the basis of the estimation of the thickness of sediments and the extrapolation of the sedimentation rate of the mud formations.

Detection of pre movements of landslide or deep collapse using InSAR and LiDAR

KOARAI, Mamoru[1*] ; NAKANO, Takayuki[1] ; TODA, Kenichiro[2] ; DAIMARU, Hiromu[3]

[1]GSI of Japan, [2]Nagano Prefecture Forestry Reserch Center, [3]Forestry and Forest Products Research Institute

It is possible to detect pre movements of landslide or deep collapse using SAR interferometry technology. As previous studies, there are example of the Shimegake Landslide on the foot of Mt. Gassan, Yamagata Prefecture and the Ohkamizawa Landslide in Higashi-naruse Village, Akita Prefecture. In this research, the usefulness of the monitoring methodology which combined SAR interferometry and LiDAR data will be verified for the monitoring of region where the deep collapse will occurred. This research is supported by the Grants-in-Aid for Scientific Research (No.22500994). The main verification fields are Nagano Prefecture and Shizuoka Prefecture. The used InSAR imageries are analyzed by Geodetic Department, the Geospatial Information Authority of Japan, using the data of PALSAR which is L band SAR of the earth observation satellite ”Daichi” (ALOS).

Near the Kuchisakamoto Landslide of Shizuoka Prefecture, a change significant by InSAR imagery in the autumn of 2008 and the autumn of 2009 had occurred, and about 6-7 cm deformation to the LOS direction was observed in one month and a half of 2009. In field survey, the authors checked that the large landslide had occurred between November, 2012 and June, 2013 (Nakano et al., 2013; Koarai et al., 2013).

In west side of Sakamaki hot spring of Nagano Prefecture, about 6-7 cm deformation to the LOS direction was observed in InSAR imagery of one year from 2008 to 2009, and large collapse occurred in September, 2011. In LiDAR data imagery taken before the collapse occurred, it is possible to detect linear depression behind collapse slope.

In this presentation, the authors report many case of pre movement of landslide detected by field survey or LiDAR data in the areas where InSAR imageries show small deformation in Nagano Prefecture.

Prediction and stability evaluation of potential sites of deep-seated catastrophic landslide

CHIGIRA, Masahiro[1*] ; SAKASHIMA, Toshihiko[2] ; FUNAYAMA, Atsushi[2] ; MINAGAWA, Jun[2] ; SHIBUYA, Kenichi[3]

[1]Disaster Prevention Research Institute, Kyoto University, [2]Pacific Consultants Co. Ltd, [3]Aero Asahi Corporation

Chigira (2009) and Chigira et al. (2013) analyzed geological structures and topographic features of deep-seated catastrophic landslides induced by rainstorms in accretion complexes of the southwest outer belt of Japan, and found that those landslides had been preceded by gravitational slope deformation typified by small scarps along their future crowns, which could be a clue to predict potential sites of catastrophic deep-seated landslide. This paper summarizes the methodology of potential site prediction and stability evaluation of catastrophic landslides, including stratified rocks in addition to broken beds and mixed rocks in accretion complexes.

In order to extract potential sites of catastrophic landslide, we need to judge whether deep-seated gravitational slope deformation may develop to catastrophic failure or not, considering possible structures of gravitational slope deformation on a certain geologic background. We examined the relationships among morphological expression of gravitational slope deformation, geologic body, geological structure, and deformation mechanisms, then took account of upslope and downslope conditions, and finally tried to evaluate the probability of catastrophic failure with the help of our experience of previous catastrophic landslides.

Irregularly shaped bumpy slope:

This is typically made when incipient sliding zones are being made in a rock body with complex discontinuities like broken beds or mixed rocks. Only this topography does not suggest the high probability of catastrophic failure, but additional eye-brow shaped small scarps and failures in the lower part of a slope may suggest high probability.

Linear depressions and wrinkles:

Symmetric alignment of linear depressions on both sides of a ridge suggests lateral spreading with the settlement of the ridge top, which does not likely develop to catastrophic failure.

Linear depressions and wrinkles developed on one side of a ridge are made flexural toppling of steeply dipping foliations of bedding or cleavage. This type is self-stabilizing deformation, but when downslope-facing eye-brow scarps are made and lower part of the slope is failed, catastrophic failure likely occur. Ridge-top depressions, when connected to steps and to a hollow on the side margin of a deformed area, catastrophic failure also likely occur.

Large head scarps or ridge top depressions:

These topographies on an under-dip cataclinal slope suggest buckling deformation, which may be stable when a competent rock layer exists or deformation extent is less, but when the deformation progresses further and lower slope is failed, the probability of catastrophic failure becomes high.

Large head scarps or ridge top depressions on an over-dip cataclinal slope suggest sliding in a strict sense with mature and continuous sliding zones. Such a landslide may continue slow movement without catastrophic failure, but when the foot is cut by failure, it may develop to catastrophic failure.

Landslide is one of the severe disasters triggered by rainfalls or earthquakes. Recently, landslides tend to increase by global-warming. Therefore, exploration into behavior of landslide becomes more important disaster prevention.

In order to explore landslide's behavior, we verified if there is slip-surface or not using magnetic approaches. In previous research, we had selected a test slope at Nishiikawa, Tokushima and we had performed electrical resistivity exploration and core-sampling. The core-sampling results indicate that there exists the structure which corresponds to slip surface. To verify this result, anisotropy in magnetic susceptibility (AMS) and natural residual magnetization (NRM) of samples that include that structure and periphery of it were measured. AMS result showed that slip-surface region provides the oblate ellipsoid characteristics, which was consistent with the developmental mechanism of slip-surface during sliding. And result of NRM indicated that magnetic minerals in slip-surface region oriented certain direction. This describes that magnetic minerals was able to move in saturated region and then were oriented to direction of earth magnetism.

These studies showed the possibility to identify slip-surface using rock magnetic approach. However, we found necessity of consideration of core-sampling technique to estimate the direction of slip using this approach because samples had rotated during core-sampling.

The details will be provided in the presentation.

Dendrochronology of a fossil log from the dammed lake deposit by Dondokosawa rock avalanche, the Southern Japanese Alps

KARIYA, Yoshihiko[1*] ; MITSUTANI, Takumi[2] ; INOUE, Kimio[3]

[1]Senshu University, [2]Nara National Research Institute for Cultural Properties, [3]Sabo Frontier Foundation

Large-scale rock avalanche deposits (Dondokosawa rock avalanche deposits; DRAD, V=1.9×10^7 m^3) are present in the east side of Mount Jizo, the Akaishi Range. The age of DRAD has been determined by a ^{14}C-method as AD780-870 or as AD778-793 (with help of wiggle matching). However, precise age determination of DRAD is further required as the some uncertainties remain in the previous age data. Therefore, we performed dendrochronology of a fossil wood log of Japanese cypress (*Chamaecyparis obtusa*) with 226 tree rings and bark obtained from the dammed lake deposits formed by DRAD. As a result, the fluctuation pattern of tree ring width of the sample log (DDK-A) clearly coincided with the pattern during a period from AD662 to AD887 of the 2705-year-long standard curve (705BC-AD2000) established from some tree ring samples of Japanese cypress. Statistical analysis showed that a degree of agreement between DDK-A's tree ring curve and the standard curve (t) is 7.9. Generally, it can be judged that there is high agreement between two tree ring patterns when t-value is more than 3.5. We also observed cell structures of the outermost tree ring for determining the kill season of DDK-A. The early wood ring was completely formed and the late wood ring was almost invisible. Therefore we concluded that DDK-A was dead in the late summer of AD887.

The old Japanese documents *Nihon-Sandai-Jitsuroku* and *Fuso-Ryakki* described the mega earthquake(M 8-8.5) , the *Goki-Shichido* earthquake, in AD887 August. This earthquake was considered to occur along the Suruga and Nankai Troughs off central Japan. Slope movement related to DRAD would be caused by this historical earthquake.

Occurrence of large landslides in past 40 years and sediment supply in the southern Japanese Alps

NISHII, Ryoko[1*] ; IMAIZUMI, Fumitoshi[2]

[1]University of Tsukuba, [2]Shizuoka University

Many large landslides are distributed in the southern Japanese Alps which consists of high relief and steep slopes. A lot of sediments deposited in dams suggest that sediments are produced actively in upper streams. To evaluate the sediment supply from landslides, this study addressed the mapping of landslides (>10000 m^2) in Ooi River and Hayakawa River (total area is 862 km^2) using aerial photographs and orthophotographs in 1970s and 2000s (partly including 2010s). In addition, we computed the volume of sediment supply in several large landslides based on the difference between DEMs from LiDAR data in multiple shooting periods. One hundred eighty landslides were extracted from photographs in 2000s to 2010s. The comparison between the distribution maps of landslides in 1970s and 2000s indicated that an initial large landslide (>100000 m^2) had not occurred since 1970s. In contrast, some landslides had enlarged gradually. Erosion rate computed from LiDAR data indicated the order of 10^{-1} to 10^{-2} m yr^{-1}. Such erosion rate suggests that the bare grounds after landslides are important as sediment supply area.

Cause and age of the Yabusawa Gravel in the northern foot of Mount Senjo, the Akaishi Range, Japan: a reappraisal

KUROSAWA, Hiroshi[1*] ; KARIYA, Yoshihiko[2] ; MATSUSHI, Yuki[3] ; MATSUZAKI, Hiroyuki[4]

[1]Graduate School of Senshu University, [2]Senshu University, [3]Kyoto University, [4]University of Tokyo

The Yabusawa gravel (YG) consists of poorly-sorted thick angular clasts of sand stone, mud stone, and hornfels, forming a geomorphic feature like fluvial terraces along Yabusawa River from Mount Senjo. The previous authors had considered that YG was of glaciofluvial or large landslide origin. However, there is no clear consensus as to the origin and age of YG. We therefore carried out new analysis of geology, geomorphology, and geochronology of YG. The following results were obtained. On the outcrop walls of YG, rock clasts clearly exhibit jigsaw crack structures, although specific sedimentary facies reflecting fluvial processes such as lamination and imbrication are not observed at all. A lithotype of rock clasts in YG is almost restricted to single geology at a given outcrop locality. Surficial topography of YG has hummocks and levee-like terrain. Terrestrial cosmogenic nuclide dating of sandstone fragments obtained from three localities apart from each other gave 10.3-8.4 ka, 10.0-8.1 ka, and 9.4-7.6 ka (in ^{10}Be scale). On the basis of these facts, we concluded that YG was produced by catastrophic rock slide (rock avalanche) in the early Holocene as single event. Although the previous authors stressed degradation of mountain permafrost for landslide occurrence, we invite attention to paleoearthquakes caused by nearby active faults or convergent plate margins as well as early Holocene pluvial climate and long-term gravitational rock deformation. A multidisciplinary study for better understanding of basic factors, onset triggers, kinematic behavior of landslide is further required

Gravitational rock deformation since the late Pleistocene on the Hounose-dendeiro Ridge, the southern Kanto Mountains

SAWABE, Koichiro[1*] ; KARIYA, Yoshihiko[2] ; SHIMIZU, Chosei[3]

[1]Graduate School, Senshu University, [2]Senshu University, [3]Komazawa University

We describe the geology and geomorphology related to gravitational rock deformation on the Hounose-denndeiro Ridge(HB), the upper Tama River Basin. HB is a broad ridge line 200 to 300 m wide running from northwest to southeast, and its altitudinal range spans from 1050 m to 1180 m ASL. The bedrock geology of HB is Cretaceous sedimentary rocks of Shimanto Group that generally show NE-SE strike and east dip at 60 to 80 degrees.

Linear depressions and step-like slopes both parallel to HB are present on and around the ridge-top. Depth and length of depressions are usually less than 20 m and several tens to hundreds meters in many cases. Features of valley bulging with downhill-facing scarp and gentle slopes are also found from valley side slopes immediately below ridge-top linear depressions and step-like slopes . In the area of gravitational slope deformation where bulging features occur, rock deformation caused by toppling and buckling can be observed.

We recovered sediment drill cores in the linear depressions on HB (P1 and P2). The bottom of surficial humic soil gave 4.1-4.3 cal ka (P1, -64 cm) and 9.5-9.8 cal ka (P2, -162 cm). Also a vitric ash layer Aira-Tanzawa (30 ka) was found from -153 cm (P1) and -325 cm (P2). In addition, a patch of pumice grain of Ontake-Ina (93 ka) was discovered at -709 cm of P2. These facts indicate that linear depressions as depositional sinks on HB were already formed before 30 ka at P1 and before 93 ka at P2.

Relief, bell-shape and distortion indexes as critical topography of creep deformation due to mountain gravity

YAGI, Hiroshi[1*] ; HAYASHI, Kazunari[2] ; IMAIZUMI, Fumitoshi[3] ; SATO, Go[4] ; HIGAKI, Daisuke[5]

[1]Fac. Art, Science & Education, Yamagata University, [2]Okuyama Boring Co.,Ltd., [3]Fac. Agriculture, Shizuoka University, [4]Teikyo-Heisei University, [5]Fac. Agriculture & Life Sciences, Hirosaki University

1.Introduction

Double ridges or up-hill facing scarplets distributed on mountain ridge in high relief are known as indicators that mountain bodies are undergoing gravitational creep deformation and as signs of landslide in large scale. However, such micro topographies on ridges in Japan Alps has developed since 30 ka before. That is presumably attributed to one of the para-glacial phenomena. Trench study in Southern Japan Alps clarified that they have intermittently developed in a time scale of 10000 year and the last event, but a slight deformation occurred about 500-600 years ago. It is quite gradual movement. Consequently dense distribution of the up-hill facing scarplets is not always a pre-causious sign of sudden collapse of the mountain body in near future, though the earthquake occurs near the mountains. Other causative factors are required to induce landslide for hazard susceptibility mapping. We analyzed topographic features of mountain around Mt Shichmenzan and Ooyakuzure, which locate along the marginal mountains in Shizuoka Pref, and where huge co-seismic landslides occurred in 17th and 18th century, using DEM of 10m grid scale and more precise scale.

2.Topographic feature of mountain collapsed by earthquakes

Mountain ridges around Mt. Shichimenzan and Ooyakuzure show gentle and round and are fringed by distinct break of slopes. Mountain profiles of high contrast between steep lower slope and gentle ridge ridge tops are similar to a bell-shaped mountains of high relief. In another word, the bell-shaped profile is one kind of the concavity in ridge profiles.

3.Critical topography of creep deformation

Dense distribution of uphill facing scarplets are observed along the main ridges of the study area by aerial photograph interpretation. However, co-seismic landslides occurred only at Mt. Shichimenzan and Ooyakuzure. We analyzed relief of ridges, considering those of the surrounding slopes and ridge scale over the study area. We call it the relief index. Also we analyzed degree of bell-shape, weighting the area of convex part of the profile. These two indexes are highly scored around Mt. Shichimenzan and Ooyakuzure, but not so high along the main ridge from Mt. Yambushi-toge to Mt Dainichi-toge where the uphill facing scarplets are densely distributed. These are considered as very convenient indexes to know the high susceptibility of landslide induced by earthquake. And distortion index that is calculated ratio of total length of up-hill facing scarplets to a original slope length is also introduced as critical topography of creep deformation due to mountain gravity.

Development of Lake Shibire and its geomorphological relationship with landslides in Misaka Mountains, central Japan

SUZUKI, Terumi[1*] ; KARIYA, Yoshihiko[2] ; KUROSAWA, Hiroshi[1]

[1]Graduate School of Senshu Univ., [2]Senshu Univ.

Geomorphological classification mapping and geological investigation were carried out to reconstruct the development of Lake Shibire (890 m ASL, max depth 9.5 m, perimeter 1.2 km) in Yamanashi Prefecture. Lake Shibire was formed on a closed depression of the hilly mound with antislopes that was produced by landslide on the steep slopes adjacent to the lake. Other smaller landslide bodies were also identified next to Lake Shibire. Lacustrine deposits with plant macro fossils and a thin vitric ash layer (Aira-Tanzawa, 30 cal ka) were discovered from the side slope of a small channel close to Lake Shibire. Radiocarbon age of a plant macro fossil sampled from the bottom of the lacustrine deposits was 47-46 cal ka. The paleo Lake Shibire was likely to consist of independent two or more basins in the late Pleistocene and only one basin has survived to the present-day Lake Shibire. It is also likely that a single basin was decoupled into two or more basins due to occupation of landslide masses caused by secondary landslide activities adjacent to the basins, and only the certain basin linked to the present-day Lake Shibire has endured.

Geological implication of the lahar disaster by Typhoon Wipha on October 16, 2013 in Izu Oshima Volcano

KOYAMA, Masato[1*] ; SUZUKI, Yusuke[2]

[1]CIREN, Shizuoka University, [2]Izu Peninsula Geopark Promotion Council

Heavy rain (over 800mm per 24 hours) triggered by Typhoon Wipha on October 16, 2013, caused many slope failures and associated lahars in the western part of Izu Oshima Volcano, Japan. Tephrostratigraphic study revealed a mechanism of the slope failures and history of similar lahars for the past 700 years. Seven fallout ash or scoria layers, which were ejected during the 7 eruptions since the early 14th century, are distributed in the study area. These tephra layers are interbedded with eolian dust (loess) layers, each of which was deposited during a 10-200 years dormant period. Stratigraphic horizons of the slope failures concentrated at the boundaries between ashes and underlying loess layers. This means that more permeable ash layers were saturated with rainwater and slid down along the upper surface of less permeable loess layers. We newly found that three lahars (Lahar A, B, and C) occurred in historic time. Lahar A and B are correlated to the disaster documents of 1856 (or 1932) and of the late 16th century, respectively. Lahar C overlies directly on the Y5.2 scoria and associated Motomachi Lava and thus occurred in the early-middle 14th century.

Preliminary report on the landslides, Oct. 2013, Izu-Oshima Volcanic island, central Japan: Shallow landslide, landforms

SUZUKI, Takehiko[1*] ; TMU GROUP FOR, Izu-oshima typhoon wipha (1326) disaster[1]

[1]Tokyo Metropolitan University

Before dawn of 16th October 2013, the heavy rain associated with Typhoon Wipha (1326) caused landslides disaster in Izu-oshima volcanic island, 120 km south of Tokyo. Many shallow landslides occurred on the west slope of the Younger edifice of Pre-caldera volcano, facing Moto-machi Town. Several reports (e.g. Ministry of Land, Infrastructure, Transport and Tourism; http://www.mlit.go.jp/river/sabo/h25_typhoon26/izuooshimagaiyou131112.pdf) have suggested that the distribution of the landslides overlap the area of lava flow effused 14 Centuries (AD1338?). For examine this relation between landslides and the geomorphological and geological conditions, we preliminary surveyed shallow landslides, landforms and geology along the Gojinka Sky Line on the slope of the Younger edifice of Pre-caldera volcano, 7th and 8th of December and 4th to 6th of January. In presentation, we will report results of field survey for shallow landslides, landforms and geology in detail.

Landslides of granite porphyry induced by Typhoon Talas 2011 around Mt. Myoho at Nachikatsuura, Wakayama, Japan

HIRATA, Yasuto[1*] ; CHIGIRA, Masahiro[2]

[1]Department of Geophysics, Graduate School of Science Kyoto University, [2]Disaster Prevention Research Institute, Kyoto University

Typhoon Talas brought heavy rain in Kii Peninsula, Japan on September 2-5, 2011, causing a large number of rock-avalanches and debris flows in the southeastern part of Kii Peninsula. We mapped the landslide scars on aerial photographs at the scale of 1:20000, made rainfall distribution maps by using the rainfall data analyzed by radar-AMeDAS, and compared position of landslides with rainfall distribution and the geological map by Geological Survey of Japan. The result shows that almost all of the landslides occurred in both over 80 mm/h of rainfall zone and Kumano granite porphyry area. In order to clarify the geological topographical background of the landslides, we also made field investigation around Mt. Myoho at Nachikatsuura, Wakayama Prefecture, where the landslide disaster concentrated.

The field investigation showed that the landslides had different attributes at inside area of granite porphyry mass and at the edge of the mass. Mt. Myoho consists of the Kumano granite porphyry around the top and the Kumano group (sedimentary rock) of Miocene age which occupies at the lower part of surrounding slope and below plain land. Slope is gentle around the top and gets steeper from the surrounding slope break, and eventually becomes gentle again below the boundary between granite porphyry and the Kumano group. The granite porphyry shows typical spheroidal weathering with corestones in the surface layer of gentler slope. The corestones were included in deposits caused by the landslides. Accordingly, landslides within granite porphyry area had scarps at the slope breaks, where weathered and/or reworked material of granite porphyry seemed to have collapsed. At landslides near the boundary between granite porphyry and the Kumano group, the shale of the Kumano group was altered to dark gray clay. Talus deposit of the saprolite and corestones on the clay seemed to have collapsed there.

We estimated volumes of some rock-avalanches around Mt. Myoho to be range from 10^2 to 5×10^5 cubic meters, and their equivalent friction coefficients were 0.20-0.46 on the basis of positions from the rock-avalanches and following debris flows plotted on topographical maps at the scale of 1:25000. These landslides of granite porphyry were similar to those of granite in Hiroshima Prefecture induced by heavy rain on June 1999 in terms of volume and equivalent friction coefficient. In the case of weathered granite in Hiroshima, however, corestones were formed slightly and it was a different type of landslide that saprolite collapsed and transformed into debris flows.

Interpretation of landslides triggered by 1944 Tonankai earthquake around Owase City using U.S. military aerial photos

SATO, Hiroshi, P.[1*]

[1]Japan Map Center

Shallow landslides were interpreted around Owase City, Mie Prefecture using U.S. military aerial photographs (1/16,000 in scale) taken on 7 December 1944, just three days after Tonankai earthquake (M7.9). It is thought that some of landslides were triggered by the earthquake. Result of the interpretation will be reported.

Long-traveling conditions for the rock-on-snow landslide: insights from the field and lab evidence

YAMASAKI, Shintaro[1*] ; KAWAGUCHI, Takayuki[1] ; NAKAMURA, Dai[1] ; YAMASHITA, Satoshi[1] ; SHIRAKAWA, Tatsuo[1] ; HAS, Baator[2]

[1]Kitami Institute of Technology, [2]Asia Air Survey Co., Ltd.

On March 12, 2011, the M 6.6 earthquake hit the typical deep snow area of Niigata and Nagano prefectures. This earthquake (2011 north Nagano Earthquake) induced a lot of landslides, and some of them travelled on snow moving long distance. We are studying that type of landslides which named rock-on-snow landslide by field observations and lab experiments. The rock-on-snow rock avalanche differs from other conventional earthquake-induced landslides because of high mobility, and slash avalanche because water before the event does not drive rocks. Then its high mobility is important to consider earthquake disaster prevention for deep snow area.

The physical properties of snow under the moving mass could affect long-travelling property. We investigated the Tatsunokuchi landslide induced by the earthquake and found temporal liquefaction zone which lay between landsliding mass and autochthonous snow (Yamasaki et al., 2013). The condition of snow getting liquefaction depends on temperature and pressure. Snow also has effect of friction reducing as skiing. However, all rock-on-snow landslides including small rock falls on snow do not travel long-distance, rather most of them stop shorter distance from the origin than normal rock falls. Thus, condition of the long-travelling could be limited. We conducted lab experiments that miniature rock fragments slides on snow slope which tilt angle is 20 degrees, the width is 20 cm and the length is 300 cm, and then we try to understand basic properties of relation between rock and snow and processes during the sliding. The results and our field observations gave us insights to understand larger phenomena.

Definition of the database fields for landslide hazard database by NIED

UCHIYAMA, Shoichiro[1*] ; YAMADA, Ryuji[1] ; ISHIKAWA, Haruna[2] ; SUZUKI, Hinako[1] ; USUDA, Yuichiro[1]

[1]National Research Institute for Earth Science and Disaster Prevention (NIED), [2]Advantechnololy Corporation

The history of natural hazard at a certain place is greatly related to the current risk there. It provides indispensable information to the hazard and the risk assessment. The Research Institute for Earth Science and Disaster Prevention (NIED) is building a comprehensive database of natural hazard events over the historical period in Japan, and distributing these information with Web API. Such a hazard event database is, however, no more than an index with a limited amount of information about the reality. Therefore, especially for the large natural hazards that had big social impacts, it is important to provide specific databases classified with types of hazards such as earthquake, volcano, storm, flood, slope, snow and ice disasters. We discuss about the database for slope disasters in particular here.

Submarine mass-transport deposits of the Paleogene Muroto Formation in the Kuromi coastal region, Kochi Prefecture

IKAWA, Yu[1] ; TONAI, Satoshi[1*] ; SHIBATA, Tadahiro[2]

[1]Faculty of Science, Kochi University, [2]Muroto Geopark Promotion Committee

We report stratigraphy and geologic structures of ancient mass-transport deposits exposed as a nearly 2 km continuous outcrop of the Kuromi coastal region, Shikoku Island, Japan to provide detailed information on internal structures of mass-transport deposits and their relationships with encasing sediments. It is allowing important considerations on triggering mechanisms and transport/depositional process of mass-transport deposits.

The mass-transport deposits studied here are in the Upper Eocene to Lower Oligocene Muroto Formation which is a part of the Paleogene Shimanto accretionary complex. The Muroto Formation, about 650 m thick in this area, consists of six lithofacies. These units are thick-bedded mudstone, thin-bedded very fine grained sandstone and mudstone, thin- to medium-bedded fine sandstone and mudstone, thick-bedded sandstone, folded thin-bedded sandstone and mudstone, and chaotic deposits. These sediments are interpreted as a deep-sea channel-levee system with occurrence of submarine landslides.

A field-based study of the Muroto Formation reveals that folded thin-bedded sandstone and mudstone and chaotic deposits are made up of at least two distinct mass-transport deposits, the larger of which reaches thickness of more than 270 m. Fold hinges in these mass-transport deposits are uniformly orientated and parallel to the host bedding. Axial planes in these mass-transport deposits show a girdle-like distribution which are perpendicular to the host bedding. These patterns of fold orientations show that the style of their transport is mainly flow and partly is turbulent flow including broken detrital blocks. These characters show that huge mass-transport deposits may be often formed on plate convergent margins and involved in accretionary prism.

Feature of slump and associated structure observed at Daini-Atsumi knoll, the gas production test site from gas-hydrate

SUZUKI, Kiyofumi[1*] ; TAKAYAMA, Tokujiro[1] ; SANADA, Yoshinori[2] ; FUJII, Tetsuya[1]

[1]JOGMEC/TRC, [2]Japan Agency for Marine-Earth Science and Technology

The Daini-Atsumi knoll became famous as the first offshore gas production test site from methane hydrate-bearing marine sediments, is one of outer ridges along northeast Nankai trough, near central Japan. Several slumps were found on seismic sections around Daini-Atsumi knoll. Fortunately, several wells had been penetrating slump deposits and logging data were measured. As a result of seismic profile observations, a strong negative-impedance seismic reflector (NISR) was found in the turbidite sequence beneath the slump deposits. A seismic reflector containing the NISR has good continuity with variable reflectivity from a bottom-simulating reflector (BSR) sequence; that is, the NISR does not indicate a slump basement or the boundary of a chaotic unit. Nevertheless, very normal thin-layer turbidites were found at the depth of NISR from LWD measurement and coring, however, fluid data could indicate difference between upper slump unit and beneath turbidites unit. It implies that NISR does not mean pressured fluid but some fluid stagnation.

Role of slump deposits in a high-methane-flux gentle continental slope

MORITA, Sumito[1*]

[1]AIST-GREEN

A great number of submarine landslide deposits (slump deposits) are known to be buried in Pliocene and the upper formations in northern part of Sanrikuoki Basin (Morita et al., 2011). The slump deposits are mainly made up of imbricated thrust sheets of stacked sedimentary layers which were peeled off from ancient bottom surface. The slump deposits often show dimmed facies as an acoustic characteristic and have dewatering structure from the slip surface, and sometimes have gas chimney at the roof of the slump deposits. These indicate that the slump deposits are strongly related to natural gas in formation water. A key to grasp the nature of the slump deposits is likely in a comparison with a result of previous scientific drilling. Site C9001 is a drill site which was operated by D/V CHIKYU in this survey area (Higuchi et al., 2009). By the result of the expedition, the sedimentary basin is mostly composed of mud and few thin ash and sand layers. The sediments are normal and the parts judged as mass transport deposits (MTD) by visual core description are very limited even in the depth domain interpreted as slump deposits in seismic data. However, methane detected in head space gas and methane hydrate bearing sediments recovery were reported only in the slump deposits domain interpreted in the seismic data. Previous reports with respect to MTD indicate that MTDs generally have the nature as seal where the beds have higher shear strength and density due to compaction. Nevertheless, the nature of the slump deposits in the Sanrikuoki Basin is opposite to those of the other MTDs, and may indicate as if reservoir. The difference of the natures is maybe caused by the environment of very gentle continental slope where the slumping has repeated. There is a hint of it in the fact that slump deposits in the survey area avoided fatal collapse by sliding on the very gentle slope and basically formed the imbrication of block-supported structure.

Liquefaction-induced water-film mechanism in submarine slide

KOKUSHO, Takaji[1*]

[1]Kokusho Takaji

As one of possible mechanisms of seismically triggered submarine slides in cohesionless sandy & gravelly deposits, void redistribution or water film effect seems to be deeply involved (Kokusho, 1999, 2000). In this view, fine soil sublayers sandwiched in coarse grain deposits are considered to play a key role in flow failure. The formation of water films between liquefied sand and overlying lower-permeability seams has been observed under level ground conditions in a number of model tests. Fig. 1 shows a typical example of water film formed beneath a thin silt seam sandwiched in a uniform horizontal sand layer. It has also demonstrated that water film can be generated not only in sands beneath silt seam but also in gravels beneath smaller permeability sands (Kokusho & Kojima 2002). Visit http//:www.civil.chuo-u.ac.jp/lab/doshitu/index.html for video images of the model tests.

For sloping ground conditions it has been demonstrated, based on model shake table tests, that the water film plays an important role in post-earthquake large lateral flow in liquefied ground. Fig.2 shows typical test results where clean fine sand was rained in water to make saturated sand slope shown in (d) in a transparent soil box (Kokusho 2003). Fig.2(a) indicates a case of a uniform sand model where small flow deformation occurs mostly during shaking. The locations of markers in the model are shown in (d) with the same symbols. If a silt seam shown with chain-dotted arc is sandwiched in the uniform sand, a larger flow deformation above the arc occurs not only during but also after shaking as indicated in (b). These results in (a) and (b) are for the input acceleration of 0.31 G. Interestingly, for weaker input acceleration of 0.18G given to the same model in (c), much larger post-shaking flow than (b) occurs, while only minimal deformation takes place during shaking. In these tests, very thin water film can be observed beneath the silt arc.

A basic question may arise that sand which can be so dilative if sheared under a low confining stress may absorb ambient excess pore water and hence block the water film development. It can be pointed out, however, based on the comparative observation of the cases with and without a silt seam that a water film formed beneath the seam serves as a shear stress isolator which prevents deeper soils developing shear strain and positive dilatancy (Kokusho, 2000). Consequently, sand can experience large shear strain beneath the silt seam without suffering from the dilatancy effect, whereas it stops moving after the end of shaking if the sand is uniform.

Another shaking table tests has shown that a soil mass slides even on a very gently inclined water film, which breaks at weak points of the overlying sublayer, triggering the boiling failure in the sand above and a mud avalanche of the upper layer (Kokusho 1999, 2000). For video images of these model tests, visit http//:www.civil.chuo-u.ac.jp/lab/doshitu/index.html.

If water films are formed continuously, they will tremendously reduce the residual strength down to zero if sliding occurs all the way through a continuous water film. Kabasawa and Kokusho (2003) quantified the residual shear resistance exerted during the delayed flow along a water film in the model tests. The result shown in Fig.3 indicates that the residual strength along the water film is almost independent of sand density and other test parameters and remains around 20% that of the uniform sand. Considering that soil deposits are naturally stratified with sandwiched low permeability seams, it seems quite reasonable to identify the water film effect as a major mechanism for seismically induced submarine slides in gently sloped sandy or gravelly sea-bed near coastal areas.

Thus, liquefaction may be highly responsible in earthquake-induced submarine slides, particularly in near-shore sites where the seabed is composed of liquefiable loose sand or gravel.

Factors controlling submarine landslide occurrence: Lessons learned from plate-boundary decollement zones

UJIIE, Kohtaro[1*]

[1]University of Tsukuba

Most submarine slopes are inherently stable. However, once submarine landslide generated, it could induce destruction of seabed infrastructure and tsunamis. The factors controlling submarine landslide occurrence remain poorly understood, mainly because there has been very limited access to slip surface of landslide. Initiation and evolution of plate-boundary decollements in subduction zones may be useful to understand the location of slip surfaces and the slip behavior of submarine landslides. Here, I review decollement processes in subduction zones, which have been revealed from deep ocean drilling in the last 20 years. The decollements develop along (1) weak, smectite-rich layers, (2) the zones of elevated pore pressure, and (3) the mechanical boundary between cemented and non-cemented intervals. These results provide important implications for submarine landslide occurrence. The slip surfaces may localize along an interval of smectite-rich lithology. Such smectite-rich lithology could link to the increased volcanic activity as smectite is commonly derived from alteration of volcanic ash/tuff. The permeability contrast in slope sediments could also play an important role on the development of slip surfaces. The rapid sedimentation of coarse-grained sediments onto fine-grained, argillaceous sediments may cause the generation of elevated pore pressure, which in turn facilitates the onset of submarine landslide. The trap of the hydrate-derived fluid beneath the low permeability sediment may also cause the development of overpressure. The slope sediments may contain the cementation boundary (e.g., opal-A to opal-CT reaction) particularly when geothermal gradient is high. In such case, the submarine landslides may generate along the surface bounding different cementation states.

Flow dynamics of Nankai Trough submarine landslide inferred from internal deformation using magnetic fabric

KANAMATSU, Toshiya[1*] ; KAWAMURA, Kiichiro[2] ; KITAMURA, Yujin[3] ; NOVAK, Beth[4] ; STRASSER, Michael[5]

[1]Japan Agency for Marine-Earth Science and Technology, [2]Graduate School of Sciences and Engineers, Yamaguchi University, [3]Department of Earth and Environmental Sciences, Graduate School of Science and Engineering, Kagoshim, [4]Department of Geology Western Washington University, [5]Geological Institute, Seiss Federal Insitute of Technology ETH Zurich

Submarine landslide deposits in one of the most active subduction zone was investigated by Integrated Ocean Drilling Program (IODP) Expedition 333 as ”Nankai Trough Submarine Landslides History” (NanTroSLIDE). The expedition recovered a Pleistocene to Holocene sequence of stacked mass-transport deposits (MTDs) within a slope on the footwall of the megasplay fault at Site C0018, Nankai Trough SW Japan (Strasser et al., 2012). A series of MTDs interbeded with coherent intervals were recovered from the upper 190-meter at C0018 site. We present results of detail fabric analysis using drilled succession of buried mass transport deposits in the slope of Nankai Trough in order to investigate rheology of mass transportation in the subduction zone. Despise very limited lithological information of core research, AMS is proved useful tool to identify MTD deformation and recognize depositional process of MTD (Kitamura et al., 2013, Noback et al., 2013).

Magnetic fabric patterns reveal inhomogeneity within each MTD unit indicating a different compaction and shear occurred during flowing and subsequent deposition (MTD2, MTD3, MTD5). Magnetic fabric in upper interval of each unit generally indicates vertical compression. On the other hand lower interval involve magnetic fabrics showing effect of shear. In the largest MTD (MTD6), a distribution of magnetic foliations images tightly folded strata. Using available paleomagnetic data the shear directions are reoriented, and two different directions are obtained in term of MTD flow directions. It is considered that such variation in flow types and directions derived from the results occurred in responding to a change of slope environment controlled by the tectonic evolution of Nankai accretionary wedge. Through such analysis we can improve our understanding for submarine landslide formation in the active margin.

Potential tsunamigenic submarine landslides in active margins

KAWAMURA, Kiichiro[1*] ; JAN SVERRE, Laberg[2] ; KANAMATSU, Toshiya[3]

[1]Yamaguchi Univerisity, [2]University of Tromso, [3]JAMSTEC

A review of modern, historical and submarine landslides from the geological record shows that landslides in active continental margins can generate tsunamis. The tsunamis may damage coastal and seabed infrastructure and so represent an important element of marine geohazards research due to their potentially significant impacts on society. The primary trigger mechanism of tsunamis in this type of setting was thought to be earthquake activity; however, there are also a number of alternative hypotheses regarding the likely initiation mechanism including the generation of submarine landslides. In this paper, we briefly review the geological features and trigger mechanisms of tsunamigenic submarine landslides on active margins. Large tsunamigenic submarine landslides appear to occur mostly on margins characterized by non-accretion. These observations has implications for tsunami warning systems as the Japanese system does not consider the scenario of tsunami excitation by submarine landslides

Temporal changes of internal stresses and pore pressures of a large-scale submarine debris flow

OTSUBO, Makoto[1*] ; NARUSE, Hajime[2] ; MIYAKAWA, Ayumu[1]

[1]Geological Survey of Japan, AIST, [2]Graduate School of Science, Kyoto University

Mass-transport deposits are major components of depositional systems in the deep sea environments. These deposits usually are composed of muddy chaotic deposits, and are expected to conduct as permeability seals over channel deposits. These mass transport deposits appear as transparent layers on seismic data and chaotic intervals in cores (e.g., Weimer, 1991). Regardless of their common occurrence and distinctive geometry, the dynamics of subaqueous mass transport processes (debris flows) are not well known. It is great difficult to observe directly a subaqueous debris flow.

Naruse and Otsubo (2011) documented quantitatively the internal structures of a mass-transport deposit in the Akkeshi Formation, from the middle part of the Cretaceous-Paleocene Nemuro Group, Japan. The paleostress analysis using meso-scale faults (Yamaji, 2000) of a large-scale mass-transport deposit revealed that the flow experienced two different stress fields: (1) a vertical uni-axial compressional stress field with the sigma1-axes oriented normal to the bedding surface (Phase I) and (2) horizontal tri-axial compressional stress fields with the sigma1-axes oriented parallel to paleocurrent direction (Phase II) (Naruse and Otsubo, 2011).

We examined the temporal changes of internal stresses and pore fluid pressures in a submarine mass transport from the relationships between the principal stresses axes and attitude of fault planes in the mass transports deposits in the Akkeshi Formation. We used 22 fault data and stresses of two Phases in a mass transport deposits. We attribute fault variations to the degree of fault overpressure acting on faults to estimate the pore fluid pressure ratio in the submarine mass-transport deposits. The theory can be explained using the Mohr circles. The inferred internal stresses results imply that the stress fields of Phase I are created by a radial spreading of the flow during its downcurrent movement, while the stress fields of Phase II result from compression during deposition on the basin plain (Naruse and Otsubo, 2011). The increase of pore fluid pressure ratio from Phases I to II represents that the pore fluid pressures have been recognized as playing an important role in the occurrence of the faults in Phase II. On the subdivided Phase II, pore fluid pressure ratio increases until Phase IIa and decreases after Phase IIb while sigma-hmax increases during Phase II.

CCS-geoengineering: the only one reasonable climate geoengineering technology at present

KOIDE, Hitoshi[1*]

[1]Climate Change Geosystem

The climate geoengineering is already inevitable to avoid imminent global climate disasters. Even extreamly cautious approach is not enough for any grand-scale practices of climate geoengineering as we never understand the complex global climate system exactly. However, modern human beings have unintentionally done the global-scale climate geoengineering that increases the atmospheric CO2 level with the wide-spread massive burning of fossil fuels.

The CCS-geoengineering in the broad sense includes the CO2 capture and sequestration, CO2 capture and CO2-EOR/EGR, air capture and sequestration, air capture and CO2-EOR/EGR and also underground microbial CO2 recycling. The CCS-geoengineering only reduces the artificial emission of CO2 into the atmosphere or suck the excessive CO2 from the atmosphere. The CCS-geoengineering is a naturally safe geoengineering technology as the CCS-geoengineering restore the atmosphere only toward the natural CO2 level minimizing untoward effects.

The influence of measurement methods on evaluation of threshold pressures

KAMEYA, Hiroshi[1] ; ONO, Masaki[1*]

[1]Oyo Corporation

In site selection process for the geological sequestration of greenhouse gas, threshold pressures should be evaluated as sealing efficiency of a seal layer. Threshold pressure means the minimum gas injection pressure over which constant gas flow will occur through a sealing layer. For evaluating threshold pressure, strictly conditioned tests to reproduce in-situ stress, fluid pressure, temperature and type of injected gas will sometimes be planned. On the contrary, easy evaluation by simple method will sometimes be planned by estimating capillary pressure curves from pore size distributions and surface tensions. The former will provide more strict evaluations of threshold pressures but this process will be limited by using a particular test apparatus. So, researches for comparing the test results from some methods to verify the accuracy of each test have been studied. In the research on CO2 geological sequestration, three methods are usually used; i.e. (1) threshold pressure test using supercritical CO2, (2) threshold pressure test using N2 gas, (3) threshold pressure estimation from a mercury intrusion test result. In abroad, some researcher report that the results from different methods are consistent considering the surface tensions of relevant fluid system, but others say that the results are inconsistent because of the sample preparation process or anisotropy of samples. Also, there are only few studies in Japan. The authors conducted three kinds of tests using domestic and foreign sedimentary samples (mudstones and sandstones) and examined the consistencies of their results.

Comparing the results using supercritical CO2 and N2 gas, the threshold pressures might be consistent considering the surface tensions in relevant fluid systems. However, there are some inconsistencies with the anisotropic young sediments which could not be reused because of their low solidification. On the other hand, the threshold pressures from mercury intrusion tests with estimation are almost equal to or a little lower than those from N2 threshold pressure tests. This discrepancy may be caused by the anisotropy or shrinkage during drying process.

In Japan, the candidate of seal formation will be thought as not only massive mudstones but also alternated layers of mudstones and sandstones. In latter case, a limit number of strictly conditioned tests should be compensated by sufficient number of lower quality test results. So, the approach in this study will be important in future site selection process.

Evaluation of permeabily fault related damage zone in sandstone from a viewpoint of microstructure

SATO, Minoru[1*] ; TAKEMURA, Takato[2] ; TAKAHASHI, Manabu[3] ; ANMA, Ryo[1]

[1]Tsukuba University, [2]Nihon University, [3]National Institute of Advanced Industrial Science and Technology

It is known that strengthened fragmentation is often observed in damage zones along the fault planes. Studying permeability of faults and damage zones is important because they control fluid migration in subsurface environment (e.g. oil migration and reservoir development, carbon dioxide storage, methane hydrate development). Field and laboratory permeability test have shown that permeability within shear bands, fault gouge or cataclasite is lower than of wall rocks (Zhang and Tullis. 1998), and permeability of damage zones is higher than wall rocks (Fowles and Burley. 1994). The authors compared permeabilities of the wall rocks and damaged zones and their relation to the changes in porosity and pore-size distribution obtained by mercury porosimetry.

The sample was chosen from sandstones from the Nichinan Formation. We conducted shear test on cylindrical sample 90mm in diameter and 180mm long to develop damaged zones in the sample. Cylindrical sample of 50mm in diameter and 25mm long were then cored from the 90mm sample, that intersected the shear plane and damages zones at right angle. The permeability tests were conducted on the cored sample using transient pulse method (Brace et al. 1968) at effective confining pressures 5 and 10MPa. We calculated permeability by Hsieh method (Hsieh et al. 1981) that considered the specific storage value of sample and apparatus. Porosity and pore-size distribution were measured using mercury porosimetry on 10mm cube samples taken from 0 to 10mm, 10 to 20mm, 20 to 30mm, 30 to 40mm from the shear plane.

The permeability of the intact wall rock was 9.40×10^{-9}m/s at 5MPa effective confining pressure, and 2.52×10^{-9}m/s at 10MPa. Permeability of damaged zones were 1.41×10^{-8}m/s at 5MPa effective confining pressure, and 2.70×10^{-9}m/s at 10MPa. Porosity of the intact wall rock was 7.9% and the pore size was dominantly ˜0.1 micro meter. Along the damaged zone, the frequency of 0.1 micro meter pore decreased and that of 0.5 to 10 micro meter pore increased with decreasing distance from the shear plane. On the other hand the porosity of the damaged zones was 5% in average and no clear correlation was observed between the distance from the shear plane and porosity. We suggest that pore structure was affected by micro-fractures or rearrangement of grains from the porosity reduction in the damaged zone samples; nevertheless permeability of the damaged zone samples is higher than that of wall rock samples.

Injection-induced seismicity: insights gained from laboratory AE study using sedimentary rocks

LEI, Xinglin[1*] ; LI, Xiaying[2] ; LI, Qi[2]

[1]Geological Survey of Japan, AIST, Japan, [2]Institute of Rock and Soil Mechanics, Chinese Academy of Science

Injection-induced seismicity associated with applications, in which fluids are intensively pressed into deep formations such as Enhanced Geothermal System (EGS), fracking shale gas, geological sequence of CO2, have attracted growing attentions. Motivated by the desire to better understand the mechanism of damaging events so that they can be avoided or mitigated, we have started an integrated study on rock fracturing and fault reactivation in multiscales. In the present paper, we present some preliminary results of an ongoing experimental study utilizing acoustic emission technique in laboratory. Samples of typical sedimentary rocks collected from Sichuan basin, China, where a number of injection-induced seismic swarms with sizable earthquakes ranging up to M4˜5 have been observed in some gas/oil reservoirs. Since most injection-induced earthquakes are located in sedimentary formations of a wide range of lithology and depth, the fracturing behaviors of such rocks are thus important. In order to investigate the role of over pressured fluid in triggering fault instability, the authors carried out two rock fracture tests under tri-axial compression in laboratory. Detailed space-time distribution of acoustic emission due to microcracking was used to examine pre-failure damages and failure behaviors. Our experimental results demonstrate that dolomitic limestone, shale, and porous sandstone from the Sichuan basin show both brittle and ductile fracturing behaviors depending on a number of factors, including drainage condition and confining pressure.

Geochemical reproduction of deep water related to Matsushiro earthquake swarm for TOUGH-FLAC simulation

OKUYAMA, Yasuko[1*] ; FUNATSU, Takahiro[1] ; FUJII, Takashi[1]

[1]Institute for Geo-Resources and Environment, AIST

A technique of fluid flow ? rock mechanics couple simulation is attracting attentions in the research on CO2 geological storage (CGS) as a promising tool to assess stress conditions in reservoir and caprock associated with CO2 injection. The assessment is important in CGS to set conditions for sustainable injection that does not cause dynamic responses of underground rock mass such as plastic deformation, minor fracturing, re-activation of small faults and so on. AIST is conducting a study using TOUGH-FLAC simulator developed by LBNL, USA, to numerically simulate the 1965-1967 Matsushiro earthquake swarm as a natural analogue of dynamic leakage of stored CO2 associated with fault re-activation. The study using natural data was chosen as the basic data on ground motions and recognizable seismicity would never be obtained in actual CGS demonstration sites because the dynamic responses of rock mass must not occur in the demonstration. The objective of this natural analogue study is to customize the simulator applicable to Japanese CGS sites having bedrocks composed of so-called ”soft rock”.

It is necessary for fluid flow ? rock mechanics coupled simulation to give salinity of formation water in a geologic model as an initial condition. In the case of Matsushiro simulation, the salinity of injected water is also necessary since the Matsushiro earthquake swarm is considered to be caused by a forcible intrusion of saline water beneath the Marsushiro area. The salinity of initial formation water is determined from water geochemistry on several deep wells obtained in the survey during 2010-2011. The salinity of input water is newly estimated based on the similar dataset combined with hydrogen and oxygen isotopic ratios. The hydrogen and oxygen isotopic ratios of well water fall on a line having a gentle slope as compared to the meteoric water line (MWL), a similar relation reported by Yoshida et al. (2002). The extension of this line presents a field of ”andesitic water” by Guggenheim (1992). Assuming that the deep water caused the earthquake swarm has isotopic characteristics of the minimum of ”andesitic water”, the ratio of dilution of the deepest well water was determined from the isotopic ratios of the ”andesitic water” and of the shallow ground water on the MWL. The geochemistry of the deep water caused the earthquake swarm was then determined by using the dilution ratio and the compositions of the deepest well water. The salinity of the deep water caused the earthquake swarm is found to be comparable to present sea water. The salinity is about 7 times higher than that assumed in the previous study of TOUGH-FLAC modeling of the Mtaushiro earthquake swam (Cappa et al., 2009). Similarly, the concentration of HCO3 is estimated by using well water data. The estimated amount of CO2-related soluble species indicates that the initial deep water was oversaturated with respect to CO2 at the postulated temperatures and pressures of Matsushiro simulation.

Seismic monitoring at the commercial-scale CO2 geological storage site, Cranfield, U.S (Part 3)

TAKAGISHI, Makiko[1*] ; HASHIMOTO, Tsutomu[1] ; HORIKAWA, Shigeo[2] ; KUSUNOSE, Kinichiro[3] ; XUE, Ziqiu[1]

[1]RITE, [2]Suncoh Consultants Co., Ltd., [3]AIST

Public concerns about felt seismic events induced by fluid injection have been raised recently. These felt events have magnitudes of more than $M_L 3$ and occur in the area where seismicity not active. The induced seismic events were triggered due to the pressure changes at the reservoir. CO_2 geological storage, a kind of the fluid injection activities, is regarded as a key potential technology to mitigate greenhouse gas emission. Since this technology involves long-term and large amount of CO_2 injection, some researchers warm that CO_2 geological storage would trigger felt seismicities at the site. Passive seismic monitoring is conducted at CCS sites around the world since 2000's. A few of the sites reported occurrences of seismic events related to CO_2 injection and these events were unfelt with small magnitudes. To ensure the safety against induced seismicity and obtaining public acceptance, seismic monitoring is necessary for operating CCS project, especially for countries with high seismicity such as Japan.

RITE has performed a long-term seismic monitoring at the commercial-scale CO_2 injection site in the U.S. to elucidate the relation between CO_2 injection and occurrences of seismic events collaborating with Lawrence Berkeley National laboratory (LBNL) and Bureau of Economic Geology, University of Texas at Austin (BEG) since 2011. Seismic monitoring is conducted at the Cranfield oilfield, Mississippi. This oilfield is the CO_2-EOR field and a million tonnes of CO2 is annually injected into the Cretaceous sandstone reservoir (porosity 20 ˜30%, permeability for 10 ˜200mD) at the depth of about 3,100m. A total of more than four million tonnes of CO_2 have stored as of January 2013. We composed a circle seismic monitoring array deploying 6-3component of seismometers at the depth of 100m in a 3km radius.

We have monitored seismicities more than two years now, but we have recorded no seismic events at the Cranfield site. The recorded of vertical components of waveforms were examined by semi-automated processing and visual judgments for the entire monitoring of period, and the triggered signals were all identified as artificial noises, noises due to weather changes such as lighting or strong wind, and distant earthquakes.

In this presentation, we discuss why seismic events were not recorded at the Cranfield site. We estimated minimum detectable magnitudes of our monitoring array by means of theoretical calculations based on discrete wavenumber integration method which concerned geological properties from surface to the reservoir. We confirmed that the array could detect seismic events with more than Mw0.4 at the hypocentral distance of 3.2 km. We also discuss the question in terms of pressure changes at the reservoir and other studies conducted at the Cranfield site.

Risk Assessment Study of Bio-CCS (2)

TANAKA, Atsuko[1*] ; SAKAMOTO, Yasuhide[1] ; HIGASHINO, Haruyuki[1] ; SUZUMURA, Masahiro[1] ; KANO, Yuki[1] ; MAYUMI, Daisuke[1] ; YUJI, Nishi[1] ; NAKAO, Shinsuke[1]

[1]National Institute of Advanced Industrial Science and Technology (AIST)

Among in-situ geo-microbes within depleted oil/gas reservoir, there are some species those generate methane gas from residual oil. Mayumi et.al (2013) identified some methanogens in depleted oil reservoir, those generate more methane gas when they are cultivated in higher CO2 partial pressure environment than in CO2 poor environment. CO2 acts as a catalyst in the reaction. If we maintain preferable conditions for methanogenesis archaea during geological CCS, we will be able to abate greenhouse gas emission and produce natural gas as natural energy resource at the same time. We named the technology concept as 'Bio-CCS'. Assuming Bio-CCS site, CO2 is injected from a well for to abate greenhouse gas emission and cultivate methanogenic geo-microbes, and CH4 is produced from another well. The procedure is similar to the Enhanced Oil/Gas Recovery (EOR/EGR) operation, but in Bio-CCS, the target is generation and production of methane out of depleted oil/gas reservoir during CO2 abatement. We are evaluating the basic practicability of Bio-CCS. In our project, while biologists are identifying the most effective cultivating conditions for methanogenic archaea, geologists, environmental scientists and system scientists are evaluating feasibilities of the technology concept. To evaluate total feasibility of Bio-CCS concept, we are estimating: CH4 generation volume, environmental impact along with life cycle of injection well, and risk-benefit balance of the Bio-CCS. For that purpose, we assumed two conceptual sites of Bio-CCS: One is depleted oil field and the other one is depleted gas field. In our presentation, we will introduce methodologies and interim results of our feasibility study on Bio-CCS.

Horizontal wells placement optimization for CO2 geological storage in confined aquifers subjected to brine recycling

VILCAEZ, Javier[1*] ; LI, Hualong[1] ; SATO, Kozo[1]

[1]Graduate School of Engineering, The University of Tokyo

Geological storage of CO_2 has potential of mitigating CO_2 emissions into the atmosphere. CO_2 in geological formations can be trapped through solubility, residual, mineral, and structural trapping mechanisms. Of these trapping mechanisms structural trapping is likely to be the least secure because CO_2 accumulated at the cap-rock can potentially leak through pressure-induced fractures in the cap-rock.

In order to maximize the trapping of CO_2 and at the same time prevent the leakage of CO_2, placement of injection and production wells were optimized in a saline aquifer subjected to brine recycling under the constraint of a fixed maximum bottomhole pressure which corresponds to the breakthrough pressure of the cap-rock. Contrary to previous well placement optimization studies, in this study the target geological formation is a confined saline aquifer, permeability is heterogonous (10 - 100 md), and wells for CO_2 and brine injection are horizontal. TOUGH2-ECO2N and an iterative Latin hypercube sampling optimization method were employed for the multiphase flow and optimization calculations, respectively. Optimization variables included the locations of two CO_2 injection wells and one brine production well, as well as the injection rate of CO_2. The total volume of the geological model is 20 km $\times$ 20 km $\times$ 0.1 km which has 4 layers initially containing only brine at a temperature of 40 ℃ and pressure of 10 MPa at the top layer. Simulations were performed for 30 years of CO_2 injection at rates of 5 - 20 kg/s, and 10 years of brine production and/or recycling. The two injection wells for brine recycling were located above the two CO_2 injection wells.

Optimizations of wells placement were performed for two scenarios: 1) injection of CO_2 without brine recycling, and 2) injection of CO_2 with brine recycling. Our optimization results indicate that placing brine injection wells above CO_2 injection wells in conjunction with equal fractions of brine recycling and CO_2 injection to each well leads to highest amounts of dissolution and residual trapping of CO_2. The trapping of CO_2 was improved by 5.4% with brine recycling in comparison to the trapping of CO_2 obtained without recycling (13.26 Mt). Although CO_2 was confirmed to be produced along with brine from production wells located near the injection wells, placement of the production well has shown to have little to no affect on the trapping of CO_2 under the given conditions. With regard to the optimal placement of injection wells, 3 and 6 potential areas were clearly identified for scenario 1 and 2, respectively. It is theorized that heterogeneous permeability formations may have multiple local optima; however this is yet to be confirmed.

Reservoir Rocks of CO2 Micro-Bubble Storage (CMS) and its Dissolution Characteristics

SUZUKI, Kenichirou[1*] ; MIYOSHI, Satoshi[1] ; HITOMI, Takashi[1] ; OKUZAWA, Koichi[1] ; MIIDA, Hideaki[2] ; YUKI, Noriyuki[2]

[1]Obayashi Corporation, [2]Engineering Advancement Association of Japan (ENAA)

Among many different portfolios in the CCS technology, CO2 micro-bubble storage (CMS) system that stores CO2 by injection in the gas phase and dissolution at shallower depths has been proposed. Basic concept of CMS is the replacement of underground water with CO2 dissolved water. CO2 is stored safely once it is dissolved and there is low leakage risk because of residual micro-bubbles having little buoyancy forces. CO2 dissolved in water is weakly acidic and can react with the minerals in the surrounding rocks. It is well-known that acidic solution is neutralized by rocks as it soaks into the ground, however the ability of neutralization is not completely estimated.

In this paper, in order to estimate the ability of rocks to neutralize CO2 micro-bubble dissolved water, two types of dissolution experiments of rocks were carried out using crashed and column specimens of sedimentary rock such as limestone, sandstone, and tuff. A batch type dissolution experiment in which rock samples were treated with the solution of CO2 dissolved in pure water using micro-bubble under CO2 partial pressure 0.0003 atm. And a flow-through type dissolution experiment was carried out using limestone samples for over 40 days in order to investigate the change of pore structure between before and after experiment. From these experimental results, the dissolution rate and the ability of neutralization of reservoir rocks were discussed.

Dawsonite synthesis/dissolution experiment under the relevant condition of CO_2 underground storage

TAKAYA, Yutaro[1] ; NAKAMURA, Kentaro[2*] ; KATO, Yasuhiro[1]

[1]Frontier Research center for Energy and Resoueces (FRCER), Graduate School of Engineering, Universit, [2]Department of Systems Innovation, Graduate School of Engineering, University of Tokyo

Geochemical trapping is a mechanism for defining the longer-term security of CO_2 underground storage. Especially, mineral trapping improves the storage security by the transformation reaction of injected CO_2 (liquid or supercritical phase) to carbonate minerals.

Recently, several studies based on the computer simulation predicted the formations of dawsonite ($NaAlCO_3$ $(OH)_2$) as an initial phase of mineral trapping and that dawsonite may play important role for the storage security in the early stage of CO_2 storage. However, it has not been reported the formation of dawsonite in the experiments under the relevant condition of the CO_2 underground storage to date and the problem "whether dawsonite will be formed in the CO_2 reservoir and will contribute the improvement of the CO_2 storage security" is still remaining.

In this study, therefore, we conduct the synthesis/dissolution experiments of dawsonite under the CO_2 reservoir condition and discuss the formation/preservation condition of dawsonite. We further discuss the possibility of dawsonite formation in the CO_2 reservoir based on our experimental results.

Liquid carbon dioxide storage beneath man-made hydrate-seal layers

OHSUMI, Takashi[1*] ; SHIDAHARA, Takumi[2]

[1]School of Science, Tokai University, [2]NEWJEC Inc.

The findings by Sakai *et al.* (1990) that carbon dioxide (CO_2) hydrate occurs on the Okinawa Trough seafloor of 1,335m in depth and at a temperature of 3.8^{o}C stimulated the research on how to isolate the anthropogenic CO_2 from the atmosphere. Various offshore sites under the CO_2-hydrate stable conditions, *i.e.* above 4.4MPa and below 10^{o}C, are found in the Japan Archipelago. Above all, there are ten or more places where from the coastline the ERD well can make a direct access to the sub-seabed under the CO_2-hydrate stable conditions (Ohsumi, 2012). Sakai *et al.* postulated that CO_2 hydrate fills in the pore of the sediment right beneath the sea bottom, which can be explained by the fact that the density of $CO_2 \bullet nH_2O$ as calculated to be 1.07 ~ 1.04 g cm^{-3} corresponding to n = 7 ~ 8, is larger than that of the bottom seawater, and hence the even thin hydrate layer functions as a barrier for the underlain fluid (its estimated density is 0.92 g cm^{-3}) composed mainly of liquid CO_2 tending to leak to the bottom waters.

Koide *et al.* (1997) pointed out that the formation of CO_2 hydrate in pores and gaps, in rocks and sediments, could almost completely block the migration of fluid. CO_2 that is injected into a deep reservoir would migrate upward into cooler aquifers and eventually form a CO_2 hydrate cap. Numerous engineering studies thereafter were targeted at how such a sealing layer can be created in the CO_2 storage site. It should be noted that CO_2 hydrate exposed to the open bottom water will be dissolved easily even under the low-temperature, high-pressure stable conditions. Nevertheless, in his examination on how underwater pavement operation could realize the CO_2-hydrate storage beneath seabed, Ohsumi (2012) illustrated that a 1-m thick sediment layer would be enough to serve as an effective barrier. Since the solute CO_2 diffusion in sediment pores between the hydrate layer and the sea-bottom is rate-limiting, the seepage flux of CO_2 would be below 0.1 kgCO_2 m^{-2} per year.

There is an offshore steep slope to the Sagami Trough at the north-east coast of the Izu-Oshima Island. A 440-m isobath is near to the shoreline (the nearest point is 1.1 km offshore) and hence due to the fact that the sea bottom temperature will not exceed 10^{o}C throughout the year, the CO_2-hydrate stable conditions spread over the offshore bottom and its sub-seabed. The offshore geology consists of ”old volcano” bodies, several hundred thousand years of age, of which volcanism is probably similar to the present volcano of the Izu-Oshima Island. Hence, we can suppose that it is composed of alternating layers of basalt lava and pyroclastic rocks. When the pores of horizontally permeable layers are filled with CO_2 hydrate, the underlain formations can hold the liquid CO_2 for storage. Ikegawa *et al.* (2012) proposed the injection method of CO_2-in-water emulsion applicable to the sedimentary layers for the purpose of enhanced recovery of methane hydrate. By their method, while avoiding hydrate blockage in the horizontal pore space flow, as shown in Figure we might be able to create the effective CO_2-hydrate seal layers with a large area coverage. A horizontal coverage of the supposed storage site could be 5×1 km. When storage layers with 200-m effective thickness are selected, 10% of the effective pore volume ratio for liquid CO_2 storage gives 100 million tCO_2 as an attractive storage potential.

Use of sodium polytungstate as an X-ray contrast agent to reduce beam hardening in hydrogeological experiments

NAKASHIMA, Yoshito[1*]

[1]AIST

Iodine is conventionally used as a contrast agent in hydrogeological experiments using polychromatic X-ray computed tomography (CT) to monitor multi-phase Darcy flow in porous geological media. Undesirable beam hardening artifacts, however, make the quantitative analysis of the obtained CT images difficult. CT imaging of porous sand packs saturated with iodine and tungsten-bearing aqueous solutions, respectively, was performed using a medical CT scanner. The result (Fig. 1) shows that sodium polytungstate ($Na_6H_2W_{12}O_{40}$) significantly reduced the beam hardening compared with potassium iodide (KI). This result is due to the location of the K absorption edge of tungsten, which is nearer to the peak of the polychromatic X-ray source spectrum than that of iodine. As sodium polytungstate is chemically stable and less toxic than other heavy element bearing compounds, we recommend it as a promising contrast agent for hydrogeological CT experiments.

Acknowledgements:
The medical CT experiment was performed under the cooperative research program of Center for Advanced Marine Core Research (CMCR), Kochi University (13B034) with the support of JAMSTEC.

Time-lapse gravity measurements with a combination of absolute and relative observation array will reduce uncertainties caused by regional gravity variations. The technique is called hybrid gravity measurement. By adding continuous measurement with a superconducting gravimeter (SG) to the hybrid system we are applying the super-hybrid gravity monitoring at the Farnsworth unit (FWU) in TX along with SWP. We started baseline measurement in January 2013. Using SG and barometric data at FWU, we obtained average gravity-atmosphere admittances. The observed admittances during storms can be far from the mean admittance. We often observed several outstanding responses to atmospheric pressure changes. Comparing with precipitation, soil moisture and atmospheric pressure the residuals were attributed to hydrologic components and/or local atmosphere admittance. Several circular irrigation systems work at FWU. At each system water is pumped from a nearby well to the center of the system. The process will result in the redistribution of mass which may result in gravity signals. Basically the booms rotate to cover the circular field over an approximately three day cycle during agricultural season, however the exact watering pattern varies from field to field. We have tried to monitor the watering effects.

This research is funded and supported by Ministry of Economy, Trade and Industry (METI).

Analysis of topographical characteristics of flooded areas for constructing simple warning system of pluvial flooding

SATO, Rina[1*] ; OGUCHI, Takashi[2]

[1]Graduate School of Frontier Science, The University of Tokyo, [2]CSIS, The University of Tokyo

Pluvial flooding is a major disaster in Japanese urban areas. Physical models are often used for assessing pluvial flood risk, but the models are complex. Therefore, this study aims to analyze topographical characteristics of flooded areas in the 23 wards of Tokyo as the basis for constructing a simple warning system. At first, we extracted four factors as topographical characteristics: depression depth, catchment volume, elevation difference and slope using a digital elevation model (DEM) for the whole study area, but there were some problems when the methods were simply applied to the DEM. Accordingly, we extracted the factors only for roads, and then compared the obtained values for flooded and non-flooded areas. According to t-test, there were significant differences between the two types of areas for all factors. However, similar values sometimes occur for these areas, indicating that not only topography but also rainfall and drainage systems should be analyzed in future work.

Effect of the definition of a single rainfall event on the rainfall threshold of mass movements

CHEN, Chiwen[1*] ; OGUCHI, Takashi[1]

[1]Department of Natural Environment Studies, The University of Tokyo

This study analyzes mass movements caused by rainstorm and typhoon events in Taiwan during 2006 to 2012. Data for 263 mass movement events were collected from the reports of the Soil and Water Conservation Bureau of Taiwan, including 172 landslides and 107 debris flows caused by nine frontal rainstorm events and 15 typhoon events. After checking the location of each event, we compiled relevant rainfall data by interpolating data from the surrounding rain gauges. This approach is useful to analyze rainfall conditions for the events and discuss the mechanism of the rainfall-induced mass movements. This study uses two different definitions of a single rainfall event in relation to the triggering of mass movements. One is defined as a period from the time when hourly rainfall becomes greater than 4 mm to the time when the hourly rainfall becomes less than 4 mm for the next six consecutive hours. The other is defined as a period delimited by a non-rainfall period of more than 24 h. These two definitions gave significantly different results concerning the rainfall condition of mass movements. The first definition represents higher rainfall intensity, shorter duration and less cumulative rainfall. The second definition represents lower intensity, longer duration and more cumulative rainfall. We also used the rainfall intensity-duration (*I-D*) relationship from these two definitions to establish two *I-D* thresholds of mass movements in Taiwan. Comparing the thresholds from this study to those for Taiwan and Japan from previous studies, we found that the definition of a single rainfall event and the number of data are two important factors affecting the rainfall threshold of mass movements.

Implementation of Random Forest in landslide susceptibility study, a case study of the Tokamachi area, Niigata, Japan

PAUDEL, Uttam[1*] ; OGUCHI, Takashi[2]

[1]Graduate School of Frontier Sciences, The University of Tokyo, [2]Center for Spatial Information Science, The University of Tokyo

Random Forest (RF), a bagged trees ensemble, is widely appreciated for its superiority amongst classification algorithms and is popular in various fields of data mining. However, the application of RF in susceptibility analysis of landslide hazard remains very limited. This study highlights the results of such an attempt. The study area was selected on the basis of landslide density distribution. A density map of landslide distribution in Japan was prepared from the landslide inventory provided by the National Research Institute for Earth Science and Disaster Prevention (NIED). The Tokamachi area in Niigata Prefecture has a very high density of events and was thence selected for this study. Seven topographic factors (aspect, curvature, drainage density, elevation, plan curvature, profile curvature, and slope) derived from the 10 m DEM obtained by the Geospatial Information Authority of Japan (GSI) were used for the analysis. The classification data concern 9747 landslide events and 20685 randomly generated instances from the areas with no landslides. Unlike the values of a centroid used in many other studies, each landslide event in the classification data was represented by a mean of values of the respective factors in each landslide feature. Information gain for each factor was also evaluated and it was found that the profile curvature is the most effective factor in classifying landslides in the area, whereas elevation is the least effective. A 10-fold cross validation of the RF model with 200 trees resulted in an 'out of bag error' of 0.1443, an accuracy of 85.87%, and an ROC area of 0.926. These results suggest the suitability of RF in susceptibility analysis, the stability of which can be further strengthened with an increase of factors and the number of trees.

Viewshed analysis of the trails in SriPada mountain area in Sri Lanka

SIRIWARDANA, Halgamage malinda[1*]

[1]University of Tsukuba

Each year about 3 millions of people climb SriPada Mountain. The trail system around SriPada in the Peak Wilderness has been used over centuries in good harmony. According to local people, there used to be 18 trails to reach the top of SriPada Mountain. Some of those trails were rarely used and thus getting vanished over time. This research focuses on analyzing Viewshed and the flow of people alone some of the trails.

Geospatial analysis of deforestation factors in central Cambodia after 2000s

MATSUURA, Toshiya[1*] ; MIYAMOTO, Asako[1] ; KURASHIMA, Takayuki[1] ; SANO, Makoto[2] ; CHANN, Sophal[3] ; PAK, Chealy[3] ; LENG, Chivin[3]

[1]FFPRI, [2]Forestry Agency, [3]Forestry Administration Cambodia

Reducing emissions from deforestation and forest degradation; and the role of conservation, sustainable management of forests and enhancement of forest carbon stocks in developing countries (REDD-plus) have attracted interest in Southeast Asian countries where deforestation has been a serious issue. To estimate future deforestation, the REDD-plus requires analyses of trends in land cover changes and the effects of various factors including infrastructure development, national policies and natural environment such as topographic conditions. This study analyzed the spatial characteristics and important factors of recent deforestation by taking eastern Kompong Thom, central Cambodia as an example.

We used three periods (i.e., 2002, 2006, 2010) of forest cover maps produced by Cambodian Forestry Administration (FA) and an object-based image analysis map made from Landsat 8 imagery taken in January 2014. We examined three types of geographic factors, namely, (1) distances from roads, rivers/water bodies, settlements, and forest edges (2) terrain features, e.g., gradient and relative slope position generated from 90-m SRTM DEM, and (3) zoning categories such as forest concession, economic land concession (ELC), community forestry and protected forest, in order to clarify the trend and explanatory variables of deforestation. All the spatial data were converted into 90 m resolution raster. A generalized linear model (GLM) with logit link function (i.e., logistic regression) was then used to analyze the effect of each factor on deforestation.

Between 2002 and 2006, deforestation mainly occurred in canceled forest concessions. During the period 2006-2010, this trend of deforestation accelerated particularly in and around the newly designated ELCs for rubber plantation. After 2010, deforestation further increased due to the development of small-scale agriculture by local farmers in addition to the newly designated ELCs. Factors consistently selected during the study periods with negative effects were “ forest concession ” and “ distance from forest edge ” . These indicate that deforestation occurred more readily in the canceled forest concessions and closer to forest edges. The magnitude of the effect of “ distance from roads ” has become smaller, indicating that recent deforestation occurred more in the forest interior. Gradient had a negative effect, highlighting the difficulties in farming on slopes. Community forestry and the protected forest established by the FA from the late 2000s also had negative effects on deforestation, indicating that these zoning have their value for forest conservation.

ENSEMBLE-CELLULAR AUTOMATA (CA) MODELS FOR IMPROVING FOREST COVER CHANGE SIMULATION

KAMUSOKO, Courage[1*]

[1]Asia Air Survey Co., Ltd

Reliable spatial simulation models are a prequisite for understanding temporal and spatial forest cover changes. However, spatial simulation models require accurate transition potential maps, which represent the probability of change from one forest cover class to another. Previous studies have shown that conventional methods such as logistic regression, weights-of-evidence and neural networks fail to adequately model forest cover transition potential. The objectives of this study are to: (1) evaluate the performance of adaboost (AB) and random forests (RF) algorithms for computing transition potential maps, and (2) simulate forest cover changes using the computed transition potential maps and cellular automata (CA) model. Our results show that adaboost-CA and random forest-CA models produced better simulation accuracy than logistic regression/ weights of evidence-CA models. These results provide valuable insights, which can be used to improve transition potential modeling and forest cover change simulation in complex landscapes.

Capacity building initiative for satellite data utilization for evaluation of environmental degradation using FOSS4G

IWASAKI, Nobusuke[1*] ; MORI, Toru[3] ; HESHIKI, Kanetaka[3] ; KAYAMA, Yoichi[4] ; FURUHASHI, Taichi[5] ; MASUMOTO, Shinji[2] ; YONEZAWA, Go[2] ; YOSHIDA, Daisuke[2] ; RAGHAVAN, Venkatesh[2]

[1]National Institute for Agro-Environmental Sciences, [2]Osaka City University, [3]Orkney Inc., [4]Aero Asahi corp., [5]MAPconcierge

Recently, satellite image data become more and more easily accessible. For example, NASA provide MODIS and LANDSAT data as Open Data. ESA will provide Sentinel data free and open access for any user. In addition, GIS data will also become accessible under the influence of the global trend of promoting Open Data. In such circumstance, a demands for utilizing satellite images and GIS also have been growing steadily and widely. But, it is still complicated to get original satellite data and how to deal with it for for the non-specialist, such as public employees.

Under such circumstances, Ministry of Education, Culture, Sports, Science and Technology in Japan (MEXT) has considered the plan of removing the barriers on satellite data usage. From 2009 to 2014, we have taken part in this project, and have strived to overcome this problem through the following three points.

1. Developing the Free & Open Source Software for Geospatial (FOSS4G) tools, such as GRASS, QGIS, GDAL/OGR and Proj.4.
2. Making tutorial about processing and analyzing the satellite data with FOSS4G tools.
3. Constructing the e-learning contents of satellite data usage and conducting outreach activity and capacity building in not only Japan but also developing countries.

(cf. http://www.osgeo.jp/foss4g-mext)

In first three years, main targets of our project were Japanese and novice user. We translate QGIS and GRASS GIS menu and manuals into Japanese and improve such FOSS4G tools to adapt Japanese data format and projection. Also, basic and advanced the tutorials for satellite data utilization were published as e-book and e-learning system including video tutorials.

The software and knowledge base have been rapidly improved by our works. These achievements are anticipated to expand base of satellite data users and to create a new utilization scene for space derived products. One of the effective results from this project was shown in actions against the Tohoku Earthquake in 2011. Many people could collaborate on that software base and offered ortho-image of Tohoku region (i.e. Iwasaki et al. 2011, GISA-Japan).

Based on previous result, we are started next project to develop an evaluation system for environmental degradation based on above GRASS and QGIS. In the project we use Global Map (http://www.iscgm.org/cgi-bin/fswiki/wiki.cgi) as a fundamental information for evaluating environment. The project had started from 2102 and focused on natural hazard and environmental degradation, especially in developing countries. We will report the status and progress of the project.

Assessment of Natural Landscape Resources for Tourism Development in Hangzhou, China

ZHAO, Wenqi[1*]

[1]University of Tsukuba

This study aims to establish criteria based on various factors and then provide comprehensive assessment to the value of main natural landscape resources in Hangzhou, China. Twenty-two attractions in Hangzhou are selected to be the research objects of this study. Also, eight factors are selected as the criteria of this study, which are general scientific value, rarity, aesthetic value, integrity, scale, popularity, transportation and hotels. The model of Analytic Hierarchy Process(AHP) is utilized in this study to determine the weights of the 8 factors.

In order to collect the root data for determining AHP weights, a questionnaire form was sent out to 12 experts. The other data for measuring the 8 factors are collected from the previous papers, census and reports, the websites and pamphlets of the attractions, Google earth, and also collected by questionnaire survey to the public and doing fieldwork. ArcGIS is a supplementary tool for making evaluation with spatial distribution, especially being used when measuring the factors of transportation and hotels. After evaluating the attractions with abstract scores, rank the scores of the 22 attractions and see the spatial distribution with the map.

Hangzhou's natural landscape resources are mainly categorized into volcanic rock, Karst landform, granite, scenery with hills and waters, waterfall scenery, lakes, wetland and rivers. As the result of the assessment, 9 of the 22 attractions comprehensively have high value, and 10 of them have medium value, and the left 3 have low value. Hangzhou is originally famous for the West Lake, however, after the research it is learnt that the west region of Lin'an city also has abundant natural landscape resources with remarkable value, where should be paid more attention in the future development and preservation. As the suggestion to the future, it is better to construct more nature preserves and Geoparks in Hangzhou.

Tsunami Vertical Evacuation Sites: A Case Study of Shizuoka City

VOULGARIS, Gerasimos[1*]

[1]University of Tsukuba, Graduate School of Life and Environmental Sciences

The City of Shizuoka directly faces the Nankai Trough which has given two M8.1 earthquakes in modern history (1944 and 1946), which were tsunamigenic. After the great Tohoku earthquake the Japanese government updated its worst case scenario for a tsunami from the Nankai trough, which is expected to have a maximum run-up of 34m. This study aims to use GIS in order to locate vertical evacuation sites in the City of Shizuoka within the existing urban structure, and to assess their potential in supporting the population for immediate evacuation under an extreme 34m run-up tsunami event. This study is still in its initial phase, however, spatial analysis of the current designated evacuation locations in the city indicates that under extreme circumstances only a very small minority of sites would remain if such an extreme tsunami were to happen. Therefore, there is an apparent need to investigate for new evacuation sites that will be suitable even under a tsunami of great magnitude.

Spatial Analysis of Urban Accidents; A Case Study of Tehran,Iran

HAJI MIRZA AGHASI, Niloofar[1*]

[1]The University of Tsukuba. Spatial Information Science Division

Road accidents may be seen as discrete promote events, localized in space and time. The most important objective of the study was to identify the spatial pattern of urban accidents in Tehran city in order to finding the causes and consequences as well as the temporal and spatial variation of accidents. Based on spatio-temporal data analysis method, this paper aims to analyse traffic accidents data in time and space. The spatial relationship between time of daily activities which generate trips and urban traffic accidents is examined and applied to Tehran for 2010˜2011.

The research was based on different primary and secondary data sources, which include locations of accidents and many rich attribute such as date, reason, kind, etc. Questionnaires were distributed to 600 drivers in the study area in order to gather data about drivers' knowledge, beliefs, attitude and behaviours. GIS software was used in this study and different maps were made using GIS Arc view 10.2. Tehran urban accidents point by point data with different attributes was collected from Police Department of Islamic republic of Iran, Tehran. These rich accident data were used as source of information and data analysis. The study considered different factors in urban traffic accidents. These include environmental, human and cultural factors, etc. this study stated that the concentration of educational, commercial and cultural activities that make large number of urban trips and road usage and traffic volume in peak hour and road type are among the main causes of the urban accidents in Tehran city. The spatial distribution and variation of Tehran's urban accidents indicated those accident occurrences are highly concentrated along the residential, primary, and secondary roads as well as dense in highways and freeways. This study also shows the relations ship between the occurrences of accidents with peak hours of the day. Highways and freeways are the most dangerous road type in road type variation in Tehran city. And the key reason of accidents in these road types is high speed. High occurrences of urban accidents were caused by culture and behaviour of not only drivers but also all users of the roads. It has been recommended that the improvement of knowledge and culture by education through the public Medias and the rules for offenders must be reissue soon.

Historical changes in land price formation factors over 100 years in Kyoto, Japan: comparison of the land price distribu

AOKI, Kazuto[1*] ; TAKEDA, Koji[2] ; YANO, Keiji[3] ; NAKAYA, Tomoki[3]

[1]Research Center for Disaster Mitigation of Urban Cultural Heritage, Ritsumeikan University, [2]PASCO CORPORATION, [3]Ritsumeikan University

The land price formation factor is an index, which shows the social economy situation of the time.

Although a large number of studies have been made on evaluating land price formation factors which show socio-economic situations, most of the studies have been cross-sectional analysis focusing on specific factors, such as zoning, road width and accessibility to public transportation. Little attention has been paid to historical changes of land price formation in a long-term perspective, mainly because of the lack of historical data representing land price distribution in the past. Fortunately, the Kyoto cadastral map made in 1912 was digitized to create the historical GIS database containing detailed land price information for each land parcel by the GIS research team at Ritsumeikan University. It should be noted that the city has not received large-scale disasters and war damages since the age of the cadastral map. We can thus investigate historical changes of the city without effects of such large-scale disasters. Comparing the current land price distribution with that in early 20th century in the city of Kyoto, we examine historical changes in the geographical factors of land price formations reflecting changes in urban physical and social formations of the city. With the aid of GIS-based mapping and overlay analysis, we mainly argue on the effects of the changes in urban formation on land price distributions over 100 years in the city.

The land price formation factors of quantitative getting are road width and distance from the train station is easy.However, quantitative getting of ambiguous land price formation factor represented by downtown property is difficult.In this study, for the understanding of land price formation factor of 100 years ago, take advantage of old photographs.

Spatio-Temporal Analysis of Bicycle Commuting Behavior in the Greater Tokyo Area Using a Micro-Scale Persontrip Database

GREGER, Konstantin[1*] ; MURAYAMA, Yuji[1]

[1]University of Tsukuba, Division of Spatial Information Science

Compared to other nations, the share of motorized individual traffic in the daily commuting flows in Japan is rather low. Instead, the share of railway transportation is significantly higher. In addition, this generates feeding traffic from homes and workplaces to and from the stations, which is done mostly on foot or by bike. This holds especially true for highly urbanized areas, such as the Greater Tokyo Metropolitan Area with its 34 million inhabitants, which we use as a study area in this paper.

Here we investigate the role and structure of the use of bicycles in the course of commuting traffic. This paper provides a thorough spatio-temporal analysis of bicycle behavior, since we analyze how bicycles are used in the daily commutes, by whom, and where. We investigate how bicycles are integrated in the commuting process and what spatial factors determine the use of bicycles.

For this paper we employ a massive micro scale person trip database provided by the Center for Spatial Information Science at the University of Tokyo. It contains sociodemographic data about approximately 600,000 sample individuals, as well as information about the purpose of each of their trips, their chosen means of transportation (e.g. car, bus, bike, etc.) and their location in 1-minute steps over all 24 hours of one sample day.

As the scientific discourse about bicycle traffic in Japan is scarce, we hope to be able to contribute by this study and provide valuable insights into this important mode of transportation.

Geospatial analysis of land changes in the megacities of Southeast Asia

ESTOQUE, Ronald[1] ; MURAYAMA, Yuji[1*]

[1]Graduate School of Life and Environmental Sciences, University of Tsukuba, Japan

The advancements of remote sensing and geographic information systems technologies enable us to monitor land changes at various spatial and temporal scales, and analyze the implications of such changes from different perspectives. This study assesses the spatiotemporal patterns of land changes in the megacities of Southeast Asia, namely Bangkok (Thailand), Jakarta (Indonesia) and Manila (the Philippines). The goal is to gain better understanding on the land transformation process in each megacity, which may be useful from the perspective of sustainable landscape and urban planning. Remote sensing data were used to develop land cover maps for the megacities across three epochs, i.e. t1-1990, t2-2000 and t3-2010. A hybrid classification method that integrates pixel-based and object-based techniques was employed in land cover classification. Transition matrices for the two time intervals (t1-t2 and t2-t3) were computed and geospatial tools and techniques were applied in order to reveal the spatiotemporal patterns of land changes in each megacity. The implications of the findings for future landscape and urban planning in relation to the sustainable development of the three megacities are explored.

Spatial analysis of archaeological sites and landforms in Kayseri, central Turkey using multiscale topographic data

HAYAKAWA, Yuichi S.[1*] ; OBANAWA, Hiroyuki[2] ; NARUHASHI, Ryutaro[3] ; YOSHIDA, Hidetsugu[4] ; ZAIKI, Masumi[5] ; KONTANI, Ryoichi[6] ; SUDO, Hiroshi[7] ; ODAKA, Takahiro[8] ; YAMAGUCHI, Yuji[9] ; KULAKOGLU, Fikri[10]

[1]Center for Spatial Information Science, The University of Tokyo, [2]Center for Environmental Remote Sensing, Chiba University, [3]Earthquake Research Institute, University of Tokyo, [4]Department of Geography, Meiji University, [5]Faculty of Economics, Seikei University, [6]Notre Dame Seishin University, [7]Okayama Orient Museum, [8]Waseda University, [9]Okayama University, [10]Ankara University

Human habitat and cultural activities had been significantly influenced by natural environments including landforms in the prehistoric periods. Assessment of such relationships between palaeoenvironment and artificial remains is therefore crucial in understanding the historic development. Here we examine the nature-human interactive system in the ancient period of Kayseri region, central Anatolia Highland in Turkey, in terms of spatial analysis of the distribution of landforms and archaeological settlements, targeting mainly the period from B.C. 3000 to A.D.100. We perform geospatial analyses based on several topographic data including topographic maps, satellite-based remote sensing (10 m DEM derived from PRISM sensor images on ALOS), ground-based laser rangefinder measurement with global navigation satellite system (LRF + GNSS) and ground-based structure from motion multi-view stereo photogrammetry (SfM-MVS). The topographic data at different levels of scales provides both regional- and local-scale views of landform conditions, landform classifications, and detailed characteristics of settlements. Certain effects of gradual and sudden changes in palaeoenvironment on human activities are detected, and potential of natural disasters in the study area is also discussed.

Estimation of ground displacements by Geomorphic Image Analysis, using multi-temporal LiDAR DEM

MUKOYAMA, Sakae[1*] ; HOMMA, Shin'ichi[1]

[1]Kokusai Kogyo Co., Ltd.

In the previous study, authors developed the new method which applies the technique of image matching analysis with high resolution DEM over difference times, to estimate the minute ground displacement of less than 1m order quantitatively and easily (Mukoyama et al., 2009 and Mukoyama, 2011). The present study shows the results of subsequent case studies to measure crustal movement, earthquake fault displacements, and the movement of landslides. Additionally we will show the results of comparative verification with some field observations by GNSS stations.

There are two approaches for the calculation of ground displacements from geomorphic point cloud data which is acquirable by temporal high-resolution LiDAR survey. Iterative Closest Point (ICP) is the method for 3D-matching by iterative calculation to find the positions which minimize the difference of coordinate values between paired points in the search area. The other approach is the combined methods of 2D-image measurement for estimation of horizontal component and point cloud calculation for vertical component. These two approaches share common process for finding the best position to minimize the difference between points belong the small search window in the temporal data. For this study, we applied the latter approach which is based on the technique of digital image matching analysis using geomorphic image made from grid data of digital elevation model (DEM).

In this method, the existing Particle Image Velocimetry (PIV) algorithm was used for the 2-dimentional image matching. And orthographic slope angle image was used as measurable digital geomorphic image. Although PIV method has been developed generally for fluid analysis, grayscale gradient slope angle image is suitable for PIV analysis as it utilizes the validity of random distribution image of particles in fluid. In order to estimate vertical displacements, the vertical component is available by interpolation of the elevation values of DEM around endpoints of the calculated vector.

In recent study, above-mentioned method was applied to measure ground displacement due to the Great Japan Earthquake in 2011. In the region where liquefaction had damaged the reclaimed land, 10-50cm of lateral displacements were observed in some divided small areas, and seaward deformation of sheet-pile revetment by lateral movement was also observed at the spot on the seaside. After the earthquake, northern part of Japanese Islands moved eastward 6m or less. Verification analysis was conducted in order to compare between the results of Geomorphic Image matching Analysis and GPS observations in the region where temporal LiDAR data and GPS station data was available. Generally both of the results were corresponding with a high correlativity. In the additional study, verification analysis of landslide movement was conducted with GPS observation data; and both of the results were corresponding well with small error range.

The displacement measurement technique by high-definition digital geomorphic image made from high-resolution point cloud survey is effective and simple method, which has the accuracy of about 1/10 pixels or more. It is thought that this method is practicable for measurement of the movement of landslides, earthquake faults, etc.

Landslide surface deformation detection by Iwate-Miyagi Nairiku earthquake using 2.5D analysis on SAR interferometry

SATO, Hiroshi, P.[1*] ; MIYAHARA, Basara[2]

[1]Japan Map Center, [2]Geospatial Infomation Authority of Japan

We have already reported landslide surface deformation by 2008 Iwate-Miyagi Nairiku earthquake using Synthetic Aperture Radar interferometry (InSAR) images. In this study, to detect the landslide surface deformation quantitatively in the SE area of Mt.Kurikoma, report the result of 2.5D analysis on the images (i.e., combination of the images observed from ascending and descending orbits).

Evaluation of topographic measurements using UAV- and ground-based SfM and TLS: A case study at a rocky coast bench

HAYAKAWA, Yuichi S.[1*] ; OBANAWA, Hiroyuki[2] ; SAITO, Hitoshi[3]

[1]Center for Spatial Information Science, The University of Tokyo, [2]Center for Environmental Remote Sensing, Chiba University, [3]College of Economics, Kanto Gakuin University

Recent advances in measurement methodologies of high-resolution topographic data, including terrestrial laser scanning (TLS), structure from motion photogrammetry (SfM) on unmanned aerial vehicle (UAV) and ground-based SfM, enabled detailed investigations of land surface morphology in terms of morphometry and processes. Although such advanced methodologies are becoming widely applied in geomorphological studies, the nature of such data including error estimates needs to be carefully assessed when being applied in geomorphological researches. In this study we examine similarities and differences among three methods for the topographic data acquisition at a local scale (˜100 m): UAV-SfM, ground-based SfM and TLS. The study site is a coastal bench at Aburatsubo in Miura Peninsula, central Japan, which suffers from intermittent uplift by large earthquakes such as the 1923 Kanto earthquake (M 7.9). UAV-based SfM was performed from higher altitude (ca. 30 m) to lower (ca. 10 m) using a quadcopter on which a digital camera with single-focus lens is mounted. We also used a digital camera mounted on a 4-m long pole for ground-based SfM. TLS measurement was carried out using a short-range scanner from 6 scan positions. Also, coordinates of three benchmarks on ground that are commonly used in all the methods were measured using global navigation satellite system (GNSS) capable of receiving dual radiowaves and post-processing based on career-phase correction with an accuracy of centimeters. The comparisons of the point clouds and digital elevation models (DEMs) obtained by three different methods indicate that 1) SfM-based data shows good accuracies in and around, but significant discrepancies outside of the benchmarks, 2) TLS sometimes give significant lack of data in shadow areas, and 3) data quality of SfM partly depends on the altitude of its platform (either UAV and pole). These characteristics we assessed will give insights into the selection of appropriate methodology for different purposes of geomorphological surveys.

Comparative analysis of knickpoint extraction using semi-automatic and automatic methods

ZAHRA, Tuba[1*] ; PAUDEL, Uttam[1] ; HAYAKAWA, Yuichi S.[2] ; OGUCHI, Takashi[2]

[1]Graduate School of Frontier Science, The University of Tokyo, [2]Center for Spatial Information Science

Extraction of knickpoints (or knickzones) from a DEM has gained immense significance in studies of fluvial erosion and/or slope failures because of their geomorphological significance. Previously, knickpoint extraction from a DEM included a vector-based semi-automatic, but somewhat tedious and time-consuming data processing because GIS and spreadsheet software were separately used. Raster-based Python scripting, developed in our study and deployed in the form of a toolset, can automate the processes making the extraction of knickpoints automatically, fast and user friendly. Both the methods are based on the assumption that the slope gradient along a bedrock river changes with change in measurement length and any locally steep segment of the riverbed may then be considered a knickpoint. The relative steepness index R_d or the rate of decrease of gradient along the measurement length is calculated by solving a linear regression equation, $G_d = ad + b$ where, G_d (m m^{-1}) is the stream gradient at a point and d (m) is the measure distance, while a and b are coefficients and $-a$ is regarded as R_d which means the rate of gradient decrease with increasing d. In the former method G_d is measured at the mid-point of a segment of variable length d along longitudinal stream profiles where; $G_d = (e_1 - e_2) / d$ where, e_1 and e_2 are elevations at both ends of the segment, thereby analyzing both the upstream and the downstream segments along a stream. The automated Python processing, however, follows a slightly different approach from the one previously used and thus requires a comparative analysis of the two prior to its future use. The methods differ in the calculation of the stream gradient G_d; the former employs both the upstream and downstream elevations $d/2$ apart, whereas the latter uses the elevation at the point and d downstream. In this study, the Python toolset has been applied to a 10-m DEM of a mountainous region near Mount Ontake in the Northern Japanese Alps. The results were then compared and validated with the previous method. In order to study the fluvial characteristics of the knickpoints, analysis were confined only to the stream locations, the results of which provide insights into morphological developments of the watersheds.

Structure from motion and multiview stereo (SfM-MVS) in geomorphometry

UCHIYAMA, Shoichiro[1*] ; INOUE, Hiroshi[1] ; SUZUKI, Hinako[1]

[1]National Research Institute for Earth Science and Disaster Prevention (NIED)

Software that unifies structure from motion (SfM) and multiview stereo (MVS) is currently in use. Hence, the construction of three-dimensional models and digital elevation models (DEMs) has been readily achieved at low cost using PCs. Both SfM and MVS are technologies developed in the computer vision field. SfM refers to the process of estimating three-dimensional structures from two-dimensional images. MVS generates three-dimensional models as point clouds. Digital cameras images or aerial photos are used in the calculations and three-dimensional models are produced. To date, DEMs are derived by conventional photogrammetry or LiDAR. However, photogrammetry requires special software, experience, and extensive manual measurement of ground control points (GCPs); furthermore, LiDAR is expensive. To use SfM?MVS in geomorphometry, data accuracy is an issue as well as the precision of GCPs; issues that have attracted the attention of many researchers. In this study, we discuss three examples of the application of SfM?MVS to geomorphometry.

First, we present the case of a detailed topographic map in Izu-Oshima, Tokyo, where a large-scale slope failure occurred before dawn on October 16, 2013, owing to the heavy rains of Wipha typhoon. To obtain a detailed DEM of the damaged slope, we took vertical photographs by UAV and generated a DEM by using SfM?MVS. As a result, we produced a topographic map with a 0.5 m contour interval. The topography was well reproduced and well compared to the LiDAR map with a resolution of 5 m provided by the Geographical Survey Institute.

Second, we created a topographic map using a vertical movie taken by UAV and SfM?MVS processing. A movie has few total pixels per picture compared with a still picture. A 4K-resolution movie has approximately 8 million pixels, whereas a high-definition (HD) movie has approximately 2 million. Moreover, because of lens distortion corrections when a wide-angle lens is used, the pixels that can be used in the calculations decrease. However, there is noise owing to compression compared with a still picture. Thus, the results are not as good as time-lapse photography using still pictures. UAV has also the risk of crashing, thus, it is wise not to use expensive equipment. Cheap cameras without time-lapse function are also available for SfM?MVS. Moreover, old video data can be used to obtain DEMs.

Finally, third, we obtained DEMs from scanning aerial photos. In Japan, the aerial photo archives are currently exceeding 1 million sheets. Therefore, if accurate DEMs are obtained from aerial photos, comparisons are possible and changes over time can be identified. We examined color aerial photographs taken in 1978 and 2012 at downstream area of Nakama River, Iriomote island, Okinawa Prefecture. The aerial photos comprised scans of 23-cm one-side analog photographs (1978) and digital aviation camera data (2012). The data were scanned at a resolution of approximately 1,270 dpi and the total number of pixels per image was approximately 120 million pixels. The resolution of the digital aviation camera photographs was 9,920 x 14,430 pixels. We also processed them by using SfM?MVS and we obtained DEMs with ground resolution of 0.3 m. We used the processed photographs to evaluate the vegetation damage caused by the 2006 and 2007 typhoons.

We show that SfM?MVS can be used in geomorphometry taking advantage of archived records. We anticipate that this methodology will be used more in the future.

Terrestrial laser scanning approach on quantification of weathering depth of sandstone blocks in a coastal environment

AOKI, Hisashi[2] ; HAYAKAWA, Yuichi S.[1*]

[1]Faculty of Business Administration, Daito Bunka University, [2]Center for Spatial Information Science, The University of Tokyo

Weathering in a coastal environment often causes degradation of artificial constructions if they are composed of weathering-prone materials including natural rocks and cements. Conservations of the vulnerability of such construction materials to weathering processes are thus important for their maintenance. Point to point, or cross-sectional measurements using scale bars have often been effective in describing the degree of weathering of such materials. However, accurate measurements of the amount of weathering in terms of areas and volumes have not often been performed due to the limitation in the measurement method for detailed, three-dimensional surface morphology. Here we demonstrate terrestrial laser scanning to describe three-dimensional surficial morphology of a weathered material: sandstone blocks used for masonry piers of bridge on a shore platform at Aoshima, Miyazaki in western Japan. The blocks have suffered from salt weathering above the sea level since the construction of the bridge in 1951. Weathering-induced depressions of sandstone blocks well develop in the spray zone. Our approach revealed sub-centimeter scale morphology of the block surfaces, as well as weathering depths and volumes of each block. Spatial distribution of the amount of weathering was also examined with regard to the sea level and the rock surface hardness. Continuous measurement of such detailed morphology will be necessary to clarify the contemporary rates of weathering therein.

Simple technique of PM2.5 measurement in Higashi-Hiroshima city using a portable particle counter

OSHIME, Azusa[1*] ; SAKUNO, Yuji[2]

[1]Graduate School of Engineering, Hiroshima University, [2]Institute of Engineering, Hiroshima University

In recent years, we are anxious about the trans-boundary air pollution by PM2.5. Therefore the development of various measurement, monitoring methods is demanded.It was begun the full-time monitoring in Hiroshima from FY.2012. It is only ten places at the end of May, 2013 to measure PM2.5 among 39 places of atmosphere measurement station in the prefecture. In addition, because there is not the PM2.5 measurement station in Higashi-Hiroshima city that population continues increasing, we did not understand the situation of PM2.5. Therefore, in this study, a technique to measure PM2.5 with a relatively cheap portable particle counter (PPC) was considered. At first each particle size (the number of each particle more than diameter 0.3, 0.5, 0.7, 1.0, 2.0, 5.0μm) included in the atmosphere was measured using PPC (KR-12A, RION Ltd.) near Inokuchi Elementary School station (34.37268 degrees N, 132.38475 degrees E) that was one of the observation stations of Atmospheric Environmental Regional Observation System (AEROS) in order to estimate PM2.5 from PPC. All 11 data set measured was used on May 25, June 8, June 22, August 3. The number of the particles less than 2.5μm (C2.5) was calculated by the relationship between cumulative particle number (CPN) and particle size. After having aspirated the atmosphere of 1L per 1 measurement, CPN of each particle size is measured by the scattering intensity of the semiconductor laser at 790nm. On the other hand, CPN for 195 days from March, 2013 to April, 2014 were observed to check PM2.5 in Higashi-Hiroshima. On the other hand, CPN were measured for 195 days (only on weekdays) from March, 2013 to April, 2014 to check PM2.5 in the city. Statistically high correlation was observed the relationship between CPN (total count of all particle size) and the in-situ PM2.5 in Inokuchi station. The measurement limit of PM2.5 and the estimation error (RMSE) were 4.1-12.8μg/m3. The environmental standards of PM2.5 in our country are 35μg/m3 by one-day average now. Therefore, the measurement limit by this method is judged to be a value quite lower than these standard values. This simple technique can be used enough as how for it to be careful of PM2.5 at least. Moreover, as a result of creating the time series variation diagram of PM2.5 in Higashi-Hiroshima using this observation method, the percentage which exceeds environmental standards in Higashi-Hiroshima was about 16%. Moreover, the season when the probability which exceeds the standard is the highest was in August.

Examination of the green space index by using CO2 concentration at ibaraki prefecture

ISHII, Kenta[1*] ; IMAI, Yukako[2] ; KANZAWA, Masanori[3] ; KUWAHARA, Yuji[4]

[1]Depertment of Urban and Civil Engineering, Ibaraki University, [2]Graduate School of Science and Engineering, Ibaraki University, [3]U-DOM co., Ltd., [4]Center for Water Environment Studies, Ibaraki University

The objective of this study is to propose the correction method and evaluation index of CO_2 concentration data which is observed in human living sphere, Ibaraki prefecture. Since, sensor drift arise in the process of long-term continuous duty, it is important to correction process by using standard reference gas. However, sensor drift time are different in each sensor and installation location, so, it is conducted the laboratory experiment and observation data analysis to grasp the action of CO_2 sensor. The results of this study were as follows: 1) It was proposed that the correction method for observation data which is combined linear transformation. 2) It was verified of the correction effect focused on the time variation and spatial distribution of CO_2 concentration.

Estimation for water surface temperature distribution in Lake Shinji and Lake Nakaumi using Landsat-8 TIRS data

SAKUNO, Yuji[1*]

[1]Institute of Engineering, Hiroshima University

Lake Shinji and Lake Nakaumi are brackish water lakes with the rich biological resources represented by Corbicula japonica. However, the abrupt increase of blue-green algae or the spontaneous expand of aquatic macrophytes are anxious about the influence on such a biological resources of the lake in recent years. Therefore, various monitoring methodology for the elucidation of those generating mechanisms is examined. The satellite remote sensing is expected as a leading monitoring tool. Especially water temperature is important as most fundamental physical parameter. On the other hand, the Landsat-8 in the field of satellite remote sensing on February 11, 2013 was launched by NASA/USGS. This satellite has been continuing observation with 16 diurnal periodicity. The thermal infrared sensor (spatial resolution of 100 m) called TIRS (Thermal Infrared Sensor) with the multiple-spectrum sensor at visible and near- infrared bands with a spatial resolution of 30 m called OLI is carried in this satellite. Since high quantization (12 bits) and 2 band of TIR are realized as compared with conventional Landsat-7, more highly precise WT distribution estimation is expected. So, in this paper, to develop the surface water temperature (SWT) estimation by MCSST (Multi Channel Sea Surface Temperature) algorithm in these lakes using TIRS sensor and the accuracy was checked. Moreover, the SWT distribution characteristic in these lakes was considered using the proposed algorithm. The satellite data used is ten scenes from April to December, 2013. The Landsat-8 TIRS Leve l 1 product data was downloaded through the Internet site ”Earth Exploler.” The average value of 3x3 pixels of Band10 (10.6 - 11.2 μm) and Band11 (11.5 - 12.5 μm) in these lakes was extracted from the obtained satellite data. The data was changed into brightness temperature (BT). On the other hand, the SWT data at 1.0 meters under water was obtained from the Water Information System of Ministry of Land, Infrastructure and Transport. Moreover, MCSST (Multi Channel Sea Surface Temperature) which can reduce the air effect using two bands at thermal infrared for WST estimation from TIRS data was adopted. 19 datasets in the center of these lakes were used for development of MCSST. Three datasets acquired to the Yonago Bay were used for validation. WST estimation accuracy is expressed by average (bias) and standard deviation (error) of the residual substance of in-situ WST and satellite estimation WST. The WST accuracy using the single band algorithm of TIRS Band 10 and Band 11 was [bias: 1.3 oC, error: 1.7 oC] and [bias: 0.9 oC and error: 2.4 oC], respectively. On the other hand, the WST accuracy by the MC method was calculated with [bias: 1.3 oC, error: 0.6 oC]. The WST difference of the 3 data validated in Yonago Bay was an average of 1oC. Noise Equivalent Differential Temperature (NEdeltaT) of TIRS sensor, The estimation accuracy of NOAA AVHRR in Mutsu Bay using the MCSST method is considered that this result is an appropriate numerical value from their being 0.4K (= 0.4 oC) (Irons et al, 2012) and about 0.5±0.2oC, respectively. The WST map in these lakes was created using the proposed MCSST type. As for the WST in Lake Shinji lake in this period, it was checked through every year from these figures that a surface water temperature difference is about 3-5oC in the range of 5-30oC. Moreover, in the mouth of a river of Hii River and Shintate River which are located in the Shinji Kosai shore especially in a summer, the low-wash temperature pattern resulting from inflow of river water was observed.

Feasibility Study for the Estimation of the Chlrophyll-a Using ASTER Data in an Eutrophic Lake, Sri Lanka

DAHANAYAKA, D.d.g.l.[1*] ; TONOOKA, Hideyuki[1] ; WIJEYARATNE, M.j.s.[2] ; MINATO, Atsushi[1] ; OZAWA, Satoru[1]

[1]Graduate School of Science & Engineering, Ibaraki University, [2]Department of Zoology, University of Kelaniya

The objective of this study is to evaluate the performance of the previously proposed band ratio approach in estimating Chl-a in Bolgoda Lake, Sri Lanka as a representative example of Case II waters. Lake is located at western province in an area with lot of industries and also with some agricultural activities. Considerable amount of industrial effluents are discharged into it. Illegal filling and also encroachment has occurred in the recent past. This study focused on to determine the trends in eutrophication via Chl-a changes during the recent past, make predictions and recommend mitigatory measures and suggest precautionary measures to restore the environment. From March to December 2013, water samples at 5 points of Lake were collected once per month parallel to ASTER overpass and Chl-a of each sample was measured using a laboratory spectrophotometer. Cloud-free ASTER scenes acquired over Lake under clear sky conditions were selected during 2000 to 2013 for Chl-a estimation and trend analysis. All the ASTER images were atmospherically corrected using FLAASH and in-situ Chl-a data on Lake were regressively analyzed with atmospherically corrected three ASTER VNIR band ratios such as B1/B2 of the same date. Finally, the regression equation of the band ratio with highest correlation (B1/B2; R^2 = 0.78) was used to develop algorithm for generation of 15-m resolution Chl-a distribution maps using atmospherically corrected time series satellite imageries in day by day basis. This method applied for ASTER band 1/2 ratio due to Chl-a is positively correlated with the green band reflectance and negatively correlated with the red band reflectance. Therefore, the reflectance ratio of green and red bands becomes a robust parameter to estimate the Chl-a content. According to the ASTER based Chl-a distribution maps it is clearly evident that eutrophication of the Bolgoda Lake has been gradually increased from 2005-2011. Further, results showed that there were significant eutrophic conditions throughout the year 2013 in several parts of the Lake and considerable spatial heterogeneity with higher concentrations being recorded water stagnant areas and in water adjacent to freshwater outlets. It is clear that Bolgoda Lake is apparently a disposal site of various discharges of factories in addition to poor drainage and sewage systems present in this area. Highly unplanned urbanization and absolutely lack of adequate waste disposal management facilities in industries close to Lake have resulted in pollution of water. If the present trend of waste disposal and unplanned urbanization continue, they would create enormous environmental problems in future. Results of the present study showed that information from satellite remote sensing can play a useful role in determining the changes in Chl-a related to eutrophication in Bolgoda Lake and in the development of time series Chl-a distribution maps. Such information is important for the future predictions, development and management of this area as well as in the conservation of biodiversity. Therefore we recommend incorporation with this technique for routine monitoring of water quality using multi satellite data such as ASTER in inland water bodies like Bolgoda Lake in the future.

Study on the information visualization aimed at maintenance and utilization of local resources

ISHIUCHI, Teppei[1*]

[1]Akashi National College of Technology

In recent years, the problems of loss of sense of community and increase of indifferent residents, dilution of human relationships in the neighborhood, by dilution of a sense of belonging to the community, such as the moral decline is happening at local areas. Therefore, It become difficult for precisely corresponds to such changes alone to public administration ? driven. Target area of this study is Akashi city. This area has many rich rural environment and ponds, wooded area, waterway as remnant of village forest. And half of the residents of the town Uozumi-cho are a migrant.

In these areas, in order to promote community development befitting UOZUMI town, on an understanding of the digging up the history and culture of various regions, it is possible to stare life in the current region is important in the future. And, it is leading to a chance to foster protect the charm of a familiar town to residents themselves living in the town. Further, in order to form a hometown, it is necessary to dig the local resources, reaffirming residents share a town appeal. In this study, we dug up local resources existing in Uozumi-cho, and visualized as maps using the GPS positioning system. Finally, in order to convey to posterity the presence of valuable community resources, this study is proposed that the residents to re-recognize the appeal of the region by using a map.

Examination of land cover change region presumption method by using coherence value

SEKINE, Daiki[1*] ; YUKI, Sohei[2] ; KUWAHARA, Yuji[3]

[1]Depertment of Urban and Civil Engineering, Ibaraki University, [2]Graduate School of Science and Engineering, Ibaraki University, [3]Center for Water Environment Studies, Ibaraki University

In recent years, many natural disasters have occurred because of abnormal climate. In a time like this, use of satellite data is advantageous to observation of the disaster region for a wide area. However, in order that photo sensor data may tend to be subject to the influence of atmospheric, synthetic opening data attracts attention. And, this research examined coherence data among the information generated from the Synthetic Aperture Radar data. The results of the research are as follows: 1)The coherence value of a vegetation region is low. This result is expressing that the growth environment of vegetation differs for every year. 2)The coherence value of a city area is high.

Keywords: land cover change, SAR, coherence value, land cover classification map, PALSAR

A Technique for High-performance Data Processing of Satellite Observation Data via NICT Science Cloud

MURATA, Ken T.[1*] ; KASAI, Yasuko[1] ; SATO, Shinsuke[1] ; ISHII, Shoken[1] ; WATANABE, Hidenobu[1] ; UKAWA, Kentaro[2] ; MURANAGA, Kazuya[2] ; YUTAKA, Suzuki[2] ; YAMAMOTO, Kazunori[1] ; TATEBE, Osamu[3] ; TANAKA, Masahiro[3] ; KIMURA, Eizen[4]

[1]Natl. Inst. of Info. and Communications Technology, [2]Systems Engineering Consultants Co., LTD., [3]University of Tsukuba, [4]Ehime University

It is said that data-intensive/data-centric science is the fourth paradigm of science after observation/experiment, theory and computer simulation. The NICT science cloud is one of the cloud systems for scientists who are going to carry out their research works for their big-data science. The science cloud is not for simple uses: Many functions are expected to the science cloud; such as data standardization, data collection and crawling, large and distributed data storage system, security and reliability, database and meta-database, data stewardship, long-term data preservation, data rescue and preservation, data mining, parallel processing, data publication and provision, semantic web, 3D and 4D visualization, out-reach and in-reach, and capacity buildings.

The present talk is focused on the topics of applications of the NICT Science Cloud to environment sensing research works. There are three applications to be introduced: (1) real-time data processing and visualization of 3D Doppler radar, (2) GOSAT CH4 data processing for global mapping, and (3) high-performance simulation of the ISOSIM-L (Integrated Satellite Observation SIMulator for a spaceborne coherent Doppler lidar) for wind measurement from space. These three projects are started and carried out in the NICT. With help of the NICT Science Cloud, they show progressive development to either larger-scale studies or more practical uses.

Investigation of geographical feature and vegetation using for planting plan of the coastal zone at Tuvalu

KUWAHARA, Yuji[1*] ; SATO, Daisaku[2] ; HIROMUNE, Yokoki[3] ; FUJITA, Masafumi[4]

[1]Center for Water Environment Studies, Ibaraki University, [2]Dept. of Architectural, Civil and Environmental Engineering, Tokyo Denki Univrsity, [3]Dept. of Urban and Civil Engineering, Ibaraki University, [4]Dept. of Urban and Civil Engineering, Ibaraki University

The objective of this study is to investigate the geographical feature of coastal vegetation growing in Funafuti Atoll, Tuvalu. In order to maintain the living environment of the South Pacific islands countries, sea-level rise is a serious problem. Thus, in this study, analyzed was the relation of land cover of shoreline area and hinterland by using aerial photograph (1984) and satellite image (2004). Then, geographical feature conditions of the coastal vegetation growing under natural condition were surveyed, and it was found that the coastal vegetation was growing in the altitude between 1.1m - 2.2m at Fongafale-island, Funafuti atoll.

Factor analysis and vegetation change in China Inner Mongolia through Satellite Remote Sensing

BUHE, Baoyin[1*] ; KONDOH, Akihiko[1]

[1]Center for Environmental Remote Sensing, Chiba University

In this study, the spatial and temporal vegetation cover change of the Inner Mongolia Autonomous Region was analyzed by using the time series satellite SPOT VEGETATION dataset from 1999 to 2012. The vegetation change trend was analyzed by the Normalized Difference Vegetation Index (NDVI), and the result was estimated by the Mann-Kendall rank statistic method. Annual maximum vegetation biomass can respond well with maximum NDVI change trend and annual vegetation product approximately similar with total amount of NDVI trend. Vegetation index has closely correlation with annual precipitation. The results revealed that the vegetation status of Inner Mongolia was affected significantly by the precipitation. Due to the benefit of return farmland to grassland and forestry policy such as forestation, cultivation of the arable land and increase the irrigation area, the vegetation in the southeast and middle south of Inner Mongolia significantly increased. In the northeast of Inner Mongolia, due to the global warming and wetland development the forestry growing period become longer that exactly reflect the vegetation cover increasing phenomenon . The vegetation distributed in middle-west of Inner Mongolia has decreasing trend and desert area was continuously extending within 14 years.

Study on the Spatial Analysis of River Flooding in the Amur River Basin

YOU, Qin[1*] ; KONDOH, Akihiko[2] ; HARADA, Ippei[3]

[1]Graduate School of Science,Chiba University, [2]Center for Environmental Remote Sensing, Chiba University, [3]GIS Laboratory, Tokyo University of Information Sciences

Amur River is flowing through the border of China and Russia, and pour into the sea of Okhotsk. There are three plains in the Amur River basin, China famous commercialized food producing area of the Sanjiang Plain and the Songneng Plain are two of them. In order to develop the arable land in recent years, the land cover change and destroyed natural environment made the floods to be easily happened which be concerned. On the other hand, the drainage area of Amur River is 2.05 millions km^2, it is a problem for satellite observation in spatial, and for extracting the flood information when there are clouds in the sky, the microwave image is used, but it will be expensive in the area of Amur River basin. So the analysis of river flooding will be the challenge. In this study, in order to understand the flooded situation of the Amur River basin, we used high temporal resolution satellite image to extract the two big floods of 1998 and 2013 by the spectral absorption characteristics of the water. We understood that there are different courses in twice flooded, and at the downstream of Amur River where is well to flooding, because of the wetland be changed and topography relief bring about drain off water difficulty.

A preliminary study on using MODIS NDVI time series for monitoring abandoned farmlands in mountainous areas

SAKUMA, Asahi[1*] ; SHIMAZAKI, Hiroto[1]

[1]Kisarazu National College of Technology

This study preliminary evaluated the feasibility of Normalized Difference Vegetation Index (NDVI) time series for monitoring abandoned farmlands in mountainous areas in Chiba prefecture. NDVI time series was derived from 8-day composite of MODIS Surface-Reflectance Product (MOD09) for the period from 2003 to 2013. The noise component in NDVI time series, which was induced mainly by cloud contamination and atmospheric variability, was reduced with the method based on Savitzky-Golay filter. The refined NDVI time series was then decomposed into trend, seasonal, and reminder components. A simple linear regression model was fitted to the trend component of each pixel, and model parameters (i.e., intercept and slope) estimated were considered to be candidate features to find the occurrence of abandoned farmlands in the pixel area. This idea was based on the assumption that (1) overall NDVI in mountainous areas would be higher than that in other areas because of relatively-dense vegetation; and that (2) NDVI in specific seasons would have differences between farmlands and abandoned farmlands due to the effect of cropping activity. Classification performance was measured with the area under the receiver operating characteristic (ROC) curve (AUC). The results showed that the model parameters were poor (AUC=0.6) in terms of classification performance. Further efforts are needed to evaluate the feasibility of NDVI time series for detecting abandoned farmlands in mountainous areas.

Visual Surveillance of Natural Geography by means of UAV

HASEGAWA, Hitoshi[1*] ; ISOGAI, Tatsuhiro[1] ; ONO, Isamu[1]

[1]Kokushikan University

Unmanned aerial vehicle (UAV) systems can lead to major advances in physical geography. We have obtained a high-resolution digital aerial photographs using UAV (Unmanned Aerial Vehicle). UAV can make an automatic flight under the GPS control and take aerial photographs repeatedly with the same flight route. In this study, UAV was flying at 50 to 100m altitude. We have taken aerial photographs at coral reefs ,mangrove forests and the trench site of active fault. The high-resolution aerial photographs, a detailed classification map could be created, and it would also allow the extraction of dynamical topographic and vegetation development temporal changes.

The acquisition of geospatial information by small UAV

TANAKA, Kei[1*] ; KONDOH, Akihiko[2]

[1]Japan Map Center, [2]Center for Environmental Remote Sensing, Chiba University

The recent advances of MEMS devices(GPS, gyro and acceleration sensor) has made possible low-cost and miniaturization. Thereby, multi-copter mounted with these sensors have appeared.That it requires a high level of technology and knowledge in the handling of RC traditional helicopter,beginners to steer is difficult.To enable even beginners to get easily geospatial information of high-resolution by multicopter.

In this study, we examined method of acquiring geospatial information(orthophoto, DSM, NDVI, and temperature distribution) by using small UAV.

UAV application and possibility for disaster prevention.

SAITOU, Osamu[1*] ; KUWAHARA, Yuji[1]

[1]Center for Disaster Prevention and Security, IBARAKI University

Videos of the tsunami taken from the airplane conveyed the horror of the recent great disaster which attacked the various places in eastern Japan, the Great East Japan Earthquake of 2011. Numerous engineers and researchers were shocked by the images. Moreover, many real-time movies and images of this disaster exist. Especially in the past several years, other disasters caused by extreme weather because of our changing climate, such as heavy typhoons, rain cataracts, flurries, and tornadoes, also cause widespread destruction. When these disasters or earthquakes occur, rapid situational assessment is crucially important, but it is difficult because transportation systems including roads and railways often shut down under those circumstances. Therefore, a monitoring system that provides information immediately when a disaster occurs is required. When a disaster occurs, monitoring from an airplane or satellite is effective but such systems are not easy to use. This study examines the possibility of disaster monitoring systems using uncrewed aerial vehicles (UAV).

Proximity air measurement of the radiation by unmanned small helicopter

KAJIWARA, Koji[1*] ; HONDA, Yoshiaki[1]

[1]Center for Environmental Remote Sensing, Chiba Univ.

The decontamination work of the radioactive material which dispersed in the accident of Fukushima nuclear power plant accompanying the Great East Japan Earthquake, is continuing to residential area, cultivated land, etc.

However, the still high dose is measured in the forest region.

It is a question whether safety can be guaranteed or not, even if it performs the roof of a house or building, and decontamination of only soil, when a forest is in living environment.

The radiation measuring instrument which enabled it to adjust the distance to the target for measurement with the winch attached to the small unmanned helicopter in this research is used, the dose of a tree crown from the position close to about 100m has been measured, and it was shown that field dose measurement in the forest is possible.

Moreover, even if it was the decontaminated place, it checked that a space dose in case it approaches and a forest exists changed with altitudes.

Generating three-dimensional models by a software that unifies SfM and multiview stereo (MVS)

UCHIYAMA, Shoichiro[1*]

[1]National Research Institute for Earth Science and Disaster Prevention (NIED)

In recent years, the software which unified Structure from Motion (SfM) and multi-view stereo (MVS) was developed. By this, construction of three-dimensional models and its Digital elevation models (DEMs) can be achieved with PC at easy and low cost. This paper shows a method for generating three-dimensional models by using with a SfM-MVS software and images captured by a handheld camera or an UAV's.

Safety measures for multicopter aerial photo survey

INOUE, Hiroshi[1*] ; UCHIYAMA, Shoichiro[1] ; SUZUKI, Hinako[1]

[1]National Research Institute for Earth Science and Disaster Prevention(NIED)

Low-altitude aerial photographing using multicopters, radio-controlled multi-rotor helicopters, became easy for everybody because of their recent technical advancement and price declines of the equipment. The technology will become popular rapidly as one of the methodologies of field surveys. Multicopters, however, can crash into the ground. We have experienced crash or near-crash accidents through our surveys and test flights in the past. The causes are sometimes a simple pilot error, loss of a propeller, unexpected strong wind, and out of battery, and are sometimes unclear, like GPS signal loss and barometer error, and their combinations. The crashes could have made serious injuries if the multicopters hit humans judging from the damage to the equipment we experienced.

The measures we take are careful pre-examination of the flight plan, making propeller guards, knowing battery capacity-flight time characteristics, monitoring battery voltage during the flight, regular maintenance of the batteries, pre-flight equipment checks, acceleration and compass calibrations, communication between the pilot and copilot, full utilization of autonomous flight, training of manual control for emergency, and following the safety check list.

Multicopter survey could cause problems to the society if accidents occur often as the result of popularization. If the usage becomes too strictly regulated, we may limit or even lose the large potential of applying the multicopter technology to our field survey. We therefore need to establish the safety measures to be obeyed, and share experiences of accidents for wider recognition of its potential danger, clarify individual causes, in order to strengthen the measures. Compliance to the aviation and wireless communication laws and regulations are indisputable. We also have to buy an insurance to compensate the possible damage caused by an accident.

Mapping active faults by using small unmanned aerial vehicle and structure from motion: a case study on Midori fault

UCHIYAMA, Shoichiro[1*] ; NAKATA, Takashi[2] ; INOUE, Hiroshi[1] ; KUMAHARA, Yasuhiro[2] ; SUGITA, Satoru[3] ; GOTO, Hideaki[2] ; IZUTSU, Jun[3] ; FUKUI, Hiromichi[3] ; SUZUKI, Hinako[1] ; TANIGUCHI, Kaoru[4]

[1]National Research Institute for Earth Science and Disaster Prevention, [2]Hiroshima University, [3]Chubu University, [4]National Institute of Advanced Industrial Science and Technology

We photographed the geomorphometry of the Midori fault scarp formed by the 1891 Nobi earthquake in Motosu city, Gifu Prefecture (Japan) by using a multirotor radio control helicopter as a small unmanned aerial vehicle (sUAV), and we analysed these images. A digital surface model (DSM) of 0.09 m mesh and an orthophoto with a resolution of 0.03 m were generated from these images by PhotoScan software produced by structure from motion (SfM). A topographic map with 1 m interval contours and a cross-section profile were processed using a DSM produced by ArcGIS. We expect that the new technology will be applied to tectonic landform survey and geomorphology research. In addition, our results should help to ensure flight safety and compliance with the law.

Multicopter Aerial Photo Survey of Building Damages by 2013 Bohol Eearthquake in the Philippines

INOUE, Hiroshi[1*] ; HANAZATO, Toshikazu[2] ; IMAI, Hiroshi[1] ; MELOSANTOS, Arnold[3] ; ALCONES, Ponzch[3] ; SORIANO, Karl vincent[3]

[1]National Research Institute for Earth Science and Disaster Prevention(NIED), [2]Mie University, [3]Philippine Institute for Volcanology and Seismology(PHIVOLCS)

We demonstrate the effectiveness of multicopter aerial photographing for recording earthquake damages of low to medium-rise buildings. M7.2 shallow inland earthquake occured on Bohol Island in the Philippines on October 15, 2013, which caused thousands of building damages and more than 200 casualties in the western part of the island. Post- earthquake surveys by PHIVOLCS showed the maximum earthquake intensity in Tagbilaran city near the epicentral area was VII in Philippines Eearthquake Intensity Scale, which is equivalent to VI in JMA intensity scale. We visited the island three weeks after the earthquake, to make the damage survey focusing on church buildings using a multicopter. We also carried out aerial photogrammetric survey of the surface rupture of the earthquake fault and the coastal uplift(Nakata et al., JpGU 2014) and the landslide damage of chocolate hill, a distinguishing morphology on the island.

A number of stone masonry churches founded in the 16th century in the Spanish colony times were damaged by the earthquake. The existing building of Baclayon Church, which was constructed in 1727 and known as the oldest church in the Philippines, lost the upper half of the bell tower and the whole front wall of the cathedral. Loboc Church and the adjoined museum in the Loboc city lost most of the side walls except their lower part. Maribojoc Church in the west and Clarin Church in the north of the island collapsed completely. Notable damages are also on non-structural masonry walls confined by RC columns and beams of public buildings, such as Sagbayan city hall and Tubigon city hall.

We used a small and easy-to-fly multicopter named DJI Phantom and a high-resolution and compact digital camera GoPro Hero3 Black Edition for the aerial photographing. We attached the camera facing obliquely down and manually controlled the copter in GPS stabilized mode. We used a FPV (First Person's View) system FatShark Telepoter V3 for watching the camera view. Photos were taken continuously in 2 seconds interval, while the copter was flying around the subjects. We limited the duration of each flight to five minutes and attached propeller guards to the rotors in order to reduce the possible dangers by crash as much as possible because people's activities in the areas around the churches were normal. We had no accident during the survey. We found that FPV is very useful in building damage survey because it can reduce the risk to crash to the building when taking photos, while it is difficult to know the distance from the copter to the subject in manual control from the ground.

The left figure shows the multicopter aerial photos of the damaged Baclayon Church. We can observe the fracture surfaces of the upper structure and its inside which are invisible from the ground. Aerial photographing using multicopter right after an earthquake is an efficient tool to easily get full picture of the damage even when approaching from the ground around a building is difficult. We then processed about 50 aerial photos using an SfM (Structure from Motion) software PhotoScan to reconstruct the 3-D model of the bell tower as shown in the right figure. The techniques enable modeling fractures of buildings and their analyses. The 3-D models are also valuable as digital architectural remains of disasters. Aerial photogrammetry using multicopter and SfM is easier than 3-D measurement using laser scanner. Creating a miniature of damaged building from the digital model using 3-D printer will also be useful for planning repairs and earthquake resistant design of buildings.

Production of vegetation/landcover and dose rate maps by small helicopter and UAV

KONDOH, Akihiko[1*] ; HONDA, Yoshiaki[1] ; KAJIWARA, Koji[1] ; NORO, Naoki[2] ; TAKARA, Yohei[2] ; ANDO, Fuminori[2] ; FUJIMORI, Takahiro[2] ; NONAMI, Kenzo[3] ; YAMAGUCHI, Hidetoshi[4]

[1]Center for Environmental Remote Sensing, Chiba University, [2]EBA JAPAN CO.,LTD., [3]Graduate School of Engineering, Chiba University, [4]SWR CO.,LTD.

The most essential and important information for restoration of the area contaminated by radioactive materials is dose rate and landcover map. The map should cover the SATOYAMA watershed with several hundreds to several kilometers scale, because the life in mountain village depend on water and material cycles in SATOYAMA watersheds and mode of deposition is strongly affected by vegetation type such as deciduous broad-leaved or evergreen coniferous forests. However, large scale maps on present vegetation and dose rate distribution are not available at present, so our team attempts to create vegetation/landcover map and dose rate distribution map by using UAV(Unmanned Areal Vehicle).

Manned helicopter (Robinson R44), radio controlled gasoline engined helicopter (YAMAHA/RMAX), and radio controlled electric multicopter (Minisurveyer MS-06L) are used as platform of dose rate measuring system. Dose rate is measured by radiation detector module (C12137-01, Hamamatsu Photonics) controlled by small laptop computer.

Hyperspectral camera (NH-7, Eba-Japan Co.,Ltd.) and video camera are installed on manned and unmanned helicopter to map precise vegetation and landcover map. In hyperspectral camera operation, both pushbroom and still images are taken. Motion video is captured to get still images, and mosaicked to ortho-areal photo.

Field campaign are carried out two times during August and November in 2013, and various photographing modes three-dimensional dose rate mapping, and dose rate on various landcover such as forest canopy are attempted.

The campaign reveals the feasibility of low-cost, on-demand photographing and dose rate survey buy using UAV. Next subject is implementation to the actual scene. We plan to continue dose rate survey in Yamakiya district, Kawamata Town in Fukushima Prefecture.

Airborne LiDAR bathymetry survey in Japanese Pacifc coast in 2013

MATSUNAGA, Tsuneo[1] ; ISHIGURO, Satoshi[1*] ; YAMANO, Hiroya[1] ; OGUMA, Hiroyuki[1]

[1]National Institute for Environmental Studies

In 2013, Airborne lidar bathymetry survey in Japanese Pacific coast was planned and partially conducted at several selected-sites.

The objective of this survey is to acquire detailed bathymetry data in Japanese Pacific coast which are important for Tsunami simulation as well as monitoring of coastal environment and ecosystem heaviliy damaged by the Great East Japan Earthquake occurred in March 2011.

An airborne lidar bathymetry system, Fugro LADS Mk. III, was brought to Japan for the first time in October 2012. Data acquisition flights over several coastal areas in Hokkaido, Tohoku, Mie, and Tokushima were conducted in November and December, 2012, and remaining areas in Tohoku and Izu were conducted in September and October, 2013. Obtained data are currently being calibrated and evaluated.

In this presentation, the outline of the survey including instrument specifications, mapping areas, and the survey schedule as well as lidar data acquired will be presented.

Identification of sidewalk steepness from LIDAR data for Tsukuba University campus bicycle riders

MURAYAMA, Yuji[1] ; LWIN, Koko[1] ; ZHOU, Yifei[1*]

[1]Graduate School of Life and Environmental Sciences, University of Tsukuba

(1) Motivation

Bicycles are the most prominent travelling mode in many universities. Measurement of safety factors for sidewalk bicycle riders is essential for university authorities in order to concern public safety and to improve campus facility management information system. Information of sidewalk steepness is useful for daily bicycle riders inside the university campus in order to prevent unnecessary accidents while they are riding, especially at night.

(2) Data and Methods

In this study, we used very fine scale Light Detection And Ranging LIDAR data to identify the sidewalk steepness by integrating with Smart Field Data Collection System∗and deliver the information through Campus Web-GIS.

(3) Results

Based on our study, LIDAR data are much promising to detect sidewalk steepness in open spaces. However, the accuracy was reduced in some areas where the sidewalk covered with trees and bridges. Intensive field investigations are required to correct them. We built a *Smart Field Data Collection System* to correct and modify the results by using Android smart phone application.

(4) Prospect

Identification of sidewalk steepness from LIDAR data is cost and time effective. Additional user friendly real-time Web-based GIS field data collection system to collect, store and modify the results by multiple users is a great benefit for data validating purposes.

The Buffer Zone Model of Natural Conservation Area

TANKA, Kazunari[1*] ; YOSHIKAWA, Shin[1]

[1]Osaka Institute of Technology

1. Introduction

In the Kii mountainous region in the south Kinki area, there are preserved beautiful forest and river. However, the area faces problems of sustaining local industries as number of successors was declining due to the decrease of birthrate which is the major problem of Japanese society. Especially the decline of population and competitiveness of local industries are serious problems.

The 'Sacred Sites and Pilgrimage Routes in the Kii Mountain Range' are registered under the World Heritage Site in July 2004. This is the second example of linear type World Heritage Site. The first Site was the 'Camino de Santiago', which means the 'Way of St. James' in northern Spain.

The buffer zone of the 'Sacred Sites and Pilgrimage Routes in the Kii Mountain Range' is set as fifty meters from the center of the trails for both sides. This fifty meters' buffer zone was set without theory in terms of conservation of the environment around the World Heritage registered area.

The core area of the 'Camino de Santiago' is linear type as well. It connects cultural monuments, cathedrals and beautiful nature sites in Spain and in France. The buffer zones of the area was set for thirty meters from the center of the trails for both sides. However, if considering the visibility of the Pyrenees mountainous areas, wider area should be covered as buffer zone. As there are no standard criteria for the buffer zone setting that the study aims to develop GIS, which can determine the appropriate buffer zone.

2. Purpose of Report

In this report, we tried two studies; one was to survey the visibility of forest with plants laser measurement device. Secondly, the study achieved the method to describe the forest model in digital format. As for the further step, we will analyze the relationship between the result of the survey and the model. Based on the data we obtained, we will try to make a model to set buffer zone for conservation area.

3. Analysis

The analyzed area of this report is Koyasan Cyoichi-michi trail in the 'Sacred Sites and Pilgrimage Routes in the Kii Mountain Range' World Heritage Site. We surveyed several points using 3D laser scanner. The points were determined based on the pre-survey by photo and conventional measured. The points we surveyed differ such as vegetation and geographical conditions. The typical vegetation was the cluster of plants of cryptomeria. On an average within the seventeen meters there were many obstacles, which disturb visibility (24.7%).

We also analyzed to application of the survey results to a model plantation area for the comparison. The artificial plantation model is created from the typical trunks of trees with locations and even distances, which make the model to be quantitative.

We set the viewpoint surface every one meters. We estimated that the visible area and invisible area can be determined by setting lines between human visions and trees within. It showed the difference between visible area and invisible area. The percentage of the transitivity of visibility is calculated based on the above results.

The model is set based on periodical growth of plants. The previous study indicated that statistically cryptomeria of forty to sixty years old is majority of plantation. We calculated the distances of transitivity (an average distance) based on the visible-invisible analysis using GIS system. Finally, we verified the results (photographs) at the actual sites.

4. Conclusion

The study found out the possibility of the method that make the model of the buffer zone related with real space. The model we established in this study can expect statistically reliable results from simple survey method and objective data. The study will fine-tune results in applying the detailed data. Simultaneously, we aim to develop criteria based on the differences of the part of trees, as well as other natural environment.

Effects of the buffer models in the estimation of the spatial SPM distribution at the sky of the Yokohama city

YAMAKAWA, Junji[1*]

[1]Graduate School of Natural Science and Technology, Okayama University

In the estimation of the SPM distribution on successive region of interest from the concentrations observed at the observatories located in various places, the kriging method (Matheron, 1973) has been frequently employed. At the case, the universal kriging with auxiliary maps is used for minimize the variance of the estimation. In this study, two types of the auxiliary maps were used in the universal kriging estimation of the SPM concentration distribution. One of the map was a terrain map based on the DEM, and the other map is a buffer map generated from the buffer model based on the buffer distance from the coastline. However, if the region of interest is a wide area that includes a sea part and the land part, and if the observed values of SPM concentration at sea part have not been obtained, the validity of the estimated SPM distribution by the universal kriging may be affected by the used buffer models. Therefore, the effect of the buffer maps in the estimation of the SPM spatial distribution by a universal kriging was investigated in this study.

The SPM concentration data used in this study were published by the National Institute for Environmental Studies. The DEM data was extracted from the digital elevation models that have been published from the Geographical Survey Institute used with the FGDV application. The buffer model were created by the GIS applications based on the coastline data extracted from 1:200,000 Japan seamless geological map that was published from the Geological Survey of Japan. The coordinate projection method of all data were converted to Japan datum 2000 (JGD2000) to minimize the occurrence of error due to the difference of the projection method in geospatial computing. In the representation and geospatial statistical analysis of the data, the R language and its geospatial packages and, the Google earth and FOSS4G were used.

In this study, the observation points of the SPM concentration were present only on the land area and not present on the sea part. Moreover, the altitude of the sea part were all zero in the DEM data. Therefore, in the prediction by the universal kriging at the sea part, even if the variance of the prediction is small, the accuracy of the prediction may be lost at the relatively large buffer distances. So, some care may be required when the predicted distributions are used.

Investigation of indoor positioning technology focused on signboard in railway station

SHIMIZU, Tomohiro[1*] ; YOSHIKAWA, Shin[2]

[1]Graduate School of Eng., OIT, [2]Faculty of Eng., OIT

The acquisition of the outdoor location information has become convenient and precise by the appearance and development of the satellite positioning technology. Recently, it has been more high precise positioning on a centimeter level by the launch of the quasi-zenith satellite in 2010. So, the various services utilizing the location information have been produced. In this way, the location information has become more important and essential as a kind of social infrastructures. Under such circumstances, the acquisition of location information in the indoor environment where the satellite radio wave cannot reach has been regarded important as a next step.

In this study, the authors are going to investigate an indoor positioning estimation technology focused on the railway station. In the railway station, the various needs, such as the advancement of amenities, the facilitation of pedestrian movement, the universal design associated with an aging society, the creation of a compact space appropriate for the population decline society and so on, have been required. In particular, the development of the railway station with multiple functions like business has been recently promoted in the metropolitan areas. So, the spatial structure of the railway station has been complicate because it has been required to play various daily roles for urban residents. And the precise acquisition of location information is more important in the indoor environment like the railway station which has much complexity in recent years. Therefore, the authors are going to investigate an indoor positioning estimation technology in the railway station space. Especially, the authors pay their attention to the signboards of important information indicating ”positional relations of the space” in the railway station.

First of all, the authors built the database of the sign system and the floor maps to estimate the indoor location. The authors built it with three-dimensional information including the display height in addition to the plane information by extracting the signboard from the photograph. Also, they built the attribute information like the size and direction of sign boards, and the type and number of pictograms in the database. So, they tried to estimate an indoor location by using the photograph. Actually, they extracted signboards in the photograph by using the image processing technology. After that, the rough location where the signboards were taken in photos can be grasped by matching the attribute information. It is necessary to set an area in each signboard. In this study, the authors set up ” the effective visual field range ” of signboard , because they assumed to take a photograph when the signboard is confirmed. Finally, they are going to estimate a detailed indoor location by using photogrammetry technology. For the purpose, it is necessary to orient the already known three points with coordinates. Therefore, in this study, the detailed location is estimated by using three-dimensional coordinates on four corners of the signboard in the database. This study could obtain certain results as an indoor positioning technology through the investigation of ”the extraction of a signboard from the photograph ”, ”the estimation of the area from effective visual field range” and ”the estimation of the point location by photogrammetry technology”.

In future, it is necessary to make an effort for the improvement of accuracy related to the technology used in this study. In addition, the authors have to build the system that can automatically estimate an indoor position from the photograph.

Handling non-aggregated person trip data with Web-GIS

MURAYAMA, Yuji[1*] ; LWIN, Koko[1] ; GREGER, Konstantin[1] ; ESTOQUE, Ronald[1] ; KUBO, Takafumi[1]

[1]Yuji Murayama

Understanding of human mobility from spatial perspective is important for urban transport planners, human geographers, social scientists and other spatial information users. Advances in geospatial data collection methods and communication devices, we can nowadays collect, store and integrate large amounts of data with GPS and GIS technologies, including mobile phone log data, real-time weather information, person flow data etc. However, handling of these Spatial Big Data require computational power and considerable period of time. Extraction of information from these Spatial Big Data is also challenging for end users in terms of time consuming and requires knowledge on spatial data handling and processing. Here we construct a Web-GIS to extract, visualize and analyze the Person Trip Survey (PTS) data by providing common GIS analytical functions to novice to expert users in timely manner.

The Process of Growth and Cityscape Transition in Modern Osaka

NISHIMOTO, Takahiro[1*] ; YOSHIKAWA, Shin[2] ; TANAKA, Kazunari[2]

[1]NEWJEC Inc., [2]Faculty of Eng.,OIT

Most of big cities in modern Japan had been growing up remarkably with modernization from the Meiji period. Especially, the structure of space has been changing dramatically throughout a revival development in the post-war and in the high economic growth period. As the result, it have been become difficult to see the cityscapes of the past which built up with the modernization. However, in recent years after the arrangement of urban infrastructure settled down, the community development or a tourism using the historical environment have been carried out, and the interest in history has been increasing. In other words, to keep the historical environment has been increasing importance as property of city. On the other hand, GIS becomes more familiar to us by geospatial information technology spreads rapidly in recent years, in the middle of a highly information-oriented society. Especially, the utilization GIS is effective for the historical research, because it can process long-term spatiotemporal information like transition analysis.

Osaka was prosperous as the Aqua Metropolis in Edo period, and has become the modern city crowded with public transport and high-rise buildings in Kansai area at present. In this study, the authors are trying to investigate the historical transition in Osaka with modernization by using geospatial information technology. And they are going to recognize again the existence of characteristics in urban space which formated and disappeared with modernization, and to aim at reconstructing the historical environment.

It becomes necessary to arrange the long-term change efficiently in the study of urban transition. Therefore the authors decided to use the topographical map for six terms in this study from the middle of Meiji period when the modernization began. The authors make the spatial data which the street and the wetlands from this topographical map. And they constructed the urban transition database by using both these data and the database which was already built the river and the railway in our laboratory. As a result of expressed urban transition, the authors grasped that Yodo River which was the most catchment area in the present was formed with repairing Nakatsu River in the late Meiji period. And, the Dohjima canal was dug in Umeda from the early Meiji until before the war, the authors thought that this area was different urban space from present day. Paying attention to the street, the right bank area of the old Yodo River focusing Umeda has been becoming earlier urbanization than the other areas. At the same time, the reconstruction of buildings in the built-up area repeated with modernization, and the authors found the possibility that a changing of the scene was taking place close to the old Yodo River. From these results, the authors direct their attention to Umeda and the old Yodo River basin, and tried to simulate of the cityscape transition using the three-dimensional models in this study.

A terrain model is important for constructing urban model. In this study, the terrain was created 140 kilometers square using digital elevation model (DEM) data based a knowledge of the precedent study. The features are created as landmarks and general houses using CAD/CG. The authors selected Osaka station of Umeda and the mint of the old Yodo River basin for landmarks. These are reconstructed in great detail basing historical materials. As a results of the simulation, the authors could visualized the landscape transition in Umeda and the old Yodo River basin with modernization.

As the result of this study, the authors clarified the historical transition in the part of Osaka by using GIS and CAD/CG. At the same time, they reconstructed the historical environment as property of Osaka. In the near future, they are going to construct the animation of the transition of Osaka for the communication tool by using created spatial data. And it is necessary for three-dimension models to improve the accuracy.

Landscape analysis of daimyo garden using photograph information

ONO, Yoichi[1*] ; YOSHIKAWA, Shin[2] ; TANKA, Kazunari[2]

[1]FUKKEN CO., LTD., [2]Faculty of Engineering, Osaka Institute of Technology

In recent years, social media in the information technology have been developed remarkably. The scenes at sightseeing are photographed, and the photos are accumulated as the personal spatio-temporal information in a non-structured state on the Internet. In this study, the authors analyze the landscape phenomenon by using personal photographs, the photos are accumulated on the Internet in daimyo gardens.

Specifically, they take photograph images and spatio-temporal information on site and they pay theirs attention to the both sides of the space and time, and analyze the data on using GIS. At first, they choose the case study area from daimyo gardens where many tourists visit at present. Then, they pay theirs attention to the flickr is a photograph community site, and they make a photograph information database and grasp the scene phenomenon by using it.

Among other things, the three famous gardens in Japan are Kairakuen, Kenrokuen, and Korakuen. And Riturin-park is a beautiful garden as well as the three famous gardens. In addition, there are sightseeing spots that many people visit at present. Then, they collected spatio-temporal information and photograph images taken by the visitors in the four gardens by using the flickr API. As a result, Kenrokuen was selected as the case study garden for analysis.

At first, they utilize the Exif information contained in the photographic image data. This metadata is the information of the camera itself, and various information including the F-number and the focus distance are recorded with the positioning data. The Exif information is the index recorded at the time of the photography. In this study, the authors grasp visual characteristics of Kenrokuen by using the focus distance and a photography direction.

Based on the positional information, they plotted the focus distance on GIS with conversion into the 35mm film camera. As a result, they were able to grasp the characteristic in the garden. First of all, around the Ume grove, an angle of view range is narrow and people look the fixed scenes. People watched the buds and the flowers of the plum closely. The second is around the Kotoji-torou area. This area is an angle of view range is wide, and photography is carried out of showed, using the plural focus distances.

Then, the analysis was focused on the photographic images, The photography position is not usually fixed and shows a variety of distribution for one object. Therefore, the authors grasp each viewpoint field by a directional distribution analysis. In this analysis, the point cloud are photography positions, so the standard deviation ellipse created by the analysis is regard as the photography viewpoint field.

First of all, they classify the photographs and create the photography viewpoint fields. As a result, it was revealed that the place, where plural viewpoints fields were overlapped, while people went round the gardens. So, in the sequence around the garden, the people do not watch an object in turn, and it is thought that the features were seen under the complicate influence. In addition, as they investigate the relationship between the subject and the viewpoint field individually, they found several characteristics from the positional relationship between the object and the shape of the standard deviation ellipse. So, they classified photography viewpoint field based on the analysis and grasped viewpoint field with four different characteristics. They grasp on landscape phenomenon in viewpoint field at minute time, and they were similar to expression of the camera work.

In this study, the authors grasped visual characteristics of the case study area by using the Exif information. In addition, they grasp each viewpoint field for every photography object, and was able to model the viewpoint field.

GIS analysis of Australian urban social geography by using Census Table Builder Data designated by ABS

TSUTSUMI, Jun[1*]

[1]Graduate School of Life and Environmental Sciences, University of Tsukuba

A body of literature about multi-cultural aspects in Australia can be found in the fields of international politics, international relations and Australian history as well as Australian geography. Diverse origins of immigrants had a great impact on the changing structure of metropolitan areas in Australia. Based on some previous studies, non-English speaking immigrants, e.g. Greek and Italian in the 1960s, tended to live in the suburbs located 10-15 km apart from the Melbourne metropolitan core. These suburban areas were relatively " less convenient area " in terms of public transportation, but newly developed area supported strongly by motorization. New university, huge industrial parks, distribution centres and relocated suburban offices have been established in these newly developed areas. Immigrants in 1960s could only find affordable houses in these " new suburbs, " resulted in the expansion of the metropolitan area.

After 1990s and later, Australian cities are strongly affected by a " surge " of immigrants from Asian countries. They tended to live in the existed Asian communities located at the peripheries of the metropolitan area, much farther than " new suburbs. " Footscray in the west, Glen Waverley in the east and Springvale in the southeastern suburbs are typical examples of those communities.

In this paper, I focused on the changing structure of Sydney and Melbourne metropolitan areas in terms of diverse origins of immigrants. A GIS-based mapping with " table-builder data " distributed by Australian Bureau of Statistics was used to identify the process. This paper not only provides a methodological innovation but also a new and practical contribution to urban-social process studies.

Land use change in the Loess Plateau of North-Shaanxi and East-Gansu Province, China

HARA, Yuta[1*]

[1]GSGES, Kyoto Univ.

The Loess Plateau in China has some problems about erosion, desertification and economical problems. Erosion has a major influence on agriculture, forestry and grazing, because it cut the cropland and ruin the ecosystem (Matsunaga 2013, Saito 2008a).

From the end of 1990s, the Conversion of cropland to forest and grassland, namely the afforestation project to steep slope, started by the Chinese government for deal with these problems. However, these are not only the fruits (Saito 2008b). The reason, the Loess Plateau has diversity about the environment and humanity due to extensive.

From 2000, there are many investigations about the Land use change in the Loess Plateau. They made the quantitative spread about the green land clear caused by the Conversion of cropland to forest and grassland in China. However the quantitative land use change in the wide area of the Loess Plateau is unknown, because the study areas of the investigations are each basin of the Yellow River. Their compared years are deferent. The compared years are 2 after 1980s.

This study cleared the land use change by remote sensing in North-Shaanxi and East-Gansu Province of the Loess Plateau. In addition, I made the division map based on the change of forest and grassland. Used satellite photos are Landsat/MSS, TM. I did supervised classification by Maximum likelihood estimation. Moreover I did logical disjunction operation using the ArcGIS.

The following results were obtained : 1. There are conflicting differences to changes of the forest in Huanglong Mountains and Ziwu Mountains. 2. There are differences about more than one degree of desertification in the adjacent area of Mu Us desert. 3. Since 1990s, there are conflicting differences to changes about desertification in the hilly-gullied loess region as administrative boundary of Gansu and Shaanxi province. Moreover I estimated the first factor due to local differences using the SRTM.

Review of development of AMS in the past 30 years and future perspective

NAKAMURA, Toshio[1*]

[1]Center for Chronological Research, Nagoya University

One of the main aims of Quaternary research is to understand global environmental changes of the past and to predict the expected changes in the near future. To pursue this aim, high-resolution age estimation is particularly important. Dating methods so far used for Quaternary research can be classified into five categories: (1) age estimation based on the decay procedure of cosmogenic radioisotopes such as radiocarbon (14C) and 10Be, U-series nuclides and a K-Ar pair; (2) age estimation by cumulative dose from natural nuclear radiation and cosmic rays such as TL, OSL, ESR, FT dating methods; (3) age estimation with geological or geochemical evidences of prehistoric events such as paleomagnetic reversals or excursions, oxygen stable-isotope-ratio variations, tephra stratigraphy; (4) age estimation with paleontological records of prehistoric events such as diatom, pollen, nanno-plankton and shellfish assemblages, as well as semi-global fluctuations of tree ring width; (5) age estimation based on archeological evidences. These dating methods are selectively applied dependent on the characters of geological and archeological events to be analyzed. Among the radio-isotopic dating methods, 14C dating is most frequently used because of its applicability to many different types of Quaternary samples, as well as age range covered by this method (a few hundred to 50,000 yr BP).

Developments of accelerator mass spectrometry (AMS) have triggered a wide area of application in radiocarbon (14C) dating. The AMS system requires only 1mg of carbon in precise determination of 14C/12C and 13C/12C isotope ratios, and this advantage has broadened the applicability of 14C measurements. Nowadays, AMS contributes to almost all kinds of research that utilize 14C dating in archeology, cultural property science, geology, and those that employ 14C tracer in environmental sciences, medical sciences and even forensic studies.

For example, a Tandetron AMS system dedicated to 14C measurement was installed at Nagoya University, and its routine operation for 14C measurement was started in 1983 for the first time in Japan. In 1996, another AMS system (HVE-Model-4130-AMS) was purchased and has been used for high precision 14C measurements. By 30 minutes measurement of carbon isotopes repeated for consecutive three days for a sample, one-sigma uncertainty of +-17 to +-30 years is achieved. A reproducibility test for 2000-year-old archeological samples yielded a fluctuation error as small as +-11 years. We also have evaluated accuracy in our 14C measurements by participating in international 14C inter-comparison tests, and confirmed that our14C results were quite consistent with the consensus values by all the participants. After the critical tests, we are sure that our AMS system can be applicable to historical samples that require high precision as well as high accuracy 14C measurements.

Quite frequent applications of 14C dating with AMS to the Quaternary samples in the last bidecade are promoted by the following reasons: (1) a very small amount of carbon (about 1mg of carbon for the final target preparation) is required; (2) uncertainties of 14C ages are from +-17 to +-30 yr, mainly owing to the 14C counting statistics; (3) calibration of 14C age to the calendar age scale become quite popular, for 14C ages up to 50,000 cal BP; (4) marine reservoir effect on 14C age has been recognized and investigated recently, and a realistic correction for the effect is becoming possible partly.

Along with 14C, other cosmogenic radioisotopes such as 10Be, 26Al, 36Cl, 129I are also measured with AMS systems. We briefly describe history of development of domestic AMS groups as well as worldwide AMS groups, along with the research fields of AMS applications and future perspective.

Present status of YU-AMS

TOKANAI, Fuyuki[1*]

[1]Center for YU-AMS

Yamagata University (YU) installed an AMS (YU-AMS) system in the Kaminoyama Research Institute to meet the requirement of ^{14}C AMS for microdosing and medical studies as well as that of radiocarbon dating in the same facility. An automated graphitization line was also installed in the same research institute for sample preparation. This AMS system is the first AMS system installed in a university in north Japan (Tohoku-Hokkaido region). The facility also provides radiocarbon dating for samples from other universities, institutes and public organizations. Currently, we are planning to install a second new ion source and an automated graphitization line until March in 2014. In this paper, we describe the status of the YU-AMS system.

Development of isobar suppression system using Laser in Accelerator mass spectrometry

MIYAKE, Yasuto[1*] ; MATSUZAKI, Hiroyuki[1] ; HASEGAWA, Shuichi[2]

[1]Department of Nuclear Engineering and Management, School of Engineering, The University of Tokyo, [2]Nuclear Professional School, The University of Tokyo

For Accelerator mass spectrometry (AMS), isobar separation is quite important to improve measurement accuracy and the background. In order to suppress isobar interference, gas-filled magnet or gas counter have been conventionally used [1,2]. Nuclides of interest are separated from isobars by interaction between ions and materials in these devices.

In the 1980s, Berkovits et al. tried to remove stable isobars before acceleration with laser light[3]. In this method, the difference of the electron affinity (EA) was utilized for isobar suppression. If the EA of the nuclide of interest is higher than the EA of the isobar nuclide, only negative isobar can be selectively neutralized by photodetachment with photons of energy, which is higher than the EA of isobar nuclide but lower than the EA of the nuclide of interest. Consequently, only nuclide of interest can be injected into the accelerator and isobar suppression can be effectively achieved. However, due to the limited laser performance, the laser-ion interaction time was too short to suppress isobar sufficiently at that time. Therefore, this technique has not been in practical use yet.

Recently, as laser improved in quality and the way to increase the laser-ion interaction time effectively was proposed, development of isobar suppression system is going on. For example, Liu et al. developed the RFQ ion cooler to slow ions [4]. This apparatus is filled with a buff gas and ions collide with gas molecules, which results in the deceleration of ions and the long interaction time. This photodetachment system can remove isobar interference in AMS measurements for nuclides, such as Cl-36 (EA=3.62eV) with S-36 (EA=2.08eV), Ni-59 (EA=1.156eV) with Co-59 (EA=0.661eV) [4]. Furthermore, even if the EA of the nuclide of interest is lower than the EA of the isobar nuclide, photodetachment could be useful by converting the nuclides into the molecular ions and reversing these electron affinities.

In order to make laser interact with ion beams effectively, the ion beam optics including the devices like the ion cooler should be optimized. This device will be installed after the electrostatic deflector or after the injection magnet in the beam line. In this study, as a preliminary step, optimization of the ion beam optics including some components to decelerate ion will be dicussed.

Development of C14-free laboratory animals.

KOBAYASHI, Koichi[1*] ; AMS, Dating group[1]

[1]Paleo Labo Co.,Ltd.

In the early stage of pharmaceutical researches, ^{14}C labeled chemicals with very high radioactivity are administrated to laboratory animals to study pharmacokinetics. However, when $^{14}C/^{12}C$ of the laboratory animals could be reduced, the radioactivity level of the chemicals is expected to be reduced lower. Also when ^{14}C-free (DC ; denoted as dead carbon) laboratory animals were developed, the radioactivity level for the study is expected to be reduced down by five orders of magnitude or lower by using AMS technique. That means that we need not the ^{14}C labeled chemicals but natural level chemicals for the study of pharmacokinetics. In this case, it is also expected that we can be free from the hazardous high radioactivity and from the strictly regulated troublesome laboratory to handle the high level radioactive materials.

In Dec. 2010, we started the project to produce ^{14}C-free lives as feed for the ^{14}C-free laboratory animals. This is a preliminary report on the project, and parts of the investigation were already reported at 13th Japanese Symposium on AMS (Kobayashi et al., 2011). Here will be also introduced some recent studies.

When lives were cultivated in DC surroundings they grow up inevitably to be DC lives. For example, photosynthetic lives like vegetables or some kinds of microbes with chloroplast like euglena (midorimushi ; in Japanese) can easily be DC lives when they were cultivated in DC surroundings.

For the first step, we cultivated some plants and euglena using ^{14}C free water set in a glove box that was filled with artificial air (N_2, O_2 and dead carbon CO_2 with proper concentration) irradiating with some artificial lights. ^{14}C concentrations in the plants and the microbes were measured by AMS. Since the modern carbon (natural carbon) CO_2 could not be perfectly removed from the air and the water and air tightness of the glove box system was also not perfect, the percentages of dead carbon to modern carbon (DC ratio) in the samples could not be higher than about 80 %.(Kobayashi et al., 2011a ; Kobayashi et al., 2011b)

While investigating the cause of the imperfect DC ratio, we got 96% DC Euglena by using a little different way. That is to use a small glass bowl with an airtight lid, in which were set CO_2 tablets, a small amount of chemical fertilizer and Euglena. From outside of the bowl, fluorescent lamps irradiated adequate amount of light to them. One or two months later, the euglena was carefully collected on glass filters in a glove box filled with DC air. $^{14}C/^{12}C$ of the euglena was measured by AMS and the ^{14}C concentration was 3.71 ± 0.02 pMC (percent Modern Carbon) which leads to DC ratio as 96% (Kobayashi et.al., 2012).

In order to make sure that mice really eat the euglena tablets, we fed the mice with euglena tablets which were mixed with chlorella powder by 20%. The tablet is on the market for people as a health food. After three months feeding on three mice, there were no large differences compared to the other three mice which were fed by ordinary food for comparison. The experiment concluded that mice will grow up healthy by eating the euglena tablet.

Those two above data show the possibility to realize the DC animals.

Recently, we have started to extend the project to realize for business, supported by a grant.

^{14}C measurement of the Southern Japanese tree by the AMS method for high-precision radiocarbon calibration

HAKOZAKI, Masataka[1*] ; NAKAMURA, Toshio[1]

[1]Center for Chronological Research, Nagoya University

Radiocarbon (^{14}C) dating method has contributed to the age determination of samples of the past 50,000 years in geology and archaeology. However, since ^{14}C date is not in agreement with the calendar year, the calibration using a dataset which consists of ^{14}C data of calendar year known samples is required for it. Moreover, since there is regional difference of ^{14}C concentration in the atmosphere (regional ^{14}C offset; Hogg et al. 2002), in order to be high-precision calibration, the dataset for each area needs to be established.

The Center for Chronological Research (CCR), Nagoya University has measured ^{14}C data of tree-rings of a Yaku cedar from the Southern Japan, in order to establish a calibration dataset for Japan. Previous measurement has shown that the cedar shows 14C date older than global standard calibration dataset IntCal13 (Reimer et al. 2013) in various times for the past 2000 years (Nakamura et al. 2013). This report shows the measurement result of the tree-rings formed in the 5th century.

Sample is a Japanese cedar from Yaku Island, Kagoshima prefecture (sample code: Yaku_A). Dendrochronological analysis with a master-chronology (Kimura unpublished) has carried out, and the calendar year of this sample is known. After exfoliating the annual rings of AD434-502 of a sample in one year respectively, only even-numbered years was measured (n = 35). The tandetron AMS II of CCR was used for this measurement. Measuring only even-numbered years in order to understand a whole tendency previously, it also measures the samples of odd-numbered years in the future.

Thirty five ^{14}C dates of tree-ring samples showed that it will be older than IntCal13 for an average of 28 $\pm$ 22 years, a maximum of 76 $\pm$ 21 years (in AD488). These ^{14}C dates were mostly located in the middle of IntCal13 and SHCal13 (the calibration dataset for the Southern Hemisphere; Hogg et al. 2013).

Since Yaku Island touch the northernmost end of the Intertropical Convergence Zone in a summer, it is thought that the Southern Hemisphere atmosphere with regularly low ^{14}C concentration is easy to be supplied (Nakamura et al. 2012). This measurement result might suggest that ^{14}C concentration in the atmosphere of the Japanese neighborhood fell in the 5th century, and the atmospheric supply from the Southern Hemisphere may have become strong. Sakamoto et al. (2013) measured the tree-ring samples in the 5th to 6th century of the Japanese cedar from Nagano Prefecture Central Japan, and they has reported that the data is older than a IntCal13. Our result harmonizes with the measurement result of the trees from Nagano, and this time can consider a possibility that the influence of the Southern Hemisphere atmosphere had reached to central Japan. From now on, the tree-rings of Yaku cedar in formed the 6th century will measure, and it will compare with the result of Sakamoto et al. (2013).

C-14 dating and geochemical analyses of the tsunami sediments in continuous soil deposits from Tohoku area, Japan

WATANABE, Takahiro[1*] ; HOSODA, Norihiro[1] ; TSUCHIYA, Noriyoshi[1] ; NAKAMURA, Toshio[2] ; YAMASAKI, Shin-ichi[1] ; NARA, Fumiko[1]

[1]Graduate School of Environmental Studies, Tohoku University, [2]Center for Chronological Research, Nagoya University

Past tsunami sediments preserved in continuous soil and lake sediments are crucial and unique clues to reconstruct the past tsunami invasion area. Generally, the tsunami sediments originated from sea floor, sandy beach and/or coastal land soils containing gravels, sands, muds, shells and microfossils. In particular, muddy tsunami sediments should be found to detect the limit of tsunami invasion areas, because relative small particles move to more inland area with tsunami in comparison with sand deposits. Additionally, dating of tsunami sediments is indispensable to refer for historical disaster events. Therefore, we have to make age models of continuous soil deposits with tsunami sediments and new techniques for detection of invisible muddy tsunami sediment in strata. In this study, we performed the nine radiocarbon measurements of plant residues in continuous soil deposits as well as geochemical characteristics of tsunami sediments. 2m-continuous soil deposits were taken by the handy geoslicer (Fukkenn co. ltd.) from the Pacific coast of Tohoku area in northeast Japan. The samples were composed of cultivated surface soils, peaty clay, silt and sub-rounded medium sands. The sandy deposits were found between the peaty clay layers. To show the sedimentary ages of sandy deposits, plant residues were taken from the sandy and peaty clay layers in the continuous soil sediments. The plant residues were washed with ultra pure water using ultra sonic cleaner to remove soil particles containing relative old carbon. Then, the samples were treated sequentially with 1.2M-HCl, 1.2M-NaOH and 1.2M-HCl at 60 degrees of Celsius for 3 hours. After neutralization and freeze-drying, the samples were combusted in evacuated quartz tubes. Then, the purified carbon dioxide was reduced to graphite using Hydrogen gas with iron catalysts. Radiocarbon measurements were performed by the Tandetron AMS system (Model-4130, HVEE) in Center for Chronological Research, Nagoya University. Total organic carbon contents of the plant residues were from 45.9 to 54.5 wt.% (50.4 wt.% in average) and stable carbon isotope ratios of the plant residues ranged between -26.7 and -30.1 permil (vs. PDB), which consist with those of modern terrestrial C3 plants. As a result of this study, part of the calibrated ages of plant residues taken from just above the sandy tsunami sediments was about 1000-1300 cal BP, and these ages were agreed well with those of the Jogan earthquake and tsunami in the Sendai plain.

AMS radiocarbon dating of tephra layers on Adak Island, central Aleutian

OKUNO, Mitsuru[1*] ; NAKAMURA, Toshio[2]

[1]Fac. Sci., Fukuoka Univ., [2]CCR, Nagoya Univ.

The Holocene tephra layers distribute on Adak Island located in the central part of the Aleutian Islands. Radiocarbon (ˆ{14} C) age determination of charcoal fragments in the soil layer has been performed. Moreover, tephra is intercalated with sand layer of dune. Since sand dune has high depositional rate and low contamination of organic matter, a possibility of polluted charcoal sample from below and above tephra is low. Thus reliable age was able to be obtained by the AMS method to these small samples. We report those results.

Radiocarbon dating of stalagmites from the Ryugashi Cave, Shizuoka

KATO, Tomomi[1] ; MINAMI, Masayo[2*] ; HORIKAWA, Keiji[3] ; NAKAMURA, Toshio[2]

[1]Graduate School of Environmental Studies, Nagoya University, [2]Center for Chronological Research, Nagoya University, [3]Graduate School of Science and Engineering for Research, University of Toyama

Stalagmites are cave deposits precipitated from drip water. Drip water consists of carbon derived from soil CO_2, which has atmospheric ^{14}C values in isotopic equilibrium with atmosphere, and carbonate-dissolved CO_2, which has ^{14}C-free (dead) carbon through interaction with cave host bedrock. As a result, drip water contains a percentage of dead carbon, which will make the ^{14}C ages of the stalagmite older. Therefore, a correction of the dead carbon fraction is needed for ^{14}C dating of stalagmites. In recent years, young stalagmites of 10-20 ka have been ^{14}C dated by comparing the ^{14}C on samples of known calendar age with the tree ring record of atmospheric ^{14}C during a period of overlap (Hoffmann *et al*., 2010; Southon *et al*., 2012). This procedure involves the implicit assumption that dead carbon fraction in stalagmite remained constant through its growth time. In this study, therefore, we examined dead carbon fraction in two stalagmites from the Ryugashi Cave in Hamamatsu, Shizuoka by investigating seasonal variation in ^{14}C concentrations of drop water coupled with soil CO_2, atmospheric CO_2, and host limestone, in order to reveal possibility of accurate and precise ^{14}C dating on stalagmite in Japan.

The drip water samples showed ^{14}C of 1130 BP to 980 BP and $\delta^{13}C$ of -10.1 ‰ to -9.1 ‰, which are lower in fall and winter, and higher in spring and summer, and have the annual means of ^{14}C of 1025±140 BP and $\delta^{13}C$ of -9.4±0.4 ‰. The RYGS12 stalagmite of 7 cm in length showed 945±30 BP at its top and 2150±40 BP at its bottom, and had a growth rate of about 60 μm/yr. The calibrated age of RYGS12 was estimated by comparing the ^{14}C with the IntCal13 calibration curve, resulting that the stalagmite had a constant dead carbon fraction through its growth time and gives ^{14}C ages of 1050 years older than the true age. The carbon isotopic fractionation between drip water and stalagmite was negligible. The results indicate that high-resolution ^{14}C measurement can be performed on stalagmites in the Ryugashi Cave.

The RYGS12 sample showed rapid decrease of $\delta^{13}C$ from -8.3 ‰ to -11.8 ‰ at around AD1450 The decrease suggests an increase of soil input to the stalagmite, since soil CO_2 has low $\delta^{13}C$ of -22.0 ‰. It is reported that there was a great earthquake of magnitude 8.6 (Meio earthquake) accompanied by a catastrophic tsunami in this study area in AD1498. Therefore, the $\delta^{13}C$ decrease might be caused by the Meio earthquake. In the presentation, we will present ^{14}C result on another stalagmite sample RYG08 of 30 cm in length.

14C-based source apportionment of carbonaceous component in PM2.5 in Nagoya city

IKEMORI, Fumikazu[1*] ; YAMAGAMI, Makiko[2] ; HONJYO, Koji[3] ; NAKAMURA, Toshio[4]

[1]Graduate School of Environmental Studies, Nagoya University, Nagoya City Institute for Environmental, [2]Nagoya University, Nagoya City Institute for Environmental, [3]Graduate School of Environmental Studies, Nagoya University, [4]Center for Chronological Research, Nagoya University

The measurement of radiocarbon (14C) has been used to estimate the relative contributions of fossil and contemporary carbon sources in particulate matter throughout the world. In this study, we use 14C to provide quantitative estimates of carbon origin sources in Nagoya in April 2003 to March 2004. pMC and OC/EC showed similar seasonal variations and high values (range 39.8 to 68.4, 1.0 to 2.0; average 53.4, 1.5, respectively) in May and early June, whereas the values of pMC stayed relatively low values (range 28.3 to 41.9, 0.7 to 1.2; average 34.2, 1.0, respectively) after middle June. To estimate the source region of high pMC values, backward air mass trajectories were calculated during the sampling period in April to June. The air mass appeared to have passed through eastern Siberia when the pMC values showed high values in May and early June which also showed high values of OC/EC ratio and OC concentrations. In 2003, many researchers reported the influence of large forest burning in Siberia. This large forest burning occurred in spring to summer. The smoke from this forest burning had reached to Korea, Japan, and North America. The influences from the Siberian forest fires had an important implication for air quality over East Asian region. We conclude that high pMC values measured in spring are originated from large forest fires in Siberia and transported long distance.

Decadal change in bomb-produced radiocarbon in the Pacific Ocean revealed by WHP repeat hydrography

KUMAMOTO, Yuichiro[1*] ; MURATA, Akihiko[1] ; KAWANO, Takeshi[1]

[1]Japan Agency for Marine-Earth Science Technology

Radiocarbon produced by nuclear weapon tests is one of ideal tracers for the air-sea gas exchange and ocean circulation. In the 2000s, radiocarbon in dissolved inorganic carbon was measured during revisit cruises along the WOCE (World Ocean Circulation Experiment) lines of P01 (47N approx., 2007), P03 (24N approx. 2005), P06 (32S approx., 2003), P10 (149E approx., 2005), P13N (165E approx., 2011), P14N/C (179E approx., 2007), P17N (135W approx., 2001), and P21 (17S approx., 2009) conducted in the 1990s in the Pacific Ocean. Comparison of radiocarbon data from the 1990s and 2000s revealed decadal changes of radiocarbon concentration in the thermocline, most of which were due to temporal changes in the bomb-produced radiocarbon. Vertical profiles and vertical-integrated inventories of the bomb radiocarbon in the subarctic and equatorial regions have not changed significantly. In the subtropical regions, radiocarbon decreased in upper thermocline from surface to about 500-m depth. In contrast, radiocarbon increased in lower thermocline from about 500-m to 1500-m depths. In the southern and northeastern subtropical regions, the two opposing directions in radiocarbon change resulted in small temporal changes of the total inventory of the bomb radiocarbon. On the other hand, the water column inventory significantly decreased in the northwestern subtropical region because the radiocarbon decrease in the upper thermocline was larger than the radiocarbon increase in the lower one. These decadal changes are primarily due to the meridional transport of the bomb radiocarbon from high latitude into temperate zone. The decrease in the vertical-integrated radiocarbon in the northwestern subtropical region implies that the turnover time of the thermocline circulation in the region is faster than those in the other subtropical regions in the Pacific Ocean. In addition the loss of the bomb-radiocarbon in the North Pacific Ocean could be explained by its transformation to the Indian Ocean via Indonesian Through Flow. This work was partially supported by Japan Society for the Promotion of Science (JSPS) KAKENHI Grant Number 18310017 and the Common-Use Facility Program of JAEA (2007A-F03, 2007B-F05, 2008A-F02, 2009A-F05, 2010A-F06, and 2011A-F04).

Study on property of soil organic matter decomposition by global warming using radiocarbon

ARAMAKI, Takafumi[1*] ; LIANG, Naishen[1] ; TERAMOTO, Munemasa[1] ; TOMITA, Ayako[1]

[1]National Institute for Environmental Studies

Current research indicates that future atmospheric CO_2 concentration may be increased more than predicted value by furthering of soil organic matter decomposition due to global warming. The information on soil organic matter decomposition property in long-term warmer environment has not yet been obtained. We have carried out artificial soil warming experiment in six forest sites having different vegetation in Japan for long time. We planed vertical ^{14}C measurement of soil core at an even-green Japanese oak forest in Setonaikai region (Higashi-Hiroshima). A soil core was collected from both the soil warming and the control plot in December 2011, and was cut into 1cm layers in laboratory. Each sample was hydrolyzed with 1N HCl overnight to remove inorganic carbon in the sample, and then was analyzed particulate organic carbon (POC) and organic nitrogen (PON) by an elemental analyzer. For ^{14}C analysis by an accelerator mass spectrometer (AMS), soil samples adjusted to a weight of approximately 3mg-C were first converted to CO_2 gases by combustion with CuO and Ag foil at 900 ℃, and then purified cryogenically in a vacuum line. The CO_2 gas samples were reduced to graphite with H_2 gas over Fe powder. The $^{14}C/^{12}C$ ratios of the sample graphite were measured at the Tandetron AMS Facility in the Mutsu Office of the Japan Atomic Energy Agency. The ^{14}C results are expressed as $\Delta^{14}C$. The typical analytical error of the $\Delta^{14}C$ values was about $\pm$ 4 ‰ based on the 1σ value of the counting statistics.

Both of POC and PON weight percent in the soil were high above 3cm depth and decreased sharply with depth from 5cm to 15cm. Both of POC and PON of the soil warming plot were 20-30% lower than those of the control plot irrespective of depth above 15cm depth. The result indicates that the soil warming experiment was encouraged the microbial decomposition of soil organic matter up to comparatively deep layer. The $\Delta^{14}C$ profile of the warming plot was unique with a maximum (220 ‰) at 5cm depth, although the $\Delta^{14}C$ of the control plot was approximately constant from surface to 10cm depth. In terms of $\Delta^{14}C$ vertical profile above 10cm depth, although the $\Delta^{14}C$ of the warming plot above the 3cm depth having POC $>$15 wt% were lower than those of the control plot, the $\Delta^{14}C$ of the warming plot below the 3cm depth were obviously higher than those of the control plot. The results indicate that microbes selectively decomposed young POC at surface layer and old POC at intermediate layer by the soil warming experiment.

^{36}Cl is cosmogenic nuclide (half-life:301 kyr) produced mainly by a reaction of $^{40}Ar(p, n\alpha)^{36}Cl$ in the upper atmosphere. Cosmogenic nuclides fall on the Earth's surface at a rate depending on the nuclide production rates and hence reflecting the cosmic ray intensity. Therefore we can reconstruct fluctuations of cosmic ray intensity, by determining the past ^{36}Cl depositional flux. Such fluctuations of cosmic ray intensity may indicate paleo solar activity and/or variations in the Earth's geomagnetic field.

In this presentation, we report the results of cosmogenic ^{36}Cl measurements during 10.55 - 18.42 kyr b2k in the ice core drilled at the Dome Fuji station, Antarctica (Motoyama et al., 2007). ^{36}Cl in the ice was measured with the accelerator mass spectrometry (AMS) system at the University of Tsukuba (Sasa et al., 2010). The results show that ^{36}Cl conc. is 0.21 - 1.80 $\times$ 10^4 atoms g^{-1} and ^{36}Cl flux is 0.54 - 3.25 $\times$ 10^4 atoms cm^{-2} yr^{-1}. The variation of ^{36}Cl flux in early Holocene shows similar fluctuations of ^{10}Be flux in the same ice core. $^{36}Cl/^{10}Be$ is constant at 0.10 $\pm$ 0.01 in early Holocene. This means that this value can be used for radioactive age dating of the old ice core. $^{36}Cl/^{10}Be$ varies in the last deglaciation. It suggests that the decrease in $^{36}Cl/^{10}Be$ ratio is linked to climate change.

Correlation between the concentrations of cosmogenic Be-7, Be-10 in atmosphere and solar activities.

YAMAGATA, Takeyasu[1*] ; NARAZAKI, Yukinori[2] ; NAGAI, Hisao[1] ; MATSUZAKI, Hiroyuki[3]

[1]Collage of Humanities and Sciences, Nihon University, [2]Fukuoka Institute of Health and Environmental Science, [3]School of Engineering, the University of Tokyo

The concentrations of ^{7}Be and ^{10}Be were investigated at Dazaifu, Fukuoka (1998-2002), Hachijo-Island (2002-2005) and Tokyo (2002-2008) during 1998 to 2008. The seasonal variations were same each year; high concentrations and high isotopic ratios of ^{10}Be/^{7}Be that was caused by strong stratosphere-troposphere exchange (STE) were appeared in February to June, and various concentrations but constant ^{10}Be/^{7}Be by vertical convection in troposphere were appeared in July to December. The concentrations were reconstructed by the box model formula. The parameters of the mean residence time and STE intensities, and period, were constant. The amplitudes of production rate were higher than the amplitude of cosmic ray neutron flux observed at Moscow near earth's surface by a factor of 4. Since the neutron flux amplitude at polar region that was little influenced by geomagnetic field was only 10% higher than Moscow, the high amplitudes of production rate were assumed that caused by changing of energy spectrum of galactic cosmic ray.

Distributions of radionuclides Cl-36 and I-129 in surface soils before Fukushima accident

SUEKI, Keisuke[1*] ; KITAGAWA, Jun-ichi[2] ; SASA, Kimikazu[1] ; TAKAHASHI, Tsutomu[1] ; MATSUKURA, Masumi[1] ; KINOSHITA, Norikazu[3] ; TOSAKI, Yuki[4] ; MATSUSHI, Yuki[5] ; MATSUZAKI, Hiroyuki[6]

[1]University of Tsukuba, [2]High energy acclerator research organization, [3]Shimizu corporation, [4]The National Institute of Advanced Industrial Science and Technology, [5]Kyoto University, [6]The University of Tokyo

The long-lived radionuclides ^{36}Cl and ^{129}I are generated by the nuclear tests or interaction with cosmic rays. They have descended to ground or sea level surface, and they have remained ground surface afterward. We have measured amount of ^{36}Cl and ^{129}I by accelerator mass spectrometry (AMS) before nuclear accident at the Fukushima No. 1 nuclear power plant.

We have collected surface soil samples from the Sea of Japan to the Pacific Ocean at the equal-latitude cross-sectional areas (37 ^{o} 20' N - 37 ^{o} 30' N) in the south Tohoku, Japan. Inorganic chlorine in soil developed an improved leaching process that uses diluted HNO3 as an extractant, activated carbon to remove organic matters without decomposition, and H_2O_2 to remove residual organic matters. After leaching from soils, the AgCl samples for AMS-target made from the obtained solutions at ordinary treatment. Isotopic ratios of ^{36}Cl/Cl were determined by AMS at Tandem Accelerator Complex, University of Tsukuba. Preparation of Iodine-129 target was following ordinary method. Isotopic ratios of ^{129}I/I were determined by accelerator mass spectrometry (AMS) at MALT, the University of Tokyo. Moreover, we determined ^{137}Cs concentrations by gamma spectroscopy and LOI (loss on ignition used by an electric furnace) which related to the amount of the organic matter in soil.

We obtained the distributions of radionuclides ^{36}Cl and ^{129}I in surface soils. The measured ^{36}Cl/Cl ratios of 34 surface soil samples which were about 0-10 cm in depth from 6 sites at the equal-latitude cross-sectional areas were between 0.1 x 10^{-13} and 4.1 x 10^{-13}. It was shown that the ^{36}Cl/Cl ratios are lower at both sea sides. The concentrations of ^{129}I and ^{129}I/I ratios in surface soil (0-10 cm) at 28 points were determined to be 0.18 - 1.13 mBq/kg and 4.3 x 10^{-9} - 11.7 x 10^{-9}, respectively.

The depth profiles of ^{36}Cl/Cl, ^{129}I and ^{137}Cs were examined that the difference of distribution. The concentrations are higher at close surface in each nuclide. The results of ^{36}Cl/Cl profiles in soil cores up to 1 m long suggested that bomb-produced ^{36}Cl remains in uppermost sections, typically for ˜20 cm deep, in undisturbed soil layers. The observed close correlation between organic matter content and ^{36}Cl/Cl ratio implies that presence of biological activity contributes the retention of fallout ^{36}Cl in the surface zone. The concentration of ^{129}I is shown the highest in uppermost surface. It is thought that the influence of global fallout has been received until now. In both nuclides, a constant amount exists in deeper than 30 cm. The concentrations of ^{137}Cs are not detection in deeper than 40 cm. It is showed that ^{137}Cs was lower mobility in soils. Therefore, the sampling soils were not a disturbance.

Geoscience studies using by AMS at JAEA-AMS-TONO in the Tono Geoscience Center of the Japan Atomic Energy Agency

KOKUBU, Yoko[1*] ; MATSUBARA, Akihiro[1] ; HANAKI, Tatsumi[1] ; YASUE, Ken-ichi[2] ; UMEDA, Koji[2]

[1]Tono Geoscience Center, Japan Atomic Energy Agency, [2]Geological Isolation Research and Department Directorate

The JAEA-AMS-TONO facility was established in 1997 at the Tono Geoscience Center, Japan Atomic Energy Agency (JAEA). Our AMS system is a versatile system based on a 5MV tandem Pelletron type accelerator (National Electrostatic Corporation, US) and has been made available for ^{14}C-, ^{10}Be- and ^{26}Al-AMSs. These multi-nuclide AMSs have been mainly applied to neotectonics and hydrogeology, in support of our research on geosphere stability applicable to the long-term isolation of high-level radioactive waste. Furthermore, the ^{14}C- and ^{10}Be-AMSs are used for geoscience, environmental science and archaeology by researchers of universities and other institutes under the JAEA's common-use facility program.

Major contribution of radiocarbon (^{14}C) dating through our ^{14}C-AMS to geoscience studies are as follows. Yasue *et al.* identified fault displacement and stratigraphic correlation of black soils based on ^{14}C ages (presented in this conference). They conducted ^{14}C dating of the black soil collected from a trench wall of the Atera Fault, Gifu. The results of ^{14}C date show that the soil age varies from 4,000 to 2,000 y with depth of the sampling points and the soil was deposited at approximately constant rate. Imaizumi *et al.* (2006) estimated the faulting age based on ^{14}C dating of soils at the Senya Fault in the Toen Fault Zone, Yokote Basin, Akita. It was found that the ages range between 1000 - 1300 y, indicating that the Senya Fault was caused by the Rikuu Earthquake in the year of 1896. Sasaki *et al.* (2006) studied local climate change in an inland basin. Pollen records and ^{14}C ages of sediments in Ohkute Basin, Gifu were used to reconstruct past climate change. The results suggested that the local climate has been warmer for the last 10000 yBP.

Since the fiscal year of 2013, the ^{10}Be-AMS has been routinely measured and used to study long-term erosion rates of weathered granitic soil surfaces using cosmogenic ^{10}Be depth profile under the joint research program with the National Institute of Advanced Industrial Science and Technology (AIST). Recently, we have started development of ^{26}Al-AMS. The system tuning and test measurement have been carried out for routine measurement. The development has so far done well and the routine measurements of the ^{26}Al-AMS will be started in near future. The ^{10}Be- and ^{26}Al-AMSs will be used to estimate the exposure age of basement rocks as well as the sedimentation rate and the assessment of volcaniclastic material ejected during volcanic eruptions.

Radiocarbon dating of charcoal by the ABOX-SC method

TOMIYAMA, Shinji[1*] ; MINAMI, Masayo[2] ; NAKAMURA, Toshio[2]

[1]Department of Earth and Environmental Sciences, Graduate School of Environmental Studies, Nagoya Uni, [2]Center for Chronological Research, Nagoya University

Charcoal is one of the most important samples for radiocarbon dating. It is necessary to remove contaminants from charcoal sample to obtain the reliable date. ABA (acid-base-acid) method is usually used for chemical pretreatment of charcoal: First, a sample is treated with HCl to remove carbonate contaminant. Next, the sample is treated with NaOH to remove organic contaminants derived from soil during burial. After then, the sample is treated with HCl again to remove absorbed atmospheric carbon dioxide during NaOH treatment. The residue is combusted with CuO at 850?C and graphitized to be 14C-dated.

However, the ABA treatment often cannot completely remove contaminants from poorly-preserved and/or old charcoals (>about 30 ka). Bird et al. (1999) showed that the ABOX-SC (acid-base-oxidation stepped combustion) method removes organic contaminants more efficiently than the ABA treatment. The age of the charcoal sample treated with the ABOX-SC was reported to be older than that of the charcoal sample treated with the ABA (Brock et al., 2010).

The ABOX-SC method consists of 3 step chemical pretreatments: HCl and NaOH treatments followed by K2Cr2O7-H2SO4 treatment in a sealed tube at 60?C for 20 hr (Brock et al., 2010). The mixed solution of K2Cr2O7 and H2SO4 removes organic contaminants effectively from charcoal samples, and can extract carbon fraction of oxidation resistant elemental carbon, OREC, which is resistant to oxidation and is less affected by contamination during burial (Bird et al., 1999). After the ABOX chemical treatment, the OREC is heated at 630?C with CuO for 2 hr to remove atmospheric CO2 contaminants adsorbed during sample treatment and contaminants remained after the ABOX treatment. Finally, the residue of OREC is oxidized completely into CO2 at 850?C for 1 hr, and the CO2 is graphitized to be 14C-dated.

In this study, we apply the ABOX-SC method to some charcoal samples of known age to measure 14C ages. The charcoal samples, which were excavated from Tang-e Sikan cave in Arsanjan city, Iran, have been dated at about 40 ka and 26 ka by the ABA method, and are considered to be attributed to Upper Paleolithic period. In this study, we confirm the age difference of Paleolithic charcoal samples by the two pretreatment methods of ABA and ABOX-SC.

AMS radiocarbon dating of Japanese tree rings for regional calibration curve

SAKAMOTO, Minoru[1*] ; OZAKI, Hiromasa[2] ; IMAMURA, Mineo[1]

[1]National Museum of Japanese History / The Graduate School for Advanced Studies, [2]The University Museum, The University of Tokyo

Calibration of radiocarbon data can be achieved by comparison of measured radiocarbon age of samples with known calendar age. Tree rings that determined by dendrochronology are one of the important data set for calibration. IntCal13 calibration curve was launched mainly based on trees grown in the northern high latitude. These rings were sampled in ten years each at once to cancel the variation of solar activity, and to obtain sufficient sample size for conventional radiocarbon measurement as well. AMS radiocarbon dating can measure less than 1mg of carbon efficiently and is capable of date annual tree rings. Recent advance in accuracy of AMS radiocarbon measurement reveals that the resolution of IntCal may be insufficient for precise calibration. In particular, regional effect on the calibration curve had turned out to be a major problem. AMS radiocarbon dating of Japanese tree rings with actual age has been carried out to accomplish Japanese regional calibration curve. Tree ring preserves atmospheric ^{14}C concentration at that time, therefore the offset between radiocarbon age of Japanese tree ring and IntCal should indicate the inhomogeneity in the northen hemisphere.

Radiocarbon dating of archeological remains related with the 13th century Mongol Inversion to Japan

NAKAMURA, Toshio[1*]

[1]Center for Chronological Research, Nagoya University

The shallow sea floor off Takashima, Matsuura, Nagasaki Prefecture, has been investigated archeologically as a potential site where many Mongolian warships exist under the sea sediments. It is historically recorded that more than 4000 Mongolian warships were destroyed by a typhoon during the Mongol invasion to Japan in 1281. The underwater investigations have been performed since 1980, and a lot of archeological remains related with the invasion have been collected there. In 2006, we were allowed to get some archeological remains for 14C dating with AMS. The samples were fragments of palm-bark ropes, lacquer products, bamboo ropes and charred rice. 14C ages for the samples were all consistent with the age of Mongol invasion in 1281.

Recently a body of submerged wrecks most probably originated from Mongolian warship has been discovered in the 1m-deep horizon of the sea sediment off Takashima. During the survey of the new warship, shell samples were collected near the ship. Some shells were recognized to be hull-fouling species, which may have grown up on the bottom of Mongolian warship and preserved along with the broken ship in the sea sediment. We have conducted 14C dating for some shell samples and found out that shells belong to hull-fouling species showed 14C ages consistent with the time of Mongol Inversion. Some other shells not belonging to hull-fouling species showed younger or older dates as compared with the time of Mongol invasion.

AMS radiocarbon dating of peaty layers in Kimotsuki lowland, southern Kyushu

FUJIKI, Toshiyuki[1] ; OKUNO, Mitsuru[1*] ; NAKAMURA, Toshio[2] ; MORIWAKI, Hiroshi[3]

[1]ACRIFIS-EHAI, Fukuoka Univ., [2]CCR, Nagoya Univ., [3]Fac. Law, Econ. Human., Kagoshima Univ.

Since the middle Holocene, peaty layers have accumulated on the Kimotsuki lowland in south Kyushu, Japan. They can be applied radiocarbon (ˆ{14} C) wiggle-matching for establishing high-resolution chronology. Moreover, several tephra intercalated with the peat bed which originated from Kaimondake, Sakurajima, and the Kirishima volcanoes, and they can certify the reproducibility of ^{14} C dates. On the other hand, the age of the tephra by them can be determined correctly. We present here the results of AMS ^{14} C dating on the core sample, and report the age of each tephra determined from these dates.

Offset in radiocarbon ages between shell and plant pairs in the Holocene sediments around the Korea

NAKANISHI, Toshimichi[1*] ; HONG, Wan[1] ; SUNG, Kisuk[1] ; SUNG, Kilho[1] ; NAKASHIMA, Rei[2]

[1]KIGAM, [2]AIST

Since 2009, a research project to evaluate the marine reservoir effects of the coastal sites of Korea has been progressed by KIGAM. Estimating the reservoir effect of this area is difficult because age-known marine samples obtained before AD 1950 are rare. In order to solve this problem, 61 sediment cores were collected with 1 m intervals by a percussion drilling tool from 52 coastal sites in the southern area of the Korean Peninsula. These drilling sites were roughly preselected by the interpretation of modern air photos of internet map services provided by the websites such as Daum and Google. Topographic maps in 1918-1926 with 1/50000 scale and old air photos were also used for the site selection. The length of each core was less than 5 m and the total length was 132 m. Based on analysis of lithology and mollusk assemblages, we selected marine shell and terrestrial plant pairs from same horizons. These samples were cleaned by physical and chemical pretreatments, and reduced by automatic graphitization system in KIGAM. The radiocarbon ages of the samples were measured by the AMS facility of KIGAM. This presentation will report about spatial and historical variation of radiocarbon marine reservoir effect around Korea.

Estimation for the growth rate of benthic biotic communities in Antarctic lakes

TANABE, Yukiko[1*] ; UCHIDA, Masaki[2] ; KONDO, Miyuki[3] ; UCHIDA, Masao[3]

[1]Waseda Institute for Advanced Study, Waseda University, [2]National Institute of Polar Research, [3]National Institute for Environmental Studies

Antarctica is an ice continent. It has one of the most extreme environments for life in the world. There are very little ice-free regions with life in it, so these regions are sometimes called polar oasis within the polar desert. The ice-free regions are scattered along the coastal regions and around mountainous peaks (Nunataks) in continental Antarctica or concentrated in Antarctic Peninsula in maritime Antarctica. The biota is simple due to lack of remarkable organisms at the top of food webs, and primary producers such as cyanobacteria, algae, lichens, mosses, heterotrophic microorganisms and metazoans dominate the sparse communities. A remarkable diversity of lakes exists in Antarctica, ranging from hypersaline with nearly 10 times the conductivity of seawater, to brackish and freshwater, sub-glacial, permanently ice-covered and seasonally ice-covered lakes. These lakes are unproductive with typical photosynthetic levels of 0.5 — 30 μg-C/L/day from phytoplankton. Phytoplankton cannot bloom and hardly survives in the water column during the best light-available summer around the Syowa region. This results from low annual levels of photosynthetically active radiation and ice cover that attenuate light into the water column or photo-inhibit photosynthetic systems due to continuous low temperatures and the lack of any significant input of inorganic nutrients. Despite such severe situations, one of the most productive ecosystems in continental Antarctica is found in freshwater lakes, where benthic microbes form thick mats, and aquatic mosses can flourish on the lakebeds of the Syowa region. These lakes were exposed by glacial retreat after the Last Glacial Maximum. The benthic mats consist of almost organisms, dominantly cyanobacteria, algae, and mosses in the lakes, because there are a little inorganic particles and organic matters inflow to the lakes from the water catchment, and as pointed out above, almost no phytoplankton in the water column. This negligible level of any sedimentation and turbulence situation is specific to Antarctica, which is suitable to estimate the growth rate of benthic biotic communities in fine-scale. We collected sediment cores from 17 freshwater lakes in S$\hat{o}$ya Coast on the south area of Syowa station, continental Antarctica during January-February in 2009 — 2010. The core samples were vertically sliced in each 1 cm as soon as possible after sampling in the field hut, and transported to Japan at -20 ℃. Then, we analyzed the samples by using an AMS (accelerator mass spectrometry), and estimated the growth rate of the benthic biotic mats in each Antarctic lake.

Black SOM dynamics during reforestation of Japanese grassland

IIMURA, Yasuo[1*] ; UCHIDA, Masao[2] ; KONDO, Miyuki[2]

[1]School of Environmental Science, The University of Shiga Prefenture, [2]National Institute for Environmental Studies (NIES)

The dynamics of the polyaromatic structures of black humic acids (HAs), which are presumably derived from charred materials, are of significant interest for the global carbon cycle. However, the details of those dynamics are not yet well understood. We investigated differences in the degree of darkness (A600/C values), isotopic ratios (δ13C, δ15N, and Δ14C values), and 13C NMR spectra of size-separated black HAs extracted from Japanese volcanic ash soils in order to estimate the variations in the polyaromatic structures of black HAs during ca. 100 years of natural reforestation of Japanese pampas grassland. For several hundred years, all the study sites were managed similarly as grassland by burning. Subsequently, their management differed: at site G (Miscanthus sinensis: C4 plant), maintenance as of the time of this study was still performed by mowing, while at sites P (Pinus densiflora: C3 plant) and Q (Quercus crispula: C3 plant), maintenance was discontinued ca. 30 and 100 years ago, respectively. Thus, the sites range from grassland (site G) to coniferous forest (site P) to broad-leaved forest (site Q). For all HA size fractions at all sites, we found that δ13C values correlate positively with δ15N values, although the gradients are much lower for fractions of small to medium molecular size than for fractions of medium to large molecular size (denoted as lower-size and higher-size fractions, respectively). Overall, for the lower-size fractions, the contribution ratio of C4-plant-derived carbon shows a significant positive correlation with A600/C values and a negative correlation with Δ14C values, and their aromatic characteristics are greater than those of higher-size fractions within the same black HA. Furthermore, the relative proportion of lower-size fractions decreases with reforestation, especially from site P to Q. The δ13C values for all size fractions are similar for sites G and P, but are relatively low for site Q. The aryl C contents of the lower-size fractions are lower and the O-alkyl C contents and the aliphaticity (alkyl C:O-alkyl ratio) are clearly higher for sites P and Q than for site G. These results strongly suggest that stimulation of HA biodegradation might be achievable by continuous input of new plant litter during reforestation, even for lower-size HA polyaromatic structures, despite the fact that lower-size HAs biodegrade more slowly than higher-size HAs.

Potential sink of soil organic carbon in a Japanese cool-temperate forest based on bomb radiocarbon based residence time

KONDO, Miyuki[1*] ; UCHIDA, Masao[1] ; OHTSUKA, Toshiyuki[2] ; MURAYAMA, Shohei[4] ; SHIRATO, Yasuhito[3] ; SHIBATA, Yasuyuki[1]

[1]National Institute for Environmental Studies, [2]Gifu University, [3]National Institute for Agro-Environmental Studies, [4]Environmental Management Technology

Functional roles of SOC pool for carbon dynamic remains almost unknown. In this study, residence time (RT) based on carbon and radiocarbon (14C) inventories, was f investigated in a Japanese temperate forest (Takayama) under Asian Monsoon climate, and the potential of soil carbon sequestration were also investigated. Soil organic matter was divided to two fractions as low density humified material (LOM) and high density mineral-associated material (HOM). Our results were thoroughly compared with those in a temperate forest (Harvard forest) conducted using a similar approach [Gaudinski et al., 2002]. The LOM was the major part of the SOC (76%) and its contribution was higher even in the deep layer. 14C contents of LOM in surface layer were similar to those of atmospheric CO2 and roots, whereas those in deep layer are significantly low (?14C <-200 per mil) as well as HOM fractions, although LOM fraction seems to consist of labile carbon. RTs for low density fractions as derived from their radiocarbon content are 53 ?330 yrs BP in surface layer and 1760 ?2780 years BP. Storage of SOC in our site was larger, irrespective of depths and differed considerably from that in Harvard forest. We also measured soil 14CO2 profile to determine the rate of CO2 production from heterotrophic respiration of two SOM fractions. The ?14C values of soil CO2 profile was constant down to 75 cm depth, which were close to those of atmospheric CO2 and fine roots, suggesting that most of soil CO2 is derived from recent photosynthetic fixed C. These results indicate that this forest might be higher sequestrating soil carbon as low density fractions semi-permanently, which is also concerned about instability of near future climate change.

Source diagnosis of PAHs using compound class specific 14C analysis and Monte Carlo source appotionment at Kolkata canal

KUMATA, Hidetoshi[1*] ; UCHIDA, Masao[2] ; KONDO, Miyuki[2] ; SHIBATA, Yasuyuki[2] ; SAHA, Mahua[3] ; TAKADA, Hideshige[3]

[1]Tokyo Univ Pharm Life Sci, [2]NIES, [3]Tokyo Univ Agri Technol

Atmospheric polycyclic aromatic hydrocarbons (PAHs) originate mostly from incomplete combustion of carbon-based fuels. PAHs account for most (35-82%) of the total mutagenic activity of ambient aerosols. Reduction of air pollution by PAHs is essential for an effective air quality control, which requires reliable source apportionment. It has been reported that atmospheric pollution by PAHs in Indian megacities, such as Kolkata, Mumbai and Chennai, is comparable to the highest levels across the globe and Kolkata air exhibit the highest level among them. Also, our previous survey revealed that sediments from Kolkata city canals have the highest PAHs concentrations (i.e., 15.9±11.6 μg of $\sum$14-parent PAHs/g dw, n=12) among the 174 surface sediments from 8 tropical Asian countries.[1] Examining methylated-to parental PAHs ratios of three homologous series and C30-hopane/$\sum$PAHs ratios both in sediment samples and in probable source materials, the high level sedimentary PAHs were ascribed to those emitted from combustion sources. However, relative importances of combustion sources were not solved. The present study aimed to apportion sources of combustion to PAHs in highly contaminated sediments from Kolkata, India by using combined approaches of CCSRA technique, molecular fingerprinting and Monte Carlo source apportionment.

Furthermore, three- and four ring PAHs (MW178, 192, 202) in leftover extracts were harvested on PCGC and analyzed for 14C on AMS at NIES-TERRA, NIES (Tsukuba, Japan). PAHs isolated from Kolkata canal sediments showed mostly fossil carbon isotopic signatures, i.e., ^{14}C signal of PAHs with MW178, 202 and those with MW?228 were 10.6±0.1, 5.9±0.4, 7.6±0.5 pMC (KKNC), 8.4±0.5, 8.3±0.4, 8.5±0.3 pMC (KKSC). By using source end-members of MW202 and MW276 isomer pair ratios, Monte Carlo source apportionment[2] revealed that most of fossil-PAHs were derived from coal combustion, i.e., relative contributions (median) from coal and petroleum combutions were 50% and 11% in KKNC and 13% and 56% in KKSC.

Accurate age estimation using ^{14}C in human teeth enamel.

KUNITA, Keisuke[1*] ; NAKAMURA, Toshio[2]

[1]Graduate School of Environmental Studies, Nagoya University, [2]Center for Chronological Reserch, Nagoya University

Radiocarbon (^{14}C) concentration in the atmosphere showed a stable value until 1955. However, as a result of the nuclear bomb testing, modern ^{14}C concentration in the atmosphere dramatically increased during late 1950s and early 1960s. These bomb-produced ^{14}C is then oxidized to form CO_2, and incorporated into plants by photosynthesis. Then, by eating plants or animals fed by these plants, the ^{14}C concentration in human body reflects the ^{14}C value of atmospheric CO_2 at a certain time. Recent studies insisted that these ^{14}C can play important role for forensic analysis, especially age estimation using ^{14}C in human teeth enamel.

Teeth enamel is such a harder part of the human body that they are hardly destroyed by a natural process. And, the most important is, there is no turnover of enamel after its formation has completed. Although there are previous works which estimate the birth year of individuals by using ^{14}C concentration in enamel, their samples are teeth from Swedish, Scottish and American people, and study areas are mainly at high latitudes of the northern hemisphere. The precision of age estimation using teeth enamel is determined by enamel formation time of teeth and atmospheric ^{14}C concentration in a certain area at a certain year. It is known that teeth formation time of Japanese is different from that of Caucasian. It has been found that ^{14}C concentration in the atmosphere indicates 5 different zones according to different peak ^{14}C concentration of the nuclear bomb testing. These zones are named NH zone1, NH zone2, NH zone3, SH zone3 and SH zone1-2 from north to south. The boundary between NH zone1 and NH zone2 is Ferrel cell - Hadley cell boundary. It is nearly located at 35 ^{o}N. So it means that previous works mainly focused on NH zone1 samples, not NH zone2 samples. One of NH zone2 samples, teeth enamels of Japanese have not studied sufficiently. The aim of this study is to clarify whether age estimation using teeth enamels of Japanese can determine the precise year of birth of individuals and to discuss the mechanism of carbon fixation of enamels or other parts of the teeth.

7 of 44 collected tooth samples have been analyzed. They are 5 third molars and 2 second molars. The year of birth of each individual is 1943, 1946, 1951, 1951, 1951 for third molars, and 1933 and 1959 for second molars. In order to get the estimated year of birth, a model age for enamel completion of Japanese was subtracted from the year given by the ^{14}C analysis of samples. The result shows that age estimation using teeth of Japanese gives precise age determination. Needless to say, taking account of the degree of individual variation and possibility of differences in local environment or in diet is important, however, this result seems to be uninfluenced by those effects. Larger number of, more and more various parts of teeth (for example, first molars, anteriors, such as early-completed teeth.) have to be analyzed.

To determine whether an individual is born before or after the peak of atmospheric ^{14}C concentration (in 1964, in NH zone2), root of teeth have to be analyzed. Since root completion age is some years after enamel completion age, it can be easily found that the sample age is whether rising or falling part of the atmospheric ^{14}C curve. We now are preparing for analysis of ^{14}C of root dentine collagen and root inorganic matter. Their results will give more compelling data, now discover what is waiting for you!!

Observations of atmospheric radiocarbon in carbon dioxide at Hateruma Island and Cape Ochi-ishi, Japan

TERAO, Yukio[1*] ; MUKAI, Hitoshi[1]

[1]Center for Global Environmental Research, National Institute for Environmental Studies

Atmospheric radiocarbon in carbon dioxide ($^{14}CO_2$) is a powerful tracer for understanding of carbon cycles, e.g. oceanic and biospheric CO_2 exchanges and CO_2 emissions from fossil fuel combustion. Observation sites for radiocarbon concentrations, $\triangle^{14}C$, are not many enough to evaluate the global and regional carbon flux. We present an analysis of trends, interannual variability (IAV) and seasonal cycle of $^{14}CO_2$ in background air from July 2004 to December 2012 at two NIES/CGER monitoring stations; Hateruma Island (HAT; latitude 24.06N, longitude 123.81E) and Cape Ochi-ishi (COI; latitude 43.16N, longitude 145.50E). The air samples were collected in 2 L Pyrex glass flasks. The sampling frequency was monthly. CO_2 was extracted from the whole air at NIES and CO2 samples were converted to graphite and analyzed ratios of $^{14}C/^{12}C$ by accelerator mass spectrometry (AMS, National Electrostatics Corp., 1.5SDH) at Paleo Labo Co., Ltd., Japan. Analytical precision in $\triangle^{14}C$ determined from statistical uncertainty (number of ^{14}C counts) was $\pm$1.7-2.0 ‰ for most samples. The repeatability of measurements using modern reference air was $\pm$1.9 ‰ . A decreasing trend in $\triangle^{14}C$ was -5 ‰ yr^{-1} in average but large IAV was observed at both stations: large decreases in 2007-2008 and in 2010-2011 (-8 to -9 ‰ yr^{-1}) and almost zero decrease in 2009. We also observed clear seasonal cycle of $\triangle^{14}C$. The peak-to-peak amplitudes in the seasonal cycle determined from the smooth curve fits were 7 ‰ at both stations and the maximum of $\triangle^{14}C$ appeared in July and the minimum in January at HAT, and the maximum in September and the minimum in May at COI. The differences in phase of $\triangle^{14}C$ seasonal cycle between HAT and COI suggested that the atmospheric $\triangle^{14}C$ at COI was influenced by CO_2 emitted from terrestrial biosphere.

Radiocarbon based source apportioning of PM2.5 carbonaceous aerosols at Cape Hedo, Okinawa and Fukue island, Japan

UCHIDA, Masao[1] ; KONDO, Miyuki[1*] ; KANEYASU, Naoki[2] ; ARAKAKI, Takemitsu[3] ; HANDA, Daishi[3] ; KUMATA, Hidetoshi[4]

[1]National Institute for Environmental Studies, [2]National Institute of Advanced Industrial Science and Technology, [3]University of Ryukyus, [4]Tokyo University of Pharmacy and Life Sciences

Radiocarbon (14C) analysis of the carbonaceous aerosol allows an apportionment of fossil and non-fossil sources of air-borne particulate matter (PM). A chemical separation of total carbon (TC) into its sub-fractions organic carbon (OC) and elemental carbon (EC) refines this powerful technique, as OC and EC originate from different sources and undergo different processes in the atmosphere. Although 14C analysis of TC, EC and OC has recently gained increasing attention, Nowadays gigantic brownish haze from various burning and combustion processes is also blanketing India and surrounding land and oceans during the winter season. In China and surrounding countries, same kind of atmospheric pollution are widely observed and occurred as well. Additionally this soot-laden Brown Cloud is affecting South and East Asian climate as much or more than carbon dioxide and cause hundreds of thousands of premature deaths annually, yet its sources have been poorly understood. In this study, we investigated the contribution of continent derived aerosol to Japan. Aerosol samples with diameter of 2.5mm were collected at Fukue island, one of Goto islands and at the Cape Hedo is located at the northern end of Okinawa Island. The 14C contents of EC of PM2.5 aerosols collected from October, 2009 and May, 2010 including the Kosa event in Cape Hedo and Fukue were measured. The 14C content represents in the unit of pMC . Results of EC-14C in both sites were 25-30pMC in Cape Hedo and 18-44pMC in Fukue, respectively. These results mean that relative apportions of biomass burning and fossil fuel were 25-30% and 18-44% in Cape Hedo and 25-35% and 65-75% in Fukue, respectively. The observed variations of pMC in Cape Hedo during February and March were relatively smaller than those of Fukue, which was more than 20%. According to back trajectory analysis in this duration, because ca. 70% of air mass in both sites was derived from the continent. The aerosols particulate matter to be transferred to Cape Hedo from continent would be relatively smaller than those to Fukue. Our data of EC-14C obtained during the Kosa event showed the relatively higher contribution of biomass burning sources in Fukue although these interpretation need to consider variation of the magnitude and concentration of EC in both sites. In further study we need to investigate details of the source of EC during this period.

Study on monitoring of volcanic activity using ^{129}I / ^{127}I ratios in crater lake and hot spring at Zao volcano

MATSUNAKA, Tetsuya[1*] ; SASA, Kimikazu[1] ; SUEKI, Keisuke[1] ; SHIBAYAMA, Nao[1] ; TAKAHASHI, Tsutomu[1] ; MATSUMURA, Masumi[1] ; SATOU, Yukihiko[1] ; MATSUZAKI, Hiroyuki[2] ; GOTO, Akio[3] ; WATANABE, Takahiro[3] ; TSUCHIYA, Noriyoshi[3] ; HIRANO, Nobuo[3] ; KIZAKI, Akihisa[3]

[1]University of Tsukuba, [2]The University of Tokyo, [3]Tohoku University

Volcanic tremors and mountain gradient changes have been detected at Zao volcano in Miyagi and Yamagata since January 2013, volcanic activity began to intensify although Zao volcano will not erupt immediately[1]. Since the water quality of crater lake are correlating with volcanism changes[2][3], basic water quality of crater lake and hot spring at Zao volcano have been studied by the group of Tohoku University from September 2013. As a part of this project, we are trying to monitor the volcanic activity using ^{129}I / ^{127}I ratios (atomic ratio of radioiodine and stable iodine) in crater lake and hot spring of Zao volcano.

Natural ^{129}I (half-life: 15.7 million year) are produced by nuclear spallation reaction of ^{129}Xe with cosmic ray in the atmosphere and spontaneous fission of ^{238}U in the geological layer. In the ocean, steady-state ^{129}I / ^{127}I ratio of the seawater is estimated to be 1.5×10^{-12}[4]. Sunken iodine by the ocean plate having lower ^{129}I / ^{127}I ratio (older ^{129}I age) compared to the steady-state ratio of seawater, are supplied to the atmosphere mainly via magmatic activity. In general, ^{129}I / ^{127}I ratio in hot spring water and brine water are used as indicator of origin and behavior of iodine in the water[5][6]. ^{129}I / ^{127}I ratio of hydrothermal at Zao volcano are considered to become lower by the supply of chronologically-old iodine in terms of global iodine cycle.

In September 2013, water samples of 2 L were collected from the surface of crater lake (Okama, diameter: 350 m, maximum depth: 35 m) located at 1,560 m in elevation and hot spring (Kamoshika Hot Spring) located at 1,230 m in elevation in the eastern side of Zao volcano. Water temperature and pH were measured on site. After water samples were filtered by 0.2 μm filter, ^{129}I / ^{127}I ratio were measured for the isotopic diluted water samples by adding carrier (^{127}I standard) at MALT, The University of Tokyo. ^{127}I concentrations were measured by ICP-MS, and original ^{129}I / ^{127}I ratio of water samples were estimated.

Water temperature and pH were 10.2 ℃ and 3.3 at Okama; 40.0 ℃ and 3.3 - 4.0 at Kamoshika Hot Spring. ^{129}I / ^{127}I ratios of Okama and Kamoshika Hot Spring were respectively, estimated to be $(1.5 \pm 0.4) \times 10^{-9}$ and $(0.78 \pm 0.2) \times 10^{-9}$, 500 - 1000 times higher than the steady-state ratio of sea water (1.5×10^{-12})[4]. Since ^{129}I / ^{127}I ratio of anthropogenic metric water were over 9.0×10^{-12}[7], surface water of Okama and Kamoshika Hot Spring water were very likely to be strong affected by the meteoric water including anthropogenic ^{129}I. For the monitoring of volcanic activity using ^{129}I / ^{127}I ratio, it is necessary to decide the site as few anthropogenic ^{129}I as possible through the measuring of ^{129}I / ^{127}I ratio of the Okama bottom water and some hot spring around Zao volcano. Continuous water quality survey of 1 - 2 times for Okama and 1 time per 1 - 2 months for hot springs are planned from June to November of this year.

Speciation analysis of the Fukushima accident derived I-129 in the soil using sequential extraction method

HONDA, Maki[1*] ; MATSUZAKI, Hiroyuki[2] ; SAITOU, Takumi[3] ; NAGAI, Hisao[4]

[1]Graduate School of Integrated Basic Sciences, Nihon University, [2]Department of Nuclear Engineering and Management, School of Engineering, The University of Tokyo, [3]Nuclear Professional School, School of Engineering, The University of Tokyo, [4]College of Humanities and Sciences, Nihon University

In previous study, we investigated the depth profile of the accident derived ^{129}I ($T_{1/2}$ = 1.57x10^7 y) and downward migration speed in soils of near field of Fukushima Dai-ichi Nuclear Power Plant (FDNPP), including crop fields and man-made fields. ^{129}I in soil was measured by AMS and stable iodine (^{127}I) was measured by ICP-MS at MALT (Micro Analysis Laboratory, Tandem accelerator), The University of Tokyo. It was found that ^{129}I was concentrated near surface but distributed deeper compared with ^{137}Cs ($T_{1/2}$ = 30 y). From the estimation of relaxation length using depth profiles, the FDNPP derived ^{129}I move 0.6 cm/y downward and ^{137}Cs 0.3 cm/y for it. It was also found that ^{129}I seems to move downward more quickly than ^{137}Cs.

To investigate the adsorption mechanism and the elemental process of migration of the accident derived ^{129}I in soil, it is important to know what kind of component the ^{129}I combines with.

Recent studies on the X-ray absorption fine structure (XAFS), especially near edge structure (XANES), reported that the stable iodine (^{127}I) in soil existed as an organic component[1]. However, it had not yet been proved that it was also the case with the accident derived ^{129}I because it had been incorporated in the soil system only recently and the abundance of ^{129}I in soil was more than 8 orders of magnitude smaller than sub-ppm level stable iodine (^{127}I).

In this study a progressive sequential extraction method including the dialysis was newly developed to obtain only the iodine sticking to the soil organic component. The advantage of sequential extraction over other method is that stable iodine can be quantified by direct analysis of the fraction and ^{129}I can be quantified by AMS method of the fraction added with carrier. The fraction of the organic component for ^{127}I and ^{129}I can be evaluated respectively by comparing with the other fraction and/or with the total concentration obtained by the bulk analysis (e.g. by the pyrohydrolysis).

Repeatability is 20% for the water soluble, oxides and organic fraction, 10% for Exchangeable fraction and 50% Residue (mainly minerals).

The results show that 60% of the total ^{129}I are associated with oxides and 30% associated with organic matter in crop field soil. The former, the oxides bond iodine, it takes a form of iodate (IO_3^-) absorbed in amorphous oxides, especially goethite or delta-MnO_2. They are formation of monodentaten mononuclear outer-sphere species and bidentate, binuclear inner-sphere species [2]. The latter iodine are linked to organic carbon directly by a covalent bond.

Relationship between progress of borehole investigations and the geometric data of fractures at the crystalline rocks

ISHIBASHI, Masayuki[1*] ; SASAO, Eiji[1] ; NAKAJIMA, Makoto[2] ; ATSUMI, Hiroyuki[2] ; ONOE, Hironori[1] ; SAEGUSA, Hiromitsu[1] ; KAWABATA, Junichi[2] ; MASUMOTO, Kazuhiko[2] ; SENO, Shoji[2] ; IWANO, Keita[2]

[1]Japan Atomic Energy Agency, [2]Kajima Corporation Technical Research Institute Rock Mechanics and Hydrogeology Group

In order to evaluate deep geological environment for geological disposal of high level radioactive waste (HLW) and underground storage of liquefied petroleum gas, understanding of the geometry of water conducting features such as fractures is essential. Geometric data of fractures are obtained by borehole investigations. But, methodology to understand the geometry of fractures has not been established in terms of planning borehole investigation such as number and total length of boreholes. Thus, relationship between progress of borehole investigation and increase of the geometric data of fractures is studied.

In this study, discrete fracture network models with the size of 100×100×100m cube were used as virtual fractured rock mass, and virtual boreholes were drilled in the virtual rock mass. Five boreholes with the length of 100m each were located in four directions. One dimensional fracture intensity (as the number of fractures per unit length; P10) of virtual boreholes is calculated. The P10 is depending on the relationships borehole directions and fracture orientations. In addition, The P10 is become constant at each direction of borehole as investigations progressed.

These results suggest that in order to obtain the geometric data of fracture, the borehole investigation should be planned in consideration of distribution of the fracture orientations.

Characterization of the fracture zone on the basis of fracture spacing, case study at the Toki granite, central Japan

SASAO, Eiji[1*] ; ISHIBASHI, Masayuki[1]

[1]Japan Atomic Energy Agency

In order to evaluate deep geological environment for geological disposal of high level radioactive waste, understanding of the geometry of water conducting features such as fractures is essential. The fracture zones have been divided based on the fracture intensity that has been obtained deep boreholes. But fracture intensity could be changeable in different portion of the rock body. The method to divide the fracture zones based on fracture spacing is studied. In this study, cumulative frequency curve of fracture spacing based on fifteen deep borehole with the total length of ca.12,000 meters was used. Cumulative frequency curve shows that half of fracture spacing is lower than 1m. Thus, fracture could exist in fracture zones. The fractures with the dip of middle to high angle are needed to divide into fracture zones based on the fracture spacing. In the future, we will establish the methodology to divides the fracture zones coupled with spatial distribution of fracture spaces.

An approach to establish information basis of Weathered zone for the Safety Assessment to HLW Disposal over long-term.

SHIMEMOTO, Hidenori[1*] ; WAKASUGI, Keiichiro[2] ; SHIBATA, Masahiro[2] ; YAMAGUCHI, Masaaki[2]

[1]Japan Atomic Energy Agency (*Present position: Mitsubishi Materials Techno Corporation), [2]Japan Atomic Energy Agency

The consideration of evolution on geological environment is required in the safety assessment of geological disposal for the high level radioactive waste (HLW). The HLW repository can be expected to come close to ground surface assuming a continuous uplift and erosion for a long-term period. Therefore, the consideration of shallow zone (weathered zone) environment is also required. Since the geological condition in the near-surface underground is different from that in the deep underground due to weathering, the basic information and understanding for the near-surface condition are essential for the scenario development. Therefore, information regarding weathered zone is surveyed and arranged based on available literatures.

As a result, 37data of depth (thickness) of weathered zone were extracted. Then the data distribution and these characteristics for the thickness of weathered zone were discussed. In order to understand the formation process of weathered zone, the relation between weathered zone and landform was also discussed and categorized into four patterns. The key factors which account for the patterns are also analyzed in a qualitative manner.

Regarding the geological property/condition in the weathered zone, although information on hydraulic and chemical conditions are very limited, information on tensile strength and porosity are available.

For the sake of condition setting for near-surface underground in the long-term safety assessment, continuous research and development for the characterization on weathered zone are important.

A Bayesian approach to assess the probability of concealed active faults existing using helium isotope ratios

MARTIN, Andrew[1*] ; ISHIMARU, Tsuneari[2] ; UMEDA, Koji[2] ; ASAMORI, Koichi[2]

[1]NAGRA, [2]Tono Geoscience Center, JAEA

In Japan, numerous studies have been carried out to assess the stability of the geological environment including in particular, the spatio-temporal distribution of active faulting in the context of site selection of a radioactive waste repository and/or assessing the safety of current nuclear facilities etc. One key concern is the existance of active faults that do not show any surface rupture.

High He-3/He-4 ratios which tend to be found in volcanic regions have also been measured in non-volcanic regions. This has been attributed to degassing from the mantle with faults potentially acting as conduits (e.g., Kennedy et al., 1997). Studies carried out in the western Tottori district have shown the potential of using He-3/He-4 ratios as a means of providing indirect evidence of the existence of source fault(s) that caused the 6 Oct 2000 Tottori earthquake (Mw 6.8), but which had no apparent surface indication prior to the earthquake (Umeda and Ninomiya, 2009).

Here we introduce a new technique based on Bayesian inference in an effort to quantify this theory. In the Bayesian paradigm, we make *a priori* assumptions based on the tectonic setting of the study area as a starting point. 'Known' active faults are divided into equal distant fault segments. The *a prior* assumption here is that 'unknown' fault segments do not exist far from 'known' fault segments. It is also assumed that the probability of 'unknown' faults existing decreases with distance from the 'known' faults.

2D *a priori* probability distributions of unknown fault(s) existing are then calculated using kernel functions (Martin et al., 2003) centered over the known fault segments. A Cauchy probability density function (PDF) is assigned here conservatively as the *a priori* distribution in the first step so that probability is never zero.

In the second step, the method developed by Martin et al. (2004, 2012), is adapted to remap He-3/He-4 ratios into a PDF, called a likelihood function based on Kolmogorov-Smirnov statistical tests. The *a prior* PDF from the first step above is then combined with the likelihood PDF using Bayes's rule to produce a *a posteriori* PDF.

Carrying out the calculation using data from before the Tottori 2000 earthquake, the *a posterior* 2D probability maps showed increased probability of unknown active fault(s) existing in the region above the source zone of the 2000 earthquake. Thus, in the case of the Tottori region, the *a posterior* probabilities corraborate the theory that faults could be acting as conduits for mantle helium.

The potential of the methodology to incorporate other information such as gravity and crustal strain rates will also be presented and discussed.

An active shear zone, southwest Japan: electromagnetic geophysics and noble gas geochemistry

UMEDA, Koji[1*] ; ASAMORI, Koichi[1] ; MAKUUCHI, Ayumu[1] ; KOBORI, Kazuo[1]

[1]Japan Atomic Energy Agency

In 1997, the Kagoshima earthquake doublet with two Mw ˜6 strike-slip events struck 5 km and 48 days apart in southwest Japan, where an E-W trending discontinuity along 32 degree N latitude in GPS velocities across southern Kyushu Island is clearly defined, indicating a highly active left-lateral shear zone. However, there was no obvious prefaulting indication at surface (active fault) in relation to the shear zone. Three-dimensional inversion of magnetotelluric sounding data observed in the source region of the the earthquake doublet reveals a near-vertical conductive zone with a width of 20 km, extending down to the base of the crust and perhaps into the upper mantle. The prominent conductor corresponds to the western edge of the active shear zone. Elevated 3He/4He ratios of groundwaters sampled around the seismic source region suggest the emission of mantle-derived helium from the electrical conductor. The geophysical and geochemical observations provide significant evidence that the invasion of mantle fluids into the crust, driven by upwelling asthenosphere from the Okinawa trough, triggers off the notable left-lateral shear zone in the present-day subduction system. In addition, the conductive fluids enhance stress concentration in the seismogenic layers leading to mechanical failure of strong asperities, resulting in the occurrence of the 1997 earthquake doublet.

Predominant process for transport of radiocaesium released by the TEPCO's Fukushima Daiichi Nuclear Power Plant Accident

NIIZATO, Tadafumi[1*] ; ISHII, Yasuo[1] ; ABE, Hironobu[1] ; WATANABE, Takayoshi[1] ; SASAKI, Yoshito[1]

[1]Fukushima Environmental Safety Center, Japan Atomic Energy Agency

Understanding the environmental dynamics of the radiocaesium (particularly Cs-134 and 137) released from the Fukushima Daiichi Nuclear Power Plant provides the firm foundation for a remediation of the Fukushima environment because it is the main radionuclide to radiological dose within the contaminated area. One of the main sources of radiocaesium under the current situation is a mountain forest, where the decontamination work has not been carried out as yet. Therefore, transport process, flux and chemical form of the radiocaesium flowing from the mountain forest are crucial issues for an evaluation of a radiation exposure, taking into a dynamics behavior of radiocaesium from the highest contaminated mountain forests down through the river to eventual deposition in the sea. This paper discusses the predominant process of the radiocaesium transport in the mountainous region, Fukushima, Japan.

The four investigation areas, which have different characteristics of vegetation, geomorphology and soil type, were selected in the Abukuma Mountain, eastern part of Fukushima. The soil samples were obtained from ridge, slope, and valley bottom in the areas by soil sampler and scraper plate to the depth about 40 cm and 20 cm, respectively. The observation plots, which have an area of 40 to 60 m2, for a monitoring of surface runoff and soil loss are also installed. The concentration of radiocaesium in the uppermost soil horizon is related to the geomorphological aspects, that is, the concentration trends to be higher in the depositional area than in the erosional area. Additionally, the radiocaesium concentration of solid phases (soil particles and fragmented organic materials) including in surface runoff is one to two orders of magnitude greater than that of a liquid phase (running water).

Therefore, predominant process of the radiocaesium transport is the surface runoff accompanied with a detachment of soil particles from the mountain slope.

Current State of the additional geological surveys of crush zones at the fast breeder prototype reactor ”Monju” site

ISHIMARU, Tsuneari[1*] ; SHIMADA, Koji[1] ; SASAKI, Akimichi[1] ; TANAKA, Yukumo[1] ; MIYAZAKI, Masashi[1] ; YASUE, Ken-ichi[1] ; NIWA, Masakazu[1] ; SUEOKA, Shigeru[1] ; UMEDA, Koji[1] ; IKEDA, Makinori[1]

[1]Japan Atomic Energy Agency (JAEA)

Background: In the fast breeder prototype reactor Monju of the Japan Atomic Energy Agency (JAEA), a report of the additional geological survey regarding the crushed zones at the Monju site was submitted to the Nuclear Regulation Authority (NRA) on April 30, 2013. The NRA instructed to develop a further additional research plan on September 25. Accordingly, JAEA compiled and submitted the plan on October 3, followed by a ”preliminary report” on November 29, and a ”complete report” in March 2014.

Overview of additional research: The instructions from the NRA of September 25, 2013 were as follows:

1. to implement the dating of materials within the crushed zones, to research the displacement markers, and to understand their formation age, etc.,in order to enhance understanding of the activity of crushed zones at the Monju site in the bedrock of the site investigation area; 2. to investigate the distribution of the fracture zones, the relationship of the sediment layer, and the depositional age of the sediment layer (14C dating, tephra analysis, etc.) for data expansion of the extended portion of the L-2 lineament located near the Monju site; and 3. to implement marine seismic surveys in the coastal sea area and geographical and geological surveys ofthe coast, etc., in order to understand the geological structure and activities of the coastal seabed in the extended portion of the Shiraki-nyuu active fault and the L-2 lineament.

JAEA developed a research plan in response to these instructions and conducted the stripping investigation over an expanded area, the additional detailed geographical and geological surveys around the mountains/terrace boundary, and the marine seismic surveys in the coastal waters.

Summary of findings: The basement rock of the northern Tsuruga peninsula where the Monju site is located is composed of the Late Cretaceous-Paleogene granite known as the Kojyaku granite. In the on-site investigation, the stripping area was extended in the northern direction of the longest fracture zone in the reactor building foundation rock. The fracture zones were grouped into 2 systems called α-system and β-system. We examined the cross-cuttingrelationships and displacementsof the fracture zonesand confirmed that the α-system was formed after the β-system. The α-system fracture zones are left-lateral faultsthat have mesh-like clay veinlets, and the width of the α-system fracture zones is several centimeters. The K-Ar ages of the basalt dyke displaced by the α-system fracture zones were about 19Ma. In addition, U-Pb and FT dating of apatite and zircon separated from the fracture zone materials and granite were conducted to reconstruct their thermal histories. The investigation results so far obtained were similar to the survey results of April 30, 2013, offering no clear evidence that the on-site crushed zones are of an active fault. It can be considered that these crushed zones are small-scale older (pre-Quaternary?) geological structures formed under the hydrothermal environment of the deep part before exposure of the granitic body. On the detailed geographical and geological surveys around mountainous/terrace boundary, no fracture zone along the strike of the boundary was observed. From the C-14 dating and tephra analysis of the depositional layer covering the granite, the distribution of sediments from about 40,000-50,000 years ago was confirmed in a few outcrops. The marine seismic surveys in the coastal waters were performed in conjunction with the bathymetric survey in December 2013. Currently, the data are being analyzed.

Upcoming: In order to further enhance the reliability of the investigation results and accumulate further data related to on-site geology and the underground, voluntary investigations are being conducted on a continuous basis. In addition, a basic study is also being carried out on the evaluation method of the activity of the fault zone not applicable to the overburden strata method.

The linearity of geographical features and a planation surface along the seashore around the fast breeder reactor Monju

SASAKI, Akimichi[1*] ; YASUE, Ken-ichi[1] ; SHIMADA, Koji[1] ; TATEISHI, Ryo[2] ; ISHIMARU, Tsuneari[1] ; TANAKA, Yukumo[1]

[1]Japan Atomic Energy Agency, [2]OYO Corporation

We have not only conducted a survey of crush zones near the reactor building in the fast breeder prototype reactor Monju site but also carried out geographical investigations such as terrace classification and lineament investigation around the site. This presentation reports the results of the geographical and geological survey on the linearity of geographical features and a planation surface along the seashore around the site.

1. An investigation into the linearity of the mountain/terrace boundary

It is estimated that the lineament of the NW-NNW direction, also called the L-2 lineament, exists to the south of the Monju site. Geographical and geological surveys by JAEA suggest that this lineament is highly likely to be a structural landform. The mountain/terrace boundary to the north of this lineament extends in a straight line-like form in the NW direction. During an expert meeting of the Nuclear Regulation Authority, it was suggested that an active fault might exist along this boundary. It was in response to this suggestion that we carried out the geographical and geological survey.

Geographical investigation: We carried out a terrace classification, field survey, and analysis of the survey data for regions around the mountain/terrace boundary. The mountain slope directly faces the sea; the slope of the present stream bed and terrace surfaces is comparatively steep in the investigation area. In the topographical map before artificial change, we can recognize that the stream makes the loosely curved dissected topography without winding greatly and that the mountain/terrace boundary is loosely curved similarly.

Geological survey: Outcrop investigation was conducted on the mountain/terrace boundary by paying attention to the existence of crush zones and the development style of the joints. In addition, we also estimated the age of the sedimentary layers.

The results clearly indicate that the joints are progressing mainly in the NW or the NE direction, and the comparatively hard granite is also distributed. Moreover, although crush zones were observed in some outcrops near the mountain/terrace boundary, we could not detect crush zones that continue in the same direction as the mountain/terrace boundary. In the outcrop near the northwestern end of the mountain/terrace boundary, it was observed that the covering layer, which was deposited after about 40,000-50,000 years ago and covers a crush zone, is not displaced.

The results of the above-mentioned geographical and geological survey suggest that the linearity of the mountain/terrace boundary has not originated from fault displacement.

2. An investigation into the linear coastline and planation surface along the seashore

A linear coastline extending in the NE direction can be seen around the Monju site. In addition, a planation surface is observed in parts along the seashore. We performed a geographical and geological survey to determine the origin of such a geographical feature and whether such a planation surface could exist elsewhere.

Geographical investigation: While carrying out the air photograph interpretation, the contour line maps and topographic profiles were created using a digital elevation map created from aviation laser survey data. As a result, except for one place which is present at an altitude of about 5 m, a geographical feature that can be recognized as a comparatively flat field was not observed.

Geological survey: We carried out an outcrop investigation that paid attention to the development of joints and searched for evidence that suggested the upheaval of land. The results suggest that the direction of the coastline and the direction of developing joints are similar. Moreover, we could not observe the remains of living things which suggest the possible upheaval of land.

On the turn determination of crush zone activity, a lesson from granitic basement rock holding the fast breeder reactor

SHIMADA, Koji[1*] ; TATEISHI, Ryo[2] ; ISHIMARU, Tsuneari[1] ; SASAKI, Akimichi[1] ; TANAKA, Yukumo[1] ; MIYAZAKI, Masashi[1] ; YASUE, Ken-ichi[1] ; NIWA, Masakazu[1] ; SUEOKA, Shigeru[1] ; UMEDA, Koji[1] ; IKEDA, Makinori[1]

[1]Japan Atomic Energy Agency, [2]OYO Co.

Activity evaluation of crush zones encountered in basement rock is an issue of the seismic safety assessment of nuclear plant and geological isolation of radioactive wastes. The selection of crush zone of which has been evaluated should be defined as the latest one by means of turn determination of crush zone activity based on stratigraphic or structural geological method. A lesson from granitic basement rock (Kojaku granite) holding the fast breeder reactor "Monju" is presented. The Kojaku Granite form the oval Tsuruga peninsula (ca. 8km in width) on the southeastern coast of the Sea of Japan and the age is 68.5±0.7Ma (Zircon U-Pb age).

1. Stratigraphy-oriented turn determination of crush zone activity.

(1.1) Turn determination using cover sediments

The age determination of undeformed cover sediments indicates the activity of crush zone older than the sediments. In the case of crush zones observed at separate outcrop, deformation of the same strata can be utilized for the turn determination.

Trenching evidence (with tephra chronological analyses) of the active Shiraki-Nyu fault near the Monju site indicate repeated activity after ca. 30ky strata (including AT-tephra). On the other hand, crush zones in the Monju site affect no deformation on the strata of identical age observed during the site construction. These data indicate the last movement of the latter is older than the active fault, and no movement in sympathy with the active faulting repeatedly during, at least, ca. 30ky.

(1.2) Turn determination using dyke, mineral and clay vein ("Dyke", hear after)

Undeformed dykes intersecting crush zones indicate that the movements of crush zones are older than the dyke formation. Age determination of the dyke constrain the latest age of the crush zone activity.

Excavation survey of basement rocks at the Monju site shows a basaltic dyke (ca. 19Ma, Plagioclase K-Ar age) cut by the crush zone (crush zone alpha-3 and alpha-4) indicate that the movements of these crush zones are later than the dyke formation.

2. Structural-oriented turn determination of crush zone activity

Intersecting relationship between crush zones indicate which of them is the latest one at least locally. This rule can be hold in the case of conjugate set, although they suggest the contemporaneous development in one tectonic stage. Conjugate relations should be judged from traditional Griffith-Coulomb failure criterion as well as the Maximum effective moment criterion(1). Despite of the development of remarkable clay rich zone, cross cutting crush zone with meso- and microstructures developed under the higher temperature and pressure indicate the movement of the clay rich zone is older.

Excavation survey of basement rocks at the Monju site shows conjugate like development of the crush zone beta and younger alpha-3 with 50-55 degrees between them. The crush zone beta is composed of clay rich vein. Along the crush zone arpha-3, drugged sigmoidal quartz veins, drugged biotite along shear layers and preferred orientation of quartzo-felspathic lenses composed of foliated cataclasite with P-Y-R_1 fabric are observed. These ductile features suggest that relatively higher temperature and pressure during the development of crush zone arpha-3. Hence, the crush zone beta is old structure.

These stratigraphic and structural evidences for the turn determination indicate that the activity of crush zone arpha-3 is the object of the evaluation.

Depth-dependent coseismic groundwater level changes by seismic ground motion of the 1999 Chi-Chi earthquake, Tiwan

HIGA, Mayumi[1*] ; NAKAMURA, Mamoru[2] ; KOIZUMI, Naoji[3] ; LAI, Wen-chi[4]

[1]Faculty of Science and Graduate School of Engineering and Science, University of the Ryukyus, [2]Faculty of Science, University of the Ryukyus, [3]Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, [4]Disaster Prevention Research Center, National Cheng Kung University, Taiwan

The coseismic water level change (Cw) has been reported (Montgomery and Manga, 2003; Koizumi, 2013). One of the causes of the Cw is crustal displacement (static strain change and vertical displacement etc.), and seismic ground motion(dynamic volumetric strain change and hydraulic conductivity change etc.)(Lee *et al*., 2002; Lai *et al*., 2004; Wang *et al*., 2001). The static strain change has been assumed as one of the main factor of the water level change from the comparison of water level change with static strain change in the earthquakes. However, the relation between water level change and static strain change doesn·t correspond clearly. Although the dynamic strain change by the ground motion would be more effective to the cause of Cw, the effect has not been known yet.

The Chi-Chi earthquake (Mw7.6) occurred in central Taiwan at 1:47 (local time) on September 21, 1999. The earthquake was the largest event which occurred recently in the inland of Taiwan. Since the both networks of strong motion seismometer (Lee *et al*, 1999) and water level monitoring system (Koizumi, 2001) are distributed densely around the source fault of the Chi-Chi earthquake, good seismic waveform and the data of Cw has been obtained.

For the previous study of Cw in the Chi-Chi earthquake, Wang *et al*.(2003) has been analyzed the relationship between Cw and seismic ground motion from the point of view of liquefaction at the shallow groundwater in the alluvial plain part. They showed that there is correlation between the spectrum velocity or acceleration and water level. However, they did not account much for the effects of the permeability or other characteristics in each aquifer although they analyzed the Cw of all wells at once. Since the hydrogeological conditions effects to the occurrence of liquefaction similar to the effect of ground motion, the effect for the hydrogeological conditions, that is the geological characteristics and permeability of aquifer in confined aquifer or unconfined aquifer, must be investigated.

We divided the aquifer to similar hydrogeological categories and examined the Cw response by the ground motion in each aquifer. We put target groundwater of two aquifer, the shallow aquifer 1(unconfined aquifer)and underlying aquifer 2(confined aquifer), and investigated whether there are the different character in those. I measured the degree of Cw. Therefore the wells observed Cw were 84 wells, fall wells were 14 wells in these wells. I used the observation wells with water level rises in the alluvial plain part, because the mechanism of water level change for water level fall is different. We investigated the relationship spectral response of seismic wave and groundwater level change, because spectral response can read the effect to the ground in comparison spectrum of normal. We calculated the response of Cw against the frequency of 1 Hz (high-frequency) and 0.1 Hz (low-frequency) to evaluate the groundwater level change as a function of frequency. We calculated the acceleration, velocity, and displacement spectral response of vertical, horizontal, and 3 components from acceleration waveform data. I investigated the correlation coefficient between spectrum and Cw in each aquifer. The result frequency band in those show different response was obtained. Correlation between the response spectrum and water level change in the high-frequency side (1 Hz) was higher in the aquifer considered unconfined aquifer, but the correlation in low-frequency side (0.1 Hz) was higher in the aquifer considered confined aquifer. In common to both aquifer, correlation between hydraulic conductivity and water level change showed strong positive correlation.

Occurrence of faults and water conducting features at 350m gallery of the Horonobe URL project

HAYANO, Akira[1*] ; MATSUOKA, Toshiyuki[1] ; ISHII, Eiichi[1]

[1]Japan Atomic Energy Agency

In the Horonobe Underground Research Laboratory Project, methodology development for the investigation of geological structure in sedimentary rocks has been carried out through construction of underground facility. As part of the methodology development, hydrogeological models have been constructed and the geological structure associated with water-conducting features (WCFs) has been conceptualized on the basis of the surface-based investigations including geophysical survey, outcrop observation and borehole investigation. The horizontal gallery named ‘ 350m gallery ’ and having approximately 740m long in total has been excavated at a depth of 350m below the surface by January 2014. This study presents the predictive distribution of geological structures contributing to WCFs in 350m gallery based on the surface-based investigations and the characteristics of geological structures observed in 350m gallery.

Permeability variation in Toki granite and its relationships with crack structure and alteration processes

KUBO, Taiki[1*] ; MATSUDA, Norihiro[1] ; KASHIWAYA, Kouki[1] ; KOIKE, Katsuaki[1]

[1]Kyoto University

Understanding of physical and chemical properties of rock mass is essential to implement the geological disposal of the high level nuclear waste. Especially, extraction of highly permeable zone that acts as channel of fluid flow is required. In this study, permeability measurements of Toki granite were carried out to reveal the permeability variation in rock mass and to understand factors causing that. Image analysis was applied to disc-like specimens and thin sections of the granite, for quantitative characterization of crack structure. Additionally, fluorescent X-ray analysis (XRF) was carried out to obtain elemental compositions of granite cores showing various degrees of alteration and to consider the relationship of the permeability with the alteration degree.

Permeability was measured using the gas permeameter. The samples are cores collected from about 1 kilometer depth range boreholes in Tono area (Mizunami, Gifu, Japan) drilling by Japan Atomic Energy Agency (JAEA). Over 40 granite cores were sampled at 25-meter intervals ranging from 100 to 1000 meters depth to measure the permeability. Permeability was larger in the altered and fault zones. In addition, the anisotropy was appeared around the fault part and the permeability was enhanced along E-W direction. This direction is consistent with the fault strike, and thus the anisotropy of the permeability was presumably caused by the cracks developed in the fault movement.

Next, the crack structures were quantitatively characterized using an image analysis and compared with the permeability data to clarify their relationship. The specimens were impregnated with fluorescent resin and images were acquired to characterize the mesocrack structure using a fluorescent scanner equipped with ultraviolet ray source. Additionally, thin sections were made from the specimens and microphotographs for characterizing microcracks were taken with a stereomicroscope. Cracks were extracted from these images and length and direction of each crack were determined by the image analysis, following segmentation of crossing cracks. Positive correlation was observed between the permeability and cumulative crack length. These results suggest that cracks cause the permeability anisotropy and microcrack can be a factor controlling the permeability.

XRF was carried out to examine relationships between the permeability and the alteration processes of Toki granite. Positive correlations were recognized between the permeability and Ca concentration in the cores. Hydrothermal alteration of Toki granite is considered to follow three steps, 1) chloritization of biotite, 2) illitization of plagioclase, and 3) precipitation of calcite (Nishimoto and Yoshida, 2010). Considering that precipitation containing Ca is formed in the illitization of plagioclase, strong hydrothermal alteration presumably occurred in the altered and fractured zones that show relatively high Ca concentration. It implies that these zones were highly permeable as forming flow paths of hot water in the past. Although the fault-zone core had high permeability, its Ca concentration was relatively low. Fault movement caused development of fault gouge in addition to fracturing of granite. Permeability was enhanced by the fracturing, but the impermeable fault gouge occurred in the fault interfered circulation of hot water and addition of Ca precipitation.

These results suggest that fractured zone accompanying densely distributed microcracks and altered zone can be groundwater flow paths. Distribution of the highly permeable zones is essential to understand the hydrogeological structure.

Acknowledgement: We would like to express our sincere thanks to the co-researchers of Japan Atomic Energy Agency for their supports and many constructive comments for this study.

The relation between imaging of soil structure with GPR and depth profile of radioactive cesium

WATANABE, Takayoshi[1*] ; MITACHI, Katsuaki[1] ; ABE, Hironobu[1] ; NIIZATO, Tadafumi[1]

[1]Japan Atomic Energy Agency

Radionuclides such as radioactive cesium, now the main radiological contributor, were released in the environment by the Fukushima Dai-ichi nuclear power plant accident. The government and local governments have proceeded with decontamination plans to reduce dose rate in living spheres. But most areas of forests have been still contaminated. Japan Atomic Energy Agency initiated a project entitled 'Long-Term Assessment of Transport of Radioactive Contaminant in the Environment of Fukushima' (F-TRACE project) in November 2012. Main objective of this project is to implement a comprehensive system for predicting radioactive cesium transport in the future and the impact of various countermeasures by understanding transport of radioactive cesium from forests to living spheres and the sea through rivers and dams.

To understand radioactive cesium transport in forest, we have conducted forest investigation at Ogi district, Kawauchi Village and Yamakiya district, Kawamata Town, Fukushima Prefecture since December 2012. As a part of the investigation, we carried out geophysical exploration of soil structure with ground penetrating radar (GPR) with 100MHz and 500MHz radio wave.

In this presentation, we report correlation between imaging of soil structure obtained by GPR survey and depth profile of radioactive cesium in soil.

Current situation and improvement of methylene blue adsorption testing method for bentonite

HORIUCHI, Yu[1*] ; MIYOSHI, Youko[1] ; TAKAGI, Tetsuichi[1]

[1]Geological Survey of Japan

Large amount of bentonite will be required as shielding material for radioactive waste disposal from nuclear power plant and contaminated soil management of Fukushima disaster. The testing methods of bentonite performances are important in terms of the safety of the disposal facility. Methylene blue (MB) adsorption test, which has generally been used for determining either cation exchange capacities (CEC) or surface areas of bentonite, is one of the important testing methods. However, current testing method of MB adsorption is different for each company and it is difficult to compare the performance of bentonite products. Since the current standard testing methods, which are developed by JBAS in the 1970s, are obsolete already, it is necessary to renew the standard testing methods. Therefore, we are planning to propose new standard testing methods for bentonite as JIS, based on this study.

In this study, we interviewed 13 companies and conducted questionnaire about the details of the current MB adsorption testing method. As the result, 10 companies are currently doing MB adsorption test. Of the 10 companies, MB adsorption test based on conventional JBAS method is conducted in eight companies. In addition, four companies are using their own methods, such as colorimetric method which is not defined in the JBAS, including 2 companies using compound of JBAS and colorimetric methods. The tests based on conventional JBAS methods have variation among companies in terms of determining the end point, reagents and sample preparations. Short testing time and simple decision of end point were raised by several companies, as the reasons for using their own methods such as colorimetric method.

As consider in result of interview, the method which aims to propose in this study is required of eliminating the ambiguity of the conventional method, minimal use of consumables, and streamlining for time saving. At the same time, sufficient accuracy is required with this method for ensuring safety in waste disposal. In future, it needs to consider time of reaching adsorption equilibrium, and dispersion and adsorption properties of bentonite by different localities and conditions.

The sedimentary process and distribution of tsunami deposits in coastal lakes: a flume experiment

YAMAGUCHI, Naofumi[1*] ; SEKIGUCHI, Tomohiro[2]

[1]Center for Water Environment Studies, Ibaraki University, [2]Center for Research in Isotopes and Environmental Dynamics, University of Tsukuba

A series of flume experiments were performed to examine the sedimentary process and distribution of tsunami deposits in coastal lakes. In the experimental program, a fixed slope of 1/20 and terrestrial area including a pool as a coastal lake were installed, and tsunami-like solitary wave was generated. The tsunami flow transported sediments from a sand bed placed on the slope, and deposited them on the terrestrial area. When the tsunami flow irrupted into the pool, hydraulic jump was occurred. In the area where the hydraulic jump made turbulence, little sediment deposited. Thus, the distribution of the tsunami deposits in the pool did not always show the thinning-landward trend in the present experimental series. The dependence of the amount of sediments on magnitude of tsunami waves was more pronounced in the pool than the land area.

Variations of terrigenous organic carbon content in flood and slope failure sediments

OMURA, Akiko[1*] ; IKEHARA, Ken[2] ; KATAYAMA, Hajime[2] ; USAMI, Kazuko[2] ; IRINO, Tomohisa[3] ; KUWAE, Michinobu[4] ; ASHI, Juichiro[5]

[1]JSPS Research Fellow, Univ.Tokyo, [2]IGG, AIST, [3]Hokkaido Univ., [4]Ehime Univ., [5]Univ. Tokyo

In this study, we analyzed the stable organic carbon isotope of sea floor sediments, which were deposited by the modern large floods with typhoon and the slope failure with earthquakes. Stratigraphic variations of terrigenous organic carbon content in the flood sediments were different from those of slope failure sediments.

Sediment cores KH-11-9-FB12 and FB14 were corrected from the deep-sea floor off the Kumano River mouth, which is located on the Kii Peninsula. The sediment cores contain flood-induced sediments by large typhoon in September, 2011, the largest 20^{th} century typhoon, and the large 19^{th} century Totsukawa flood (Ikehara et al.,2012). These flood-induced sediments have high terrigenous organic carbon content. The base of turbidite, which include wood fragments, has highest peak of terrigenous organic carbon content. On the other hand, terrigenous organic carbon content of the lower part of turbidite mud are lower than those of the middle and upper parts of turbidite mud. The stratigraphic variations of terrigenous organic carbon content is not recognized in the middle and upper parts of turbidite mud.

Sediment cores 95A and 104A were corrected from the shallow depression on shelf off the Saru River mouth, Hokkaido, in 2007. These cores contain the sediments by the severe flood with typhoon in August, 2003. The shallow depression on shelf, which is thought to be the old river path during lowstand of the last glacial age, was suitable for preservation of the flood-induced sediments (Katayama et al., 2007). The lower part of the turbidite mud has low terrigenous organic carbon content and the middle and upper parts have high terrigenous organic carbon content. The stratigraphic variations of terrigenous organic carbon content is not recognized in the middle and upper parts of turbidite mud. The turbidite mud off the Saru River mouth have same characteristics as those off the Kumano River mouth. These results suggest that the lower part of flood-induced sediments were formed by erosion and deposition of sea-floor sediments during the early stage of flood. The middle and upper parts were considered to be formed by continuous supply and deposition of terrigenous materials from river mouth during the flood.

The sediment core BP09-6 was corrected from the Beppu Bay. The sediment core contains the slope failure sediments by the large earthquake in 1596 (Keicho-Bungo earthquake; Kuwae et al., 2013). The slope failure sediments are characterized by upward decreasing of terrigenous organic carbon. This result suggests that the turbidity currents were caused by collapse of delta slope sediments, which contain both terrigenous and marine organic materials.

Stratigraphic variations of terrigenous organic carbon content might be important information, when we investigate the records of paleo natural disasters with sea-floor sediments.

In the Upper Miocene - Early Pliocene time, Japanese island had a warm and subtropical climate. The mineralogical and chemical compositions of sand and mud of the Upper Miocene Tokiguchi Porcelain Clay and the Early Pliocene in the Kobiwako Group were examined for sedimentary petrography and geochemistry to clarify the influence of the warm climatic condition on sediment composition. Both sediments are considered to have been produced from felsic crystalline basement provenance. These sediments are characterized by the deposition in warm and humid climate on the basis of plant and diatom fossils.

The humid tropical climate produced quartz rich sand and kaolinite rich mud. The Upper Miocene sediments indicate that mafic silicates and feldspars were destroyed so that the sand rages from arkoses with plagioclase rich sand to subarkoses with dominant of K-feldspar. The Upper Miocene mud show kaolinitic clay mineral composition and aluminous chemical composition. In contrast, the Pliocene sand is arkosic to litharenitic with abundant of feldspars and accessory minerals. In the Pliocene mud, an increase in the relative abundance of smectite accompanies the breakdown of volcanic fragments and volcanic glass is detected.

The intense weathering, rare earth elements (REE) are concentrated in mud. The Miocene sand shows the REE concentration less than one of PAAS level, whereas the Miocene mud display similar level of concentration in PAAS. In many samples, the REE concentration is mostly by biotite and zircon evidenced by HREE concentration.

The intense weathering condition, such as high temperature with humidity, affects the sand and mud compositions with selective destruction of minerals and newly formation of clay minerals. The relative increase of HREE, which is mainly housed in durable minerals, and mineral assemblage of sand and mud probably provide quantitative estimation of weathering degree for the sediments derived from felsic plutonic rocks.

Depositional environment of the recent Yangtze Delta sediment deduced from the natural gamma-ray spectroscopy of YD13-G2

IRINO, Tomohisa[1*] ; WANG, Ke[1] ; SAITO, Keita[2] ; TADA, Ryuji[2] ; SUZUKI, Yoshiaki[2] ; KUBOKI, Yui[2] ; SUGISAKI, Saiko[2] ; ZHENG, Hongbo[3]

[1]Hokkaido University, [2]University of Tokyo, [3]Nanjing Normal University

The Yangtze River has transported approximately 500 mt/yr of sediments which formed a well-developed tide-dominated delta on its mouth during the Holocene high-stand. Sediment transport is dominant in rainy summer season or during flooding events, and the 40% is deposited in the estuary and the remaining sediments are transported offshore by tide forming a submerged delta or re-transported southward during stormy winter season. Due to these seasonally contrasted and event driven feature of sedimentation, spatial distribution of the accretion and erosion of the delta body is highly heterogeneous.

The Holocene subaqueous delta sediment has been also used as good sediment archives of the history of the Yangtze discharge and flooding due to its high sedimentation rate and good coverage of the Late Holocene. We also performed drilling of the delta sediment and collected two ˜30 m drilling cores and four gravity cores in order to reconstruct the flooding history and the associated change in the detrital provenance. The drilled site (YD-13) is located on clayey bottom with the water depth of 40 m. The top 10 m of the sediment core consists of homogeneous clay with rare sand patches, which could be formed during the Holocene high stand. One of the gravity core (YD13-G2) recovers the 140 cm of surface sediments, and we decided to examine the natural gamma-ray spectrum and stacking pattern of this gravity core at 1 cm resolution in order to stationarity of sedimentation.

Since Cs-137 was not detected from the YD13-G2 sediment, even the surface material was judged to be older than 1950. Pb-210 is detected from the top 50 cm interval, which suggests the near-surface sediments were deposited during these ˜100 yrs. However, the vertical profile of Pb-210 shows highly variable from zero to 25 Bq/kg with zigzag shape, which suggests repeated intercalation of old materials. Th-234 / K-40 and Ac-228 / K-40 ratios varies consistently suggesting some varieties in the provenance or grain size. Further examination is necessary to resolve potential event sedimentation and the apparent age of the related sediments.

Understanding the complex evolution of the natural environment in response to changes in climatic boundary conditions is a major challenge. Changes in frequency and magnitude of flooding of the Yangtze in association with the variations in East Asian Summer Monsoon (EASM) precipitation during the Holocene is one of such examples. The Yangtze River catchment is particularly sensitive to periodic flooding and droughts caused by temporal and spatial variations in the seasonal precipitation regime.

As a joint research project with Nanjing Normal University, we conducted Yangtze Delta drilling to reconstruct temporal and spatial changes in precipitation within the Yangtze River drainage during the Holocene. Core YD13-1 (31’02’ 59.9250” N, 122’50’00.2538” E) was recovered from Yangtze subaqueous delta at a water depth of 37 m, its penetration depth is 39.5 m, and probably covering the entire Holocene. The project focus on decadal/centennial-scale variability of river discharge and its provenance in the lower Yangtze reaches, deltaic system and East China Sea (ECS). It includes the study of the reconstruction of the flood history, the variability of fresh-water input and redistribution of Yangtze-derived sediments and Holocene floodplain development in these areas.

A new tool that use of electron spin resonance (ESR) signal intensity of the E1’ center and the crystallinity index (CI) of quartz is introduced to characterize the provenance of the Yangtze River Delta sediments, which were derived from various parts of the Yangtze River drainage, and its temporal changes that should have reflected the spatio-temporal changes in precipitation and flooding. The result will contribute to a more accurate understanding of the changes in spatial precipitation pattern associated with rapid climatic changes, of evolution of the lower Yangtze river-delta-shelf system, and of the environmental and climatic conditions under which the process took place. Our previous research result from the mudbelt core in ECS suggests possible scenarios for the response of the Yangtze catchment to the changes in monsoon intensity and extreme events. New analytical result of the provenance proxy for core sediments from Yangtze River Delta will be presented and possible scenario will be discussed.

Yangtze river is the largest river in eastern Asia. The rain front is accompanied with the development of summer monsoon, and moves within the Yangtze drainage, bringing heavy rain. Thus, the spatial fluctuation is also important for understanding the behavior of summer monsoon.

A paleoclimate record is needed for reconstructing the distribution of precipitation before metrological record. In Yangtze, over 95% of yielded sediment is suspended particle matter(SPM). The precipitation in drainage is proportional to water discharge, and water discharge is also proportional to suspended sediment concentration.

In this study, as a basis for reconstructing the past distribution of rain in Yangtze drainage, 1) analyze the ESR(Electron Spin Resonance) signal intensity of each tributary, 2) confirm that ESR values can explain the mixture of sediments in the mainstream, 3) discussing how large flood can be detected as a change of ESR values in the river mouth.

The sediments from major tributaries of Yangtze shows different ESR values each other. Using ESR values of each tributary as end members, the modern ESR value at rivermouth is estimated. The estimated value is consistent with the analyzed ESR value of sediments near rivermouth. So, ESR signal intensity can be used for estimating mixture of sediments.

We also calculated how large ESR value at rivermouth can change on the assumption that the flood occurs in specific tributaries. As a result, the flood can be detected as the change of ESR value at rivermouth when the sediment yield increases 5 times than usual.

Chemical weathering is closely coupled with erosion and driving landscape evolution. Silicate weathering plays a major role of fixing atmospheric CO2 in the carbon cycle in time scales longer than 105 years. Therefore, quantitative estimation of chemical weathering rate and evaluation of its controlling factors are critical to understand its role on landscape evolution and controlling the carbon cycle on a long time scale. Researches on evaluating controlling factors of the weathering rates have been conducted using various methods and on various temporal and spatial scales, including theoretical approaches based on mineral dissolution experiments, empirical approaches based on analyses of river water, suspended material and sediments, and numerical modeling approaches to synthesize these data. Although empirical formulations of the chemical weathering and physical erosion rates specific to a certain river have been presented, processes of weathering and erosion should be considered together both from physical and chemical aspects in order to obtain more generalized formulas. Besides, in order to reconstruct the past processes of chemical weathering and erosion from the knowledge of the present processes, it is necessary to establish methods for reconstructing chemical vs physical weathering processes by using sediments which are the end products of weathering and erosion.

Toward the objective above, this study aims to explore the present processes of chemical weathering and erosion in the Yangtze River drainage as an example. Yangtze River is the longest river in Asia with the great water discharge and sediment flux. Hence, the river's role on material cycle on Earth's surface is significant. In addition, water and meteorological data are accumulated for long time period by many gauging stations and meteorological stations in the basin.

Mineral and chemical compositions of suspended particles and sediments as well as chemical composition of dissolved matter are analyzed for water samples and river bank sediments obtained from Yangtze River and its tributaries in the summer of 2011. Using these results, together with river discharge data and dissolved/suspended load concentrations, the fluxes for each element are calculated, and then the inputs from each watershed are obtained. Then, the relative contribution between chemical weathering and physical erosion is estimated. The calculation revealed that chemical weathering rate increases downstream but the relative contribution between chemical weathering and physical erosion in the uppermost part is the maximum in the upper, erosional part. In the lower, depositional part, dissolved carbonate is diluted after the main stream has merged with Poyang Lake, and then increased again toward the river mouth. The processes of chemical weathering and physical erosion in each watershed and their possible controlling factors will be discussed.

Underwater topographic survey for inaccessible water areas, and its applications to submarine and sublake landslides

YAMASAKI, Shintaro[1*]

[1]Kitami Institute of Technology

Landslides, volcanoes, active faults and other hazard related topographies exist on the sea floor or lake bottoms. It is important to investigate them for assessing future hazard potential. But investigations for these underwater topographies are not so easy because it needs quite high cost, and its heavy weight equipment also requires a ship big enough to hold it. These days, dramatically advanced leisure-use fish finders enable us to investigate underwater topographic survey from shallow to several hundred meters deep. These fish finders are low cost and light weight, so can be equipped on inflatable rafts that is accessible into ultra shallow area of 0.5 - 20 m deep that is usually inaccessible for usual scientific research vessels. Thus the investigating method using the fish finder and an inflatable raft is more versatile than other technical ways. Some advanced fish finders have a side-scan sonar system that obtains 2D image of acoustic reflections, and it can identify bottom materials and underwater structures. Now we are trying to apply for studying submarine and sublake landslides in water areas that have not been surveyed. This presentation shows successful examples of our conducted investigations for the sublake landslides in Lake Kussharo and the 1923 Nebukawa landslide that a part of the landslide dived into the sea. These results have contributed the innovative discussion in generation of tsunamis on the lake, and revealed unknown submarine ruins that landslide devastated.

A development of monitoring system is important for understanding more detailed process of the bathymetric change and sediment transport. At the nearshore zone, to monitor the nearshore features such as sand ripple migration, and the sediment suspension processes, optical back-scatter sensors (Downing et al., 1981), rotary sidescan sonar system (Traykovski et al., 1999), and sand ripple profiler (Masselink et al., 2007) were developed and used. Those systems can provide the very high-resolution morphological change and transportation, but not suitable for investigation of large-scale sediment erosion and deposition generated by high-energy waves in the surf zone. Where change in water depth is large (e.g. more than 1 m) in short span, the systems will be destroyed, lost, or submerged.

In the present study, we developed a new instrumentation for the monitoring of bathymetric change and related sediment transport in the high-energy shallow marine environment using optic fiber cables. The system consists mainly of four components: (1) an array of optical sediment sensors (OSSs); (2) a support structure (steel pipes); (3) an electronics unit that transmit and receive the LED through the optic fiber cables; and (4) a digital data acquisition system. The OSSs are mounted in a vertical steel pipe, 2 m long; and the spacing between the sensors is 10 cm. The steel pipe with OSSs was embedded to the seafloor at two places beneath a pier (427 m long) of Hazaki Oceanographical Research Station (HORS) owned by the Port and Airport Research Institute (PARI) at Sudahama Coast facing the Pacific Ocean, Japan. Both the electronics unit and the data acquisition system were installed in an observation room on the pier. In addition, those points of measurement are aligned perpendicular to the coastline in water depth approx. 4-5 m. Since active sediment transport that creates and deforms the longshore bar have been observed in this area (e.g., Kuriyama, 2010), detailed process of change in the cross section will be acquired by the present systems. In this presentation, we will show the system and data, and discuss those availability and future plan.

Acknowledgment: We would like to thank Dr. Satoshi Nakamura and Mr. Masayuki Banno belonging to the PARI for understanding and support of using the HORS, and MIKUNIYA Construction Co., Ltd. for installation work of the pipes. We wish to express our deep gratitude to the above-mentioned individuals and organizations.

Deposition and preservation of fine-grained turbidites around the Japanese islands

IKEHARA, Ken[1*] ; USAMI, Kazuko[1] ; NISHIDA, Naohisa[1]

[1]Geological Survey of Japan, AIST

We will report the sedimentological characteristics of fine-grained turbidites occurred around the Japanese islands such as off Sanriku, off Kumano, Suraga Bay, Beppu Bay, Japan Trench and off Hidaka. Some of these are thought to be formed in relation to the slope failures by the earthquake-ground shaking. Sometimes, subaqueous debris flow deposits were observed below the fine-grained turbidites. Agitation of the shelf floor by the tsunami waves is another mechanism to create the fine-grained turbidites. Third mechanism is the hyperpycnal flows related to the flood events. Preservation potential of the fine-grained turbidites will be discussed based on the repeated surveys of surface sediments off Sanriku region after the 2011 Tohoku-oki earthquake and its related tsunami. Based on these observation, we will discuss on the depositional processes of the fine-grained turbidites and preferable setting to preserve them as the geological records.

Recurrent giant earthquakes at the plate boundary along the Sagami Trough have been considered as one of the greatest thread of the Tokyo Metropolitan area. At the southwestern tip of the Miura Peninsula, in south of Tokyo, the tide gauge station records the coseismic uplift amount of 1.4 m and the interseismic subsidence amount of 0.3 m in and after 1923 earthquake, respectively. It is effective to reveal evidences of the past coseismic uplift to know the future earthquake.

Wave-cut benches which emerged in 1923 are widely distributed along the rocky coast. Higher wave-cut benches, good indicators of coseismic uplift prior to 1923, are also recognizable. It is, however, often difficult to spatially compare one another due to the erosion.

We investigated the distribution of the tidal-flat deposits and the 1923 wave-cut benches at two small bays in the southwestern and southern parts of the Peninsula. The aggradation of the coastline associated with the 1923 uplift was identified by the comparison between the 1:25,000 topographic maps before and after the 1923 earthquake. Observations of outcrops and drilling cores at the 1923-formed marine terrace showed that the tidal-flat deposits consist of shelly sand and gravels. The elevation of tidal-flat deposits indicates the coseismic uplift in 1923 and the interseismic subsidence after 1923. The uplift amount was estimated approximately 0.9 m and 2.1 m at the southwestern and southern parts of the Miura Peninsula, respectively. The uplift amount inferred from the tidal-flat deposits is concordant with that inferred by the wave-cut benches.

The paleosols and topography of sedimentary basin relationships in the upper Miocene Clay deposit, central Japan

HATANO, Nozomi[1*] ; YOSHIDA, Kohki[2]

[1]Division of Science and Technology, Graduate School of Shinshu University, [2]Department of Geology, Faculty of Science, Shinshu University

The Tokiguchi Porcelain Clay Formation is fluvial deposit distributed in central Japan in middle to late Miocene period. The sedimentary facies analysises were carried out in this formation. Those studies, however, were insufficient to reconstruct fluvial environment, because the fluvial deposit essentially have been bounded by short hiatuses due to sub-aerial erosion and paleo-surface formation. In this study, therefore, we focused on paleosols so as to reconstruct the weathering environment during the hiatuses. In general, paleosol formation in the fluvial sediments also depends on the supply of detritus and drainage conditions. Consequently it is very useful to research paleosol features for reconstruction of the topography in the small sedimentary basin where Tokiguchi Porcelain Clay Formation was deposited.

The clay-dominated sediments, which are interpreted to have been deposited in small sedimentary basin within a radius of 2 kilometers, were examined in two mines, Hishiya and Nakayama mines, across Toki and Tajimi Cities in Gifu Prefecture. The sediments in Hishiya mine shows the deposition in proximal area of the sedimentary basin, whereas those in Nakayama mine displays the facies formed in marginal area of the basin. On the sedimentary facies analysis, 13 facies are recognized in the formation. The sedimentary facies associations indicate the deposition mainly in backswamp environment with minor channel incision. Furthermore the coarse-grained sediments which were deposited as channel-bar and levee deposits intercalating debris flow deposits, with high accumulation rate, were particularly deposited in the marginal area of the basin. In contrast, the fine-grained sediments which were deposited with low accumulation rate in lakes and swamps, were particularly distributed in the proximal area of the basin. For this result, the fluvial system with lakes and swamps was developed near mountain slope side. In the whole are of the basin, approximately 20 paleosol horizons were founded in the lake and swamp deposits within a thickness of approximately 30 meters. In the proximal of the basin, these paleosol horizons range sparser. These paleosol horizons, with various pedogenic features, such as root with approximately 150 centimeters length and trunk traces with approximately 50 centimeters wide, pedogenic concretions, ped structures and microfabric of clay minerals, are formed thickly and developed clearly. In addition to, abundant siderite nodules covered with bright clay are present in lake deposit in the proximal area of the basin.

As a result the characteristics of the sedimentary facies could depend on the sedimentation rate depending on variation of the distance from the rim of the sedimentary basin. Besides the characteristics of the paleosol features could be affected by the drainage conditions due to morphological variation related to the location in the sedimentary basin. The characteristics of the sedimentary facies and paleosol features, however, suggest the large change of water level in the whole sedimentary basin. Concretely the redox condition had shifted from reductive condition in lakes or swamps to oxic condition in bushy grounds. The plausible cause for this change of redox condition in the sedimentary basin could be responsible for water-level change which was frequently occurred by damming of rivers formed from debris flow deposition.

Applications of a method to detect varved sediments

SASAKI, Hana[1] ; ISHIHARA, Yoshiro[1*] ; SAITO-KATO, Megumi[2] ; KOMATSUBARA, Junko[3]

[1]Fukuoka University, [2]National Museum of Nature and Science, [3]Geological Survey of Japan / AIST

Studies of lacustrine deposits, especially on varved sediments, have further clarified the high-resolution record of paleoenvironments. Varved sediments are very useful for these studies because they are expected to contain annual records of depositional environments. In order to obtain annual records such as annual thickness, color tones, and chemical compositions, at the very least, it is necessary to detect the boundaries of annual bands. In addition, the detection and measurements should be reproducible.

Methods to measure boundaries of varved sediments are divided into two main categories: (1) measurment by visual judgment and (2) measurment by image analyses. The latter method uses photographs of the sediment, soft-X ray images, element maps, and so on. In order to detect boundaries, a threshold value, wavelet analysis, and wave analyses of the gray value of images have been previously used. While the visual judgment method has the disadvantages of human error and criteria, the image analysis method also has limitations as follows: one threshold value cannot be used for all locations in successive images; this method is dependent on the resolution of images, and it is affected by noise in the image-values.

In this study, we used a new method to detect the boundaries of banded deposits using the following procedure: (1) smooth the images, (2) calculate the inclination of ”gray-value map” of the images, (3) calculate a mid-value in one wavelength of the ”gray-value wave” in the map, and (4) detect a boundary as a point of the maximum inclination around the mid-value. The result obtained using this a method shows well-defined ”boundary map” of the bounded deposits, similar to the result obtained by visual judgment. Using this method, internal information, such as the transmittance value of soft-X ray in a lamina, can also digitized like a lamina thickness. Since a time-series of lamina thickness and internal information of the lamina can be calculated based on this method, lamina-by-lamina facies analysis, such as that performed for detection of flood deposits, can be employed in studying varved deposits automatically and quickly.

Depositional cycle and flood and slope-failure events in an 8,000-yr varve of Pleistocene Hiruzenbara Formation, Japan

SASAKI, Hana[1*] ; ISHIHARA, Yoshiro[1] ; SAITO-KATO, Megumi[2] ; NARUSE, Hajime[3]

[1]Fukuoka University, [2]National Museum of Nature and Science, [3]Kyoto University

Paleoenvironmental changes can be reconsructed from varve deposits. The Middle Pleistocene Hiruzenbara Formation, which is distributed in the Hiruzen Highland, Maniwa city, Okayama Prefecture in Japan, is composed of mostly pure lacustrine diatomite that contains finely-laminated varves. From these varves, researchers have found decadal-scale depositional cycles that are thought to correspond to solar activities (Ishihara and Miyata, 1999), and intercalated flood- and slope-failure events have been detected. However, the relationship between the solar cycles and hydrogeological events remains unclear. In the present study, we sampled the finely laminated varves in the Hiruzenbara Formation, and obtained an 8,000-yr time-series of varve-thickness, gray-values for each lamina, variance of the gray-values, and deposits of flood- and slope-failure events using image analysis methods. Wavelet analysis and a fast Fourier transform (FFT) were applied to these time-series data to evaluate event-cyclicities.

In the time-series of varve-thickness, a long-term cyclicity of 1,000 - 2,000 yr was recognized. The upper parts of varves were light-green in color, and these were likely deposited during the winter season. Clear increases in thicknesses of the light-green parts were observed from the lower to upper parts of the analyzed section. Results from frequency analyses using the FFT and wavelet analysis of the time-series of varve-thickness data suggest that periods of 8 to 12 yr, 20 yr, and 30 to 35 yr dominate in this region. These periods were also found by Ishihara and Miyata (1999) and Masuda et al. (2004) in other sections of the formation. The periods in varves of 8 - 12 yr and around 20 yr correspond to solar activity, and a 35-yr periodicity of lake environmental change has been reported previously. In this study, however, these periods were not stable in the analyzed section, which is similar to the results obtained by Ishihara and Miyata (1999) and Masuda et al.(2004) who measured varve-thickness using a microscope.

One hundred-forty seven flood deposits were identified in the 8,000-yr record. Portions of the high-frequency parts and low-frequency parts were repeated in the analyzed section. Mean thickness of the flood beds was around 2 mm. Thirty-three deposits from slope failures were found in the section. These deposits were rare in the upper and lower most parts of the section, but were dominant in the lower part. There was no repetition of domination for the deposits that were observed during the flood events. Mean thickness of the slope-failure deposits was around 5.5 mm.

In the sections where flood deposits dominated, the mean varve-thickness tended to thinner without exception. In the upper part of the analyzed section, which lacked flood event signatures, the mean varve-thickness was generally greater. These trends suggest that climate conditions and the frequency of flood events might have affected the productivity of diatoms (thickness of the lamina). In addition, the periods detected by frequency analyses were not clear in the flood-deposit dominated sections. Results showing that dominations of slope-failure deposits were not related to the varve-thickness and the gray-values suggest that the slope-failure events were influenced by local phenomena related to lake development.

Keywords: Banded diatomite, Varve, Image analysis, flood deposit, slope-failure deposit, Solor activity

Subsidence and a change of depositional environment by the 1662 Hyuganada earthquake in southern Miyazaki Plain

IKUTA, Masafumi[1*] ; SATO, Yoshiki[1] ; NIWA, Masakazu[1] ; KAMATAKI, Takanobu[2] ; KUROSAWA, Hideki[3] ; TAKATORI, Ryoichi[4]

[1]Japan Atomic Energy Agency, [2]Akita University, [3]OYO Corporation, [4]Chi-ken Sogo Consultants Co.,Ltd.

The Miyazaki Plain, southern Kyushu Island, have been damaged repeatedly by a number of great earthquakes (measured or estimated to be >M7-8) occurred in not only the Nankai trough but also the Hyuganada coastal region. A total of six great earthquakes happened in the Hyuganada coastal region in the range of AD1909 to 1984. Historical documents indicate such great earthquakes had also occurred in AD1662, 1769 and 1899. Furthermore, the great earthquakes in the Nankai trough, such as the 1707 Hoei Nankai earthquake and the 1946 Showa-Nankai earthquake, had also attacked the plain with terrible tsunamis (Usami *et al*., 2013).

Recently, the Nankai trough has received extensive attention as hypocenter of great earthquake attacking the Miyazaki Plain, because the Central Disaster Management Council (2012) proposed a new source model of the earthquakes including the Hyuganada coastal region. On the other hand, previous geological and seismological studies about past Hyuganada earthquakes are much less than the Nankai trough despite of their high seismic activity indicated by historical documents.

For example, historical documents shows that the 1662 Hyuganada earthquake brought about serious social and natural damages to the plain (Hatori, 1985). Especially, around the estuaries of the Oyodo-gawa River and the Kaeda-gawa River in southern area of the plain, the tsunami with about 4-5 m height and ˜1 m subsidence occurred. This coseismic subsidence made a coastal lagoon around the estuarine area of the Kaeda-gawa River (Shimayama region). After buried by riverine debris, this lagoon was reclaimed and became paddy fields (Miyazaki-city, 1978).

The purpose of our study is to clarify depositional changes around the Shimayama region including coseismic geomorphological change. A multiple geological borings were carried out in the study area. Depositional environments were reconstructed inferred from paleontological, geochemical analyses. Depositional ages of core sediments were estimated by radiocarbon ages. The surface geology was divided into four layers mainly (layer A, B, C and D) in ascending order. The layer A was composed of alternate layers of grayish sand and silt with many angular pumices and organic materials. The layer B consisted of alternate layers of gray or grayish brown mud and sand including numerous well-preserved molluscan fossils. The bottom of the layer B, which covered the layer A above ˜-1.5 m T.P. with 10 to 40 cm thick, was black or dark gray muddy fine sand with bioturbation including rip-up clasts, shell fragments and volcanic rocks with >1 mm diameter. The layer C was composed of gray silt with several thin layers of fine to medium sand and plant fragments. The layer D consisted of silt to fine sand layers and surface cultivated sediments with ˜20 cm thick overlying them.

Result of some analyses showed their quantitative differences corresponding to depositional facies. The main diatom components of the lower part of the layer A was fresh water benthic species such as *Cymbella turgidula* and *Gomphonema parvulum*, and the upper was few diatom fossil. On the other hand, the layer B showed abundance of brackish to marine water species such as *Cocconeis scutellum* and *Thalasionema nitzschioides*. In addition, absorbed water analysis of the core sediments showed that K, Ca, Na, Mg and SO_4^{2-} concentration, which are rich in sea water, were few in the layer A but increased drastically at the bottom of the layer B. And grain size and molluscan fossils species were also different between the layer A and B.

These results indicate that depositional environment changed drastically from fresh water marsh or shallow pond to tidal or inner bay. Depositional ages of the layer A, B and C were estimated from radiocarbon ages to be AD1445 to 1595, AD1549 to 1771 and AD1651 to 1771 respectively and suggest that the depositional environment between the layer A and B correlate to crustal deformation by the 1662 Hyuganada earthquake.

Selected organisms for systems of life-support in closed bio-ecosystem, and the chemical circulation

TOMITA-YOKOTANI, Kaori[1*]

[1]University of Tsukuba

Living organisms on the earth have been evolved since its origin a long time ago. They equip several important functions affecting each other. Knowledge on those functions and interaction of the ecology is essential for secure design of a closed-ecosystem with limited number of living species under the harsh environments, such as space and deep sea or desert. The important elements related to the closed bio-ecosystem have to be discussed among the researchers, having each specialized field . Here, we will discuss the detail of species of several selected organisms for the closed bio-ecosystems and its chemical circulation.

Dry heat tolerance of the dry colony in *Nostoc* sp. HK-01 for useful usage in closed bio-ecosystems

KIMURA, Shunta[1*] ; KATOH, Hiroshi[2] ; SATO, Seigo[1] ; TOMITA-YOKOTANI, Kaori[1]

[1]University of Tsukuba, [2]Mie University

Closed bio-ecosystem as an artificial design requires the high flexibility and versatility system. As one of elements for all of introduced organisms, heat tolerance is important one such closed environment. *Nostoc* sp. HK-01 is one of terrestrial cyanobacterium having a high dry tolerance and it has several ability, photosynthesis, nitrogen fixation and usefulness as a food, it is thought that it can be used for bio-chemical circulation in a closed ecosystem, including space. Besides, a study on each tolerance predicted at the time of introduction to a closed bio-ecosystem is necessary. Therefore, as one of the tolerance that are intended to space environment, dry heat (100 ℃, 10 h) tolerance of dry colony in *Nostoc* sp. HK-01 has been investigated, but the detail function of them has not yet been elucidated. We focused on the extracellular polysaccharides (EPS) having the various tolerance, desiccation, low temperature, NaCl, and heavy particle beam. We will consider the function and useful usage of this cyanobacterum in closed bio-ecosysitems after the consideration of the results of contribution of the possibility that EPS improves dry heat tolerance under a dry condition.

Keywords: bio-chemical circulation, closed bio-ecosystem, cyanobacteria, dry heat tolerance, extracellular polysaccharides, *Nostoc* sp. HK-01

Utilization of the terrestrial cyanobacteria

KATOH, Hiroshi[1*] ; YOKOSHIMA, Mika[2] ; KIMURA, Shunnta[2] ; FURUKAWA, Jun[2] ; TOMITA-YOKOTANI, Kaori[2] ; YAMAGUCHI, Yuji[3] ; TAKENAKA, Hiroyuki[3]

[1]Mie University, [2]University of Tsukuba, [3]MicroAlgae Corporation

The terrestrial, N_2 -fixing cyanobacterium, *Nostoc commune* has expected to utilize for agriculture, food and terraforming cause of its extracellular polysaccharide, desiccation tolerance and nitrogen fixation. Previously, the first author indicated that desiccation related genes were analyzed and the suggested that the genes were related to nitrogen fixation and metabolisms in *Nostoc*(*Anabaena*) sp. PCC 7120. In this report, we suggest possibility of agriculture, using the cyanobacterium. Further, we also found radioactive compounds accumulated *Nostoc commune* (cyanobacterium) in Fukushima, Japan after nuclear accident. Thus, it is investigated to remove radioactive compounds from soil by the cyanobacterium and showed to accumulate radioactive compounds using the cyanobacterium. We will discuss utilization of terrestrial cyanobacteria under closed environment.

We have been studying life-support in closed bio-ecosystem to provide food and oxygen for the habitation area in the sever environment. To select the species of organisms is very important matter because it is difficult to use all the species of creature for the system. We have been proposing the several species of organism as the candidate species. In this time, we have selected and show terrestrial cyanobacteria and tree that have a possibility as high contributed materials for the induction into the closed systems. Here, we will discuss about the changes of the functional components produced from each materials, after their cooking.

Study of Closed Life Support System for Manned Space Exploration

SAKURAI, Masato[1*]

[1]JAXA

To further advance manned space exploration, a critical issue that must be addressed is recycling of resources, especially air revitalization and water reclamation. Japan is already a leader in terrestrial environmental technologies, and aims to apply this know-how to develop air and water recycling technologies for space applications. To support proposed post-ISS missions such as manned lunar or asteroid exploration and an Earth-Moon Lagrange point (EML1) space station, JAXA is developing an air revitalization system for an on-orbit demonstration on the International Space Station (ISS) early in the extended ISS operation period (2015-2020). The requirements for this technical demonstrator have been investigated and its specifications established. Regenerative life support functions include oxygen recovery from carbon dioxide using a combination of CO_2 reduction by a Sabatier process and O_2 generation by electrolysis. Each air and water re-vitalization subsystem is planned to be transported to the ISS separately by H-II Transfer Vehicle (HTV) launches in the Water Electrolysis This paper presents the air re-vitalization system developed by JAXA, and gives details of water electrolysis in microgravity.

A technical issue with space electrolysis systems is that gas-liquid separation is fundamentally different in a microgravity environment to its behavior in a gravity field. It is supposed that the electrode surface will become covered with generated gas. In microgravity, the gas will have to be removed using forced convection. A water/gas separator will be used to separate gas and water.

Human body and oxygen

SHIMIZU, Tsuyoshi[1*]

[1]Shimizu Institute of Space Physiology, Suwa Maternity Clinic Hospital

We found recently that a mild hyperbaric condition with a mild hyper oxygen-concentration ,which was maintained in the special container called as Ishihara's original oxygen capsule, was effective to treat infertility women patients. This result did let us realize again an importance of oxygen for cells and tissues of human body . In space development effects of microgravity, space radiation and other various environmental factors have been extensively investigated and discussed, however we should also remember again that oxygen is the basic component to support our body in the space environment as well as on the earth. In this presentation I will summarize over again the meaning of presence of oxygen related to human body for future space development.

Growth of Hydrobryum puncticulatum(Yakushimakawagoromo) may be blocked by the increase of Melosira varians in Isso River

KITABUCHI, Hiroyuki[1*] ; NAGAFUCHI, Osamu[1] ; NAKAZAWA, Koyomi[1] ; YOKOTA, Kuriko[2] ; TETUKA, Kenshi[3] ; AYUKAWA, Kazuyasu[4] ; TANABE, Masahiro[5]

[1]The University of Shiga Prefecture, [2]Toyohashi University of Technology, [3]Yakutane-goyou Research Group, [4]Environmental System Co., Ltd, [5]Nikkaki Bios Co., Ltd

Hydrobryum puncticulatum (*Yakushimakawagoromo*), the national monument and endangered species are making their habitat only in Isso river of Yakushima. For the first time in our observation, the bloom of *Melosira varians* which is periphyton of diatom was observed to be covered over the *H.puncticulatum* from 2011. This impact for the *H.puncticulatum* is a serious concern .The purpose of this study is to clarify the cause of bloom of *M.varians*. We examined the annual variability of dissolved nutrient concentration which was most accessible to *M.varians*. As a result, there was no increase in concentration of NO_3-N, SiO_2-Si from 2009 to 2013. In addition, PO_4-P was much lower concentration(0.003 ± 0.001 mg/ l). Therefore, we assumed that there was no relationship between the bloom of *M.varians* and dissolved nutrient concentration in Isso river. Meanwhile, the floating mud which was deposited in the bottom of the river has been continued during dry-spell. Tachibana et al (1986) reported that an algae can intake the suspended nutrient same as dissolved nutrient. It suggests that the *M.varians* and *H.puncticulatum* can take suspended nutrient.

Environmental response in bacteria to an applied magnetic field

ABE, Makoto[1*] ; YAMANA, Masao[2] ; ABE, Tomoko[2]

[1]Graduate School of Science and Engineering,Graduate School of Tokyo Denki University, [2]School of Science and Engineering,Tokyo Denki University

Metabolic changes in living cells under various magnetic fields should be considered in closed-ecology on planets.

Magnetic fields may induce multiple effects in biological systems, including change in DNA replication or RNA transcription and modification of ion and protein flow across membranes. In recent years, influences of various electromagnetic fields on cell and organisms have been investigated by many researchers. However, the detailed mechanisms in the effects of magnetic field on organisms are still controversial.

In this study, we had focused on influences of the magnetic field on environmental microbes. Some bacteria susceptible to the applied magnetic field were isolated from the soil. To investigate expression changes of intracellular proteins involved in regulating cell growth by the applied magnetic field, cellular proteins in the bacteria cultured under the applied magnetic field were analyzed by SDS-polyacrylamide gel electrophoresis.

Useful utilization in closed bio-ecosystems of *Nostoc* sp. HK-01 having the tolerance of gamma-ray

AJIOKA, Reiko[1*] ; KIMURA, Shunta[1] ; KATOH, Hiroshi[2] ; SATO, Seigo[1] ; TOMITA-YOKOTANI, Kaori[1]

[1]University of Tsukuba, [2]Mie University

Photosynthetic organisms contribute to the circulation of oxygen or carbon dioxide and utilization of foods as a induced organism in closed bio-ecosystems. A terrestrial cyanobacterium, *Nostoc* sp HK-01, having a high drought tolerance, photosynthetic organism, is one of candidate organisms that can be introduced into the closed environment. It has a possibility that HK-01 has also a high gamma-ray tolerance in according to the results from several reports related to the interaction of drought tolerance and gamma-ray tolerance. Here, we will show the several influences on the growth of HK-01 after the exposure of gamma-ray in the dry colony.

Long-baseline laser strainmeter in Kamioka

TAKAMORI, Akiteru[1*] ; ARAYA, Akito[1] ; MORII, Wataru[2] ; UCHIYAMA, Takashi[3] ; OHASHI, Masatake[3] ; TELADA, Souichi[4]

[1]Earthquake Research Institute, University of Tokyo, [2]Disaster Prevention Research Institute, Kyoto University, [3]Institute for Cosmic Ray Research, University of Tokyo, [4]National Institute for Advanced Industrial Science and Technology

In order to facilitate the gravitational-wave astronomy, ‘ KAGRA project ’ has been proceeding under international collaboration hosted by the Institute for Cosmic Ray Research of University of Tokyo. The authors are constructing a long-baseline laser strainmeter with a 1.5 km long baseline in the Kamioka underground site as the part of the project (left figure). It will be the longest baseline laser strainmeter in Japan, and one of the largest instruments worldwide. The longer baseline was opted to achieve the superior sensitivity for the ground strain, more than 10 times better than the currently available 100 m strainmeter. The better sensitivity is anticipated to enable more detailed studies in the ground deformation caused by the fault activities and the Earth ’ s free oscillations.

The basic design of the long-baseline strainmeter is adopted from the 100 m strainmeter, consists of the highly asymmetric Michelson interferometer using the Iodine-stabilized laser as the standard of length (right figure). Nevertheless, there are some technical challenges required due to the gigantic scale of the new instrument. The outline of the instrument and the status of R&D will be reported in this presentation.

Development of software for precise LLR data analysis, Part 2

NAGASAWA, Ryosuke[1*] ; OTSUBO, Toshimichi[2] ; SEKIDO, Mamoru[3] ; HANADA, Hideo[4]

[1]Graduate University for Advanced Studies, [2]Hitotsubashi University, [3]National Institute of Information and Communications Technology, [4]RISE Project Office, National Astronomical Observatory

We are developing new analysis software for precise determination of lunar orbital/rotational motion and tidal deformation using lunar laser ranging (LLR) observation data.

As the first step of the study, we construct an LLR observation model. This model consists of the lunar orbit and libration obtained from DE430 (provided by NASA JPL), and the other newest physical models compatible with IERS Conventions (2010) such as Earth orientation, solid Earth/Moon tides, and some factors affecting propagation delay. For the purpose of calculating these components precisely, we use the modules of the geodetic data analysis software ”c5++” (Otsubo et al., 2011). LLR observation data are provided as normal points. In this calculation, there are 3577 points distributed from June 1996 to July 2013, obtained at Apache Point, Grasse, Matera and McDonald. Comparing the observed and calculated one-way ranges, the mean and the standard deviation of the residuals are about 5.7 cm and 4.8 cm respectively.

The presentation contains the result of the above-mentioned modeling and comparison, and the current status of the software development.

Scale parameters of the Earth sensitive to the optical response of spherical SLR targets

OTSUBO, Toshimichi[1*] ; MATSUO, Koji[2] ; SHERWOOD, Robert a[3] ; APPLEBY, Graham m[3] ; NEUBERT, Reinhart[4]

[1]Hitotsubashi University, [2]Kyoto University, [3]NERC SGF Herstmonceux, UK, [4]GFZ Potsdam, Germany

Recent technology upgrades in SLR technique, especially driven by kHz laser ranging systems, make it possible to measure the station-satellite distance at mm precision. The optical response of a sphere-shaped SLR target has been one of the major error factors in measuring the two-way distance, and, following the study on AJISAI, LAGEOS and ETALON (Otsubo and Appleby, JGR, 2003), we look into relatively smaller targets, STARLETTE and its twin STELLA. Based on the detailed optical response simulation adjusted by the actual kHz laser ranging data obtained at Herstmonceux and Potsdam, it is calculated that the standard centre-of-mass correction value for STARLETTE is too small by 3 mm. The impact can be up to 0.5 ppb for the terrestrial reference frame scale and up to 1.7 ppb for the gravity constant (GM) of the Earth.

Long-term worldwide technology upgrades can have a systematic impact on the long-term trend of such scale parameters. As the intensity of photons received at a given detector is reduced, the detection point (timing) goes rearwards and the center-of-mass correction gets smaller as listed in Appleby and Otsubo (LW18, 2013). This can map a non-negligible drift especially in the GM parameter.

VLBI application for Frequency Transfer and Development of GALA-V System (III)

SEKIDO, Mamoru[1*] ; TAKEFUJI, Kazuhiro[1] ; UJIHARA, Hideki[1] ; MIYAUCHI, Yuka[1] ; TSUTSUMI, Masanori[1] ; HASEGAWA, Shingo[1] ; HOBIGER, Thomas[1] ; ICHIKAWA, Ryuichi[1] ; KOYAMA, Yasuhiro[2]

[1]National Institute of Information and Communications Technology, Space-Time Standards Laboratory, [2]National Institute of Information and Communications Technology, International Relations Office

NICT is developing the frequency comparison technology using the VLBI as one of the remote frequency comparison technologies. The small broadband VLBI station, which is an important element of this project (Gala-V), is semi-compliant with the specification of the broadband geodetic VLBI system VGOS (VLBI2010 Global Observing System) specifications. Many VLBI observation stations compliant with the VGOS are under development several countries as an international standard specification for the next generation geodetic VLBI. Our Gala-V system is aimed for the comparison of the frequency standard, but of course this is useful for the geodetic observations too.

[broadband feeding development for large diameter antenna]
Most of the VGOS VLBI stations under development are adopting the special optical system so called ring-focus, That is because of wider beam width characteristic of wide frequency band (2-14GHz) feed, currently available. The receiver feed, that has sensitivity about 3 octaves of frequency, has generally wide beam angle, and therefore, existing Cassegrain reflector antenna is difficult to use it. We have been developing a new broadband feed for our 34m antenna. The first test feed become ready and it was mounted on the 34m diameter modified Cassegrain parabola in the end of 2013, and successfully we observed 6.7GHz, and 12.2 GHz emission line of the Methanol maser simultaneously.

[Zero redundant frequency array - Direct Sampler]
The Gala-V system, which is under the development at NICT, is designed to use four bands of the 1 GHz bandwidth with intervals of zero redundancy in the 2-14 GHz frequency range. This enables a fine delay resolution function without uncertainty (Ambiguity), and the precision of delay measurement could be improved by a one order higher than conventional.
In addition to a conventional analog frequency conversion method, we are experimentally adopting a method to acquire specific frequency band with a digital filter with a direct sampler, which acquires data without frequency conversion via a high-speed sampler. If a direct sampling method is established, system components and cost necessary for the system are simplified and reduced.

[development of the broadband signal composition technology]
The VGOS system is targeting to achieve high precision delay measurements by synthesizing 2-14 GHz broadband signal coherently. A new data processing software, which enables estimation of nonlinear phase change caused by the ionosphere and derivation of precise delay from the super broadband signal, and broadband stable phase calibration system are required.

Development of a new precise positioning technique using multi-GNSS signals

FURUYA, Tomoaki[1*] ; SAKAI, Kazuki[1] ; MANDOKORO, Motomu[1] ; TSUJI, Hiromichi[1] ; YAMAGUCHI, Kazunori[1] ; MIYAGAWA, Kohei[1] ; YAHAGI, Toshihiro[1] ; HATANAKA, Yuki[1] ; MUNEKANE, Hiroshi[1] ; KAWAMOTO, Satoshi[1]

[1]GSI of Japan

Geospatial Information Authority of Japan (GSI) is developing and standardizing new precise positioning techniques which deal with multiple GNSS constellations, GPS, QZSS, GLONASS, and Galileo, in order to mainly encourage effective surveys at places where are currently difficult to carry out them using only GPS satellites.

In FY 2013, we examined analysis methods to correct Inter System Bias for using single/double differences between GPS and other GNSS. We developed the new analysis software named GSILIB based on RTKLIB developed by Mr. T.Takasu. In addition, we obtained multi-GNSS data in eight cities and evaluated the effects and problems using multi-GNSS signals.

This presentation shows results of FY 2013 and future plans from FY 2014.

Notes on the quality of GEONET coordinate solutions

IMAKIIRE, Tetsuro[1*] ; KAGAWA, Akira[1] ; HATANAKA, Yuki[1] ; MUNEKANE, Hiroshi[1]

[1]GSI of Japan

The routine solutions of geodetic coordinate of observation stations of GEONET, the continuous GNSS observation network operated by GSI, are fundamental data for the studies of crustal deformation and tectonics and widely utilized for a variety of purposes. As GEONET data is available freely, researchers can discuss the crustal deformation or tectonics without carrying out GNSS observation or baseline analysis. However, it should be noted that the coordinates provided by GEONET may include errors caused by various noise sources or factors, such as obstruction of observation signals by trees, multipath caused by site environment or um-modeled tropospheric noise. We present results of evaluation the effects of some of the error factors and introduce ways of examining the quality of coordinate solutions done for crustal deformation monitoring by GSI.

Positioning error estimation due to snow accumulation on GNSS antenna using winter experimental data

YOSHIHARA, Takayuki[1*] ; MOTOYOSHI, Hiroki[2] ; SATO, Takeshi[2] ; YAMAGUCHI, Satoru[2] ; SAITO, Susumu[1]

[1]Electronic Navigation Research Institute, [2]National Research Institute for Earth Science and Disaster Prevention

In research field of precise positioning using Global Navigation Satellite System (GNSS) such as GPS, it is well known that positioning error is caused by snow accumulation on GNSS antenna [1]. It is important to quantitatively evaluate the error taking account for shape of snow-cap and GPS satellite configuration, which are changing with time past. In this study, we performed two winter experiments in each winter of 2011/2012 and 2012/2013, which enabled us to quantitatively investigate reduction in receiving intensity and propagation delay due to snow accumulation on GNSS antenna. The experimental data was also able to use for positioning error estimation resulted by such effects. We installed a GPS antenna about 50 meters away from weather observational equipment, which measured pressure, temperature, humidity, wind direction and velocity, precipitation, snow depth, etc.), in observation field of Snow and Ice Research Center, National Research Institute for Earth Science and Disaster Prevention (NIED) in Nagaoka, Japan. To observe snow accumulation on GNSS antenna, a photograph of GNSS antenna was automatically took by an interval camera every 10 minutes during winter. To evaluate quantitative effects of snow accumulation on GPS signal measurement, we investigated drop events of snow-cap on GNSS antenna and analyzed gaps of rapid changes in both receiving intensity and carrier phase measurements[2]. Consequently, a snow-cap with a height of 40cm yielded reduction of several dB in receiving intensity (C/N0) and propagation delay of about 4 cm in slant range. We will show relationship between size of snow cap and positioning error based on the experimental data, including simulation analysis with range errors due to snow accumulation and satellite configuration. We will also show evaluation results to use water repellent paint on GNSS antenna radome for mitigation of snow accumulation.

Periodic displacement on continuous GPS observation in coastal area due to long term sea level elevation

OICHI, Kazuyoshi[1*]

[1]Hydrographic and Oceanographic Department, Japan Coast Guard

Since 1999, Hydrographic and Oceanographic Department carried out continuous GPS observation to survey the crustal deformation at the stations collocated with tidal stations or lighthouse etc. of Japan Coast Guard in south Kanto area. And precise positions in earth centered coordinates of these GPS stations are automatically determined by long baseline analysis from Simosato GPS station. Several stations show significant unexpected annual oscillation in its daily position series. On the other hand, hourly sea level data are available via Japan Oceanographic Data Center from tidal stations of Japan Coast Guard and Japan Meteorological Agency in this area. To eliminate annual oscillation from crustal deformation observation, correlation functions between daily precise position series of GPS stations and sea level height series of tidal stations are calculated. And I tried to evaluate an error from weight variation of sea water on precise GPS observations in coastal area.

Hydrographic and Oceanographic Department continuously observes 30 sec interval data at GPS stations in Izu islands area from 2002. And long baseline analysis from Simosato hydrographic observatory is performed with Bernese GPS Software and IGS final ephemerides. Calculated daily precise positions are utilized for crustal deformation monitoring. However, time series of calculated positions contains unexpected component other than crustal deformation. Particularly, Izu O-Shima station shows significant oscillation in a north-south direction. This oscillation is synchronous with four GPS stations of GSI in Izu O-Shima, and these show annual apparent cycle of expansion and contraction. Some oscillation of local load is suspected as cause of this deformation and move of sea water is considered as major component of these in coastal area. Analyzed positions of these stations are obtained as daily value, thus influence of major component of tide (diurnal or semidiurnal) is negligible, but long term component, for instance, annual change of sea level is inadequately considered. According to the sea level observations at adjacent tidal stations, annual oscillation of sea level shows its amplitude in tens of centimeters, thus long term component of sea water load change is expected as considerable.

To eliminate annual oscillation from GPS monitoring of crustal deformation, I tried to analyze strain caused by load change from sea level elevation. This analysis is performed with the time series of daily precise positions of four GPS stations: Izu O-Shima, Miyake Shima, Kozu Shima, Hachijo Shima, from 2002. Because of Miyake Shima, Kozu Shima and Hachijo Shima stations are collocated with tidal stations of JCG, correlation functions are calculated with time series of sea level in place of stations. And the Izu O-Shima station is collocated with lighthouse, thus analyzed with the Okada tidal station of JMA in Izu O-Shima.

Seismic waves detected by 50Hz sampled GNSS observations

KATO, Teruyuki[1*] ; MIURA, Satoshi[2] ; IKUTA, Ryoya[3]

[1]Earthq. Res. Inst., the University of Tokyo, [2]Grad. Sch. Sci., Tohoku University, [3]Faculty of Science, Shizuoka University

Application of frequently sampled GNSS data is getting increasingly attractive research field, in particular, in the field of seismology (e.g., Larson et al.; 2003, Miyazaki et al., 2004; Yokota et al., 2009; Ohta et al., 2012). As most of GEONET (GNSS Observation NETwork) sites are now archiving 1Hz sampled data, such application research will be more active in the future. Analysis of ground shake may require higher frequency observation such as 5Hz, 10Hz or higher. However, it is known that amplitude and phase of observed ground displacements show fluctuations due to characteristics of data acquisition in the receiver electric circuits (e.g., Ebinuma and Kato, 2012). Thus, we need to be careful in applying such highly sampled GPS data for geoscientific researches.

We have used commercially available GNSS receivers to record 50Hz sampling to tackle above problems. We are introducing a record of ground shake due to an earthquake of 50Hz sampled data. We used three NetR8 (Trimble Co. Ltd.) GNSS receivers and they were established at Shizuoka University (Shizuoka Prefecture) since October 2011, Katono Elementary School (Fukushima Prefecture; KTNO) and Daido-higashi Elementary School (Ibaraki Prefecture; DDHG) since March 2012. We chose latter two locations as they are among the most active aftershock area due to 2011 Tohoku-Oki earthquake (Mw9.0).

About two weeks of 50Hz sampled data are stored in the internal memory of the receiver which are refreshed automatically in the receiver. Data at KTNO and DDHG are remotely archived through internet and data at Shizuoka University are downloaded manually, after a large earthquake occurred. Several data sets due to large earthquakes have been archived so far, all of which registered at least bigger than or equal to JMA Intensity 5- at nearby GPS sites. These data are analyzed using RTNet GPS software.

Among the archived data sets, a seismic wave was detected for the 2013 September 20 Fukushima-Hamadori earthquake, whose hypocentral parameters are as follows: latitude= N37.1deg, longitude=E140.7deg, depth=20km, M5.9, and the biggest JMA Intensity was 5+ at Iwaki, which is nearly immediately below the KTNO site. We used IGS final orbits and estimated the position of KTNO by putting the reference site at Daido-higashi (Baseline distance is about 106km to south) and Shizuoka University (Baseline length is about 308km to south east). Clear seismic wave was obtained for the baseline KTNO-DDHG for three components. Also, clear seismic wave was obtained for the baseline KTNO-Shizuoka Univ., though vertical component was not very clear, probably because the baseline distance was longer.

GNSS antennas at KTNO and DDHG sites are placed at the roof of the school buildings and at the roof of observation hut of Shizuoka University. Therefore, we may have to investigate the effects of swing of the building by comparing the record with nearby recorded strong motion. Moreover, the method of correction for amplitude and phase due to receiver characteristics should be investigated, which is left for future studies.

Detection of eruption column by using the kinematic precise point positioning

OHTA, Yusaku[1*] ; IGUCHI, Masato[2] ; UEKI, Sadato[1] ; DEMACHI, Tomotsugu[1]

[1]RCPEVE, Tohoku University, [2]DPRI, Kyoto University

We investigate the ability of kinematic precise point positioning to detect volcanic plumes at Minami-dake of Sakurajima Volcano. In Houli$\acute{e}$ et al. [1], the authors processed the GPS data obtained during the eruption of Miyakejima volcano, occurred in 2000, and found anomalous values in the ionosphere-free linear combination of the L1 and L2 phase measurements (LC). They related these anomalous values to the path delay effects caused by the presence of a hot volcanic plume; by applying techniques of seismic tomography. Another test was carried out during the eruption of Mt. St. Helens on March 9, 2005, and again the GPS signal showed a clear signature of the volcanic plume presence [2].

In this study, we describe the July 24, 2012 activity at Minami-dake of Sakurajima Volcano. We analyzed the data from 18 continuous GPS stations (3 GEONET sites and 15 Kyoto University sites), which located on the volcano flanks. For the GPS analysis, we used GIPSY-OASIS II version 6.1.4 software [3]. We estimated the post-fit phase residual in the ionosphere-free linear combination for each pair of GPS satellites and ground stations for the detection of eruption column. We applied absolute IGS phase center corrections for satellite and receiver antennas. The wet zenith tropospheric delays and its gradient at all the GPS sites were estimated at all processing epochs (every 30 seconds) under the assumption of a random walk stochastic model. Firstly, we analyze the all of the GPS data in July 21, 22 and 23, 2012 for the reference. Obtained post-fit phase residual of the reference days showed the noise-level for the path delay effects caused by the volcanic plume. This reference post-fit phase residual contained many noise sources such as multipath effects, local atmospheric disturbance, and so on. The noise level of the post-fit phase residual strongly depends on the each GPS satellite and ground station pair. Finally, we analyzed the data of the July 24, 2012. The post-fit phase residual clearly shows large disturbance just after the eruption. For example, the phase residual between SVN34 satellite and GEONET 0720, which located in the east coast of Sakurajima, suddenly increased just after the eruption. The obtained residual amount reached 80mm. It is clearly larger than the noise level measured on the reference days. Furthermore, other GPS satellite and ground station pairs also clearly showed significant amounts of disturbance. These results suggest that the eruption column moved to the westward by the wind after the eruptive event.

Airport survey method for transition to the new CNS/ATM systems in east Mekong area

NAKAGAWA, Yuji[1*] ; OKADA, Kaoru[2] ; SHIMADA, Seiichi[3] ; SATOMURA, Mikio[3] ; SHINDE, Yohei[1] ; ITOH, Hirokazu[1] ; UKEI, Kazuyuki[1]

[1]Nippo Co.,Ltd., [2]Japan International Cooperation Agency, [3]NIED, [4]Hot Springs Res. Inst, Kanagawa Pref.

The project by the name of ”Capacity Development for Transition to the New CNS/ATM Systems in Cambodia, Lao PDR and Vietnam” (Jan.2011-Dec.2015) was officially announced by Japan International Corporation Agency (JICA) on April 2011, and Nippo got the order, after that we got the orders five times for two years. We would like to introduce the procedure of surveying airport coordinates.

The concept of New CNS/ATM System (Communication, Navigation and Surveillance/Air Traffic Management) utilizing satellite technologies was developed by International Civil Aviation Organization (ICAO) in 1991 for globally harmonized implementation in order to cope with the expected increase of air traffic. All the Contracting States of ICAO are required to move from the conventional air navigation systems to the New CNS/ATM Systems in accordance with ICAO Global Plan.

In order to shift air navigation from the ground-based facility use to the satellite use, it is essential to have accurate and updated data of latitude and longitude of airports and air navigation facilities based on WGS-84 coordinates as ICAO Standard. However, in Cambodia, Lao PDR and Vietnam it has not been made known whether airport survey has been conducted, applying long-baseline analysis by using International GNSS Services (IGS) points in accordance with ICAO WGS-84 Manuals (Doc9674 2nd edition).

The purpose of the project is transferring survey method and surveyed airport coordinates in accordance with WGS84 coordinate system.

Airport survey procedure and recommendation

1.Confirmation of required survey points and facilities

Runway ends, ILS, VOR/DME, control tower, TV antenna, etc.

2.Reconnaissance of Primary Airport Control Station (PACS) and Secondary Control Station (SACS). Installed two PACS survey markers near runway ends and seven or eight SACS survey markers at a regular distance.

3.Set up receivers at two PACS and one SACS and surveyed 24 hours at PACS for three days, at SACS for 1.5 hours simultaneously by differential GPS satellite surveying. (when prepared three receivers. if prepared four receivers, observe two PACS and two SACS simultaneously)

4.Install GPS receivers at other SACS points over lapping the base line on every session.

5.Install total station (TS) at every PACS and SACS and observe each other to verify the coordinates surveyed by GPS receivers.

6.Survey runway ends, radio navigation facilities (ILS, VOR/DME, etc.) and obstacles like control tower, big Buddha stature, tall building. If the obstacle cannot seen from coordinates known points PACS, SACS, set up receivers at PACS and auxiliary two points in the vicinity of the obstacle.

7.Determine the coordinates of PACS using long baseline analysis software (Bernese) by down loading ultra rapid orbit. Coordinates of SACS using short baseline analysis software.

8.Survey runway ends, radio navigation facility and obstacles by TS using SACS and PACS.

9.We surveyed a fiducial point which have x, y coordinates and above sea level height, and compared the result which obtained by Earth Gravitational Method (EGM) 2008 software in Cambodia. (The result of EGM2008 is higher than our survey by about 80cm, but we could not confirm the accuracy of the height of fiducial point.)

10.Lecture on how to choose the PACS and SACS location, how to use the long baseline software and how to maintenance the result data including process of calculation.

Vertical deformations revealed by laser scanning surveys in the Murono mud volcano

TAKAHASHI, Atsushi[1*] ; FUKUDA, Yoichi[1] ; KUSUMOTO, Shigekazu[2]

[1]Graduate School of Science, Kyoto University, [2]Department of Earth Science

In order to reveal the land surface deformation in the Murono mud volcano area located in Tokamachi city, Niigata prefecture, we have conducted the laser scanning surveys two times in June and October 2013, using TOPCON Imaging Station IS-301, which can obtain 3D point cloud data by the automatic laser scanning mode without reflector. In the same survey area, Toyama University has been conducting successive leveling surveys at 61 benchmarks so far. We also conducted the height measurements at the benchmarks using the precise ranging mode.

The obtained cloud data have been interpolated on regular grids for the two data sets, respectively, and the surface deformation has been calculated by comparing the gridded data. The obtained result showed a clear concentric uplift pattern in a part of the survey area. We thus modeled the uplift using the Mogi source model. The maximum amplitude estimated from the model was about 1.5 cm and it was almost coincident with the uplift obtained at the nearest benchmark. The result showed that the scanning mode was really beneficial to search for the spatial deformation pattern and the source of the deformation as well, even though its accuracy would be lower than the one of the precise ranging mode.

Asymptotic solutions to the quasi-static spheroidal and toroidal deformation of the SNREI earth

OKUBO, Shuhei[1*] ; TAKAGI, Yu[1]

[1]Earthquake Research Institute, The University of Tokyo

Asympotic solutions to the quasi-static deformation of SNREI earth are essential to compute Green's functions, i.e., deformations due to a point load and a point dislocation. So far, only the surface deformations have been presented by previous authors. That is, internal stress/strain fields are not left uncalculated because of lack of asymptotic solutions to the internal deformation fields. In this talk, we present complete sets of spheroidal/toroidal deformations when spherical harmonic degree n increases to infinitiy.

Evaluation of uncertainty in distance measurement by GNSS surveying instrument and EDM

YOSHIDA, Shigeru[1*] ; SATO, Yudai[1]

[1]GSI of Japan

GSI has conducted research to establish traceability for distance measurement by GNSS surveying instrument to international standard. The international standard of distance is defined based on speed of light. In order to measure a distance based on the standard, it is necessary to use Electro-optical Distance Meter (EDM) for which the traceability to the standard is established. On the other hand, the traceability for GNSS surveying instrument used in various surveys is not established, because it is difficult and complex to estimate the uncertainty in distance measurement by the instrument. Therefore, we conducted an experiment to compare results of distance measurement by GNSS surveying instrument and EDM on a 2 km baseline.

Although the EDM measurement in this experiment should have been conducted indoors to reduce an affect of meteorological condition change, it was almost impossible to find an indoor 2 km baseline. We therefore divided an outdoor 2 km baseline into 10 short baselines and measured them by EDM. After that, the distance and uncertainty of the whole baseline were estimated from the results of measurements on the short baselines. The 2 km baseline was also measured by GNSS, and the estimated distance and uncertainty was compared to the results of EDM measurements.

The distances and uncertainties estimated by the measurements of EDM and GNSS survey instrument were 1,999.9828±0.0014 m and 1999.9828±0.006 m respectively. As a result of the experiment, we verified that the traceability for GNSS surveying instrument can be established on the 2 km baseline.

Changes of E-W observed by the Quartz-tube Extensometer in the Matsushiro extending after the 2011 Tohoku Earthquake

HASHIMOTO, Tetsuo[1*] ; FUNAKOSHI, Minoru[1]

[1]Matsushiro Seismic Obsevatory JMA

We observed a coseismic step of 5.8×10^{-7} strain in the E-W direction by the quartz-tube extensometer at Matsushiro during the 2011off the Pacific coast of Tohoku earthquake. After that, an aftereffect of 0.4×10^{-7} strain continued extending in the E-W direction about 1 month. And more, the E-W extension has continued since October, 2011 and it becomes over 0.5×10^{-7} strain. Similar phenomena were observed by superconducting gravity meter in Matsushiro and Kamioka (Imanishi, personal communication). Therefore, we think that these data of the E-W extension indicate true crustal deformation.

Figure shows data of the quartz-tube extensometer, water-tube tiltmeter, thermometer, and the other points of the extensometer. The air temperature in the tunnel heated up 0.03 ℃ in this range. But the influence of the temperature change hardly caused the extension, because it is very small extension of 1.6×10^{-8} as 5.4×10^{-7} of the temperature response of the quartz-tube. And more, the tiltmeter and the other point data of the extensometer show a similar change, therefore, the change seems to be true. We can catch geophysical phenomena such as the seismic waves (not shown in the figure) of the 2011 off the Pacific coast of Tohoku earthquake, the coseismic step, the aftereffect and continuing extensive change by the one device. This extensive change may indicate a part of crustal upheaval in a geological meaning.

Acknowledgement: We thank Yuichi Imanishi Associate Professor of ERI for teaching us about the continuity of decreasing gravity by the superconducting gravity meters in Matsushiro and Kamioka after the Tohoku earthquake.

Equqtorial flattening of the cylindrical outer core

KAKUTA, Chuichi[1*]

[1]none

Zhong et al.(2007),showed that the Africa supercontinent was formed after the Pangea(330Ma)in an initially by a spherical harmonic degree-1 form with the Pacific superplume. They suggested that the degree-1structure is responsible for supercontinent assembly with downwellings(Africa) and upwellings(Pacific).Recent studies show that light elements are transferred from the mantle to the outer core (OC) through the core-mantle boundary(CMB) and that the stably stratified layer are formed in the OC beneath the CMB. The stable layer shows the superadiabatic gradient, 1 Kkm-1 and its thermal conductivity is 150Wm-1K-1. The heat flux is over 100mWm-2.The heat flux of the mantle near the CMB is 100mWm-2 in the high temperature region (Perovskite) and 50mWm-2 in the low temperature region(Post-Perovskite). The heat flux flows into the low temperature region from the OC. We assume that the OC is a thin cylindrical rotating fluid around the rotating axis. The fluid shows a low frequency motion and the effects of flow pressure fluctuations on the density is ignored (Subseismic Approximation;Smylie and Rochester, 1981). The heat flux in the OC is expressed in the form of the exponential function of the central distance which decreases outward near the CMB. We derive the 1st order variations of the Potential. The azimuthal variation of the potential shows the variation of the equatorial flattening. The maximal value of its variation relative to the mean gravitational potential at the CMB is 1.1x10-5 (flattening). This value can be compared with the value of the equatorial flattening of the OC to be 6x10-6 obtained by Szeto and Xu(1997).

A bias correction method for improving regularized solution in linear inverse ill conditioned models

SHEN, Yunzhong[1*] ; XU, Peiliang[2] ; LI, Bofeng[1]

[1]1. College of Surveying and Geo-infomatics, Tongji University, Shanghai 200092, P.R. China, [2]Disaster Prevention Research Institute, Kyoto University, Uji, Kyoto 611-0011, Japan

Geodetic downward continuation and inverse problems are often ill conditioned, and regularization is used for deriving stable and better solutions. However, the regularized estimates of parameters and residuals are well known to be biased. Theoretically the biases of the estimated parameters and residuals can only be computed with the true values of parameters. Since we do not know the true values of parameters in practice, we attempt to improve the regularized estimates by using the regularized estimates themselves to replace the true parameters for estimating the biases and then removing the computed biases from the regularized estimates. Furthermore the biases are also removed from the residuals, and then the variance of unit weight of the observation noises is estimated with the bias-reduced residuals. We derive the analytical conditions for bias correction and show that the bias-corrected regularization performs better than the ordinary regularization in terms of mean squared errors. However, for estimating the variance of unit weight, the biases still need to be full removed from the residuals. We then present the numerical examples of gravity downward continuation to demonstrate the performance of our bias correction method for improving regularized solution. The results show that our bias correction method can successfully reduce the absolute biases of the regularized estimates, and improve the accuracies with more than 5 per cent. Moreover, by removing the biases from the residuals, the derived variance of unit weight is almost unbiased.

Gravity observation using a superconducting gravimeter at Ishigakijima, Japan (part 3)

IMANISHI, Yuichi[1*] ; NAWA, Kazunari[2] ; TAMURA, Yoshiaki[3] ; IKEDA, Hiroshi[4] ; MIYAJI, Takeshi[3] ; TANAKA, Yoshiyuki[1]

[1]ERI, The University of Tokyo, [2]AIST, [3]NAOJ, [4]University of Tsukuba

About two years have passed since we started gravity observation by means of a superconducting gravimeter at the VERA Ishigakijima Station, National Astronomical Observatory Japan in 2012, with the main purpose of detecting possible gravity changes associated with the long-term slow slip events beneath the Yaeyama Islands. Up to now, we have experienced three times of events, which took place in May 2012, December 2012 and July 2013. For the two events in 2012, gravity changes possibly associated with the slow slip events were recorded. The July 2013 event was not well recorded because of the damages by the typhoon. In addition, an earthquake swarm near the Yaeyama Islands in April 2013 may have also influenced the observed gravity. The next slow event is expected to take place around February 2014. Modeling and interpretation of the data will be presented in the paper.

Various drift rates of gPhone gravimeters obtained from short-term observations at geothermal fields

NAWA, Kazunari[1*] ; MIYAKAWA, Ayumu[1] ; SUGIHARA, Mituhiko[1]

[1]Geological Survey of Japan, AIST

We carried out short-term but continuous gravity observations using gPhone (spring type) gravimeters at geothermal fields. At hot spring area of Hachijojima, we obtained 1-4 months gravity data using several gPhone gravimeters at different sites and situations of the period between February 2011 and December 2012. Using the obtained data, we calculated and compared temporal variations of the drift rate. As a result, drift rates of gravimeters showed various characteristics according to location and elapsed time from installation. In many cases, it took about a month until initial drift stabilized, that is, dirift rate became quasi-constant. Even after stabilized, drift rate of gPhone gravimeters remained a few microGal/day (on the other hand, the nominal drift rate of iGrav superconducting gravimeter is 0.5 microGal/month), although the magnitude of the drift rates were considerabty smaller than several hundred microGal/day of CG-3M gravimeters. We will show the result of gPhone-133 replaced from Hachijojima to a geothermal power plant at Kyushu District in March 2013.

Gravimetrical vertical array observation -the 2013 fiscal year-

TANAKA, Toshiyuki[1*] ; HONDA, Ryo[1]

[1]TRIES, ADEP

A vertical array of gravimeters (Mizunami Underground Laboratory; MIU) is quite rare in the world, and this method that suppresses rainfall responses and stacks signal from deep part of the crust can contribute to leveling up the potential of gravimetry (Tanaka et al., EPS, 2013). This time (Nov. 2013~Jan. 2014), we have succeeded in getting higher quality data than before with almost same configuration; namely, using two gPhone gravimeters (#130 on the ground, #90 at 300m under the ground). Though blasting for construction works had performed frequently during last year, we can detect sub-microGal responses of rainfall this time in the frequency band from hourly to daily. In the longer band, the sensor temperature of #130 is still shifting slightly, which can affect drifting rate. Here, we describe the four time-series data: data of belowground, (1); data on the ground, (2); sum of the two, (3); difference between the two, (4). We have finally got residual gravity values without tidal and atmospheric responses by using the BAYTAP-G (Tamura et al., 1991), with assuming of linear drift. When it rains, (1) should show gravity decrease, (2) should show gravity increase, (3) should offset the response, and (4) should superimpose the response. Because, only the main part of the Akeyo formation, which overlies an impervious layer from the surface to approximately 80m depth, responds to precipitation (e.g. Tanaka et al., Gcubed, 2006). Actually, we have observed such responses of rainfall. These depend on the way of rainfall; however, it seems that the amplitude of the response of (1) is slightly larger than (2). If so, the infinite slab assumption of a groundwater layer caused by rainfall is unsuitable for this gravimeter layout. On atmospheric correction, (1) and (2) should be almost same, (3) should superimpose, and (4) should offset the response. Actually, we have observed such responses and confirmed that (4) is one-tenth the atmospheric response of that of (1) or (2).

In the future, we will aim to accumulate high quality data, survey the habit of these two gravimeters (i.e. sensor drift, sensor temperature, and tilt response), and finally construct a vertical array including an absolute gravimeter.

Huge uplift event of Iwoto: Estimation of gravity change based on the result of gravimeter calibration in Sapporo-Naha

OZAWA, Taku[1*] ; MIYAGI, Yosuke[1] ; UEDA, Hideki[1] ; NAGAI, Masashi[1] ; FUJITA, Eisuke[1]

[1]National Research Institute for Earth Science and Disaster Prevention

Ogasawara-Iwoto is the volcanic island located to 1200km south of Tokyo. It has a caldera with the diameter of 10km, and its central and southwestern part appears on the sea surface. One of characteristics for its volcanic activity is to have the large uplift rate, and National Research Institute for Earth Science and Disaster Prevention (NIED) has revealed occasional ×occurrence of huge uplift events and distribution of its crustal deformation (Ukawa et al., 2006). NIED started gravity survey from 1996, and Ukawa (2006) suggested involvement of magma in a huge uplift event. Though continuous subsidence had been observed from early 2003, it rapidly changed to uplift in mid-2006. Its uplift decelerated with time after 2007, but it rapidly re-accelerated in Feb. 2011. According to GNSS observation by NIED and GSI, the amount of uplift from re-acceleration to Apr. 2012 reached 2m. In late April of 2012, discolored water was found around Iwoto, and uplift activity slowed down after that. To investigate crustal deformation and gravity change associated with this event, we carried out GNSS campaign observation and gravity survey. We presented the result of GNSS campaign observation in fall meetings of the geodetic society of Japan and the volcanological society of Japan. We also presented preliminary result for gravity survey, but there was a problem on uncertainty for temporal change of scale factors of used gravimeters (Scintrex CG-3M #284 and #371). To estimate scale factors of their gravimeters, we carried out gravity survey between Sapporo and Naha. In this presentation, we show temporal change of scale factors revealed from this calibration and gravity change of Iwoto estimated using its result.

In gravimeter calibration, we measured gravities at NIED (Bosai-BS), GSI (Tsukuba-GS and Tsukuba-FGS), Haneda airport (Haneda-GS), Chitose airport (Chitose-GS), Hokkaido University (Sapporo-GS), and Okinawa Meteorological Observatory (Naha-GS and Naha-FGS). In estimation of relative gravity, we assumed that the drift rate was constant, and estimated gravities and the drift rate simultaneously. Then we estimated scale factors so that estimated gravities corresponded to those of JGSN96 (Geospatial Information Authority of Japan, Geodetic department, 1997). Since Sapporo-GS was moved to new benchmark, we used gravity measured by GSI. Estimated changes of scale factors from those in 2006 were $+2\times10^{-5}$ and -1×10^{-4} for #284 and #371, respectively. Temporal changes of scale factors are not orderly, and then obtained scale factor is different significantly from estimated value by the linear approximation. Therefore it indicates that consideration of temporal change of scale factor is important in survey of large gravity difference.

Estimating gravity at the benchmark in Iwoto (IWO101), estimated gravities from #284 and #371 were consistent within 0.027mGal, and its average was decrease of 0.734mGal from that in 2006. Uplift in this period was 3.05m, and then gravity change rate with respect to uplift was -0.241mGal/m. This gravity change rate is in good agreement with that for the 2001-2002 huge uplift event by Ukawa et al. (2006). This result suggests that the huge uplift event from 2006 has been caused by the magma with the similar density to that in the 2001-2002 event.

Acknowledgements. GNSS and gravity surveys were supported by JSDF. A part of survey and analysis for Iwoto was carried out by Ohba Co. Ltd. Gravity calibration was supported by GSI, Hokkaido University, and Okinawa Meteorological Observatory.

Absolute gravity measurements near the Sor-Rondane Mountains, Antarctica

FUKUDA, Yoichi[1*] ; AOYAMA, Yuichi[2] ; SUGANUMA, Yusuke[2] ; OKADA, Masaki[2] ; DOI, Koichiro[2]

[1]Graduate School of Science, Kyoto University, [2]National Institute of Polar Research

In order to detect the gravity changes due to ice sheet mass changes, Glacial Isostatic Adjustment (GIA) and other effects, we have conducted absolute gravity measurements at Princess Elisabeth Station (PES) near the Sor-Rondane Mountains, Antarctica, as part of the 55th Japanese Antarctic Research Expedition (JARE-55). In addition, the first absolute gravity measurements using a field absolute gravimeter have also been conducted on the Seal rock near the Asuka station, where the gravity reference point (No.26-01) established by JARE-26 is located.

The absolute gravimeters employed were FG5#210 and A10#017, and a relative gravimeter LaCoste #805 was also used for dg/dz measurements and gravity connections. Using DROMLAN (Dronning Maud Land Air Network), we moved to PES with the instruments via Novolazarevskaya from Cape Town in South Africa. The length of our stay in PES was for 18 days from Nov. 29 to Dec. 16, 2013. Belgian researchers have already conducted absolute gravity measurements using a FG5 in North Shelter (NS), a small observation hut built on an outcrop a few hundred meters apart from the main base of PES. One of the main purposes of this project is to monitor long-term gravity changes by means of successive absolute gravity measurements at the same gravity point in NS. Since NS has not enough space for adjusting the gravimeters before measurements, we borrow a room in the main base for the purpose and test measurements as well. We established a tentative gravity point in the room and compared the gravity values measured by A10 and FG5. The result showed the discrepancy was within 2 micro-Gals. This means that A10 was well calibrated. Unfortunately a crucial fault arose in the dropping chamber of the FG5, and it could not be recovered to the last. For this reason, the measurements in NS were carried out using A10. The gravity value on the reference point was calculated to be 982302155.21 micro-Gals with the measured dg/dz of -4.4529 micro-Gals/cm. Although the exact comparisons with the gravity values obtained by the Belgian team have not been completed yet, the gravity values seem to be in agreement within several micro-Gals. Therefore the temporal gravity change would be very small, even if it existed.

The gravity measurements on the Seal rock have been conducted on Dec. 5th and 6th. Since No.26-01 is located near the summit of the Seal rock, where strong wind blows constantly, it is very difficult to conduct absolute gravity measurements even using A10. Therefore a tentative gravity point was set up at the foot of Seal rock, and measurements with A10 were conducted at the point. Then gravity connection to No.26-01 was conducted with the LaCoste gravimeter. The gravity value thus obtained at No.26-01 was 982406.109 mgal with the accuracy of about 15 micro-Gals including the errors due to the gravity connection.

The gravity values of No.26-01 so far obtained were 982405.33mgal by JARE-26 (GSI, 2002), and 982402.817mgal by JARE-27 (Fukuda, 1986). The new value is 0.779 mgal and 3.292 mgal larger than those of JARE-26 and JARE-27, respectively. In JARE-27, two sets of LaCoste gravimeters were employed for the gravity connection between Seal rock and Syowa Station. Since a large discrepancy between the values obtained by two gravimeters was found, Fukuda (1986) applied a step correction of 3.765mGals to the suspected gravimeter. However, judging from the present result, the correction could be applied to the wrong gravimeter. If the correction was applied to the other gravimeter, the difference of 3.292 mgal was set to about 0.5mGals, and it would be likely as the accuracy of the gravity connection. The gravity value of No.26-01 has been used as a reference value for the gravity surveys so far conducted in the Sor-Rondane area. Therefore the revisions of those values should be required from now on.

Performance of the recoil-compensation mechanism used for a throw-up type absolute gravimeter

SAKAI, Hirotaka[1*] ; ARAYA, Akito[1] ; TSUBOKAWA, Tsuneya[2] ; EMANUELE, Biolcati[3]

[1]Earthquake Research Institute, University of Tokyo, [2]Shin-ei keisoku, [3]L'Istituto Nazionale di Ricerca Metrologica

Absolute gravimeters can measure gravity acceleration in the accuracy of 8 to 9 digits. They are accurate and useful for many applications, however the apparatus is too bulky and heavy. Therefore, in the field observation, their installation site is limited. As a result, for volcanic observations, a gravity value is usually measured by an absolute gravimeter at a reference point of foot, and then a gravity value of an observation point can be obtained from the gravity difference between a reference point and an observation point measured with a relative gravimeter; such a method is laborsome, and requires long time. Furthermore it is hazardous to approach the observation points when the volcano is active. This study is to minimize absolute gravimeter in order to improve these situations. The original point of our new apparatus is to incorporate a recoil-compensation mechanism to improve the measurement accuracy.

In the absolute gravity measurements, we adopted a rise-and-fall method, while conventional absolute gravimeters usually adopt a simple free-fall method. The simple free-fall method has several problems such as bulky mechanism to lift up a test mass, repeated measurements, and long time to take for the preparation. Hence, we developed a throw-up equipment that had no need for lifting up a test mass and could measure repeatedly. This enabled to minimize one of the biggest parts in the absolute gravimeter.

The equipment which we developed this time can throw up the test mass by 3mm in height simply by applying the signal to a piezoelectric element which is incorporated in the expansion mechanism. When the test mass was thrown up, it rotated by an anchoring effect and it may cause the error in the gravity measurement. We applied other piezoelectric elements which separate the stage from the test mass just before the test mass leaves the stage to cut off the anchoring force. At the end of 2012, we carried out a performance test of the throw-up equipment at Esashi Earth Tidal Station in Iwate. At Esashi, we replaced the free fall equipment of the existing absolute gravimeter with the throw-up equipment. As a result, the throw-up equipment was able to detect a gravity change of earth tides. The resolution of the gravity measurement δg was estimated to be 40μgal. However, the absolute gravity deviated from the value expected from the past measurements up to $\triangle$g= 3mgal. This big error was inferred from the recoil effect at the time of throw that induces vibration to the interferometer.

We developed the recoil compensation mechanism of the throw-up equipment to improve the measurement accuracy $\triangle$g. Specifically, we put the same piezoelectric element and the expansion mechanism on the other side of the baseplate to which the throw-up mechanism is attached. These expansion mechanisms move symmetric by applying the same signal to the piezos. When the test mass is thrown up, the counter mass fixed by springs is launched downward at the same time to compensate the recoil effect. We could observe the recoil reduction as much as 2.7% of peak acceleration without the compensation mechanism. After performing fine adjustment of the equipment, we plan to conduct gravity measurement by the same method to 2012, and the result and the development status will be reported.

Development of a laser-interferometric gravity-gradiometer and its trial operation on the volcanic island of Sakurajima

SHIOMI, Sachie[1*] ; KAGIYAMA, Tsuneomi[1]

[1]Aso Volcanological Laboratory, Kyoto University

We have been developing a laser-interferometric gravity-gradiometer for volcanological studies. The gravity gradiometer measures differential accelerations between two test masses that are in free fall at different heights. Because its detection principle is based on the differential measurements, measured values are insensitive to the motions of observation points. That is to say, the gravity gradiometer is expected to have a good resolution even when it were used on an accelerating vehicle, such as an airship, or in an active volcanic area. Therefore, the gravity gradiometer could be useful for, for example, resource explorations and studies on volcanic activities.

The gravity gradiometer, to be used on an airship, had been developed at the Institute for Cosmic Ray Research (ICRR) of the Tokyo University from 2009 to 2012. A prototype of the gravity gradiometer was built up and tested at the ICRR. Their laboratory test showed that its resolution of measuring vertical gravity gradients was about a few μGal/m in two second measurements. However, large unexplained disturbances were observed in longer term measurements. In order to understand the sources of the disturbances, the prototype was moved to the Aso Volcanological Laboratory (AVL) of the Kyoto University in July 2012. Since then, its further development, to be used at an observatory in a volcanic area, has been carried out at the AVL.

We will report the current status of the development for volcanological studies and results of trial measurements performed at the Sakurajima Volcanological Laboratory of the Kyoto University, on the volcanic island of Sakurajima, Kyusyu, Japan.

The two components of postseismic gravity changes and their mechanisms

TANAKA, Yusaku[1*] ; HEKI, Kosuke[1]

[1]Graduate School of Science, Hokkaido University

The time series analysis of the gravity changes of the three Mw9-class mega-thrust earthquakes (2004 Sumatra-Andaman earthquake; 2010 Chile (Maule) earthquake; and 2011 Tohoku-oki earthquake) gives the strong possibility that the gravity observation separates postseismic phenomena. There are three sensors for earthquake observations: the first sensor is seismographs, the second sensor is GNSS (Global Navigation Satellite System) or SAR (Synthetic Aperture Rader), and the third sensor is the gravity observation. Seismographs cannot be used to catch the signal of postseismic phenomena because they do not shake the ground. GNSS like GPS (Global Positioning System) and SAR catch the signal of postseismic phenomena but they cannot separate those phenomena because the phenomena move the ground with the same polarities. However, the polarities to gravity changes of postseismic phenomena can be different each other. This suggests that the gravity can become the first sensor to catch the separated signals of postseismic phenomena.

GRACE (Gravity Recovery And Climate Experiment), which is the twin satellites launched in 2002 by NASA and keeps on observing the gravity field of the earth, gives the two-dimensional gravity data and the insight into phenomena under the ground when and after earthquakes occur. The results of time series analysis of postseismic gravity changes with GRACE data show that the gravity which decreases coseismically keeps on decreasing for a few months and increases for a longer period; the postseismic gravity changes have two components (short- and long-term gravity changes). This is a new discovery and this also suggests that the gravity observation gets the different postseimic phenomena with different polarities.

The mechanisms of coseismic gravity changes are well known but those of short- and long-term postseismic gravity changes are not clear completely. They are explained with afterslip and viscoelastic mantle relaxation to some extent but each of them has each problem.

Although the mechanisms of postseismic gravity changes have rooms to be discussed, the gravity observation can do what the seismographs, GNSS and SAR cannot do; the gravity observation separates the postseismic phenomena.

High resolution mapping of ice mass trend in Greenland using GRACE GFZ solution

MATSUO, Koji[1*] ; FUKUDA, Yoichi[1]

[1]Graduate school of Science, Kyoto University

The gravity satellite mission GRACE has been measuring monthly variations of the Earth's gravity field since its launch in 2002. The GRACE data has updated from RL04 to RL05 in May 2012, and have been provided in the form of spherical harmonic (Stokes') coefficients with degree and order up to 60 (d/o60) from CSR and JPL. In addition, GFZ has provided Stokes coefficients with d/o90 as RL05a product in December 2013. In this study, we examine the measurement error of GFZ RL05a product (d/o90). Then we attempt to delineate a high resolution map of ice mass trend in Greenland by making use of the full Stokes' coefficients.

First, we examine the measurement error. Following the method of Wahr et al. (2006), we derive temporal and spatial variation of the measurement error from error variance matrix of GRACE data. The global average of RL05a error is about 100cm in equivalent water thickness. Because RL04 error is about 300cm, RL05a achieves triple the precision improvement. The temporal variation of error in global average is about 200 cm from January 2003 to July 2003, and reduces to about 100cm afterwards. The spatial distribution shows large error in equatorial region (about 130cm) and small error in polar region (about 40cm). Considering these results, it can be said that the quality of RL05a is especially high in polar region after August 2003.

Next, we derive ice mass trend in Greenland from GFZ RL05a (d/o90) product. Here we apply de-striping filter (Swenson and Wahr, 2006) to alleviate the noise. In addition, we employ spherical Slepian Basis (Harig and Simons, 2012) to extract ice mass trend in Greenland effectively. In doing so, we can successfully delineate a clear ice mass trend map with about 200 km spatial resolution, which is 1.5 times as high as before. We confirmed very good agreement with ICESat result.

Establishment of GSIGEO2011 (Japanese geoid model)

KODAMA, Tokuro[1*] ; MIYAHARA, Basara[1] ; KAWAWA, Hiroshi[1] ; KUROISHI, Yuki[1]

[1]GSI of Japan

Geospatial Information Authority of Japan (GSI) established Japanese geoid model ”GSIGEO2000”. The model has enabled a translation from ellipsoidal heights to orthometric heights in GNSS survey for triangulation points, which are positional reference for surveys in Japan. As a result, the model greatly has contributed to realize efficient control point survey. In order to expand utilization field of geoid model to height determination of third-order benchmarks by GNSS satellite positioning, GSI has established new Japanese geoid model ”GSIGEO2011” and reported here.

GSIGEO2011 has established as a hybrid geoid model of a gravity geoid model and observed geoid height data. New Japanese gravity geoid model, JGEOID2008 (Kuroishi, 2009), is adopted as the base model, and least square collocation method is adopted to fit the model to observed geoid height data obtained at over 750 GNSS-based control stations all over Japan. In order to utilize for height determination of third-order benchmarks, residuals between the model and input observed geoid heights are set to 2cm in standard deviation. JGEOID2008 is greatly improved at reduction of local systematic errors which are contained in older gravity geoid models. Therefore, short wavelength components in geoid are well described and fit to observed data, and as a result, the accuracy of the hybrid model is improved.

The 2011 off the Pacific coast of Tohoku Earthquake caused huge crustal deformation in an wide area around eastern Japan. GSI urgently conducted control point surveys for restoration and opened the result for eastern Japan. GSI also conducted geoid surveys for GNSS-based control points which is located in an area experienced huge crustal deformation, and the results have been utilized for the input geoid heights data of GSIGEO2011. Therefore, GSIGEO2011 is consistent with the revised survey results in eastern Japan.

GSI has published newly established GSIGEO2011 and tired to realize height determination of third-order benchmarks by GNSS survey referring GNSS-based control points which have orthometric heights. This challenge is expected to drive further improvement in efficiency of survey procedure in Japan.

The Japan Gravity Standardization Net 2013 (JGSN2013)

YOSHIDA, Kenji[1*]

[1]GSI of Japan

Geospatial Information Authority of Japan (GSI) have established new gravity standardization net, the Japan Gravity Standardization Net 2013 (JGSN2013), from the latest absolute and relative land gravity data which covers Japanese islands. GSI already established and published the Japan Gravity Standardization Net 1975 (JGSN75), which is consistent with the International Gravity Standardization Net 1971 (IGSN71). JGSN75 have been officially referred as Japanese gravity standard.

JGSN2013 have been established by combining gravity data obtained from primary-order absolute gravity survey and first-order relative gravity survey. In Tohoku area, at least one gravity survey was done for each gravity benchmark after the 2013 off the Pacific coast of Tohoku Earthquake. Therefore, the gravity survey data include gravity change caused by the earthquake.

JGSN2013, which is the second Japanese gravity standard net established by GSI, have achieved great improvement in accuracy and special coverage by adopting FG5 absolute gravity meter as an instrument, updating station coordinates to ITRF2008 and modifying tidal correction procedure to more consistent manner through all process. As a result, JGSN2013 have a capacity not only to contribute to monitoring of earth gravity filed, which is promoting by GGOS, but also to be registered to international absolute gravity database (AGrav), which is operated as a joint project by IAG IC-WG2.1 and IGFS. The establishment of JGSN2013 is reported in the paper.

Calibration of the superconducting gravimeter iGrav10 by parallel observation with the absolute gravimeter FG5 #217

SUGIHARA, Mituhiko[1*] ; NAWA, Kazunari[1] ; MIYAKAWA, Ayumu[1]

[1]AIST

An iGrav superconducting gravimeter (SG) was re-installed in the Farnsworth field, TX for the purpose of studying the effects of CO2 injection at an enhanced oil recovery (EOR) site in December 2013. Usually the iGrav SG has an ultra-low drift of less than 0.5 microGal / month and a virtually constant scale factor. Empirically, the drift rate looks negligible using the TSoft program. However observed trend contains the drift-like component which is about 0.4 microGal / day. Strictly it is difficult to distinguish real gravity changes from time-varying instrumental drift. We made co-located measurements with the FG5 absolute gravimeter (AG) in middle of December 2013 and middle of January 2014. The gravity differences between the two periods was determined to be +1 +-2 microGal by the AG measurements, whereas -12 microGal by the SG measurements. The observed drift of the SG was much larger than the specified value, so that the SG was determined to be reset and is improved. Generally it takes at least six months to evaluate such low drift of less than 0.5 microGal / month using co-located measurements with AG. Another choice is parallel SG and SG measurements located in close proximity. We are planning such measurements at the Farnsworth site in 2014. This research is funded and supported by Ministry of Economy, Trade and Industry (METI).

Densed gravity survey on the southeastern Kego fault system

NISHIJIMA, Jun[1*] ; FUJIMITSU, Yasuhiro[1]

[1]Faculty of Engineering, Kyushu University

The Kego fault system is one of the active fault located in Fukuoka city, southwestern Japan. We have conducted densed gravity survey on the southeastern Kego fault systems. One of the purposes of the survey is to reveal the location and detailed shape of the active fault syatem. We have measured gravity value at 721 points using Scintrex CG-3+ and CG-5 gravimeter. The measurement point interval was arranged as about several tens to hundreds meters. The measured gravity values were processed with a series of correction (height, drift, tidal, the free-air, the Bouguer and terrain) in order to obtain a gravity anomaly map. We determined the Bouguer density of 2.47 g/cm^3 using an objective Bayesian approach (Murata, 1993).

According to the gravity anomaly map of the Fukuoka City area that consists of not only our gravity data but also the gravity data of other institutions, the gravitational basement, which has a high density and affects to the gravity anomaly, is thought as Paleozoic Sangun metamorphic rocks and Cretaceous plutonic rocks (Sawara Granite, etc.) (Karakida et al., 1994). And a clear low gravity anomaly extension that has a strike of NW-SE is detected and coincides with the location of Kego Fault confirmed by a trenching survey (Shimoyama et al., 2005).

We will report the result of a three-dimensional analysis using GRAV3D ver. 3.0 (Li and Oldenburg, 1998).

Crustal thickness deduced from a three-dimensional gravity modeling with seismic survey results

FUJIOKA, Yukari[1*] ; ISHIHARA, Takemi[2] ; OIKAWA, Mitsuhiro[1] ; KANEDA, Kentaro[1] ; NISHIZAWA, Azusa[1]

[1]Hydrographic and Oceanographic Department, Japan Coast Guard, [2]National Institute of Advanced Science and Technology

The Japan Coast Guard (JCG) has conducted multichannel seismic reflection and refraction surveys as part of the Continental Shelf Survey from 1983 through 2008 in the area from the northwest part of the Pacific plate to the Philippine Sea plate. On the other hand, it has also conducted marine gravity surveys in the same area and possesses enormous amount of gravity data. We calculate crustal density distribution by applying the three-dimensional gravity inversion method (Ishihara and Koda, 2007) using these data.

This method has performed in the following procedures: First, an initial density structure model constituting of seawater, sediment, crust and mantle is made by interpolation of seismic survey results with reference to a gravity distribution. Second, gravity anomalies are calculated using the initial model. Mantle Bouguer anomalies are calculated by subtracting a constant, which depends on the regional structure, from the differences between observed and calculated gravity anomalies. Finally, the Moho depths are obtained by inversion analysis to minimize the mantle Bouguer anomalies. We can estimate the crustal thickness distribution in this way.

It confirmed that the above method improves the initial model with the Moho depths due to velocity structure from refraction surveys, and that a more appropriate density structure model can be obtained.

In addition, it is necessary that whole structure depending on a sea area with the effects given by structure, such as a density and/or a thickness of sediment and/or lithosphere, should be considered if the effects of them are large. For example, in the case of the northwest part of Philippine plate, we found that the thickness of the lithosphere depending on its age strongly affects the result of the inversion. Therefore, we used the calculated gravity data after removal of variation for wave length than or equal to 400 km in order to remove effect given by the structure under crust.

We will report these revisions and the crustal thickness distribution in several sea areas. It is expected that gravity determination of the crustal thickness distribution in large sea area gives important clues on tectonic evolution of crust.

Estimation of the density structure beneath the Kanto Distinct, Japan, by 3-D gravity inversion

EDO, Tatsumi[1*] ; YAMAMOTO, Akihiko[1]

[1]Graduate School of Science and Engineering, Ehime University

We applied an improved gravity inversion technique by Bear et al. (1995) to rapidly invert Bouguer gravity data in Kanto District, Japan, for a 3-D density distribution as a source of the observed field. The technique estimates the density distribution within the source volume using a least-squares inverse solution that is obtained iteratively by singular value decomposition using orthogonal decomposition of matrices with sequential Householder transformations. The source volume is subdivided into a series of right rectangular prisms of specified size but of unknown density. This discretization allows the construction of a system of linear equations relating the observed gravity field to the unknown density distribution. Convergence of the solution to the system is tightly controlled by a damping parameter which may be varied at each iteration. Application to a gravity data set from Kanto District, Japan, has yielded a geologically reasonable result that agrees with published models derived from interpretation of gravity, magnetic, seismic, and drilling data.

The Collaboratory for the Study of Earthquake Predictability (CSEP) aims to improve our understanding about the physics and predictability of earthquakes through rigorous and prospective testing of earthquake forecast models. The system-science character of earthquake prediction research demands an open and collaborative structure for experimentation in a variety of fault systems and tectonic regions. CSEP Testing Centers in California, New Zealand, Japan, and Europe are being developed to provide adequate infrastructure for predictability research. CSEP is currently running prospective, automated evaluations of more than 350 models in various testing regions, e.g. California, New Zealand, Japan, Italy, and globally. We present the evolution of CSEP since its inception in 2007 and discuss results from several types of CSEP experiments. Finally, we describe how CSEP is expanding into other areas, including the testing of earthquake early warning systems, geodetic transient detectors, intensity prediction equations, ground-motion prediction models, and other types of hazard models.

One-day earthquake forecasting experiment in Japan after the 2011 Tohoku-oki earthquake

HIRATA, Naoshi[1] ; TSURUOKA, Hiroshi[1*]

[1]Earthquake Research Institute, the University of Tokyo

An experiment for earthquake predictability in Japan started in 2009 with a framework of CSEP. We have conducted one-day, three-month, one-year, and three-year forecasting experiments with three different regions of Japanese Islands; all Japan including sea area, main lands without sea area, and Kanto area(Nanjo et al., 2011; Tsuruoka et al., 2012). We currently have 160 modes for three regions and four periods.We conducted a retrospect one-day forecast of aftershocks of the 2011 Tohoku-oki earthquake showing that all proposed models failed in consistency tests immediately after the mainshock but in several days some of the models recovered its performance of forecasting (Nanjo et al., 2012).A current method for short-term forecasting has limitation of a period of one-day, which is arbitrarily determined. A shorter time period may be necessary for very intensive seismicity. Seismic activities in Japan have changed very much after the 2011 Tohoku-oki event, which brought us an idea that current forecasting models should be modified. We will present some new results of one-day forecasting experiments in Japan to discuss how to get information about real time earthquake hazard to mitigate earthquake risk. A new method to test performances of a model is also proposed.

Prospective evaluation of 3-month testing class of the CSEP-Japan earthquake forecasts

TSURUOKA, Hiroshi[1*] ; HIRATA, Naoshi[1]

[1]Earthquake Research Institute, University of Tokyo

Collaboratory for the Study of Earthquake Predictability (CSEP) is a global project of earthquake predictability research. The primary purposes of the CSEP is to develop a virtual, distributed laboratory. The final goal of this project is to investigate the intrinsic predictability of earthquake rupture mechanisms.

One major focus of the Japanese earthquake prediction research plan 2009-2013 is testable earthquake forecast models. So, the Earthquake Research Institute joined the CSEP and installed in an international collaboration a testing center as CSEP-Japan for rigorous evaluation of earthquake forecast models.

A total of 160 models were submitted from all over the world. And CSEP-Japan started the prospective experiments from 1 November 2009. The models are currently under test in 12 categories, with 3 testing regions and 4 testing classes of different time spans (1day, 3 month, 1 year and 3 years). We evaluate the performance of the models in the official suite of tests defined by the CSEP (L, M, N, S, R, T and W tests) against authorized catalogue compiled by Japan Meteorological Agency.

CSEP-Japan testing center has conducted over 6-12 rounds tests for 3-month testing classes including 2011 Tohoku-oki earthquake. We will discuss these results of evaluation test of the prospective experiments, and checked the performance of the earthquake models.

Does using Coulomb stress change information create quantifiable improvements in earthquake forecast models?

GERSTENBERGER, Matt[1*] ; STEACY, Sandy[2] ; MARZOCCHI, Warner[2] ; RHOADES, David[1]

[1]GNS Science. 1 Fairway Drive, Avalon, Lower Hutt, New Zealand, [2]Environmental Sciences Research Institute, University of Ulster, Coleraine, N. Ireland, [3]Istituto Nazionale di Geofisica e Vulcanologia, Roma, Italy

The Darfield, New Zealand earthquake sequence has provided an interesting and active sequence for rigorous testing of earthquake forecast models that include Coulomb stress change information. Coulomb forecast models have long been discussed in the scientific literature as providing useful forecast information during aftershock sequences; however, a challenge that has limited our understanding of their ability is the difficulty in specifying such models so that they are prospective and unbiased. With the Darfield sequence we have the opportunity to use the Collaboratory for the Study of Earthquake Predictability (CSEP) earthquake forecast testing centre, that is already in operation in New Zealand, to develop Coulomb models in such a way. By taking advantage of archived data sets to provide all of the necessary inputs into the models, we are able to pseudo-prospectively test the models within the CSEP testing centre. An initial study by Steacy et al (2013) tested several models with Coulomb information. These models include a hybrid model with STEP (Gerstenberger, 2005), a rate-and-state based model, and several non-Coulomb models. Results of this study indicate that adding Coulomb information that was available 10-days after each main event, to a more traditional Omori-based model, provides a statistically improved forecast, even when attempting to test in an unbiased fashion. The experiment also highlighted significant differences when testing models retrospectively and pseudo-prospectively; these differences are driven by the reduced quality of data available to models in pseudo-prospective tests. Following this study, we are now implementing a larger experiment in collaboration with the European Union funded Strategies and Tools for Real Time Earthquake Risk Reduction (REAKT) project. In this experiment we are testing more than 20 Coulomb and non-Coulomb models within the NZ-CSEP testing centre. These models include hybrid statistical-Coulomb models and pure statistical and Coulomb models. We will discuss both experiments and their implications.

Test of the argument for remote dynamic triggering by small mainshocks

PENG, Wei[1*]

[1]Wei Peng, [2]Shinji Toda

To understand earthquake interaction and forecast time-dependent seismic hazard, it is essential to determine whether static or dynamic stress change triggers most aftershocks and subsequent mainshocks. Felzer and Brodsky (2006) argued that the observed linear seismic density of small aftershocks with distance from small mainshocks is a product of the decay of seismic wave amplitude. They conclude that even small shocks can dynamically trigger remote earthquakes at distances more than ten source fault dimensions away. Richards-Dinger et al. (2010) counter-argue that the power law decay is an apparent product from independent aftershocks occurring along a large rupture zone or near-simultaneous occurrence in seismic swarms. To test the argument of Richards-Dinger et al. (2010), we use the Taiwanese earthquake catalog of the Central Weather Bureau Seismic Network, whose quality is as good as that in California and Japan. Further, we take an advantage of the absence of major inland earthquakes and significant swarms in the period, 2001-2011.

We follow the methodology of Felzer and Brodsky (2006) for selecting mainshocks using their declustering algorithm, and then seek all shocks that occurred within 5 minutes to make a diagram of linear aftershock density as a function of distance from mainshock. First we select as a mainshock any event that is not preceded by a larger shock within 3 days (t1) and 100 km, and that is not followed by a large shock within 12 hr (t2) and 100 km. The mainshocks and aftershocks are 2?M<3 and M?2 respectively. This yields 706 declustered mainshocks from the 110,157 candidate shocks, but the number of mainshock-aftershock pairs is just 56. We only find four pairs within 50 km distance range (the maximum considered by Felzer and Brodsky), which precludes any regression, while the others located further than 50 km are regarded as background. We then shorten the time period for both t1 and t2 to be 1.5 days and 0.25 days, which allows us to regress a power law slope of -1.16±0.45 for the 35 pairs within the 50-km distance range. The pairs are located mostly along the northern part of the Longitudinal Valley fault zone where small swarm activity and M~6 shocks often occur. We conclude that the much fewer ratios of mainshock-aftershock pairs in the Taiwanese catalog, in comparison to California and Japan, are due to lack of any large rupture and the absence of significant swarms in Taiwan, which supports the argument of Richards-Dingers et al. and renders the possibility that these small shocks are dynamically triggered untenable.

Prediction performance of empirically defined foreshocks in the Izu region

MAEDA, Kenji[1*] ; HIROSE, Fuyuki[1]

[1]Meteorological Research Institute

1. Introduction

Foreshocks have been thought one of the most promising phenomena to predict large earthquakes. However, as the physical mechanism of foreshocks is not clarified yet, it is very difficult to distinguish them deterministically from background seismicity before a mainshock occurs. Therefore, empirical approach is one of the realistic ways to use foreshock activity as a precursor of a mainshock. We investigate probabilistic features of empirically defined foreshocks and search for the best parameters to define foreshocks which present relatively high performance to predict large earthquakes. Maeda (1996) and Maeda and Hirose (2012) proposed a foreshock definition which gives relatively high performance to predict large earthquakes along the Japan trench. In this study we basically apply the same method to the seismicity in the Izu region where swarm activities related with magma movements are frequently observed, and estimate the prediction performance based on empirically defined foreshock activities.

2. Method

The method to search for parameters for foreshocks that present high prediction performance consists of four steps. 1) To eliminate small aftershocks from the original data. 2) To define foreshock candidates as the activities that have number of Nf earthquakes with magnitude >= Mf during the period of Tf days in the segment of the size of D x D degree (latitude x longitude). 3) To set the alarm period of Ta days after a foreshock candidate during which a mainshock is expected to occur. 4) To search for the values of Tf, Mf, D, Nf, and Ta which give high prediction performance by the grid search method. The prediction performance is measured mainly by dAIC, which is defined as the difference of AIC for a stationary Poisson model and a model based on a foreshock activity, and additionally by alarm rate (AR: the fraction of mainshocks alarmed), truth rate (TR: the fraction of foreshock candidates followed by a mainshock), and probability gain (PG: the ratio of mainshock occurrence rate for predicted space-time to background occurrence rate).

3. Data and Results

By applying the above method to the earthquakes cataloged by JMA for the period of 1977 - 2013/06 in the Izu region (33.5N, 138.6E - 35.3N, 139.8E), we obtained the best parameters for foreshocks as Tf=3 days, Mf=3.0 D=0.2 degree, Nf=3, and Ta=5 days for the prediction of mainshocks with M>=5.0. The prediction performance is expressed as dAIC=473, AR=68% (=44/65), TR=23% (=46/196), and PG=225. We also confirmed that the distribution of interval time between foreshocks and mainshocks is better approximated by a power law like the modified Omori's aftershock distribution rather than an exponential distribution. The 26%(=20/77) of mainshocks that occurred within 5 days after the foreshocks have occurred within 4.8 hours after the foreshock. The distance distribution between foreshocks and mainshocks is also found to be better expressed by a power law. If we focus on the specific region of Off Ito (34.8N, 139.0E - 35.1N, 139.3E) where is one of the most active foreshock region, the prediction performance of the same foreshock definition measured by AR and TR, becomes as better as AR= 100% (=18/18) and TR= 37% (=15/41) with dAIC= 166, and PG= 105. As for the Off Ito region, the JMA have been operating an algorithm for predicting the swarm activity basing on the rate increase of volumetric strain observed near the region. When we compare the timing of issuing the prediction information about the swarm activity by the JMA with that of the occurrence of the foreshock defined above, we find that there is not much difference between them. This means that the foreshock activity in this region is strongly related to the crustal deformation before the mainshock.

Foreshocks and short-term forecasting: comparisons between real seismicity and synthetic catalogs

OGATA, Yosihiko[1*]

[1]The Institute of Statistical Mathematics

Some of the statistical characteristics of foreshocks in the Japan Meteorological Agency (JMA) earthquake catalog are similar to those in synthetic catalogs simulated by the space-time epidemic-type aftershock sequence (ETAS) model or even the space-time nonhomogeneous Poisson process. However, they are quantitatively different from each other. Also, the information gain of a foreshock probability forecasting for real seismicity is significantly larger in comparison with that of synthetic catalogs. We discuss the reasons for such differences between the JMA and the synthetic catalogs.

Modelling the effect of fault geometry on earthquake triggering

GUO, Yicun[2] ; ZHUANG, Jiancang[1*] ; ZHOU, Shiyong[2]

[1]Institute of Statistical Mathematics, [2]School of Earth and Space Sciences, Peking University

This study incorporates the rupture extensions of big earthquakes in the formulation of the Epidemic Type Aftershock Sequence model (ETAS) model, which is a point process model widely applied in the studies of spatiotemporal seismicity, rather than regarding every earthquake as a point in space and time. We apply the new model to the catalog from Sichuan province, China between 1990 and 2013, during which the Wenchuan Mw7.9 earthquake occurred in May 2008. Our results show that the modified model has better performance in both data fitting and aftershock simulation, confirming that the elliptical aftershock zone is caused by the superposition of isotropic triggering effects from each patch of the rapture extension. Also, using the technique of stochastic reconstruction, we found that the direct productivities of aftershocks from each patch on the mainshock fault are positively correlated to the slip distribution. We also confirm that the elliptical aftershock zone is caused by the superposition of isotropic triggering effects from each patch of the rapture extension.

Figure: (Left panel) Reconstruction results of aftershock productivity from each patch of Wenchuan mainshock fault based on the new ETAS model, which considers the rupture extension of large earthquakes instead of regarding all the earthquakes as point source. The values are in the logarithm scale. The Wechuan mainshock is marked by the black pentagon.

History of network detection completeness in Japan

SCHORLEMMER, Danijel[1*] ; HIRATA, Naoshi[2] ; ISHIGAKI, Yuzo[3] ; NANJO, Kazuyoshi[2] ; TSURUOKA, Hiroshi[2] ; BEUTIN, Thomas[1] ; EUCHNER, Fabian[4]

[1]GFZ German Research Centre for Geosciences, 14473 Potsdam, Germany, [2]Earthquake Research Institute, University of Tokyo, Tokyo 113-0032, Japan, [3]Seismological and Volcanological Department, Japan Meteorological Agency, Tokyo 100-8122, Japan, [4]Institute of Geophysics, ETH Zurich, Zurich, Switzerland

An important characteristic of any seismic network is its detection completeness, which should be considered a function of space and time. Many researchers rely on robust estimates of detection completeness, especially when investigating statistical parameters of earthquake occurrence like earthquake rates. Contrary to traditional approaches, we do not estimate completeness using methods in which the completeness magnitude is defined as the deviation of the frequency-magnitude distribution from the linear Gutenberg-Richter relation. Here, we present a method based on empirical data only: phase data, station information, and the network-specific attenuation relation. For each station of the network we estimate a time-dependent distribution function describing the detection capability depending on magnitude and distance to the earthquake. For each point in time, maps of detection probabilities for certain magnitudes or overall completeness levels are compiled based on these distributions. Therefore, this method allows for inspection of station performances and their evolution as well as investigations on local detection probabilities even in regions without seismic activity.

We present a full history of network detection completeness for Japan and discuss details of this evolution. These results are compared with estimated completeness levels of other methods and with completeness levels in other regions of the World. We present scenario computations showing the impact of different possible network failures. All presented results are published on the CompletenessWeb (www.completenessweb.org) from which the user can download completeness data from all investigated regions, software codes for reproducing the results, and publication-ready and customizable figures.

Collaboratory for the Study of Earthquake Predictability & Global Earthquake Model - Testing Center Software Development

BEUTIN, Thomas[1*] ; LIUKIS, Maria[2] ; MAECHLING, Philip[2] ; MAK, Sum[1] ; SCHORLEMMER, Danijel[1] ; YU, John[2]

[1]GFZ German Research Centre for Geosciences, 14473 Potsdam, Germany, [2]Southern California Earthquake Center, University of Southern California, Los Angeles CA 90089, USA

The Collaboratory for the Study of Earthquake Predictability (CSEP) aims to improve our understanding about the physics and predictability of earthquakes through rigorous and prospective testing of earthquake forecast models. CSEP operates four testing centers in California, New Zealand, Japan, and Europe running prospective, automated evaluations of more than 350 models. These testing centers are the technical infrastructure of CSEP and implement all procedures and protocols for rigorous testing and evaluation of earthquake prediction experiments. These experiments run in various testing regions and comprise forecast periods of one day to many years.

The CSEP testing center software system is the general infrastructure of all CSEP testing centers and is now being used for earthquake early warning systems, geodetic transient detectors, intensity prediction equations, and ground-motion prediction equations. We present the recent developments and introduce the structure of the software system.

Lithospheric stress and deformation, and megathrust prediction

HONG, Tae-kyung[1*] ; LEE, Junhyung[1]

[1]Yonsei University, Department of Earth System Sciences, Seoul 120-749, South Korea

Lithospheres respond to stress load that is a major cause of earthquakes. Thus, understanding the lithospheric response before and during the megathrusts may allow us to find a way to predict megathrusts. We investigate the lithospheric responses for megathrusts with magnitudes greater than 8.7 since 2000 from precursory and coseismic events. The seismicity presents the cumulation or release of stress before and after megathrust, and discriminative spatial distribution of stress. Normal-faulting earthquakes were increased particularly around large slip regions at shallow depths after the megathrusts, which may be associated with lithospheric rebound and splay-fault development. The earthquake occurrence rate (b value) displays a characteristic slip-dependent feature. The earthquake occurrence rates were decreased with slip amount by forthcoming megathrust due to continuous accumulation of plate-driven stress and tectonic loading around the future rupture planes on slab

surface. The slip dependency of earthquake occurrence rates is enhanced with time until the occurrence of megathrust. The level of seismicity after megathrust is inversely proportional to that before megathrust, yielding the compatible average seismicity before and after megathrust over rupture regions regardless the slip amount of each subregion due to difference of accumulated stress depending the rock properties. It was also observed that the dynamic lithospheric response is highly associated with slip distribution on the rupture plane. Temporal changes of slip-amount-dependent b values are fitted well with an exponential function, suggesting an exponential increase of normal stress with time on locked region until the occurrence of megathrust.

Global distribution of the earthquake-induced Schumann resonance anomalies

ZHOU, Hongjuan[1*] ; CAO, Bingxia[1] ; YU, Haiyan[1] ; QIAO, Xiaolin[1]

[1]Harbin Institute of Technology at Weihai, China

Schumann resonance (SR) is a global electromagnetic resonance phenomenon. Recently, SR anomalies before some earthquakes (EQs), which are considered to be concerned with the irregular disturbance of the lower ionosphere above the epicenters, are discovered. Although the examples are limited, we can see that the SR anomalies are usually different for different EQs. This paper concerns with the distinctions of SR anomalies observed at different locations for the same EQ, with the 2011 Magnitude 9.0 Tohoku-Oki EQ in Japan, before which significant SR anomalies have been observed in China, as an example.

Zhou et al. (2013) have found an anomalous SR affect observed at YS and AJ stations of China, associated with the Tohoku-Oki EQ. The anomalies were characterized by an increase in the intensity at frequencies from the first mode to the fourth mode in both magnetic field components, and the abnormal behaviors of the north-south magnetic field component primarily appeared at 0000-0900 UT 3 days prior to the main shock, about 2 h ahead of east-west magnetic field component. The above phenomena are shown in Figures 1 and 2. Figure 1 shows the deviations of the magnetic field amplitudes from the monthly averaged values observed at YS and QJ stations from 1 to 11 March 2011. Figure 2 shows the comparison of the amplitude differences of both magnetic fields on 8 March observed at YS station with 2 standard deviations which is calculated by the spectra over $\mp$15 days around 8 March, and the areas where the amplitudes are stronger than 2 standard deviations are marked with white. After the comparative analysis of the disturbed phenomena produced by the selected 10 sites shown in Figure 3 by numerical method with a locally EQ-induced disturbance model of the atmospheric conductivity in the day-night asymmetric Earth-ionosphere cavity, it is concluded that the SR anomalous phenomena before the Tohoku-Oki EQ have much to do with the excited sources located at South America and Asia marked with red circles in Figure 3.

Another 2 observing sites, with Sites 1 and 2 located at (N35^o, E137^o) and (N0^o, E110^o) respectively, are selected besides YS in order to compare the abnormal variations of SR magnetic fields observed at different locations under the same disturbance situation. The same simulation model and method as those in Zhou et al. (2013) are used, and the abnormal variations of both magnetic field spectra of SR observed at 3 sites are shown in Figures 4 and 5, with the source located at SA2 and AS4 as shown in Figure 3 respectively. It is obvious that the differences of the abnormal variations observed at different sites are distinct.

Further, Figures 6 and 7 show the global distributions of the anomalies for the first 3 modes of both SR magnetic field components under the excitation of the source SA2 and AS4 respectively. The color codes stand for the ratio of disturbed amplitude to the regular one, and the regions with green color represent the disturbed ratio lower than 1 and also include the possible nodal points which are the results of the simple model of point sources, while white to dark red colors represent the appearance of SR anomalies. It can be seen that the distribution of SR anomalies is very complicated, and is related to the relative locations of EQ epicenter, lightning currents and the observatories, and of course the EQ-induced disturbance of atmospheric conductivities.

The present simulations are done under the simple models of lightning and disturbed conductivity, which will be improved in the next studies.

Study on long strike-slip fault model with heterogeneous dynamic stress drops on asperities

OANA, Atsuko[1*] ; ISHII, Toru[1] ; DAN, Kazuo[1] ; FUJIWARA, Hiroyuki[2] ; MORIKAWA, Nobuyuki[2]

[1]Institute of Technology, Shimizu Corporation, [2]National Research Institute for Earth Science and Disaster Prevention

Oana *et al*. (2013) has established the long strike-slip fault model for a scenario earthquake along the Median Tectonic Line fault zone using the procedure for evaluating the fault parameters by Dan *et al*. (2011), and has simulated the strong ground motions. On that fault model, the dynamic stress drops on the asperities have been homogeneous. However, this is unnatural because the all stress drops on the asperities must be inhomogeneous in the actual earthquakes. How we consider the heterogeneity of the fault rupture is very important subject on the strong motion prediction, because the heterogeneity will have great effects on the spatial distribution of strong ground motions along a fault, especially along a very long fault. The uncertainty of the fault parameters also should be considered into the evaluation of the fault parameters.

In this study, for the strike-slip fault, the procedure for establishing the fault model which takes into account the heterogeneity of the dynamic stress drops on the asperities is examined, and then the spatial strong ground motions are simulated using the fault model based on the procedure. And also, some fault models with the uncertainty of the rupture starting point, the layout of the asperities, and the relationship between the asperity area and the dynamic stress drop on the asperity are established, and then the spatial strong ground motions are simulated using these fault models.

First, the procedure for establishing the fault model to give each asperity the heterogeneous dynamic stress drop is examined. Concretely, first, the probability density distribution of the stress drop is calculated based on the data of the stress drops on the strong motion generation areas of the past earthquakes by previous studies. And then, the procedure is proposed, that gives each asperity the dynamic stress drop corresponding to the frequency of the midpoint of the probability density distribution which is equally divided by the number of the asperity. Here, to satisfy the all relationships among the fault parameters of the asperity model is impossible. So we preceded satisfaction of the relationship formula of the seismic moment, and allowed an error between the obtained short period spectral level and the relationship formula of the short period spectral level. But the error became smaller than about 6 % of the short-period level of the fault model with the homogeneous dynamic stress drops on the asperities. As one of the ideas, we assumed that the relationship between the ratio of the asperity areas and the ratio of the dynamic stress drops on the asperities is random.

Next, for a scenario earthquake along the Median Tectonic Line fault zone, we established the long strike-slip fault model with the heterogeneous dynamic stress drops on the asperities based on the above proposed procedure, and also simulated the strong ground motions by the stochastic Green's function method. As a result, the deviation for the average of the attenuation relation by Si and Midorikawa (1999) of PGA became 0.20 and that of PGV became 0.16. Each deviation is smaller than 0.25, 0.23, which are derived from Si and Midorikawa (1999). It is concluded that this result is relevant, because the attenuation relation is based on a lot of observed records of various earthquakes and sites, while this study targets for the specific earthquake, the local pass, and the local site condition.

Finally, we examined the effect of the uncertainty of the source parameters for the strong ground motions. In the cases of the various rupture starting points, the deviation for the average of the attenuation relation of PGA became 0.23 and that of PGV became 0.21. In the cases of the various layouts of the asperities, those became 0.22 and 0.17, respectively. In the cases of the various relationships between the asperity area and the dynamic stress drop on the asperity, those bacame 0.20 and 0.17, respectively.

Establishing procedure of evaluating fault parameters for predicting strong motions from intra-slab earthquakes with M8

ARAI, Kensuke[1*] ; DAN, Kazuo[1] ; ISHII, Toru[1] ; HANAMURA, Masaki[1] ; FUJIWARA, Hiroyuki[2] ; MORIKAWA, Nobuyuki[2]

[1]Shimizu Corporation, [2]National Research Institute for Earth Science and Disaster Prevention

For precise prediction of strong motions from intra-slab earthquakes, it is necessary to establish a new procedure of evaluating fault parameters based on the characteristics of intra-slab earthquakes. Although such studies had been conducted by Sasatani et al. (2006) and Dan et al. (2006), procedures of evaluating fault parameters were not fully validated by reproduction of the actual earthquake records. So, Arai et al. (2013) simulated the ground motions of the intra-slab earthquake that occurred off the coast of Miyagi Prefecture on April 7, 2011, and they pointed out the problem of existing procedures of evaluating fault parameters and suggested the ideas to overcome the problem. Hence, in this study, we simulated the ground motion of the intra-slab earthquakes with M8, the 1993 Kushiro-oki earthquake of January 15 (Mw 7.6) and the 1994 Hokkaido Toho-oki earthquake of October 4 (Mw 8.2), using the procedures of evaluating fault parameter proposed by Arai et al. (2013) and we pointed out the problem of the procedure.

In the case of the intra-slab earthquakes of the 1993 Kushiro-oki earthquake and the 1994 Hokkaido Toho-oki earthquake, there was a possibility that the results of evaluation of strong ground motions using the equation of the short period spectral level proposed by Sasatani et al. (2006) or Dan et al. (2006) became too small. So, we tried to use the procedures of evaluating fault parameter proposed by Arai et al. (2013). But, the fault model of the 1994 Hokkaido Toho-oki earthquake was unnatural because the short period spectral level of the earthquake estimated by Morikawa and Sasatani (2004) was too large. For this problem, we developed the new fault model using a method to reduce the fault area while increasing the short period spectral level. We also developed the fault model using a crack model.

We set fault models of the intra-slab earthquakes of the 1993 Kushiro-oki earthquake and the 1994 Hokkaido Toho-oki earthquake, which were derived from the relationships of intra-slab fault parameters by Sasatani et al. (2006), Dan et al. (2006), Arai et al. (2013), and the procedure developed here. And we also set the fault model using a crack model. By using these five fault models, we evaluated strong ground motions by the empirical Green's function method. As a result, in the case of the 1993 Kushiro-oki earthquake, ground motion evaluation results by using Sasatani et al. (2006) and Dan et al. (2006) were smaller than the actual records. On the other hand, ground motion evaluation results by using the Arai et al. (2013), the procedure developed here, and the procedure of using a crack model showed better agreements with the actual records. In the case of the 1994 Hokkaido Toho-oki earthquake, ground motion evaluation results by using Sasatani et al. (2006) and Dan et al. (2006) were smaller than the actual records. And ground motion evaluation results by using Arai et al. (2013), the procedure developed here, and the procedure of using a crack model were larger than the actual records especially in the period of 0.5 seconds or less. This may result from overestimation of the short period spectral level obtained by estimating the S-wave acceleration source spectrum by Morikawa and Sasatani (2004). Actually, the short period spectral level calculated from the fault parameters by Morikawa and Sasatani (2004) is smaller than the short period spectral level obtained by estimating the S-wave acceleration source spectrum. So, we will reconsider the short period spectral level of 1994 Hokkaido Toho-oki earthquake for setting fault models. In this study, we targeted the intra-slab earthquakes of the Pacific Ocean plate. The study on intra-slab earthquakes of the Philippine Sea Plate remains as a future subject.

Source effects of the intraslab and interplate earthquakes in Miyagi-ken-oki region based on spectral inversion

KASATANI, Naoya[1] ; KAKEHI, Yasumaro[1*]

[1]Faculty of Science, Kobe University

Previous studies showed that intraslab earthquakes generate stronger high-frequency waves than interplate earthquakes. For example, Satoh (2004) estimated the high-frequency levels of acceleration source spectra for seven intraslab earthquakes and four interplate earthquakes in Miyagi-ken-oki region. Their result showed the high-frequency level of intraslab earthquake is 3 to 4 times higher than that of interplate earthquake on the average. On the other hand, Katoh et al. (1999) estimated the excitation strength of high-frequency strong motions for intermediate-depth earthquakes based on the peak ground accelerations (PGA). Their result showed the focal depth is a key parameter controlling the PGA amplitudes rather than the difference of tectonic environments, such as intraslab or interplate earthquakes. Thus, the reason for the excitation strength of high-frequency waves of slab earthquake varies among studies, and this problem requires more precise investigation.

In this study, spectral inversion of NIED K-NET strong motion data is done to evaluate source effects of the intraslab and interplate earthquakes in Miyagi-ken-oki region. Then, seismic moments and corner frequencies are estimated from the evaluated source effects, and the high-frequency levels of the earthquakes are determined.

From the comparison between the intraslab and interplate earthquakes, the high-frequency levels of the former are 2 to 3 times higher than those of the latter. On the other hand, from the viewpoint of source depth, a clear trend is found that deeper earthquakes have higher high-frequency spectral levels. Here, it should be noted that the source depths of intraslab earthquakes are systematically larger than those of interplate earthquakes. Additionally, we find no significant difference between the spectral levels of intraslab and interplate earthquakes that have almost the same source depths. This is also seen for the difference between the spectral levels of upper-plane and lower-plane intraslab earthquakes.

Based on these results, we conclude (1) the trend that intraslab earthquakes have higher- high-frequency level than interplate earthquakes is apparent due to the fact that the former have systematically deeper source depths than the latter, and (2) the high-frequency level does not depend on the difference of tectonic environments, such as intraslab or interplate earthquakes, but on the source depth, and deeper earthquakes have higher high-frequency spectral levels. Difference of 4 times is seen between the high-frequency levels of deeper (˜80 km depth) and shallower (˜30 km depth) earthquakes for the depth difference of ˜50 km.

Finally, we pick up two factors, other than source-originated ones, that may effect the evaluation of the high-frequency level: effect of the waveform difference depending on source depth and depth-dependent Q-value structure. These effects are evaluated quantitatively, and we conclude that they cannot bring such biases as can change the above-mentioned trend of the high-frequency level. Thus, we have successfully enhanced the reliability of our interpretation that deeper earthquakes have higher high-frequency spectral levels.

Acknowledgments: The strong ground motion data recorded by K-NET, KiK-net, and F-net of National Institute of Earth Science and Disaster Prevention and the hypocenter data of the unified hypocenter catalogue by the Japan Meteorological Agency were used for the analysis.

Comparative study of the performance of source models for the 2011 Tohoku earthquake

NOZU, Atsushi[1*]

[1]Port and Airport Research Institute

The 2011 Tohoku, Japan, earthquake is obviously the first M9 earthquake which was recorded by dense strong motion networks such as K-NET, etc. Several source models have been proposed to explain strong ground motions from this earthquake. It is significantly important to evaluate the relative performance of these models, especially in the frequency of engineering importance. From engineering point of view, the most striking feature of strong ground motions of the Tohoku earthquake is the generation of strong-motion pulses in the frequency range from 0.2 to 1 Hz observed at many sites along the coast of Miyagi through Ibaraki Prefecture. It is significantly important to consider the generation of such pulses in the strong-motion prediction for mega earthquakes, especially when the prediction is aimed at seismic design of structures. To model strong motion pulses from the Tohoku earthquake, a source model including nine subevents with relatively small size (on the order of several kilometers) was developed (Nozu et al., 2012). The model is called the 'SPGA model'. On the other hand, several 'SMGA models' have been proposed for the same earthquake, in which larger subevents (on the order of several tens of kirometers) are considered. In this study, the errors between the synthetic and the observed ground motions are evaluated for each of these source models. The result clearly indicates that the SMGA model cannot reproduce strong ground motions in the frequency range from 0.2 to 1 Hz, which is characterized by strong-motion pulses. In this frequency range, the performance of the SPGA model is significantly better than the SMGA models. The SPGA model also reproduces the seismic intensity proposed by Sakai et al. (2002), which is in good agreement with the building damage. Based on such results, the author concludes that the SPGA model should be used to calculate strong ground motions for a future mega earthquake as long as the strong motion prediction is aimed at structural safety.

A pseudo point-source model for off Miyagi intraslab earthquake on May 26, 2003

WAKAI, Atsushi[1*] ; NAGASAKA, Yosuke[1] ; NOZU, Atsushi[1]

[1]Port and Airport Research Institute

In a recent research, a pseudo point-source model, which is a simplified version of the conventional characterized source model, was proposed and it was verified that the source model can be applied to the 2011 Tohoku earthquake, Japan. In the source model, the spatio-temporal distribution of slip within each subevent is not modeled. Instead, the source spectrum associated with the rupture of each subevent is modeled. For the future application of the source model, it is important to investigate its applicability to other destructive earthquakes.

In this study, the off Miyagi intraslab earthquake on May 26, 2003 is taken as an example, and the applicability of the pseudo point-source model is investigated. It was revealed that the source model can reproduce the waveforms and the Fourier spectra at least as well as the conventional characterized source model.

Strong ground motion simulation for the July 23, 2005 northwestern Chiba earthquake by pseudo point-source model

NAGASAKA, Yosuke[1*] ; NOZU, Atsushi[1] ; WAKAI, Atsushi[1]

[1]Port and Airport Research Institute

We propose a pseudo point-source model (Nozu, 2012) of the July 23, 2005 northwestern Chiba earthquake. The model is developed for the benchmark test (Hisada *et al*., 2013) in which various strong ground motion generation methods are compared.

In the pseudo point-source model, detailed spatiotemporal slip distributions within a subevent are not considered. Instead, the source spectrum associated with the rupture of each subevent is specified and it is assumed to follow the omega square model. This model has been applied for some earthquakes and shows good agreement with observations.

With this simplificationi, each subevent involves only six parameters, namely, longitude, altitude, depth, seismic moment, corner frequency and rupture time. In addition to these parameters, strike, dip and rake angles of the subevent are considered in this study in order to investigate the effect of radiation pattern while average value has been used in the previous studies. In this study, it is assumed that the theoretical radiation pattern becomes less evident with the increase of the hypocentral distance divided by the wavelength. This means that when the hypocentral distance is large of the wavelength is short, the radiation pattern is close to the average value rather than the theoretical value and vice versa. A new parameter Q_R is introduced to express this effect that determines how slowly the radiation pattern converges to the average.

The parameters for this particular earthquake are determined as follows. The hypocenter and the mechanism are from Koketsu and Miyake (2005). The seismic moment (=9.11×10^{17}Nm), the density (=3.2g/cm^3) and the S wave velocity (=4.46km/s) in the source region are from the F-net. The corner frequency (=0.75Hz) and Q_R(=10π) are determined so that the synthetic velocity waveforms and the Fourier spectra become consistent with the observations.

The site amplification factor for the K=net or KiK-net sites is from Nozu and Nagao (2005). For other sites (Building Research Institute and UR sites), the site amplification factors are newly determined by using the spectral ratio of the observed records between the target site and neighboring K=net or KiK-net stations. In terms of the Fourier phase information, we pick up 3 earthquakes before the main shock and chose the best one for each site.

As an example of the result, the synthetic Fourier spectra at 3 sites are compared with the observations (see the Figure).

Three-dimensional grid modeling based on analysis of borehole data

KIMURA, Katsumi[1*] ; HANASHIMA, Yuki[2] ; NISHIYAMA, Shoichi[3] ; ISHIHARA, Yoshiro[4] ; SEKIGUCHI, Haruko[5]

[1]AIST, Geological Survey of Japan, [2]Smart Solution Corporation, [3]OYO Corporation, [4]Fukuoka University, [5]Kyoto University

The article presents a 3D geologic modeling method and applies it to build a subsurface 3D geologic model in the northern Tokyo and southern Nakagawa lowlands and the adjacent upland area. The modeling method, using borehole data for ground survey consists of (1) the surface modeling of the base of the Chuseki-so (the latest Pleistocene to Holocene incised-valley fill) , which has been improved by interpolating borehole data and (2) the 3D grid modeling of lithofacies and *N*-values constrained by the above surface model. The 3D grid model is very useful for not only geologic expression, but also the ground model of seismic response characteristics, because this can be converted to be S-wave velocity and density models.

Three-dimensional structure model for modeling strong motion around the Ryukyu arc

FUJIOKA, Akira[1] ; TAKENAKA, Hiroshi[2*] ; YAMADA, Nobuyuki[3] ; NAKAMURA, Takeshi[4] ; OKAMOTO, Taro[5] ; FUJIWARA, Hiroyuki[6]

[1]Kyushu Univ., [2]Okayama Univ., [3]Kyushu Univ. of Education, [4]JAMSTEC, [5]Tokyo Institute of Technology, [6]NIED

The Ryukyu Islands have frequently been damaged by large earthquakes and tsunamis since ancient times. For instance, in 1771, gigantic tsunamis are occurred from an earthquake and more than 12000 people died in Yaeyamya Islands. From the point of view of disaster prevention, it is also important to improve the precision of strong ground motion prediction. Here we build a 3D numerical structure model for modeling of strong ground motion, which includes land and ocean-bottom topographies and a seawater layer as well as subsurface structures of the arc side and the PHS slab, partially based on the J-SHIS model for near-surface structure (NIED) and a slab-top depth model of the PHS (Headquarters for Earthquake Research Promotion, Japan). We then try to improve the near-surface structure model in the islands using our original microtremor surveys. We also conduct numerical simulations of seismic motions for three sub-oceanic earthquakes occurring near the Amami Islands, Okinawa Island and Miyako Island to confirm the applicability of the constructed structure model and to check the improvement of the near-surface model.

3-D sedimentary layers model and simulation of seismic motions around the Tachikawa fault zone

SAGUCHI, Koichiro[1*] ; CHIMOTO, Kosuke[1] ; YAMANAKA, Hiroaki[1]

[1]Interdisciplinary Graduate School of Science and Engineering, Tokyo Institute of Technology

Tachikawa fault is one of the most activity faults in the western part of the Tokyo metropolitan area. Strong motion estimation is necessary to know the possible damage due to rupture of the fault considering effects of geological structure. However, a three-dimensional subsurface structural model is not well tuned in the vicinity of the fault.

In this study, we estimated a three-dimensional structure of deep sedimentary layers around the Tachikawa fault zone using Rayleigh wave phase velocity and horizontal-to-vertical spectrum obtained from microtremor explorations and receiver functions from the obtained records of the K-NET, KiK-net and SK-net. And we simulated seismic ground motions around the Tachikawa fault zone using the three-dimensional finite difference method to validate of a three-dimensional structure of deep sedimentary layers.

To accomplish it, we first conducted the array observations of microtremors at 12 sites around the Tachikawa fault. Rayleigh-wave phase velocity at periods from 0.5 to 5.0 seconds was estimated from a frequency-wave number spectral analysis of the microtremors. We next conducted the observations of microtremors at 268 sites on nine lines across the Tachikawa fault zone. Predominant periods of the H/V spectrum clearly indicated differences of subsurface structure across the Tachikawa fault.

Then, we conducted the joint inversion of the phase velocity and the receiver function to a P and S-wave velocity profile based on the simulated annealing method. P-wave velocities, S-wave velocities and thickness of individual layers are inverted very well, and the S-wave velocities of the inverted profile are 0.5, 0.9, 1.5, 2.4 and 3.2km/s. We constructed a three-dimensional structures of the deep sedimentary layers in this area from integrating the 1-D S-wave velocity profiles at all the stations. The basement depth at hanging-wall side of the Tachikawa fault is larger than that at foot-wall side with a difference of about 1.7km in the 3-D model.

Finally, we simulated seismic ground motions around the Tachikawa fault zone using the three-dimensional finite difference method considering three-dimensional velocity structure down to 50km. The results indicate that the maximum accelerations in simulated waveforms were similar to the observed one.

The use of environmental vibration recordings (microtremors) is cost effective and easily collected data for site characterization that is a component of microzonation mapping and has become very popular around the world in the last years.

Local site conditions have a major effect on the level of ground shaking. For this reason we carried out microtremor measurements by using circular small array configuration at twenty one locations in Tekirdag, four locations in Zeytinburnu and one location in Yesilkoy. In addition to eight large array measurements for estimating S-wave velocity structures of shallow deeper soil formations for site effect analysis. These sites were selected by considering the different geological units (i.e. recent landfill, clay stone, silt stone, alluvium, lime stone, sand) in the cities. We also collected data on five buildings in Tekirdag in order to understand dynamics properties of buildings.

We estimated the phase velocities of Rayleigh waves at each site from the vertical components of recorded microtremor data by using Spatial Autocorrelation (SPAC) method. Obtained phase velocity dispersion curves are varied from area to area. The obtained phase velocities range from 100 m/s to 750 m/s along the coastline in Tekirdag while, they range from 200 m/s to 500 m/s for Zeytinburnu area.

Genetic Simulated Annealing Algorithm technique was applied for inversion of phase velocities to estimate 1-D S-wave velocity structures beneath the sites. The inverted Vs profiles are not uniformed. The preliminarily results show that similar phase velocity changes have been seen at the low and the high periods on the different geological units along the parallel direction of the coastline. When we check the velocity changes from coastline toward the inland, we can see the different phase velocities on the different geological units.

Characteristics of long-period strong ground motion in the Keihin-area during the 2011 Tohoku earthquake

UETAKE, Tomiichi[1*]

[1]Tokyo Electric Power Company

The velocity response spectra of 5% damping calculated from the observed data in the Keihin area during the 2011 Tohoku Earthquake had no significant peak at period of around 8 s and had peak over 100cm/s at period of around 3 s. The acceleration seismograms had spindle-shaped envelope and peak accelerations were recorded about 120 s after S-wave on-set. The maximum velocity response at period of around 3 s was recorded in the first half part of waveforms. It is important to realize the difference of wave propagation characteristics between in the first half part and the later part of the waveforms. In this article, the propagation characteristics of long-period strong ground motions during the 2011 Tohoku Earthquake were studied by semblance analysis using the data observed in the Keihin area.

Sixteen strong motion observatories in the Keihin area were used for array analysis. The major axis of the array area is about 18 km and minor axis is about 9km. Distance between adjacent observation points is from 0.6km to 5km. We performed semblance analysis using narrow-band pass filtered waveforms and evaluated the phase velocity for each time sections from the peak point of semblance in slowness plane. The center periods of the filters were 1, 2, 2.5, 3, 4, 5, 6, 7, 8, 9, 10, 12, 15 and 20 s. The length of time window for analysis was 20 s and the time windows were opened every 10 s in wave traces.

The peak semblance values were high for longer period waveforms and were lower value for short period waveforms. The value at period of 1 and 2s were lower than 0.5. The values calculated from large array data were lower than those from small array data. The semblance values in first part of waveform were high but the values in the later part show lower value. The phase velocities in first half part are over 3 km/s for all case. The phase velocities in later part were 1 to 2 km/s and showed the dispersion characteristics. The back azimuths of wave propagation in the first part indicated the epicenter direction but those in later part did not indicate constant direction especially in short period range.

To examine the relation between this dispersion characteristics and underground structure, we calculated phase velocities of surface waves using the underground structure model. The phase velocities evaluated in the first part were faster than phase velocity of the fundamental mode. The phase velocities evaluated for several last time windows in the later part coincided with the phase velocity of the fundamental mode. These characteristics are similar to the results from the data observed the Tokyo lowland area [Uetake (2013)].

Judging from the property of the acceleration waveform and a result of the semblance analysis, the waves caused large response in a period of 2-3 s were more likely to be a body wave not a surface wave of the fundamental mode.

The strong ground motion data used in this study were observed by TEPCO, K-NET of NIED, ERI, JMA, Tokyo Metropolitan office and Yokohama-City. I appreciate these organizations for making the data be available.

Characteristics of Long-period Ground Motion in the Osaka Sedimentary Basin due to the 2011 Great Tohoku Earthquake

SATO, Kayoko[1*] ; IWATA, Tomotaka[1] ; ASANO, Kimiyuki[1] ; KUBO, Hisahiko[1] ; AOI, Shin[2]

[1]Disaster Prevention Research Institute, Kyoto University, [2]National Research Institute for Earth Science and Disaster Prevention

The 2011 great Tohoku earthquake (Mw 9.0) occurred on March 11, 2011, and the largest aftershock (Mw 7.7) occurred in the Ibaraki-oki region, adjacent to south boundary of the mainshock's source region. Long-period ground motions (2?10s) of large amplitude were observed in the Osaka sedimentary basin about 550-800km away from the source regions during both events. We collected the strong motion records in and around the Osaka basin and analyzed the long-period ground motions. The amplitude of horizontal components of the ground motion at the site-specific period is amplified at each sedimentary station and its duration is prolonged. The predominant period is around 7s in the bayside area inside the Osaka basin where the largest pSv among the stations inside the Osaka basin were observed. The pSvs at the bedrock sites surrounding the Osaka basin also have their peak values around 7s.

Then, we focus on the propagation characteristics from the source region to the Osaka basin. We compared the pSvs of 7s at the sedimentary stations in the Osaka basin with those in the Kanto basin. The maximum pSv among the Osaka basin is comparable to the maximum pSv among the Kanto basin whose fault distance is about 500km nearer than the Osaka basin. Moreover, the amplitude of observed pSvs is systematically larger than prediction from the empirical attenuation relationship by Kataoka et al. (2008) at non-sedimentary stations in the region between the Nobi and Osaka basins. The large long-period ground motions in the Osaka basin might be generated by the combination of propagation-path and basin effects.

Thus, we simulate ground motions due to the largest aftershock using the three-dimensional Finite Difference Method (GMS; Aoi and Fujiwara, 1999). The reason we use the largest aftershock is that this event has a relatively small rupture area and simple rupture process compared to the mainshock. The size of the model space is 730km (EW) x 330km (NS) x 100km (Vertical) including the source region and the Osaka basin. A three-dimensional velocity structure model based on the Japan Integrated Velocity Structure Model (Koketsu et al., 2008, 2012) is assumed. The minimum S-wave velocity is 350m/s and the grid spacing in the sedimentary layers is 200m for horizontal direction and 100m for vertical direction, respectively. The minimum effective period in this computation is 3s. We estimated a point source using the long-period ground motions (4-10s) at a station close to the source region (KiK-net CHBH14) and used it for our simulation.

We compared the synthetic and observed waveforms in the periods of 4-10s. As well as the observed ones, the amplitude of synthetic waveforms was amplified and the durations were prolonged at the sedimentary stations in the Kanto basin, the Nobi basin and the Osaka basin. The feature of the attenuation relations in the region between the Nobi basin and the Osaka basin was qualitatively reproduced. At the period of 7s, the amplitudes of synthetic waveforms were little underestimated in the Osaka basin.

Finally, we simulate the ground motion during the mainshock. The model space is 730km (EW) x 400km (NS) x 100km (Vertical). The grid interval and velocity structure model are same as those for the largest aftershock. We assume two point sources based on the two southern SMGAs of the four SMGAs estimated by Asano and Iwata (2012). As a result of the simulation, the synthetic waveforms reproduced the observed ones qualitatively. Therefore, we conclude that the large long-period ground motions in the Osaka basin during both events mainly resulted from the combination of those two SMGAs, propagation-path and basin effects.

ACKNOWLEDGEMENTS

We used strong motion data recorded by K-NET, KiK-net and F-net of NIED, CEORKA, BRI, JMA, and Osaka prefecture. GMS provided by NIED is used for the computation.

Long-period ground motion evaluation for the Nankai Trough megathrust earthquakes

MAEDA, Takahiro[1*] ; MORIKAWA, Nobuyuki[1] ; AOI, Shin[1] ; FUJIWARA, Hiroyuki[1]

[1]NIED

We evaluate long-period ground motions associated with the Nankai Trough earthquakes (M8~9) in southwest Japan. Large interplate earthquakes occurring around the Nankai Trough have caused serious damages due to strong ground motions and tsunami. Such large interplate earthquake potentially causes damages to high-rise and large-scale structures due to long-period ground motions. The long-period ground motions are amplified particularly on sedimentary basins, where big cities have been established. Therefore it is important to evaluate long-period ground motions as well as strong motions and tsunami for the anticipated Nankai Trough earthquakes.

The long-period ground motions are evaluated by the finite difference method (FDM) using " characterized source models " and the 3-D underground structure model. The parameters of the characterized source model are determined based on a " recipe " for predicting strong ground motion [Earthquake Research Committee (ERC), 2009]. We construct various source models (more than 300 scenarios) assuming various possible source parameters, including rupture area, asperity configuration, and hypocenter location. Each source region is determined by " the long-term evaluation of earthquakes in the Nankai Trough " published by ERC. The asperity configuration and hypocenter location control the rupture directivity effects. These parameters are important because our preliminary simulations are strongly affected by the rupture directivity (Maeda et al., 2013). We apply the system called GMS (Ground Motion Simulator) for simulating the seismic wave propagation based on 3-D FDM scheme using discontinuous grids (Aoi and Fujiwara, 1999) to our study. The 3-D underground structure model used in the FD simulation is the Japan integrated velocity structure model (ERC, 2012).

We evaluate the long-period ground motions using the peak ground velocity (PGV) and velocity response spectra (Sv). The simulation shows a large variation of PGV and Sv at a site. The large variation is important to understand the seismic hazard. The variation at the Kanto region, an eastern extension of the source area, seems larger than those at the Nobi and Osaka regions. The scenarios with wider source area have larger PGV and Sv than those with smaller source area. The large number of simulations of this study allows us to select scenarios that correspond to representative (e.g. average and maximum) response spectra at each site.

Long-period ground motion evaluation for the Sagami Trough megathrust earthquakes

MORIKAWA, Nobuyuki[1*] ; MAEDA, Takahiro[1] ; IWAKI, Asako[1] ; IMAI, Ryuta[2] ; AOI, Shin[1] ; FUJIWARA, Hiroyuki[1]

[1]National Research Institute for Earth Science and Disaster Prevention, [2]Mizuho Information & Research Institute, Inc.

It is important to assess seismic hazard in consideration of uncertainty and occurrence frequency in order to mitigate disasters from future earthquake. Iwaki et al. (2013) examined the influence of the long-period ground motion on uncertainty of asperity (strong motion generation area) or hypocenter location, and the heterogeneity of rupture velocity or slip direction for megathrust earthquakes occurring at the Sagami Trough region. They showed that the asperity or hypocenter location largely affects to the amplitude and predominant period of simulated long-period ground motions. Based on their results, we simulate long-period ground motions by a large number of source models considering the uncertainty of asperity or hypocenter location, and we try to assess long-period ground motion due to megathrust earthquakes occurring at Sagami Trough by evaluating the simulation results statistically.

We set ten source regions containing Taisho and Genroku earthquakes by changing those from Iwaki et al. (2013) referring the model by Central Disaster Council (2013). The range of moment magnitude (Mw) is 7.9 to 8.6 and total number of source model is more than 150. We use a ”characteristic source model” and source parameters are evaluated by following the method in ”Recipe” by Headquarters of Earthquake Research Promotion of Japan. We use a velocity structure model by Earthquake Research Committee (2012) but we revise the topography of the Philippine Sea plate based on recent researches. The long-period ground motions are simulated using a 3D finite difference method with discontinuous grid coded by Aoi and Fujiwara (1999). As long-period-ground motion hazard assessment, we first calculate average and slightly large (i.e. +1 sigma; sigma is the standard deviation) amplitude of peak velocity and velocity response spectrum whose natural period is 5, 7 and 10 seconds respectively on engineering bedrock for every ten source region. And then we integrate them by assuming the ”weight” which corresponds to occurrence frequency of each source region.

Although a large number of source models are set up in this study, the uncertainty on the megathrust earthquake occurring at Sagami Trough cannot be covered completely. So it should be required to examine much source models. On the other hand, the source region of magnitude 8-class earthquake at Sagami Trough extends to beneath the metropolitan area. In addition, it is said that the occurrence of the magnitude 7-class earthquake, which does not take in this study, is imminent in southern Kanto region. It is necessary to advance broadband ground motion hazard assessment also including a short-period ground motion.

Emplical ground motion model for long period motions and for long distance -Distance dependent geometrical spreading ter

MOTOKI, Kentaro[1*] ; KATO, Kenichi[1]

[1]Kobori Research Complex Inc.

The GMPEs have been proposed by Sato et al.(2012), Kataoka et al.(2008), and Yuzawa and Kudo(2011). For predictions of long period ground motions on Kanto Plain for the Nankai Trough mega earthquake, the proposed GMPEs cannot be adopted because of the deficiency of applicable distance ranges. In order to establish an adoptable GMPE for long distance, we investigate the distance dependent geometrical spreading term.

We used records for magnitude equal to or greater than 5.0 and distance less than 1000 km. The dataset used in this study is provided by F-net, because of high sensitivity for long period motions and continuous recordings. Since the F-net stations can be regarded as hard rock sites, the site term was not taken into account in the regression.

First, we use a constant geometrical spreading and anelastic attenuation for distance. The regression curve at the 20sec of period decays more slowly than the average of records in the short distance less than 100km, and decays more steeply than records in the longer distance. It implies that the GMPE with a constant geometrical spreading term may underestimate near the source region and in the longer distance.

In the long period range, the dominance of seismic wave changes from the body wave to the surface wave according to the travelling distance, and the slope of the geometrical spreading depends on distance. We will evaluate the geometrical spreading term in the separated distance range to reveal how the geometrical spreading changes.

Long-Period Ground Motion Prediction Equations and Their Application to the Magnitude Estimation of Large Earthquakes

IBRAHIM, Rami[1*] ; SI, Hongjun[1] ; KOKETSU, Kazuki[1] ; MIYAKE, Hiroe[1]

[1]Earthq. Res. Inst., Univ. Tokyo

We developed long-period ground motion prediction equations (GMPEs) for peak ground velocities (PGVs) and peak ground displacements (PGDs) in a period range of 5-30 s. We only used strong motion data of KiK-net downhole stations located in layers of shear-wave velocities equal to or greater than 2000 m/s. We confirmed that the site effects due to surface geology for long-period PGVs and PGDs can be ignored at these observation stations. The dataset consists of 20 earthquakes of $6 \leq M_w \leq 9.1$ occurred in and around Japan. Two-stage regression analyses were carried out to derive the GMPEs. We fit the data with bilinear regression lines bending at M_w 7.5. Additional factors of focal depth and earthquake type were found to enhance the fitting with the observed data. Our developed long-period GMPEs predict the PGVs and PGDs of crustal earthquakes are larger than those of inter-plate and intra-plate earthquakes. The attenuation coefficients presented in the current study indicate that the long-period PGVs and PGDs increase by increasing depth.

We used the long-period GMPEs developed in this study to estimate the moment magnitude by fitting observed PGVs and PGDs at period range of 5-30 s with GMPEs. We estimated the magnitudes of the same 20 earthquakes and the 2013 Awaji Island earthquake (M_w 5.8) recorded by downhole accelerometers of KiK-net. The results are consistent with the moment magnitudes from the Global CMT project. The method is useful to estimate the magnitude of giant earthquakes such as the 2011 Tohoku earthquake (M_w 9.1). The proposed method can estimate the moment magnitude quickly if information of source area is available.

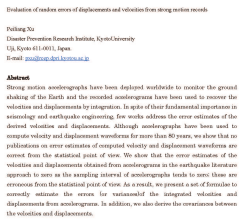
Evaluation of random errors of displacements and velocities from strong motion records

XU, Peiliang[1]*

[1]Disaster Prevention Research Institute, Kyoto University

Strong motion accelerographs have been deployed worldwide to monitor the ground shaking of the Earth and the recorded accelerograms have been used to recover the velocities and displacements by integration. In spite of their fundamental importance in seismology and earthquake engineering, few works address the error estimates of the derived velocities and displacements. Although accelerographs have been used to compute velocity and displacement waveforms for more than 80 years, we show that no publications on error estimates of computed velocity and displacement waveforms are correct from the statistical point of view. We show that the error estimates of the velocities and displacements obtained from accelerograms in the earthquake literature approach to zero as the sampling interval of accelerographs tends to zero; those are erroneous from the statistical point of view. As a result, we present a set of formulae to correctly estimate the errors (or variances)of the integrated velocities and displacements from accelerograms. In addition, we also derive the covariances between the velocities and displacements.



Evaluation of random errors of displacements and velocities from strong motion records

Abstract

Strong motion accelerographs have been deployed worldwide to monitor the ground shaking of the Earth and the recorded accelerograms have been used to recover the velocities and displacements by integration. In spite of their fundamental importance in seismology and earthquake engineering, few works address the error estimates of the derived velocities and displacements. Although accelerographs have been used to compute velocity and displacement waveforms for more than 80 years, we show that no publications on error estimates of computed velocity and displacement waveforms are correct from the statistical point of view. We show that the error estimates of the velocities and displacements obtained from accelerograms in the earthquake literature approach to zero as the sampling interval of accelerographs tends to zero; those are erroneous from the statistical point of view. As a result, we present a set of formulae to correctly estimate the errors (or variances)of the integrated velocities and displacements from accelerograms. In addition, we also derive the covariances between the velocities and displacements.

Earthquake detection from strong ground motion observation network in Himalaya, India

MASUDA, Tetsu[1*] ; KOKETSU, Kazuki[1] ; TAKANO, Kiyoshi[2] ; FURUMURA, Takashi[2] ; OKI, Satoko[3] ; ITO, Takamori[3] ; CHADHA, Rajender kumar[4] ; SRINAGESH, Davuluri[4] ; SRINIVAS, Dakuri[4]

[1]Earthquake Research Institute, [2]University of Tokyo, [3]Keio University, [4]National Geophysical Research Institute

It is an important subject to establish the technical issues and environment of data acquisition and analysis of natural hazards for the disaster mitigation, the first aid and recovery planning. The Indo-Japanese collaborative project on 'Information Network for Natural Disaster Mitigation and Recovery' of 'Science and Technology Research Partnership Sustainable Development International Collaborative Research Program' supported by JST and JICA, Japan initiated strong ground motion observation, crustal movement measurement, and building vibration measurement in Indo-Gangetic plain and foot hills of Himalaya, India.

We started the strong ground motion observation network with deployment of broadband velocimeters and digital equipments at 26 sites near the seismic active region in Himalaya, India by October 2012. The continuous time history of ground motion is digitally recorded with high resolution. Because of the broadband response of the sensor and the high resolution of the recorder, it is expected that the long- period motions or weak ground motions from small local earthquakes and distant earthquakes will be recorded as well as the short-period strong ground motions. It is a necessary task for the seismic data analysis to detect earthquakes using continuous records from the network. In this paper, we present a method developed for fast and precise earthquake detection from continuous records of the network.

The stations of the network are located in the compounds of local schools. The ambient noise is not always low but it changes as well as contains abrupt increases. We developed a detection method with simple algorithm adequate for the noisy circumstances. We compared our detections with the earthquakes reported in the NEIC catalogue. Our results show that the network detected all earthquakes of magnitude 7 or more, more than 90% of magnitude 6.5 through 6.9, more than 50% of magnitude 6.0 through 6.4 regardless of epicentral distances, and more than 80% of magnitude 6 or more from epicentral distances less than 100 degrees.

Several local earthquakes with short S-P times which were not reported in the NEIC catalogue were also detected by the network. Local seismicity is an index of the stress status, and detection of local earthquakes is important to understand the stress distribution in a small region. The preliminary results show that the network will provide data from local and global earthquakes to study the local seismic activity in the Himalayan region, the propagation path effects from the source to the stations, amplification effects at sites, the physical process of the seismic source, and subsurface velocity structure.

Liquefaction damage expansion caused by the generation of surface waves from base end section

NAKAI, Kentaro[1*] ; NODA, Toshihiro[1] ; MURASE, Kotaro[1] ; ASAOKA, Akira[2] ; SAWADA, Yoshihiro[2]

[1]School of Engineering, Nagoya University, [2]Association for the development of earthquake prediction

The 2011 off the Pacific coast of Tohoku Earthquake caused liquefaction to occur in reclaimed lands in Urayasu City and in other wide areas of reclaimed land along Tokyo Bay. One of the important characteristic of the observed liquefaction damage is that the level of liquefaction damage was nonuniform spatially, and the variation in the damage levels was large. The difference in damage levels in various parts has often been explained by the presence/absence of past ground improvement and by the difference in the dates of reclamation work. From the boring survey at Urayasu, thin layer of soft alluvial clay is located directly under the liquefiable layer on the inland side where liquefaction damage was small. However, the basement layer is inclining towards coast side and alluvial clay layer is increasing in thickness as approaching to the coast where liquefaction damage was severe. This paper examines the cause of extensive and nonuniform liquefaction damage observed in Urayasu City by focusing attention on the stratum inclination at the deeper part of the liquefiable layer with the use of 2D elasto-plastic seismic response analysis of the multi-layer ground. The analysis code employed in this report was the soil-water coupled finite deformation analysis code GEOASIA (Noda et al. 2008), which incorporates an elasto-plastic constitutive model (SYS Cam-clay model; Asaoka et al. 2002) that allows description of the behavior of soils ranging from sand through intermediate soils to clay under the same theoretical framework.

Fig.1 (a) illustrates the velocity vector distribution 50 sec after earthquake occurrence. Only the area around the sloped part is shown in this figure, and the scale in the vertical direction has been magnified by 2 times. Surface waves generate at the base end section of the inclination which shows orbit in a counterclockwise direction with ongoing wave propagation to the right-hand side. Excess pore water pressure ratio at the liquefiable layer is shown, superimposing the result of 1D analysis with same stratigraphic composition at the point. 2D analysis result shows liquefaction (excess pore water pressure ratio is greater than 0.95), even 1D analysis did not liquefy (Fig.1 (b)). In the case of 2D analysis, in addition to the magnitude, duration time of the oscillation increases in subsurface layer accompanied by the generation of surface waves (Fig.1 (c)). Excess pore water pressure ratio of 2D analysis continues to increase for a long period even after the primary earthquake motion. Fig.1 (d) illustrates the shear strain distribution 200 sec after earthquake occurrence. Although shear strains are small in the non-inclined horizontal strata, large strains are produced in the subsurface liquefiable layer. Furthermore, this strain distribution is nonuniform and localized even assuming homogeneous initial conditions for subsurface layer. The nonuniform, localized shear strain are due to the existence of the sloped boundary. In other words, in addition to the vertical component of seismic movement being generated by the stratum slope, multi-dimensional propagation is also exhibited because of complex reflection behavior in the diluvial layer. Moreover, in sloped layers such, the danger of liquefaction is increased compared with the one-dimensional model. The actual liquefaction damage observed in Urayasu City was heavy in the sloped stratum locations where midterm reclamation work had been executed. This behavior resembles the results of the analysis carried out here. The current analysis shows that even in the case of homogeneous geomaterials, stratigraphic nonhomogeneity results in large variations in ground deformation behavior and that such deformation becomes particularly large in sloped strata locations. These things cannot be taken into consideration in one-dimensional analysis and highlight the necessity of performing multi-dimensional effective stress analysis.

Relationship between liquefaction occurrence ratio and strong ground motion duration for the 2011 off the Pacific coast

SENNA, Shigeki[1*] ; WAKAMATSU, Kazue[2] ; MATSUOKA, Masashi[3]

[1]NIED, [2]Kanto Gakuin University, [3]Tokyo Inst. Tech

In this study, We first reorganized the points of liquefaction in the 2011 off the Pacific coast of Tohoku Earthquake and plotted the number of liquefaction points in 250m mesh units, because many areas had not been investigated or were insufficiently investigated, as revealed in the information on liquefaction points disclosed and summarized by December 2011.

Next, using the reorganized liquefaction data, the seismic intensity were calculated and the 'real-time seismic intensity' noted by Kunugi et al.(2008) based on the waveforms recorded by seismographs of K-NET, KiK-net, the Meteorological Agency, and the municipalities and examined the effects of earthquake duration on liquefaction using the data on liquefaction points and the method of Matsuoka et al.(2011) to calculate the liquefaction occurrence, so that the liquefaction occurrence can be examined with consideration of the effect of the duration of seismic motion in the March 11 earthquake.

Seismic hazard karte : A Tool for distribution of seismic hazard information with Multi-index

AZUMA, Hiroki[1*] ; FUJIWARA, Hiroyuki[1]

[1]National Research Institute for Earth Science and Disaster Prevention

1. Overview of seismic hazard karte

NIED distributed the ”seismic hazard karte(chart)” in July, 2013. An ”seismic hazard karte” is what summarized the earthquake hazard information for every point, arbitrary places can be searched and the diagnosis of the earthquake hazard about the place can be drawn up. A result displays many indices, such as various foundation information, hazard curves, etc. about the danger of an earthquake, like the notice of a medical examination by the view format summarized to A41 sheet using many charts and graphs.

2. Purpose of Development

It was thought possible to spread the recognition to seismic hazard by using for the user itself the form of diagnosing a certain point with the connection as a starting point, from the investigation by HERP, the argument in a comprehensive sectional meeting, etc. Although the seismic hazard karte was dispatch fundamentally turned to the whole average citizen like other seismic hazard information, when it decomposed into use-cases, it assumed roughly dividing and being used in the following domains. For insurance and real estate, as customer-oriented service data. As the teaching materials which teach the tool for advancing a measure at a workshop or a home to the local resident engaged in disaster prevention educational persons concerned and disaster prevention, and the view of the seismic hazard information on the area. It developed by being that it is easy to carry out use, respectively conscious as a sample of the way of expressing a response using J-SHIS Web API which is open API, and designing to IT persons concerned and developers.

3. Distributed Result

There are many echoes from the exhibited beginning and it is thought that effect fixed as one of the how to show the seismic hazard information evaluated across the board by the country was achieved. Nothing new as contents have in the information offered as seismic hazard karte this time, and it is already J-SHIS seismic hazard station offered, was only visualized in a different form. However, receiving a karte ”it may be very intelligible. From the thing of having also let the family know who lives in the distance”as a positive thing, many reactions ”worth of the possessions affair of our company will be influenced and it will be troubled by it if such a thing comes out” were seen by the negative thing, like when the hazard information is released newly.

JMA intensity distribution of the 1943 Tottori earthquake derived from immediately conducted questionnaire survey

NAKAMURA, Mariko[1] ; KAGAWA, Takao[2*] ; NOGUCHI, Tatsuya[2] ; NISHIDA, Ryohei[2]

[1]Okayama City Office, [2]Tottori University

Questionnaire surveys were conducted by university of Tokyo immediately after five disastrous earthquakes in 1940s to evaluate modified Mercalli (MM) intensity scale. The raw data of the surveys had been stored long time without following analyses. We have studied explanation of each item in the Questionnaire sheet and developed the relational expressions between MM and JMA intensity scales. Finally, we derived JMA intensities at 1935 sites in southwest Japan, and estimated JMA intensity distributions with almost same resolution as modern intensity observation network. The distribution map suggests radiation pattern of strike slip fault and effect of surface geology. The result is worth of basic information for earthquake disaster prevention.

Mortality in the East Japan Great Earthquake (4) Infants and elderlies should always suffer heavy rate of deaths?

OHTA, Yutaka[1*] ; KOYAMA, Maki[2]

[1]TRIES, ADEP, [2]Engr. Fac. Kyoto Univ.

With the aim of clarifying age dependency of mortality in earthquakes we have been conducting a series of studies, just employing a simple division of number of deaths over population in age intervals of 5 or 10 years from area to area in devastated region. What we have found up to now is that there are 2 dominant types approximated by the capital U and J letters in English on the 2 dimensional coordinates of X axis as increasing ages and Y axis as mortality. In case of the 2011 East Japan earthquake, the age dependency in terms of J letter type dominates in most of devastated areas, which suggests that the mortality gets heavier with increasing ages but for infants it stays milder. Such result on age-dependency looks to be apart from our general recognition as infants are very much vulnerable in mortality at many disasters. The discrepancy requests further in-depth studies. In order to settle this issue we attempted two different approaches, that is, 1) comparing natural deaths of certain population with number of accidental deaths by an earthquake (Ozaki. 2012) and 2) introducing a way of evaluating the loss of life expectancy as an weighting factor inversely changing with increasing ages.

Consequently, we succeeded to make clear that infants are still very vulnerable in the meaning of bringing heavy rate of deaths.

Disaster research in the Toyama Earthquake(1718)

SAKAMOTO, Masao[1*]

[1]Iida city Museum

1,Introduction

Of the destructive earthquakes recorded in Japan over the past approx.1600 years, the only one that caused widespread damage in the southern part of Nagano Prefecture was the Toyama Earthquake of 1718,which had its epicenter at Minamishinano Wada, Iida City. The Toyama Earthquake struck just after 2 pm on August 22, 1718 with a magnitude estimated at 7.0. This earthquake is considered to have occurred along the Median Tectonic Line.

2,Survey Results

I identified 35 places where disasters occurred in each prefecture of Nagano Gifu Shizuoka and Aichi. Among these places, a number of characteristic disaster examples are shown as follows.

(1)Minamishinano Wada,Iida City: Mt.Moriheizan located close to the epicenter of the earthquake, partially collapsed to form the elevated area called Deyama at its foot. A landslide pushing out from Oshidezawa dammed the Toyama River. **(2)Arakida, Anan Town:** The right bank of the Tenryu River is composed mostly of Neogene strata centered on sandstone and mudstone overlaying granite bedrock. The slope at the place called Kibishima collapsed due to the earthquake and dammed the Tenryu River. **(3)Furujo,Anan Town:** Geologically, this area consists of Neogene sandstone and mudstone. In the Furujo district, landslides occurred in 24 places, and fields with place names that are still in use today were damaged or destroyed in 33 places**.(4)Hisawa,Shimojo Village:** There is an oral tradition stating that the local people saw the collapsed state of mountainsides in the Ina and Akaishi Mountains from this district. **(5)Enshu Yokoyama Town** (Yokoyama Town, Tenryu Ward, Hamamatsu City, Shizuoka Prefecture): A document was found stating that the Tenryu River was stopped at a place called Enshu”Teuna”. Currently this place name is not used, but there is a place name ”Unna”, which is also along the Tenryu River, so it was presumed that this was where the river was dammed.

3,Discussion and Consideration

(1)What this survey shows: The distribution of the records concerning this earthquake disaster with its epicenter on the Median Tectonic Line in Minamishinano Wada, Iida City is quite one-sided. Records of damage were found only on the west side of a border marked by the Median Tectonic Line running roughly north-south. Because the Akaishi Mountains on the east side of the border had almost no inhabitants, no records of damage from the earthquake were left there. Also, over the course of the nearly three centuries that have passed since the earthquake occurred, the amount of documentary material has been greatly reduced as a result of natural and human causes. **(2)Geological specificity:** The disasters associated with this earthquake can be divided into three typs according to geological differences and the disaster distribution. The first type involved large-scale landslides and disasters occurring on basement granite. The second type constituted disasters occurring on Neogene strata centered on Anan Town. The third type of disaster occurred on Quaternary terrace gravels and alluvial fan gravels. **(3)Rrelation to the Hoei Earthquake:** In 1707, the Hoei Earthquake struck with an estimated magnitude of 8.6, making it one of the largest earthquakes in Japannese history. The Toyama Earthquake, which struck 11 years later, is considered to be an after-shock of the Hoei Earhquake.

A discussion on improvement of calculation technique for questionnaire survey of seismic intensities

SAITO, Ryohei[2] ; YAMAMOTO, Hidekazu[1*] ; SAITO, Tsuyoshi[1]

[1]Faculty of Engineering, Iwate University, [2]GraduateSchool of Engineeing, Iwate University

We compared the seismic intensity from the average intensity with a 1km mesh obtained in the vicinity of the instrumental seismic intensity observation sites. Only in the case of the 2011 off the Pacific coast of Tohoku Earthquake, questionnaire seismic intensities were about 0.5 larger than the instrumental seismic intensities, however, in the cases of other earthquakes, the questionnaire ones were smaller than the instrumental ones. The differences between the instrumental seismic intensity and the questionnaire one are 0.1 to 0.2 at the sites where the instrumental seismic intensities indicate 6 weak. However, at the sites where the instrumental seismic intensities indicate 5 strong, the differences were more than 0.5. Results of the earthquakes of 2008 and 2003 show that the questionnaire seismic intensity is about 0.3 smaller than the instrumental one in the range of 5 weak to 5 strong. Therefore, we compare the method by Inoue et al.(1999) as another method capable in the larger seismic intensity range with the method by Ohta et al.(1998). Inoue et al.(1999) had pointed out that the questionnaire seismic intensity estimated by Ohta et al.(1998) were low in the middle seismic intensity range near about 4.5. They proposed a method capable in large seismic intensity range using the empirical formula to modify the difference without changing the calculating method of Ohta et al. (1979). When questionnaire seismic intensities were calculated using the empirical equation by Inoue et al.(1999), they showed a better correlation with the instrumental seismic intensity for other earthquakes except the 2011 off the Pacific coast of Tohoku Earthquake.

Since 1939, devastating earthquakes with magnitude greater than seven ruptured North Anatolian Fault (NAF) westward, starting from 1939 Erzincan (Ms=7.9) at the eastern Turkey and including the latest 1999 Izmit-Golcuk (Ms=7.4) and the Duzce (Ms=7.2) earthquakes in the eastern Marmara region. On the other hand, the west of the Sea of Marmara an Mw7.4 earthquake ruptured the NAF's Ganos segment in 1912. The only un-ruptured segments of the NAF in the last century are within the Sea of Marmara, and are identified as a "seismic gap" zone. The Sea of Marmara should be focused on through a multidisciplinary research and uncertainty in magnitude, epicenter, recurrence, fault segmentation, and their cross effects should be identified and characterized. To fill the necessity above, a comprehensive multidisciplinary research on earthquake and tsunami disaster mitigation in the Marmara region and disaster education in Turkey in the framework of Science and Technology Research Partnership for Sustainable Development (SATREPS) sponsored by Japan Science and Technology Agency (JST) and Japan International Cooperation Agency (JICA) has been started.

The project is composed of four research groups.

The first is "Earthquake Source Model research" group. Long-term OBS observation, Electromagnetic observation, Seafloor extensometer observation and Trench survey studies will be conducted in order to identify the detailed seismic zone, fault geometry, 3D Velocity structure and reliable crustal deformation beneath the Sea of Marmara.

The second is "Tsunami prediction based on earthquake cycle simulation research" group. In this group earthquake and tsunami occurrence scenarios will be proposed based on especially the research Group 1's outputs and current knowledge on NAF's seismic activities. The outputs will be used for the simulation of strong ground motion, developing of advanced hazard maps and a tsunami early warning system.

The third is "Seismic characterization and damage prediction research" group. This group focuses on modeling of 3D velocity structure, theoretical prediction of ground motion and evaluation of existing structures in the selected urban areas using research outputs of the other groups. Also there will be an attempted of making an urban area model for Istanbul using available data for this area, and to execute earthquake hazard and disaster simulation for various scenarios of a possible earthquake. Improved hazard maps and visual materials for disaster education are expected.

The fourth is "Disaster education using research result visuals from each research" group In group four, effective use of media in the dissemination of disaster information will be examined and disaster management planning through regional disaster prevention community will be encouraged. as well as, using the research visuals a disaster prevention education program will be conducted through media, web, local communities and schools.

Goals of the project are as follows,

1- To develop disaster mitigation policy and strategies based on multidisciplinary research activities.

2- To provide decision makers with newly found knowledge for its implementation to the current regulations.

3- To organize disaster education programs in order to increase disaster awareness in Turkey.

4- To contribute the evaluation of active fault studies in Japan.

Through the project, the research results will be integrated for disaster mitigation in The Marmara region and disaster education in Turkey. The details of SATREPS Japan-Turkey joint research project and latest achievements will be presented.

Fragility curves of buildings during the 2011 Tohoku Earthquake using the damage data in the northern Miyagi Prefecture

WU, Hao[1*] ; MASAKI, Kazuaki[2] ; IRIKURA, Kojiro[3] ; KURAHASHI, Susumu[3]

[1]Graduate School of Engineering, Aichi Institute of Technology, [2]Department of Urban Environment, Aichi Institute of Technology, [3]Disaster Prevention Research Center, Aichi Institute of Technology

Damage ratios in subdistricts of Osaki and Kurihara cities, northern of Miyagi Prefecture are obtained from the damage data provided by the local City Offices. Ground motions in these subdistricts are estimated by use of source model proposed by Kurahashi and Irikura (BSSA, 2013) and underground velocity structures identified from microtremor H/V spectral ratios. The estimated ground motion indices (PGA, PGV, I_{JMA}, and SI) are used to relate with the damage ratios to construct the fragility curves. It is found that the correlation in small subdistricts is improved, compared with that between the observed ground motion indices and corresponding damage ratios in a wider district.

In addition, we have added some microtremor measurement at plural sites inside each subdistrict, such as Furukawa, and Tajiri, in order to assess the representativeness of ground motions estimated at only one site for the entire subdistrict. We conducted such measurement at or near the preliminary schools inside the subdistricts. The ground motions during the mainshock are estimated with the identified velocity structures from the microtremor H/V spectra ratios. It is found that the variability of ground motions in the Furukawa subdistrict is relatively small. It suggests that the ground motions used for the fragility curves are representative for the entire subdistrict. In contrast, the variability of ground motions in Tajiri is relatively large. It may be caused by the limited numbers of preliminary schools with similar amplification factors.

The earthquake vibration observation of the Yasuda auditorium using the IT Kyoshin seismometer

ITO, Takamori[1*] ; TAKANO, Kiyoshi[2]

[1]Keio University, [2]lll&ERI, The University of Tokyo

In order to reduce the seismic disaster, it seems to be the usefulness to investigate the seismic vibration of our familiar buildings such as housing, companies, schools, etc. in small earthquake, examine the weak point and improve the earthquake resistance of these building effectively. For this purpose, we devised IT strong motion seismometer as a new type self install strong motion seismometer.

With this IT Kyoshin seismometer, we continue the vibration observation of some buildings in University of Tokyo from 2006.

The repair work of the Yasuda auditorium will be carried out. We install the IT Kyoshin seismometer and will observe it to confirm an effect of the construction.

We used the high-performance sensor and, in addition to a low cost standard IT Kyoshin seismometer, observed it.

We finish observation before the construction and analyze data now.

After construction was completed, we install the IT Kyoshin seismometer again and are going to compare it.

The effect of torsional and bending vibration on shear-wave velocity extracting from building response by seismic interf

WANG, Xin[1*] ; MOTOSAKA, Masato[1] ; MASAKI, Kazuaki[2] ; IRIKURA, Kojiro[3] ; HISADA, Yoshiaki[4]

[1]International Research Institute of Disaster Science,Tohoku University, [2]Department of Urban Environment, Aichi Institute of Technology, [3]Disaster Prevention Research Center, Aichi Institute of Technology, [4]Department of Architecture, Kogakuin University

Because shear-wave velocity correlates with the shear rigidity of buildings, the decrease of it is a indicator of the loss of stiffness, which is possibly caused by structural damage or degradation. Therefore, shear-wave velocity identification is intended for use in health monitoring of upper structures excluding the effect of soil-structure interaction. Shear-wave velocity can be extracted from tracing the propagation of a pulse from normalized cross-correlation of the motion between two points based on the view of response as the wave vertical propagation process. In this study, the reference point is the top of the building (virtual source) instead of the base (physical source) which results in the transfer function including the effect of rigid-body rocking. However, for high-rise and eccentric structures torsional motion and bending motion is inevitable. In practical measurement of horizontal motions with single sensors located on the side not the core of the building plane, it is unavoidable to record the torsional response which mixed with the shear-mode motions. Therefore, the effect of torsional response to shear-wave velocity extraction should be deliberated on to avoid erroneous use of the travel time of torsional wave instead of that of shear wave. Furthermore, the extraction of shear-wave propagation from building vibration generally in bending mode is valid or not should be examined.

In this study, firstly a 3D model with eccentricity is used to calculate the horizontal and vertical impulse response to analyze the effect of torsional and bending response to shear-wave velocity extraction. And the method to eliminate the effects of torsional and bending vibrations to obtain the shear-wave propagation with high resolution is presented. Secondly, a practical use of earthquake records measured in a high-rise building to examine the effect of torsional and bending vibration to shear-wave velocity extraction. Thirdly, velocities of shear wave, torsional wave, and bending wave are extracted separately to evaluate the changes of stiffness before and after the Tohoku earthquake for health monitoring.

Global ”strong” ground motions from the 2013 Sea of Okhotsk great deep earthquake

KUGE, Keiko[1*]

[1]Dept. Geophsyics, Kyoto University

This study presents the characteristics of global ground motions caused by the Sea of Okhotsk deep earthquake (Mw8.3) of May 24, 2013. The earthquake occurred at a depth of 609 km in the subducting Pacific plate, and it is now the largest deep earthquake ever recorded. According to reports in NEIC, the earthquake was felt at very long distances in the world, including Dubai (˜76 degrees) and Moscow (˜58 degrees). In this study, by using global broadband seismic data from IRIS DMC, we examine ground motions from the earthquake. For the 1994 Bolivia deep earthquake (Mw8.3), which was formerly the largest and were felt in North America, the distant ground motions were examined by Anderson et al. (1995) from the perspective of strong motion seismology. Due to the location, the 2013 Sea of Okhotsk earthquake was recorded by a much better coverage of global stations, compared to the 1994 Bolivia earthquake. This study is an opportunity for exploring the distant ”strong” ground motions from the perspective of Anderson et al. (1995).

Peak ground accelerations (PGA) from the 2013 Sea of Okhotsk earthquake decrease as distance increases out to 120 degrees, and have a peak at a distance of approximately 140 degrees. The variation as a function of distance is similar to that of Anderson et al. (1995) for the 1994 Bolivia earthquake. The values of PGA are a few times larger than those from the Bolivia earthquake. At distances between 30 and 80 degrees, PGA are associated with vertical components of direct P waves, and the values of PGA are often in a range from 0.1 to 1 gal. Peak ground velocities (PGV) vary with distance in a similar way to PGA. The values of PGV at distances between 30 and 80 are lower than 0.1 cm/s.

Large PGA at distances between 30 and 80 degrees are observed in the Eurasian continent. The values of PGA in the western part of the continent are larger than those in the eastern part. Because this difference is also observed for PGA of P waves from an outer-rise shallow earthquake near the Kurile trench, it can be attributed to regional structure in the Eurasian continent. PGA from the 2013 deep earthquake are not low in the southern part of the continent, although from a deep earthquake beneath Sea of Okhotsk that has a different focal mechanism from that of the 2013 earthquake, PGA decrease toward the south as distance increases. The focal mechanism of the 2013 earthquake represents that the P wave radiation is the maximum along a ray toward Karachi, Pakistan. This P wave radiation can account for the observations of PGA in the southern part. Global ”strong” ground motions from the 2013 Sea of Okhotsk deep earthquake are thus likely to be affected by regional structure and P wave radiation, as suggested by Anderson et al. (1995).

Relation between smallest microtremor amplitudes and largest seismic amplitudes observed at TRIES seismographic stations

TANAKA, Torao[1*] ; OKUBO, Makoto[2]

[1]Kyoto University Emeritus Professor, [2]Tono Research Institute of Earthquake Science

In 1999 TRIES, Tono Research Institute of Earthquake Science, started to establish an observation network of seismographic stations in Tono district, the eastern area of Gifu Prefecture, and completed a 10 stations network at the end of the year. The seismographic station TRIES was the first station, and 9 stations, TOGARI, ENA, MIZUNAMI, AKECHI, IWAMURA, NATAKI, MITAKE, TOKI and INUYAMA were established one by one. In order to investigate the correlation between the smallest spectral amplitudes of microseisms and largest seismic spectral amplitudes, we started spectral analysis of microtremors and seismic waves recorded on the same seismograms. By the discrete Fourier transform we calculated the spectral amplitudes and frequencies from the observed microtremors recorded just before the first arrival of seismic waves in the frequency range from 2.0 to 4.0 Hz. Similarly we calculated the spectral amplitudes and frequencies of seismic waves by the discrete Fourier transform in the frequency range from 2.0 to 4.0Hz. We calculated the ratios of the relative amplitudes of the smallest amplitude of microtremors and largest amplitude of seismic waves to those at the station TRIES. By taking the relative amplitudes of micro tremors and largest seismic amplitudes to those at TRIES we can extract the relative site effects caused by the ground soil to those at TRIES. Since the site effect at TRIES is small, the relative largest seismic amplitudes at TOGARI, for example to those at TRIES simply give multiples of the amplitude at TRIES, at each station. Preliminary results show that the smallest amplitude of microtremors will give the spectral amplitudes of the site effect that will amplify the incident seismic waves from the underlain basements.

A study on model selection methods for ground-motion prediction equations using synthetic data

NODA, Akemi[1*] ; WU, Changjiang[2] ; SI, Hongjun[3] ; SAIJO, Yusuke[1] ; JIAO, Ning[1]

[1]Kozo Keikaku Engineering Inc., [2]Japan Nuclear Energy Safety Organization, [3]Earthquake Research Institute, University of Tokyo

Numerous ground motion prediction equations (GMPEs) have been proposed for the purpose of assessing seismic hazard. However, a critical problem is that how to select appropriate GMPEs for the application of GMPEs to practical engineering problems.

Recently some model selection methods for GMPEs that evaluate the agreement between observed and predicted data have been proposed. In present study, in order to check the properties of model selection methods, we compare the model selection methods by using artificial dataset generated by a known GMPE. As candidate model selection methods, we have chosen three methods, that is, analysis of root mean square residual (RMR), the log-likelihood method (LLH method, Scherbaum et al., 2009, BSSA) and the Euclidean distance-based ranking method (EDR method, Kale and Akkar, 2013, BSSA). The analysis of RMR is one of the simplest methods to evaluate the difference between observed data and medians of GMPE model. On the other hand, the LLH method quantifies the distance between observed data and GMPEs defined as probability density function (both of median and standard deviation), based on information-theoretic perspective. However, Kale and Akkar (2013) points out the problem that the LLH method may favor GMPEs with larger standard deviations. The EDR method considers not only ground-motion uncertainty of model through standard deviation, but also agreement between the median estimations of models and observed data trend (model bias).

First, we assumed a vertical strike-slip fault with moment magnitude 7.0. We randomly chose 200 sites, whose fault distances are up to 200km. Next, we calculated theoretical PGA and response spectral acceleration for 16 periods using ground motion prediction model of Chiou and Youngs (2008, Earthq. Spectra), which is referred to as CY08 hereafter. And, we generated three kinds of synthetic dataset by adding three types of random noise with (1) zero standard deviation, (2) standard deviation of CY08, and (3) twice the standard deviation of CY08, respectively.

We selected five candidate GMPEs, that is, CY08, Abrahamson and Silva (2008, Earthq. Spectra), Campbell and Bozorgnia (2008, Earthq. Spectra), Zhao et al. (2006, BSSA) and Kanno et al. (2006, BSSA), and ranked the performance of candidate GMPEs for each synthetic dataset. In analysis of RMR that does not account for standard deviations of the prediction models, CY08 is stably ranked the best performing model for all kinds of synthetic dataset. The LLH method basically ranked CY08 as the best performing model for synthetic dataset (1) and (2), but it favored GMPEs with larger standard deviations for synthetic dataset (3). It suggests that the standard deviation of model is emphasized more than the median when we apply the LLH method to poor quality data. In the EDR method, in principle, the parameter to measure the level of model bias of CY08 is not able to be calculated for synthetic dataset (1) that does not have random noise. For synthetic dataset (2) and (3), however, the EDR method ranked CY08 as the best performing model both in the point of view of model uncertainty and model bias.

Seismic hazard assessment using a new ground motion prediction equation

MORIKAWA, Nobuyuki[1*] ; FUJIWARA, Hiroyuki[1] ; OKUMURA, Toshihiko[2] ; FUJIKAWA, Satoshi[2]

[1]National Research Institute for Earth Science and Disaster Prevention, [2]Shimizu Corporation

In the ”National Seismic Hazard Map for Japan” by Headquarters of Earthquake Research Promotion of Japan, seismic hazard is evaluated by the ground motion prediction equation (GMPE) of peak velocity by Si and Midorikawa (1999), and conversion from peak velocity to seismic intensity by using an experiential relation. It is indispensable that earthquakes of moment magnitude (Mw) 9 class take into consideration in the present seismic hazard evaluation. However Si and Midorikawa's (1999) equation is obtained from strong motion records of earthquake up to Mw 8.3. In this study we evaluate seismic hazard by using our new GMPE obtained by using strong-motion database including the records of the 2011 Tohoku earthquake and show the comparison it with the National Seismic Hazard Maps for Japan.

The target strong-motion parameters are peak velocity on an engineering bedrock (here, it is considered as the upper surface of Vs=400 m/s layer), and peak velocity and JMA seismic intensity on the ground. The value on the ground is calculated by using the amplification factor obtained from the average S-wave velocity up to 30 m depth based on the 250m-mesh national geomorphologic classification map.

First, we compare the ground motion distributions calculated from two GMPEs. Here we target following 6 assumed earthquake. (1) crustal earthquake on the Itoigawa-Shizuoka fault zone (Mw7.4), (2) crustal earthquake on the Muikamachi fault zone (Mw=6.6), (3) subduction-zone plate-boundary earthquake at Nankai Trough (Mw=9.1), (4) subduction-zone plate-boundary earthquake at Tokachi-oki reigion (Mw=8.1), (5) subduction-zone shallower intra-plate earthquake at Chishima trench region (Mw=8.2), and (6) subduction-zone deeper intra-plate earthquake at Chishima trench region (Mw=7.5). Amplification by the deep sediments layers can be obviously seen in our new result of peak velocity distribution. As the result, amplitude in our new result becomes larger in basin region and smaller in mountain region. On the other hand, the influence of the deep sediments is not so remarkable in result of JMA seismic intensity on the ground. The calculated value from our new GMPE is smaller in the distance area (in general 100 km or more) for subduction-zone earthquakes. Midorikawa and Ohtake (2002) pointed out that Si and Midorikawa's (1999) GMPE overestimates the peak values in distant region earthquake whose focal depth is deeper than 30 km. Our results are consistent with them.

Next, we compare the seismic hazard for the megathrust earthquake occurring at the Nankai Trough. Here we use the model in probabilistic seismic hazard maps by HERP (2013).

Moreover, we use the value of variance in the National Seismic Hazard Maps for Japan as it is. The hazard by our new GMPE decreases especially at the distant area as expected from comparison of above-mentioned strong-motion distribution. However, the decrease does not serve in Kanto and Osaka area where amplification by deep sediments is large. On the contrary, JMA seismic intensity is larger when exceedance of probability is lower at some points. This is considered that that the value of the set-up variation is not in agreement for JMA seismic intensity has influenced.

On March 11, 2011, a huge earthquake hit the eastern part of mainland Japan. The earthquake caused a huge tsunami that killed more than ten thousand people. Structures were also severely damaged over the area of eastern Japan by the tsunami, ground motions, liquefaction, and so on. We focus on the Furukawa district of Osaki City, where severe residential damages occurred downtown. Ground motion records in the downtown area are available at two stations, MYG006 (K-NET) and JMA Furukawa (JMA). The damage level was different between the areas within several hundred meters from the MYG006 and JMA Furukawa stations, which are about 1km away from each other. The severe damages were concentrated within the area approximately 1x1km2 including the JMA station. This implies that the ground motion characteristics were not uniform in sub-kilometer scale, and the existing two stations are not enough to clarify the damage distribution (Goto and Morikawa, 2012).

In aftermath of the earthquake, we distributed dozens of low-cost seismometers, namely ITK sensor, around the area about 3x2km^2 in the Furukawa district (Goto et al., 2012). The observed data are sent to the remote server through internet connection in real time. The seismometers were installed beside the volunteers' houses. The volunteers can access the interactive information service, namely on-line viewer system. The observed PGA and PGV values show significant spatial variability that may be correlated to the structural damage caused by the major 2011 event.

We assumed one-dimensional horizontally-layered structure just beneath the stations and estimated ground structure by using the records based on the observation. The results indicate that the area where the severe damages were concentrated is related to the area with the thicker surface layers. The distribution is also indicated by the results obtained from gravity anomaly data.

Physics-based decomposition of ground amplification using ground transfer function expansion

GOTO, Hiroyuki[1*]

[1]DPRI, Kyoto University

Amplification of earthquake ground motions at actual deposit sites is an important factor to consider when assessing the risk of an earthquake disaster. In order to identify the amplification properties, several preprocessings such as the Fourier transform are required. I propose a series expansion of the amplification with simple ground transfer functions as a new preprocessing. I define a sequence of transfer functions based on a two-layered structure excluding an internal damping, and a function space spanned by the set of the functions. I mathematically prove that the function space is equal to L2 space. This indicates that all the functions belonging to L2 space, i.e., an arbitrary ground amplification, have a unique series expansion.

In practice, the expansion requires the observed ground amplification. It is directly observable from the spectral ratio of the Fourier spectra at the target site to that at a reference rock site (Goto et al., 2013). When the observations are available, the expansion is applicable even for the site response including a 3D basin effect as the preprocessing, whereas it requires a more precise investigation of what the extracted components physically means for the general cases.

I apply the series expansion to the physics-based decomposition of the amplification. The results indicate that the contribution from the given bases can be represented by the absolute value of their coefficients. The contribution may enable direct quantification of the similarity of models. This property potentially has wide applications, e.g., spatial interpolation of the amplifications from the sites where they are reliably determined, stochastic modeling of the amplification as a mixed state of the fundamental simple states, etc. The detailed application is currently under way.

Case study on the wavefield in the 3D structure including sedimentary basin and the effect of source depth on it

ARISUE, Maho[1] ; KAKEHI, Yasumaro[1*]

[1]Faculty of Science, Kobe University

It is widely recognized that the existence of sedimentary layers has a great influence on the excitation of surface waves. During the 2011 Fukushima-ken shallow inland earthquake (Mw 5.5, depth = 10.6 km), long-period surface wave was observed at a station in the Niigata sedimentary basin, which is over 150 km away from the epicenter, and its duration reached over 100 s. Long-period surface wave was observed also during the 2012 Fukushima-ken-oki deep interplate earthquake (Mw 5.7, depth = 53 km) at the same station, and its duration reached ˜100 s. Thus, significant difference was not seen between the surface wave duration in the Niigata basin of these two earthquakes despite of large difference of their source depths. This seems inconsistent with the recognition that surface wave is more efficiently excited by shallower source.

This study investigates the effect of source depth on the seismic wave filed in the sedimentary basin based on the numerical simulation using finite difference method for shallow and deep sources. The calculation area is from off the Fukushima Prefecture to the Niigata basin, and the following three simulations are performed.

In the simulation 1, a simple structure model composed of circular homogeneous sedimentary basin and background two-dimensional structure, two cases of source depths: 5 km and 85 km, and source duration of 3 s are assumed. The result shows the duration of the surface wave in the sedimentary basin is ˜50 s for the both shallow and deep sources, and large difference is not seen the two different source depth cases. At the station prior to the basin, wave duration for the shallow source is ˜10 s longer than that for the deep source. This difference of 10 s is shorter than the long duration of 50 s in the sedimentary basin, and this can explain the result that large difference is not seen in the basin.

In the simulation 2, a simple structure model composed of circular homogeneous sedimentary basin and background two-dimensional structure, as in the simulation 1, is assumed, and the case study on the material property values of the homogeneous basin is done. Two cases of source depths: 5 km and 75 km, and source duration of 3 s are assumed. The result shows longer duration of seismic waves is seen in the basin for smaller value of S-wave velocity of the basin medium (˜125 s for Vs = 0.5km/s, ˜90 s for Vs = 1.0 km/s, and ˜40 s for Vs = 2.0 km/s). This is interpreted to be because of larger arrival time difference of S-wave and surface wave for smaller S-wave velocity of the basin.

In the simulation 3, realistic complex three-dimensional structure model is assumed both for the sedimentary basin and for the background structure. We use the three-dimensional model by Koketsu et al. (2012), two cases of source depths: 5 km and 75 km, and source duration of 3 s. Long wave duration of ˜90 s is obtained both for the shallow and deep sources. The maximum amplitude at the station is the sedimentary basin is ˜2 times (for the deep source) and ˜6 times (for the shallow source) larger than that at the station prior to the basin.

Comparing the result of the realistic three-dimensional model case (simulation 2) and that of the simple structure model case (simulation 2), more complex and more continuous wave-packet with long duration is seen in the basin in the former case than that in the latter case. On the other hand, siginificant difference is not seen in the amplitude and duration at the station prior to the basin, both for the shallow and deep sources. This result suggests the wavefield in the sedimentary basin is mainly affected by the basin structure itself, rather than the structure model of the path from the source to the basin.

Surface wave propagation in the large-scale sedimentary basin: distinct lateral variation of Love wave velocity around m

TAKEMURA, Shunsuke[1*] ; YOSHIMOTO, Kazuo[1]

[1]Yokohama City University

By detailed analysis of surface waves recorded at dense seismic arrays in Kanto, sudden change of Love wave velocity for frequency of 0.125-0.25 Hz is found at very narrow, 20 km by 20km, region of southern Saitama.

To clarify cause of such sudden change and characteristics of surface wave propagation in thick sediments, we conducted 3D FDM simulations of seismic wave propagation assuming various basement structure (interface between sediments and bedrock) or velocity structure models in the sediments. Our simulations demonstrated that propagation velocity of Love wave is mainly controlled by shallower velocity structure at depth less than 1.5 km, rather than deeper basement structure. Our results were supported by the analysis of sensitivity kernel of Love wave in the sediments.

We constructed S-wave velocity structure in the sediments of Kanto basin using interpolation technique from 14 boreholes VSP measurements and surface wave analysis in this study. To confirm validity of our modeling, we conducted 3D FDM simulations of seismic wave propagation using constructed velocity structure and compared simulation results with observation. Our simulation results well reproduced peak amplitude and propagation velocity of Love wave for frequency of 0.125-0.25 Hz. Our results indicates that realistic modeling of shallower velocity structure and impedance contrast at the sediments-bedrock interface is important for precise evaluation of long-period ground motion in thick sedimentary basin.

Acknowledgement

We acknowledge the National Research Institute for Earth Science and Disaster Prevention, Japan (NIED) for providing the K-NET/KiK-net waveform data. We also use strong motion data from SK-net. The computations were conducted on the Earth Simulator at the Japan Marine Science and Technology Center (JAMSTEC).

Long-Period Ground Motion Simulation in the Kanto Basin with/without Accretionary Prism

GUO, Yujia[1*] ; KOKETSU, Kazuki[1] ; MIYAKE, Hiroe[1]

[1]Earthquake Research Institute, University of Tokyo

Large earthquakes in subduction zones generally excite long-period seismic waves. Once these waves enter into basins filled with thick sedimentary layers, they develop and result in largely-amplified long-period ground motions. Such long-period ground motions have caused damage to large-scale buildings during some earthquakes. For the 2003 Tokachi-oki earthquake (M_w 8.3), long-period ground motions with a dominant period of 7-8 seconds were observed in the city of Tomakomai, located on thick sedimentary layers and at a distance of about 250 km from source region. The long-period ground motions triggered the sloshing in many oil tanks, and two of them caught fire (Koketsu *et al.*, 2005). For the 2011 Tohoku earthquake (M_w 9.0), long-period ground motions were observed at a large distance from source region such as the Osaka and Kanto basins, where some tall buildings shook over about 10 minutes (JMA, 2011).

The large earthquakes along the Nankai trough which are expected to occur in the near future can generate long-period ground motions in the Osaka, Nobi and Kanto basins (Furumura *et al.*, 2008). Along the Nankai trough, a accretionary prism composed of soft materials with a thickness of several kilometers lies near the toe of the Eurasian plate. Such prism does not exist at the Japan or Kuril trench. For this reason, in evaluating the long-period ground motions during the large earthquake occurring along the Nankai trough, we should consider the additional effect of accretionary prism on seismic waves. Yamada and Iwata (2005) simulated long-period ground motions for the Kinki region, and concluded that the existence of accretionary prism reduces the amplitudes of direct S-waves and elongates long-period ground motions. In this study, we performed simulations of the long-period ground motions in the Kanto basin for the foreshock (M_w 7.1) of the 2004 off the Kii peninsula earthquake on 5 September at 19:07 (JST) in order to examine the effect of accretionary prism.

In the simulation, we assumed a point source. Except its depth, its source parameter and source time function were the same as those of Yamada and Iwata (2005). We located the source at a depth of about 16 km, which is slightly shallower than that of Yamada and Iwata (2005), to fit it to the depth of the subducting Philippine Sea plate. We used the Japan Integrated Velocity Structure Model (Koketsu *et al.*, 2008, 2012). We calculated long-period ground motions using the finite element method with voxel meshes (Ikegami *et al.*, 2008). The frequency range of the calculation was 0.05-0.3 Hz, and the time duration of synthetic waveforms was set to be six and a half minutes from the rupture starting time. Our simulation model covered an area of 564 km$\times$198 km and extended to a depth of 61 km. An absorbing boundary with a width of 54 km was also introduced outside the simulation model. According to the velocity structure, the model was discretized by variable voxel meshes with the smallest size of 175 m. We also assumed a velocity structure model without accretionary prism, where the S-wave velocity of accretionary prism (1.0 km/s) is replaced with 3.2 km/s. Then, we calculated waveforms in this model and compared them with those in the accretionary-prism model to examine the effect of accretionary prism.

Our simulation shows that, compared with the velocity structure model without accretionary prism, the long-period ground motions for the accretionary-prism model have smaller amplitudes for direct waves but larger ones for later phases. Our results are consistent with those by Yamada and Iwata (2005). In the accretionary-prism model, the waves trapped in the accretionary prism are continually converted to surface waves, and the incident surface waves to the Kanto basin propagate in the basin. We confirm that this process contributes to the reduction of direct waves and the amplification of later phases in the Kanto basin.

Semblance analysis for the 2011 Tohoku earthquake using strong-motion and 1Hz GPS data

KUBO, Hisahiko[1*] ; IWATA, Tomotaka[1] ; ASANO, Kimiyuki[1]

[1]DPRI, Kyoto Univ.

Source inversion is well used for the analysis of the earthquake source-process. However in the source inversion some assumptions and constraint conditions are used and there are cases where the settings of these affect the result. On the other hand, array analysis can produce the direct image for the seismic-wave radiation. In this analysis, we investigate the seismic-wave radiation characteristics for the 2011 Tohoku earthquake with the semblance array analysis using strong-motion and 1Hz GPS data.

We use not only the strong-motion data recorded by K-NET, KiK-net, and F-net of NIED and JMA but also 1 Hz GPS data recorded by GEONET of GSI. Additional use of 1 Hz GPS data leads to increase the station density and therefore the number of the available arrays increased remarkably compared to previous work (Kubo & Kakehi, 2013). Except for F-net data, the strong-motion acceleration waveforms are integrated into velocity waveforms. 1Hz GPS data is converted into displacement waveforms using Kinematic PPP as implemented in RTKLIB Ver. 2.4.2 (Takasu, 2013) and they are differentiated into velocity waveforms. These waveforms are bandpass-filtered from 10s to 25s and resampled with a sampling interval of 0.1s. From the comparison of the observed velocity waveforms for the 2011 Tohoku earthquake at the GEONET and strong-motion stations which distance is less than 3 km, we confirmed that the waveform of 1Hz GPS data matches one of strong-motion data at above period-band.

We use the same method of the semblance analysis in Kubo & Kakehi (2013). In this method, we firstly assumed the fault surface model consisting of some subfaults. Then the semblance value for each subfault is calculated assuming spherical-wave incidence when the subfault is the seismic-wave radiation source, and these values are plotted on the fault surface. By doing this analysis with time shift, we can obtain temporal change of the seismic-waves radiation source on the fault surface. The incident waves are assumed to mainly consist of S-wave because the estimated apparent velocity through the semblance analysis assuming plane-wave incidence is approximately 4 km/s and it don ' t have the dispersion. As the velocity structure model for the calculation of the travel time, we use one-dimensional velocity structure model in Asano & Iwata (2012). In this analysis, we constructed nine arrays at Tohoku and Kanto regions, and estimated the snapshot of semblance images at each array for 250s after the synthetic S-wave onset, which is comparable to the rupture starting time. The time length for semblance calculation is 20s and the time shift is 10s. The semblance value is obtained by averaging the three semblance values of the three-component waveforms.

The semblance images at the arrays north of 39^{o}N are different from ones at the arrays south of 39^{o}N. The images at the former arrays demonstrate that the seismic waves were strongly radiated from off Miyagi up to approximately 150s and that then the seismic waves were continued to be weakly radiated from off Miyagi. On the other hand, the images at the latter arrays demonstrate that the duration time of the seismic-wave radiation from off Miyagi is approximately 100s, that subsequently the radiation source moved to off Fukushima and Ibaraki, and that its radiation continued up to approximately 180s. This image difference indicates that the seismic-wave radiation area for the 2011 Tohoku earthquake extended to south approximately 100s after the rupture start and that off Miyagi radiated the seismic-waves during long time (~200s). We will also investigate the spatial variation for the seismic-wave radiation source along dip direction.

[Acknowledgments] The strong-motion data recorded by K-NET, KiK-net, and F-net of NIED and JMA and the 1Hz GPS data recorded by GEONET of GSI were used for this analysis.

Stochastic green function considering 3-D Qs structure-Predicting ground motion of the 2011 Tohoku Earthquake-

NAKAMURA, Ryoichi[1*] ; UETAKE, Tomiichi[2] ; HIKIMA, Kazuhito[2]

[1]Tokyo Electric Power Services Co.,Ltd., [2]Tokyo Electric Power Company

We have developed a method to simulate strong ground motions by combining the stochastic green function (SGF) and 3-D attenuation effects.

The calculation procedures of our method are as follows.

(1) To give Source spectra for sub-fault events.

(2) To calculate basement spectra considering 3-D Qs structure.

(3) To calculate ground surface spectra by multiplication of the site factors to basement spectra.

(4) To make time history of ground motions using ground surface spectra and envelope function (Boore, 1983).

(5) To create main shock ground motion by superimposing the ground motions from sub-fault events considering lapse time: ex. fault ruptures. (Kamae et al.,1991)

In this study, we reproduced strong motions of the 2011 Tohoku Earthquake (M9) by using this method. The fault plane of the 2011 Tohoku Earthquake was divided into 10∗10∗10 element faults planes, and seismic moment of Mo=4E+25 Nm and stress drop 25 MPa are given to the elements uniformly. Target sites to evaluate are ground surfaces of the K-NET and the KiK-net observation stations. The 3-D Qs model and site amplification factors estimated by Nakamura (2009) were used in this study. To show validity of this method, we compared calculation results by using the 3-D Qs model with by a uniform Qs model; $Qs=100f^{1.00}$.

The standard deviation of the logarithmic residual of PGA from the 3-D Qs model is 0.224 and that from the uniform Qs model is 0.231 for the stations with PGA>100Gal and the values are 0.253 and 0.360 respectively for the stations with PGA>1Gal. The difference was more significant for longer epicenter distance area. The response spectra calculated from the uniform Qs model are underestimated in the long distance areas, ex. Kinki and Hokkaido, whereas the response spectra using the 3-D Qs model were well reproduced the observed ones. Seismic wave spreads in deeper part for longer distance travels without attenuating. It is necessary to consider the three-dimensional Qs structure in evaluating the ground motion distribution in a broad area.

We tried to use the complex source model with SMGA. The model with five SMGA segments (Kurahashi and Irikura, 2011)) was adopted for calculation. The waveforms calculated from the uniform source model are like spindle shape generally, but the waveforms from the SMGA model are divided into several wave groups of the corresponding to individual SMGA especially for observation points close to the source. The SMGA model could explain well the observed record shape.

Estimation of Strong Motion Generation Area during the 2008 Iwate-Miyagi Nairiku earthquake using broadband strong groun

KURAHASHI, Susumu[1*] ; IRIKURA, Kojiro[1]

[1]Aichi Institute of Technology

1.Introduction

The 2008 Iwate-Miyagi Nairiku earthquake was an Mw6.7 reverse-fault crustal earthquake that occurred at Iwate prefecture, Japan. Surface ruptures associated with the earthquake were found to distribute near the eastern edge of the southern part of the aftershock zone. Strong ground motions were observed at three stations very near the fault area in addition to the Kik-net and K-NET stations. It is important that strong motion generation areas are estimated using broad-band ground motions to find out the source mechanism generating low-frequency ground motions as well as high strong ground motions.

In this study, we attempt to determine the strong ground motion area (SMGA) of the 2008 Iwate-Miyagi Nairiku earthquake using the broad-band ground motions from the earthquake.

2. The previous studies of the source model for strong ground motions

We presented the SMGA model of this earthquake by forward modeling using the empirical Green's function method by Irikura (1986) in 2008 and 2013.

The model we presented in 2008 was determined to reproduce the observed waveforms around the fault area of the mainshock. We found the first SMGA was located coinciding with large slip area in the southern part of the fault plane obtained by several authors from the waveform inversion analyses using teleseismic body wave data. We clarified to require one more SMGA in the northern part from the hypocenter. However, we realized that the location and geometry of the fault plane we assumed are not so accurate enough according to the aftershock distribution determined from temporary aftershock observation network deployed just after the occurrence of the earthquake (Okada et al., 2012).

We reanalyzed the SMGA model in 2013 using the fault plane determined by the aftershock distribution from the high dense network. In particular, we attempted to simulate the strong ground motions at IWTH25 located very near the fault plane. We obtained one of the best-fitting SMGA models from which simulated and observed ground motions agreed well including the ground motions at a very-near-field station IWTH25. However, it shall be examined whether this model can explain the broad-band ground motions at other near-field stations.

3. Estimation of SMGAs for broadband strong ground motions

In this study, we try to estimate the SMGAs using not only the strong motion records at IWTH25 but other near-field stations, Aratozawa Dam. The observed records at Aratozawa Dam show distinctive strong-motions. This suggests that one of the SMGAs possibly exists near Aratozawa Dam site. On the other hands, the observed records at Aratozawa Dam may have near-field-terms because of very-near-fields from the source area. Therefore, in order to reproduce the mainshock waveform we need to use the empirical Green's functions including the near-field terms, that is ground motion records from an element earthquake occurring very near a source in the fault area. When there is no element earthquake satisfying the near-field condition mentioned above, we use the hybrid Green's functions that have low frequency motions theoretically simulated and high frequency motions empirically obtained. We have no aftershock records at the Aratozawa Dam sites. Therefore, we attempt to simulate the broad-band strong motions at Aratozawa Dam site using only numerically calculated Green's functions to precisely estimate the SMGAs.

Source Model and Strong Ground Motion Simulation for the 2013 Northern Tochigi Prefecture, Japan, Earthquake

SOMEI, Kazuhiro[1*] ; MIYAKOSHI, Ken[1] ; IRIKURA, Kojiro[2]

[1]G.R.I., [2]A.I.T.

On February 25, 2013, an inland crustal earthquake (M_{JMA}6.4, Strike-slip type) occurred in the northern Tochigi prefecture, Japan. Strong ground motions with a peak acceleration of 1225 cm/s^2 and a peak velocity of 39 cm/s were recorded at one of the nearest strong motion stations, TCGH07, about 5 km away from the hypocenter. Maeda and Sasatani (2009) showed that a similar large ground motion of 1100cm/s^2, 75cm/s at HKD020 during the 2004 South Rumoi district, Hokkaido, Japan, inland crustal earthquake (M_{JMA}6.1, Dip slip type) is mainly attributable to the source effect, short distance from the strong motion generation area (SMGA) and the forward directivity effect. To investigate how large ground motions at TCGH07 from a source's point of view, we estimate the source model based on the two different approaches.

First, we employ the multi-time window linear waveform inversion method (Sekiguchi et al., 2000) by using the 15 strong motion waveforms (0.1-1.0Hz) recorded by K-NET, KiK-net near the source. A finite extent of the fault plane is assumed referring to the aftershock distribution and moment tensor solution determined by F-net. The fault plane is divided into 84 subfaults of 1.0 km $\times$ 1.0 km. The temporal moment release history from each subfault is expressed by a series of 6 smoothed ramp functions with a rise time of 0.6 sec separated by 0.3 sec. The first time window triggering velocity (FTWTV) was 2.4 km/s. The rise time and FTWTV are given by the smallest misfit solution. The weight of the spatio-temporal smoothing constraint value for inversion was determined based on Akaike's bayesian Information Criterion (ABIC). The velocity structure model for each strong motion station is improved by the downhill simplex method (Nelder and Mead, 1965) using the receiver function. The theoretical Green's function is calculated by using the discrete wavenumber integration method (Bouchon, 1981) with the reflection and transmission matrix (Kennett and Kerry, 1979). To validate the improved velocity structure models, we simulate the aftershock records with a point-source approximation.

The derived rupture model has a large slip area whose maximum slip of 0.98 m in the vicinity of the hypocenter. The rupture mainly propagated from the hypocenter toward the shallower northern part. Seismic moment of the estimated model is 6.67$\times$10^{17}Nm (M_w 5.8). From the contribution of the large slip area to the synthetic waveforms for TCGH07, we find both the SH-wave radiation pattern from the strike-slip fault source and the forward directivity effect toward TCGH07 mainly yield the large pulse velocity waveform (0.1-1.0 Hz) at TCGH07.

Second, the source model is constructed based on the forward simulations using the empirical Green's function method (Irikura.1986) in the frequency range 0.3-10 Hz. One rectangle SMGA is estimated to include the rupture start point, i.e., the hypocenter of the mainshock. The rupture of this SMGA mainly propagates from the hypocenter to shallow side for dip direction, and also propagates to the northward for strike direction. The obtained source model explains the observed acceleration, velocity, and displacement waveforms of this event in the broadband frequency range fairly well. As same as the result from waveform inversion (0.1-1.0 Hz), we also see the large pulse velocity waveform is caused by the forward directivity effect toward TCGH07.

Consequently, we concluded that the main factors generating large pulse velocity waveform at TCGH07 are as follows: 1) the SH-wave radiation pattern from the strike-slip fault source and 2) the forward directivity effect along dip direction toward TCGH07.

Source process of the Feb. 25, 2013 Tochigi Hokubu Earthquake (M 6.3) [2] -Analyses using Empirical Green's Functions-

HIKIMA, Kazuhito[1*]

[1]Tokyo Electric Power Company

INTRODUCTION

An M6.3 earthquake occurred in the northern part of Tochigi prefecture on February 25, 2013. A high acceleration strong motion, over 1 G, was observed at the TCGH07 (Kuriyama-west) of KiK-net, which is situated close to the source region. To explain the reason why such strong acceleration was observed, the author has made the studies using the source process analysis and spectral inversion method to separate site and path effects. However, in the source process inversion, it is difficult to calculate accurate theoretical Green's functions in good enough level, because of the difficulty of making accurate subsurface structures. Consequently, the degree of coincidence between observed and calculated waveforms was not so good.

To overcome such the drawbacks in the source process inversions, the author uses the observed waveforms from a small earthquake as empirical Green's functions (EGF) in this study.

FAULT MODEL and OUTLINE of ANALYSES

Tentative analyses are performed with same fault geometry with Hikima (2013, SSJ fall meeting). The fault model was made using the relocated hypocenters, determined by the DD method, and the F-net mechanism solution. The strike direction is NNW-SSE (165 degree in strike, 80 degree in dip). The fault plane is divided in 1km size for the inversion.

The source process is inverted by the multi time window analysis (Yoshida *et al*. (1996), Hikima (2012)). The velocity waveforms, filtered between 0.03 and 1.5Hz, are used in the inversion analyses. The waveforms at TCGH07 are not used in the inversion, because the station is too close from the fault plain. Only the transverse components are used in this study, to weight the S-wave portion of the waveforms. The waveforms from the Mw 4.0 foreshock, which occurred on 15:26, February 25, 2013, are used as EGFs.

RESULT

Tentative result shows a more concentrated slip distribution than the former results by the theoretical Green's functions (Hikima, 2013). The high moment release area is about 4km *3km. However, the image of the rupture, whose slip propagates to the north, is almost same as former results. The coincidence between observed and calculated waveforms in this study is fairly better than the result by theoretical Green's functions.

Only one result using single EGF has been explained in this abstract. However, many other small earthquakes, which will be candidates for EGFs, occurred in the source area. So the results using other EGFs will be shown and I will discuss the accuracy of resultant slip distributions at the time of the presentation.

Source rupture process of the 2011 Northern Nagano earthquake (Mj 6.7) based on strong-motion records

SHIBA, Yoshiaki[1*]

[1]CRIEPI

The slip distribution model of the March 12, 2011 Northern Nagano earthquake (M6.7) were estimated by assuming the multiple fault planes model based on the aftershock hypocenters detected from the high-dense seismometer array and the crustal deformation information derived by the interferometry synthetic aperture radar (InSAR). Since the strong-motion record with peak ground acceleration more than 700 gal was obtained at the K-NET station NIG023 near the main shock, it is important to investigate the geometrical relation between the strong motion generation area (SMGA) on the main shock fault and the observation station. Estimated source model displays the largest slip near the K-NET NIG023 and beneath the existing anticlinal structure. The reverse fault motion of this event is considered to contribute the growth of the anticline. On the other hand the secondary fault plane, which was recognized clearly from the crustal deformation data inferred from InSAR, released relatively small or negligible amount of the moment according to our examination. It might have been the deformation caused by the aftershock occurring just after the main shock.

Structural analysis of seismogenic fault of the 2013 Mw 5.8 Awaji Island earthquake, NW Japan

LIN, Aiming[1*] ; KATAYAMA, Shouichi[1] ; RAO, Gang[2] ; KUBOTA, Yasu'uchi[3]

[1]Department of Geophysics,Graduate School of Science, Kyoto University, [2]Department of Earth Sciences, Zhejiang University, China, [3]OYO Cooperation

The 2013 Mw 5.8 (Mj 6.3) Awaji Island earthquake occurred in the southwest Awaji Island, at 5:33, 13 April, 2013, ca.25 km southwest of the epicenter of the 1995 Mw 6.8 (Mj 7.2) Kobe earthquake, southwest Japan. Pre-existing geologic data and focal mechanism show that this earthquake was triggered by an unknown active fault with a thrusting-dominated mechanism at high-dip angle of >70 degree. Interpretations of aerial photographs and 3D perspective images, field investigations and structural analysis of fault rocks, reveal that: i) a new fault, called Yamada Fault here, striking NNW and dipping WSW at a high-angle of 86 degree was found along a topographic lineament developed along the geological boundary between the Mesozoic granitic rocks and the Late-Tertiary-Quaternary Osaka Group composed of interbeded sandstone and mudstone; ii) a main shear zone of the Yamada Fault consists of a fault core that includes a narrow fault gouge zone of <10 cm in width (generally 1˜5 cm), a fault breccia zone of <100 cm in width, and a damage zone of 10˜50 m in width that is composed of cataclastic rocks and fractures; iii) the foliations characterized by S-C fabrics developed in the shear zone indicate a dominantly thrusting sense, consistent with that revealed by the focal mechanism; and iv) co-seismic surface ruptures occurred locally along the Yamada Fault, which are composed of numerous short fissures ranging from centimeters to several meters in length and concentrated in a zone <5 m. Our findings show that the newly found Yamada Fault is a active fault that probably triggered the 2013 Mw 5.8 (Mj 6.3) Awaji Island earthquake. Therefore, it is necessary to reconstruct the fault model for studying the tectonic activity and paleoseismicity and to reassess the seismic hazard of the active faults for densely populated Awaji Island, northwest Japan.

Quasi-cylindrical seismic waveform modeling considering surface topography

TOYOKUNI, Genti[1*] ; TAKENAKA, Hiroshi[2] ; OKAMOTO, Taro[3] ; ZHAO, Dapeng[1]

[1]RCPEVE, Tohoku Univ., [2]Okayama Univ., [3]Tokyo Tech

An accurate and efficient modeling of regional seismic wave propagation can be achieved by the axisymmetric modeling using the cylindrical coordinates. It assumes the structural model as rotationally symmetric along the vertical axis including a seismic source, and then solves the 3-D wave equation in cylindrical coordinates only on a 2-D structural cross section (i.e., 2.5-D modeling). Therefore, this method can correctly model 3-D geometrical spreading effects and the pulse shape, with computation time and memory comparable to 2-D modeling.

On the other hand, application of the conventional purely axisymmetric approximation is difficult in practice because the structure along the measurement line of the seismic survey is rarely symmetric with respect to the source location. To overcome this difficulty, Takenaka et al. (2003) proposed a ”quasi-cylindrical approach”. They developed a numerical scheme for seismic exploration using the finite-difference method (FDM). The FDM scheme had then been improved to include an arbitrary moment-tensor point source and the anelastic attenuation for further realistic modeling (Toyokuni et al., 2013, AGU Fall meeting).

In this work, we extended the scheme to treat land and ocean-bottom topographies. We adopted the cell-based staggered-grid FDM, which places the normal-stress components at the center of a unit cell, and applies the 2nd-order FD approximation around the free surface or fluid-solid boundary (Okamoto & Takenaka, 2005; Takenaka et al., 2009; Nakamura et al., 2012). In the presentation, we will show an application of the scheme to the waveform modeling for the volcanic areas in Japan.

Spatial distribution of aftershock decay property beneath Japan Trench

IKUTA, Ryoya[1*] ; KUWAHARA, Masanori[2] ; MURAKAMI, Hiroki[3]

[1]Graduate School of Science, Shizuoka University, [2]Center of Integrated Research and Education of Natural Hazards, Shizuoka University, [3]Faculty of Science, Shizuoka University

We analyzed the aftershock sequences for individual M6-9 class inter-plate earthquakes and intra-plate earthquakes in Japan Trench for the period between October 1997 and March 2013 using JMA hypocenter catalog (final solution). The purpose is to examine a spatial relationship between the slip zone by the M9 earthquake and activity of aftershock series before the M9 and to understand the mechanism of aftershock. We approximated time variation of the number of aftershock sequences for each earthquake by the modified Omori ' s Law. Each aftershock sequence was identified from its spatial and temporal distribution. K and P parameters of Omori ' s Law were obtained by fitting the logarithmic Time-Frequency graphs of the aftershock sequence by linear function. We analyzed aftershock sequences for 44 events and adopted 17 whose K values are larger than 10 as available results because the results with smaller K values than 10 had large uncertainties due to lack of data. The results showed negative correlation between P values and Mj of the mainshocks. Before and after the M9 earthquake, there was no significant change in the aftershock parameters. However, we found a depth-dependent spatial distribution of aftershock decay properly. In the plate boundary, the aftershock sequence lasts for longtime without significant decay in the deeper portion, in contrast that the aftershock decays quickly at the shallower portion. It is known that the deeper part of plate boundary tends to slip aseismically without earthquakes. Taking this slow slipping property into account, our result suggests that the inter-plate frictional property should be responsible to the delay and decay property of the aftershocks.

Location of early aftershocks of the 2011 Tohoku-oki Earthquake using seismogram envelopes as templates

KOSUGA, Masahiro[1*] ; SAKAI, Yuuka[2]

[1]Graduate School of Sci. & Tech., Hirosaki Univ., [2]Fac. Sci. & Tech., Hirosaki Univ.

The location of early aftershocks is very important to estimate the initial size of mainshock fault, because the aftershock zone generally extends with time. However, the location of early aftershocks is often difficult due to the long-lasting coda wave of mainshock and successive occurrence of aftershocks. To overcome this situation, we developed a location method using seismogram envelopes as templates. During the process of location, we firstly calculate the cross-correlation coefficients between a continuous (target) and template envelopes, and obtain time series of station-averaged cross-correlations for all templates. We then search for templates (initial location) in the descending order of cross-correlations in a time window excluding the dead times around the previously detected events. The third process is the relative event location that accounts for the lag times between actual and template envelopes. We applied the method to the early aftershock sequence of the 2011 Off the Pacific Coast of Tohoku Earthquake (Mw = 9.0). In a time window of 30-minutes just after the mainshock, we could locate 22 events in 8 Hz band by using 96 templates recorded at 33 Hi-net stations. The number of located events by the JMA is 13. Though we should carefully examine the location of detected events, we conclude that the proposed detection method works adequately even just after the mainshock of large earthquake.

The 2011 Tohoku earthquake occurred at the plate boundary and many aftershocks followed. To obtain a precise aftershock distribution is important for understanding of mechanism of the earthquake generation. In order to study the aftershock activity, we carried out extensive sea floor aftershock observation using more than 100 ocean bottom seismometers just after the mainshock. Deployment and recovery of the OBS were repeated, and we obtained the data from OBSs just after the mainshock to the middle of September, 2011. A precise aftershock distribution for approximately three months in the whole source area, with an emphasis on depths of events, was obtained from the OBS data. In the southern source region, an aftershock distribution until September, 2011 was also estimated. Totally urgent OBS observations located 1210 aftershocks (Shinohara et al., 2011, 2012). After the urgent aftershock observation using short-term OBSs, we continued the observation using long-term OBSs to monitor seismic activities in the source area. We deployed 40 LT-OBSs in the whole source region in September 2011 and have completed recovery of the LT-OBSs until November, 2012. In this presentation, we concentrate seismic activities in the northern source region using the data from the urgent aftershock observation and long-term seafloor observation.

We selected events whose epicenter is located below the OBS network form the JMA earthquake catalog, and P and S-wave arrival times were picked from the OBS data. Hypocenters were estimated by a maximum-likelihood estimation technique with one dimensional velocity structures. Thickness of sedimentary layer changes at each OBS site was evaluated and the estimated travel times by the location program were adjusted. We will report precise seismic activities in the northern source region with spatial and temporal variation. From preliminary analysis, seismic activity in off-Miyagi region was still low until the end of the long-term observation.

A boundary of stress-field orientation in northwestern area of the Kanto plain

YANO, Tomoko elizabeth[1*] ; TAKEDA, Tetsuya[1] ; SHIOMI, Katsuhiko[1]

[1]NIED

Kanto-Tokai area is particularly important in terms of seismic hazard and mitigating disaster since this area is having high potential to economic and social impacts. Despite the fact, the Kanto region is one of the most seismic active areas due to its complicated tectonics and has an active fault zone, containing Fukaya fault, in northwestern area of the Kanto plain, which has potential to the M8 class earthquake. Many studies and research projects have attempted to understand the seismic activity and stress field. However, reliable and high-resolution catalog is required for the detailed discussion.

We have launched Japan Unified High-resolution Relocated Catalog for Earthquakes (JUICE) project since 2013. Events were relocated using the Double-Difference method for high-resolution hypocenter location to estimate seismogenic layer thickness, to evaluate active faults, and to understand the tectonic processes in Japan. We have completed for the first version of Catalog in the region of Kanto-Tokai area for the shallow (>40 km) earthquakes between M0 and M6.5 from 2001 to 2012. Here, in this presentation, we introduce the result from JUICE focusing on the northwestern area of the Kanto plain that contains a sharp boundary in which pressure and tension axis dramatically change by 90 degrees.

The JUICE catalog clearly shows a band of seismicity from Izu peninsula to the north. This seismic band has a nearly constant width of about 50 km. The focal mechanisms show that strike and thrust type dominate throughout this seismic band continuously, though there exists a area where pressure and tension axis dramatically change within this seismic band. While this " area " has been already recognized (e.g. Suzuki, 1989), JUICE helps to draw a precise " line " as a stress-field orientation boundary where happened to be close to Fukaya fault.

Bouguer gravity anomaly and seismic exploration data imply structural changes at the stress-field orientation boundary. According to the Bouguer gravity anomaly (Komazawa, 2004), the boundary appears to be associated with the gravity-low zone. The gravity anomalies show a lineation that trends NW-SE, the same direction of the boundary. Seismic profile (Sato et al., 2003) displays changes in basement character showing the pattern of depression beneath Fukaya fault. The shape of depression corresponds to the pattern of seismicity beneath this area, and also the boundary sites beneath the lowest point of the depression.

It appears to split into different regimes at the stress-field orientation boundary. We conclude that it is possible to have major tectonic boundary underneath this northwestern area of the Kanto plain. Moreover, we suggest that Median tectonic line (MTL) is a major candidate underneath this area. MTL runs parallel to the island arc through southwest Japan and divides different geological structures into outer (the forearc side) and inner arc (the backarc side). The trace of MTL disappears on the eastern side of Itoigawa-Shizuoka tectonic line, but Takagi et al. (2006) found an evidence of inner arc materials in the core sample obtained around this area. Therefore we assume that MTL is buried underneath the boundary. This finding may eventually impact on the research relates to hazard of Kanto area.

Estimating earthquake swarms in volcanic regions

KUMAZAWA, Takao[1*] ; OGATA, Yosihiko[1] ; KIMURA, Kazuhiro[2] ; MAEDA, Kenji[2] ; KOBAYASHI, Akio[2]

[1]The Institute of Statistical Mathematics, [2]Meteorological Research Institute

In the eastern Izu region, earthquake swarms have occurred repeatedly since 1978. These events are known to be triggered by magma intrusions, and the amount of magma intrusion is correlated with volumetric strain of the crust. We show the background seismicity rate is highly correlated with the volumetric strain in this region, with a short time delay. We then discuss the possibility to forecast the seismicity in volcanic regions.

To calculate the background seismicity rate, we used the epidemic-type aftershock sequence (ETAS) model extended for application to nonstationary seismic activity, introduced by Kumazawa & Ogata (2013). The time-dependent rates of both background seismicity and aftershock productivity in the ETAS model are optimally estimated from hypocenter data by Bayesian smoothing method. These rates can provide quantitative evidence for abrupt or gradual changes in shear stress and/or fault strength due to aseismic transient causes such as triggering by remote earthquakes, slow slips, or fluid intrusions within the region.

Source Characteristics and Coulomb Stress Change of the 19 May 2011 Mw 6.0 Simav-Kutahya Earthquake, Turkey

GORGUN, Ethem[1*]

[1]Department of Geophysical Engineering, Istanbul University

Abstract

On 2011 May 19, Simav district of Kutahya province in northwest Anatolia was hit by a moderate size (Mw=6.0) earthquake. Centroid moment tensors for 41 events with moment magnitudes (Mw) between 3.5 and 6.0 are computed by applying a waveform inversion method on data from the Kandilli Observatory and Earthquake Research Institute broadband seismic network. The time span of data covers the period between 2011 May 19 and 2011 August 22. The mainshock is a shallow focus normal event at a depth of 10 km. Focal depths of aftershocks range from 5 to 20 km. The seismic moment (Mo) of the mainshock is calculated $1.15x10^{18}$ Nm. The estimated rupture duration of the Simav mainshock is 30 s. The focal mechanisms of the aftershocks are mainly normal faulting with a variable strike-slip component. The geometry of focal mechanisms reveals a normal faulting regime with NE-SW trending direction of T-axis in the entire activated region. A stress tensor inversion of focal mechanism data is performed to acquire a more accurate picture of the Simav earthquake stress field. The stress tensor inversion results indicate a predominant normal stress regime with a NW-SE oriented maximum principal compressive stress. According to variance of the stress tensor inversion, to first order, the Simav earthquake area is characterized by a homogeneous intraplate stress field. Eventually, Coulomb stress analysis is performed to calculate the stress transfer and correlate it with the activated region. Positive lobes with stress more than 3 bars are obtained, indicating that these values are large enough to increase the Coulomb stress failure towards NW-SE direction.

Seismic activity in eastern Japan and the source region after the 2011 off the Pacific coast of Tohoku earthquake

UOOCHI, Akiko[1] ; KUGE, Keiko[1*]

[1]Dept. Geophysics, Kyoto University

Changes of seismic activity in eastern Japan and the source region were shortly reported after the 2011 off the Pacific coast of Tohoku earthquake (Toda et al., 2011; Kato and Igarashi, 2012). To clarify subsequent changes, we investigated seismic activity in the wide region for two and a half years since the 2011 Tohoku earthquake.

We examined a region in a range of 33.4-42N and 136-145E. The region was divided into small squares with a size of 0.2 degree, and in each square, we computed seismicity rates. First, as the background seismicity, we computed the average number of earthquakes per a year, based on seismic activity for nine years before the 2011 earthquake. Then, to obtain seismicity rates after the 2011 earthquake, we counted the number of earthquake during two periods, respectively, and computed the ratios against the background seismicity. The two periods are 0-1 and 1.5-2.5 years after the 2011 earthquake. We used hypocenters determined by JMA. In regions where large inland earthquakes occurred before 2011, the background seismicity was computed from a period excluding aftershocks. Finally, by plotting the resultant seismicity rates in maps, we searched regions where seismic activity significantly changed. By the same method, we also examined seismicity rates of interplate earthquakes in the source region of the 2011 Tohoku earthquake, based on data selected from the F-net CMT catalog.

Our results show that when two and a half years passed since the 2011 earthquake, seismicity of interplate earthquakes had been lower than the background, throughout the source region of the 2011 Tohoku earthquake except for a region off Iwata. High seismic activities for a year since the 2011 earthquake were found in Iwaki, the middle and northern parts of Akita, the southern part of the Kanto region, and also in regions near active volcanos (Bandai, Nikko-Shirane, Kusatsu-Shirane, Naeba, and Fuji mountains). When two and a half years passed, seismicity in many regions of eastern Japan had been lower than the background, including the activities near Bandai, Naeba, and Fuji mountains. However, activities in Iwaki, the middle and northern parts of Akita, the southern part of the Kanto region, and near Nikko-Shirane and Kusatsu-Shirane mountains continued to be high.

Furthermore, we carefully examined seismic activity in the regions where we detected significant changes of seismic activity. In many regions of eastern Japan, we found that locations of earthquakes and focal mechanisms were changed before and after the 2011 Tohoku earthquake.

Using JMA hypocenters, we also attempted to apply the modified Omori's law for seismic activity after the 2011 earthquake in the regions with significant changes of seismic activity. The modified Omori's law could roughly model the changes of seismic activity in many regions, even when a region is inland, away from the source region. The Omori's regression parameter, p, was estimated in a range from 0.2 to 1.1. The values ranged between 0.2 and 1.1 in the regions where seismic activity has been high for 2.5 years, whereas they were between 0.8 and 1.1 where high seismic activity for the first 1 year decreased in 2.5 years since the 2011 earthquake. In the southern part of the Kanto region, the value of p (0.2) was extremely low, compared to the other regions, which implies that the seismic activity decays very slowly. In the regions near active volcanos, the values of p tended to be high. In the source region of the 2011 Tohoku earthquake, we estimated the values of p in three regions; a whole source region, an afterslip region, and a region excluding the afterslip region. The values ranged from 1.0 to 1.1, and there was no significant difference in the three regions.

A statistical feature of anomalous seismic activity prior to large inland earthquakes in Japan

KAWAMURA, Masashi[1*] ; WU, Yi-hsuan[2] ; KUDO, Takeshi[3] ; CHEN, Chien-chih[2]

[1]Department of Geosciences, National Taiwan University, [2]Grad. Inst. of Geophysics, National Central University, Taiwan, [3]General Education Division, College of Engineering, Chubu University

To reveal the preparatory processes of large inland earthquakes, we systematically applied the pattern informatics (PI) method to earthquake data of Japan. We focused on 12 large earthquakes with magnitudes greater than M6.4 (based on the magnitude scale of the Japan Meteorological Agency) that occurred at depths shallower than 30 km between 2000 and 2010. We examined the relationship between the spatiotemporal locations of these large shallow earthquakes and the locations of PI hotspots, which correspond to grid cells of anomalous seismic activity during a designated time span. Based on a statistical test conducted using Molchan's error diagram, we investigated whether precursory anomalous seismic activity occurred in association with these large earthquakes and, if so, studied the characteristic time spans of such activity. Our results indicate that Japanese inland earthquakes with M $\geqq$ 6.4 are typically preceded by anomalous seismic activity in timescales of 8-10 years.

Coulomb stress change inverted from the seismicity rate change in southern 2011 Tohoku earthquake's source region

TAKAHASHI, Go[1*] ; TSUMURA, Noriko[1]

[1]Graduate School of Science, Chiba University

By using the analysis of seismicity rate change, we estimated spatio-temporal evolution of Coulomb stress around the upper boundary of the Pacific plate (PAC) and Philippine Sea plate (PHS) in and around the southern edge of the rupture zone of the 2011 Pacific coast of Tohoku earthquake (Mw=9.0). We used hypocenter catalog of the Japan Meteorological Agency (JMA) for the period between 1998/1/1 and 2013/3/31. Estimated stress change became large just after the 2011 Tohoku earthquake in most of rupture zone. The large stress change estimated from the seismicity reached the southern outside of the contact zone of the PHS and the PAC, while this area is located at outside of the source fault of the 2011 Tohoku earthquake. Moreover, in the October 2011 Boso slow slip event (SSE) initiation area, stress change remained large value after the 2011 Tohoku earthquake.

To estimate the effect of the mainshock and largest aftershock in our inversion result, we calculated Coulomb stress change by simulating the mainshock, afterslip and Mw7.9 aftershock for the 2011 Tohoku earthquake in an elastic half space. From similarity between the result from seismicity rate change and result of forward modeling, most of the stress change pattern in and around mainshock rupture zone after the 2011 Tohoku earthquake might be explained by the effect of the 2011 Tohoku earthquake mainshock, afterslip and the largest aftershock. On the other hand, since the result from seismicity rate change didn't correspond to the result of forward modeling in the October 2011 SSE area, this region was possibly affected by other event or closeness to break strength.

[1]Kobe Univ., [2]Earthquake Research Inst., [3]Hokkaido Univ., [4]Tohoku Univ., [5]Chiba Univ., [6]Kagoshima Univ., [7]National Research Institute for Earth Science and Disaster Prevention, [8]JAMSTEC

The 2011 off the Pacific coast of Tohoku Earthquake occurred on March 11, 2011, off shore of the northeast Japan region. Many aftershocks occurred following the mainshock. To obtain a precise aftershock activity is important for understanding the mechanism of earthquake generation, and the recovery of plate coupling at a ruptured plate boundary. In order to study the aftershock activity, we had deployed 66 long-term ocean bottom seismometers(LTOBS) off the coast of Ibaraki and the Boso Peninsula from October 2011 to November 2012.

For hypocenter determination, we selected 1606 events whose epicenter catalog which the Japan Meteorogical Agency for hypocenter determination.P- and S- wave arrival times were manually picked using the WIN system (Urave and Tsukada, 1991).Hypocenters were determined by the maximum-likelihood estimation technique (Hirata and Matsu·ura, 1987). The hypocenter location program used in this study is based one-dimensional structure with constant Vp/Vs ratio of 1.73. Because a sedimentary layer below the sea floor generally has a large Vp/Vs value, an adjustment of the station corrections is needed. To obtain the station correction, we used the following method. First, we located the hypocenter using the P- and S-wave arrival times with the assumed station correction values for the velocity structure used. The averaged differences between observed travel time and estimated travel times (O-C times) for each station were then calculated. The averaged O-C times were added to the previous station correction values, and the hypocenters were relocated. We repeated this procedure eleven times. After this procedure, the averaged O-C times were less than 0.1 s for both the P-wave and S-wavesWe estimated 458 hypocenter locations with an error of less than 5 km in the horizontal direction and less than 3 km in depth by using LTOBS data.

Most of the hypocenter locations have a depth shallower than 40km. The earthquakes form a plane dipping landward in the study area. Comparing the hypocenter locations with crustal structures obtained by active seismic studies (e.g. Miura et al., 2003). Many events occurred along the plate boundary. We also compared the hypocenter locations with aftershock distribution of the seismic observation conducted immediately after 2011 Tohoku Earthquake (Shinohara et al., 2012). Shinohara et al., (2012) reported that the low seismicity region has seen at the shallow part of the plate interface in the off-Fukushima. On the other hand, our results showed the seismicity is not low at the same region. This difference may reflect the change of stress fields at a ruptured plate boundary.

Spatial distribution of earthquakes off the coast of Fukushima deduced from a one-year OBS observation in 2013

YAMADA, Tomoaki[1*] ; NAKAHIGASHI, Kazuo[2] ; SHINOHARA, Masanao[1] ; MOCHIZUKI, Kimihiro[1] ; SHIOBARA, Hajime[1]

[1]Earthquake Research Institute, Univ. of Tokyo, [2]Kobe Univ.

The 2011 Tohoku earthquake (M9.0) vastly changes stress field around the rupture zone, and many aftershocks and other related geophysical phenomenon such as geodetic movements have been observed. The seismicity not only keeps still high rate compared with that before the 2011 earthquake but is important to figure out the time-spacious distribution during the relaxation process for understanding the giant earthquake cycle. Many studies using ocean bottom seismometers (OBSs) [e.g. Shinohara et al,, 2011, Nakahigashi et al., this meeting] have been doing since soon after the 2011 Tohoku earthquake in order to obtain aftershock activity precisely. Here we show one of the studies at off the coast of Fukushima which is located on the southern edge of the rupture zone of the 2011 Tohoku earthquake. 12 short-period type [Lennartz 3Dlite] OBSs (SOBS) and 4 broadband type [Guralp CMG 3T] OBSs (BBOBSs) in Auguest 2012 were installed. 20 SOBSs and 4 BBOBSs attached with absolute pressure gauge [Paroscientific Model 8B] were added in November 2012. After one year continuous recording, 36 OBSs were recovered in November 2013. We selected characteristic 1,000 events in the vicinity of the OBS network based on a hypocenter catalog publish by the Japan Meteorological Agency, and extracted the events' data from all available OBS data after time corrections caused by each internal clock. Each P and S wave arrival times, P wave polarity and maximum amplitude were picked manually on a computer display using the WIN system [Urabe and Tsukuda, 1991]. We assumed one dimensional velocity structure that is modification of the result from an active source experiment close to our network, and applied time corrections every station which were estimated from differences from theoretical and observational travel times for removing ambiguity of the assumed structure. Then we adopted the maximum-likelihood estimation technique [Hirata and Matsu'ura, 1987] and calculated the hypocenters. Preliminary results show that intensive activity near the Japan trench can be seen while there was a quiet seismic zone between the trench zone and landward high activity zone.

Relation between Seismicity and Stress Change Associated with Interplate Slips off Boso Peninsula: Part 2

HIROSE, Fuyuki[1*] ; MAEDA, Kenji[1]

[1]Meteorological Research Institute

Hirose & Maeda (2012, 2013, JpGU; 2013, SSJ) investigated a relation between temporal variation of seismicity rate or b-value of the G-R law (Gutenberg and Richter, 1944, BSSA) and stress change associated with slow slip events (SSEs) around Boso peninsula. For example, there are three characteristic stages about seismicity: (S-1) activation during SSE, (S-2) quiescence before 2002 and 2007 SSE, and (S-3) seismicity rate increases after 2007 SSE. On the other hand, b-value repeats a cycle as follows: (b-1) small during and just after SSE, (b-2) gradually increases up to the next SSE.

By considering the correlation of seismicity rate with stress increase and inverse correlation of b-value with stress obtained in laboratory experiments (Dieterich, 1994, JGR; Scholz, 1968, BSSA), they interpreted their result as follows: for (S-1, b-1) during SSE, the slip rate at the edge of SSE on the plate boundary where is seismically active becomes higher (We can confirm it from the distribution of slip deficit and SSE estimated by GNSS data). Then because a strain accumulation rate increases, the stressing rate increases. Thus, seismicity rate increases, and b-value decreases at the same time. On the other hand, for (S-2, b-2) in SSE interval, because the slip rate on the plate boundary becomes lower than that during SSE, the seismicity rate decreases, and b-value increases at the same time. For (S-3) seismicity rate increases after 2007 SSE, the distribution of slip deficit after 2007 SSE is not much different from that before SSE. When we consider a frame of Dieterich (1994), only steady slip rate should become higher without changing of slip deficit rate so that seismicity rate changes under this situation because slip deficit on the plate boundary is independent of the value of steady slip rate (Savage, 1983, JGR). That means the drop of the coupling rate on plate boundary (slip deficit rate / steady slip rate). Therefore, the temporal change of the seismicity and b-value is comprehensively consistent with the perturbation of the slip rate on the plate boundary.

By the way, Boso SSEs had occurred every 4-7 years, but the latest interval of occurrence has a shorter period because those occurred in the end of 2011 and early in 2014. It is considered that the shortening of interval is mainly caused by the influence of the 2011 off the Pacific Coast of Tohoku Earthquake (Mw9.0, hereinafter Tohoku earthquake). We extended data period and investigated whether the same characteristics as before are also seen for the 2014 SSE. As a result, it showed such the same characteristics that (S-1) activation during SSE, (S-3) seismicity rate increases after 2007 SSE, (b-1) small during and after SSE, and (b-2) gradually increase up to the next SSE. On the other hand, (S-2) quiescence before SSE was not recognized because the perturbation of stress caused by the Tohoku earthquake may affect the seismicity.

Microseismicity around the Nankai trough south off the Kii Peninsula

YAMAZAKI, Akira[1*]

[1]Meteorological Research Institute

The seismicity around the Nankai trough axis and its southern area, south off the Kii Peninsula, was not well understood, because most previous ocean bottom seismograph observations had been performed at landward from the trough axis. In order to investigate the seismicity around the region, Meteorological Research Institute conducted ocean bottom seismograph observations at around the Nankai trough axis and its southern area from 2005 to 2008, cooperated with Seismology and Volcanology Department, Japan Meteorological Agency (JMA). We conducted four observations, which period was approximately three months, using about ten pop-up type ocean bottom seismographs. As a result, we could detect a microseismic activity, which were not listed in the earthquake catalogue by JMA, around the trough axis.

The features of the microseismic activity are as follows. The depth of the hypocenters distributes around 10km to 25km. Since the depth of hypocenters determined by JMA at the region distributes around 30km to 40km, the true depth of the earthquakes is considered about 20km shallower than that of the JMA. There is a clear lower limit plane of hypocenters, and little earthquakes occur deeper than 25km. As a general tendency, the microseismic distribution has south incline at seaward from the trough axis, north incline at landward. The distribution of the hypocenters is not uniform, and we can detect some seismic clusters, liner arrangements and several seismic gaps of the 20km to 30km in diameter. It seems that seismic segment structures are formed within the Philippine Sea plate.

In general, seismic activity around a trough axis is causes by bending of oceanic plate. Moreover, the activity is affected by somewhat change of interplate coupling status at subduction zone. For instance, it is pointed out that the focal mechanism at outer rise region changes from compressional to tensional tectonic field by occurrence of large interplate earthquakes at subduction zone. We propose a possibility that the temporal change of the microseismic activity around the Nankai trough axis reflects a temporal change of the plate motion or a somewhat change of plate coupling conditions.

Repeating earthquake activity along the Izu-Bonin and Ryukyu trenches

HIBINO, Kota[1*] ; UCHIDA, Naoki[1] ; MATSUSHIMA, Takeshi[2] ; NAKAMURA, Wataru[1] ; MATSUZAWA, Toru[1]

[1]Graduate School of Science Tohoku University, [2]Faculty of Sciences,Kyushu University

There are several subduction systems near the Japanese islands. The 2011 Mw9.0 Tohoku-oki megathrust earthquake occurred at the northeastern Japan subduction zone and revealed a complementary relation between the slip areas for huge earthquakes and small repeating earthquakes (REs). Investigations of REs in other subduction zones and their comparison with Tohoku area are important for revealing generation mechanism of megathrust earthquakes.

We use seismograms from the High Sensitivity Seismograph Network (Hi-net) and Japan Meteorological Agency (JMA)'s permanent seismograph stations from 8 May 2003 to 31 December 2012. We detect RE along the Izu-Bonin and Ryukyu trenches, using similarity of seismogram pairs.

Although, Igarashi (2010) and Yamashita et al. (2012) have already examined RE activity in this region, we mainly follow the method of Uchida et al. (2010) to compare with the REs at Tohoku area. In the method, pair with coherence larger than 0.95 at multiple stations is considered to belong to a repeating earthquake group. We apply this method to the earthquakes along the Ryukyu trench. Along the Izu-Bonin trench, however, the signal-to-noise (S/N) ratios of the waveforms are not so good because of the limited seismic stations at sparsely distributed islands. Therefore, we adopt a coherence threshold of 0.8 and even if S/N ratios of the waveform are good at only one station, earthquake pairs that satisfy the threshold in multiple components are considered as candidates of REs along the Izu-Bonin trench.

Along the Ryukyu trench, we find RE distribution shows two dense bands parallel to the trench axis. This feature is similar to the northeastern Japan subduction zone. We consider the regions between the two bands of REs may have strong interplate locking as suggested at Tohoku.

Along the Izu-Bonin trench, in spite of the non-strict coherence threshold, we find much fewer REs than that in northeastern Japan. Our result suggests that REs are relatively rare along the Izu-Bonin trench and they mainly occur at the shallow part where the Pacific plate contacts with the crust of the Philippine Sea plate.

These varieties in the RE occurrences suggest different interplate locking patterns along these subduction systems.

Ocean bottom seismic observation in the Hikurangi subduction zone offshore the North Island of New Zealand

HAIJIMA, Daisuke[1*] ; MOCHIZUKI, Kimihiro[1] ; SHIOBARA, Hajime[1] ; YAMADA, Tomoaki[1] ; SHINOHARA, Masanao[1] ; HENRYS, Stuart[2] ; FRY, Bill[2] ; BANNISTER, Stephen[2]

[1]Earthquake Reserch Institute, University of Tokyo, [2]GNS Science

The Hikurangi Plateau which has ∼12 km thick crust subducts under the Australian plate
in the Hikurangi subduction zone offshore North Island, New Zealand. The plate interface is relatively shallow so that geometry of the plate interface has been revealed in detail by high quality seismic reflection data collected along dense profiles along the margin [Bell et al. 2010]. Distribution of interseismic plate-coupling has been estimated and series of slow slip events (SSEs) have been detected at around the lower limit of the coupling region due to recent installation of dense GPS network over the North Island. In the northern part, along-strike coupling region is narrow and the upper limit extends to near the trench axis and the lower limit is shallow at ˜15 km depth. Most of the region of strong interplate coupling is under the sea. We need to conduct seismic observation using ocean bottom seismometers (OBSs) to understand seismicity and hypocentral distribution in detail. SSEs occur at much shallower depth than other subduction zones.

We conducted a passive seismic observation using OBSs for the first time offshore Gisborne to reveal seismisity and low-frequency events accompanying SSEs. We deployed four OBSs in April 2012 and recovered all instruments after 11 months of observation. The northern two instruments were a broadband type and the other southern two were equipped with 1Hz seismometers. Although the recorder of one of the broadband type OBSs recorded only intermittently, good data were obtained from the others. An earthquake swarm occurred to the north of the array in September to November 2012. A large SSE occurred around the Hawke's Bay to the south of the array from mid-February 2013. At first we apply STA/LTA algorithm to this data to detect seismicity. The result shows seismicity was activated accompanying both the earthquake swarm and the SSE. We tried to determine the hypocenters of these events using 4 OBSs and some GeoNet onshore seismometers. We could detect more offshore events than are listed in the GeoNet catalogue owing to higher Signal-to-Noise ratios of the OBS data while most events occurred beneath the seafloor.

Greenland Ice Sheet Dynamics and Glacial Earthquake Activities

KANAO, Masaki[1*] ; TSUBOI, Seiji[2] ; TOYOKUNI, Genti[3] ; HIMEMO, Tetsuto[4] ; TONO, Yoko[2]

[1]National Institute of Polar Research, [2]Japan Agency for Marine-Earth Science and Technology, [3]Tohoku University, [4]Seikei University

The Greenland ice sheet and its response to climate change have potentially a great impact upon mankind, both through sea-level rise and modulation of fresh water input to the oceans. Monitoring a dynamic response of the Greenland ice sheet to climate change is a fundamental component of long-term observations in global science. Glacial earthquakes have been observed along the edges of Greenland with strong seasonality and increasing frequency in this 21st century by the data from Global Seismographic Network (GSN). During the period of 1993-2006, more than 200 glacial earthquakes were detected, but more than 95% have occurred on Greenland, with the remaining events in Antarctica. Greenland glacial earthquakes are considered to be closely associated with major outlet glaciers at the margins of the continental ice sheet. Temporal patterns of these earthquakes indicate a clear seasonal change and a significant increase in frequency after 2002. These patterns are positively correlated with seasonal hydrologic variations, significantly increased flow speeds, calving-front retreat, and thinning at many outlet glaciers. These long-period surface waves generated by glacial earthquakes are incompatible with standard earthquake models for tectonic stress release, but the amplitude and phase of the radiated waves can be explained by a landslide source model. The seismicity around Greenland including tectonic/volcanic events was investigated by applying a statistical model to the globally accumulated data. Calculated b values, the Magnitude-frequency-dependence parameter, indicated a slight increase from 0.7 to 0.8 in 1968-2007, implying that the seismicity including glacial events around Greenland become slightly higher during the last four decades. The detection, enumeration, and characterization of smaller glacial earthquakes were limited by the propagation distance to globally distributed stations of the GSN. Glacial earthquakes have been observed at stations within Greenland, but the coverage has been very sparse. In order to define the fine structure and detailed mechanisms of glacial earthquakes, a broadband, real-time network needs to be established throughout the ice sheet and perimeter. The International Polar Year (IPY 2007-2008) was a good opportunity to initiate the program with international collaboration. Then, the Greenland Ice Sheet Monitoring Network (GLISN) was initiated for the purpose of identifying the dynamic response of the Greenland ice sheet to climate change.

Foreshock activity of the large-scale interplate earthquakes around Japan

TANAKA, Rika[1*] ; ORIHARA, Yoshiaki[1] ; KAMOGAWA, Masashi[1]

[1]Dpt. of Phys., Tokyo Gakugei Univ., [2]Earthquake Prediction Reserch Center, Tokai University

According to Bouchon et al. (Nature Geosci, 2013), they reported that the number of foreshocks increased towards the mainshock in the interplate earthquakes around North America and Japan. But, the foreshocks were much less frequent in the intraplate earthquakes. We investigate whether such a clear difference is really found between the interplate earthquakes and the intraplate earthquakes around Japan.

Development of Acoustic Frequency Comb technology by ACROSS appropriate for active monitoring of the earthquake field

KUMAZAWA, Mineo[1*] ; HIGASHIHARA, Hiromichi[2] ; NAGAI, Toru[1]

[1]Nagoya University, [2]University of Tokyo

Acoustic Frequency Comb technology by utilizing ACROSS (Accurately Controlled Routinely Operated Signal System) has been developed since 1994 at Nagoya Univ. and Earthquake Research Institute at Univ. of Tokyo for the active monitoring method of the subsurface structures. It is now being operated routinely in several locations in Gifu, Aichi, Shizuoka, Hyogo and Kagoshima prefectures.

A group of earthquake seismologists wrote in a book"Science of Earthquake Prediction"(UT Press, 2007) as follows: Whereas ACROSS is an indispensable element for earthquake prediction works, there are problems in stability of the instrumentations, methods of data analysis, etc. To resolve the problems raised by them, our own research works are demanded rather than to complain or to criticize.

1..In the current ACROSS transmitters, single force vector F as frequency-modulated signal is generated by centrifugal force by rotation of a rather small mass M ($\sim$ 100 kg) with a displacement amplitude u as constrained by equation of motion;

$F = M\, d^2u/dt^2 = -\omega^2 (Mu)$

The centrifugal force thus generated is transmitted towards the Earth's interiors through a transmitting antenna named 'ground coupler', which is a steel-reinforced concrete block of several meters in size and $\sim$ 100 tons in weight. As specified by the formula above, transmitted force amplitude is proportional to frequency squared, so that signal transmission is difficult in the useful low frequency range. The previous transmitters designed are practically limited for the use above 5Hz. To extend the frequency to the lower span, we propose the use of a linear motion of larger inertia mass M, 100 $\sim$ 100000 times larger the current transmitter to reduce the frequency by a factor of 10 $\sim$ 100. This could be simply realized by utilizing a large ground coupler as an inertia mass. Quantitative examination of this approach is found to be promising, and we have started the works on the technical realization of this observation system.

2. Low frequency acoustic signal below 1 Hz is useful for the stationary monitoring system covering everything in the whole Japanese Islands, once we build a transmitter array consisting of several tens transmitting statins, since the signal is easily detected up to 100 km distance without any environmental pollution. Local dense array of the signal sensors would provide us with the accurate data set on the swarm of local eigen-modes within the frequency range of the transmitted signals. This approach is the frequency comb interferometry much potential than the seismic daylight interferometry commonly applied nowadays. To make the structural inversion of the data by frequency comb interferometry, we have developed a new forward method named PANW, in which wave equation as a differential equation is converted to arithmetic equation in frequency and wavenumber domain on the basis of the theory of generalized functions.

3. The combined use of observation data by frequency comb ACROSS transmitter array and the data analysis method of frequency comb interferometry by PANW theory is expected to provide us with a potential tool for the practical active monitoring methodology. The contemporary application most relevant is the safety evaluation of artificial constructions such as buildings, tunnels and so on in contact with their subsurface structures.

The prediction and/or control of the earthquakes and volcanic activities will come to be our sound research target after the accumulation of data, our experiences on the 'evolving structural sensitivity' of the materials and its detailed nature at the target zone. Additional essential factor is the associated experimental and theoretical studies on the structural sensitivity of polycrystalline materials containing hydroxyl ions under stress.

We note that the developmental works of this method have been continued for a long period of time by collaboration of so many research workers of a variety of disciplines.

Earthquakes are directed to diversity: An arithmetic seismic activity model

FUJIWARA, Hiroyuki[1*]

[1]NIED

Seismic activity is diverse. If we use the methodology in which an earthquake generation process is decomposed into individual fundamental processes and they are integrated by assembling a detailed physical model in each process, initial conditions and boundary conditions to be determined become an enormous amount.Therefore, it is difficult to describe the earthquake generation process by finding the solution of one deterministic equation system. In the prediction of seismic activity that has been attempted in recent years, stochastic or statistical techniques have been used. In approaches of stochastic processes theory, characteristics of seismic activities are modeled as probability distributions which are estimated theoretically or empirically. One of the sample path of a stochastic process that is modeled corresponds to the value to be observed. Such an approach is effective to represent the statistical properties of the entire seismic activity, but it cannot be applied to analyze a depth nature of the individual sample path. In this study, we mathematically construct a specific sample path corresponding to the observed value. By showing that they satisfy the statistical nature of seismic activity, we propose seismic activity model based on the idea that different from the stochastic processes approach. A model is proposed for seismic activity due to ”number”.

We consider a correspondence between earthquakes and prime numbers. We parameterize occurrence time of earthquakes as the prime numbers and magnitude of earthquakes as the interval of prime numbers. Then we obtain a relationship similar to Gutenberg-Richter law. We call the model obtained by this correspondence as ”arithmetic seismic activity model”. In the ” arithmetic seismic activity model”, earthquake is equivalent to prime number of prime numbers distribution theory. Earthquake prediction is something equivalent to prediction of emergence of prime numbers. Earthquake is captured as a phenomenon that corresponds to changes in the energy level of the field. Using certain quantum system, we consider to model a field of earthquake occurrence. Considering the Hamiltonian of the field of earthquake occurrence, we set earthquake occurrence as an eigenvalue problem for the Hamiltonian. If we can show that the eigenvalue problem is associated with the zeta function, we can expect to explain the similarity between the distribution of the prime and seismic activity. At present, dynamical system can explain seismic field based on this concept is not known. On the other hand, trying to capture the zero distribution of the zeta function of Riemann in the relationship equivalent to the prime number distribution as an eigenvalue problem of the quantum dynamical system, research on the distribution of prime numbers is progressing. Distribution of prime numbers is related to limits of diversity of ”number”. Distribution of prime numbers is likely to be associated with critical phenomena. Earthquake can be interpreted as an critical phenomena. For this reason, it is considered that there is a similarity between the prime numbers and earthquakes.

Comments on a Bayesian approach to earthquake probabilities of the Poisson model

IMOTO, Masajiro[1*] ; FUJIWARA, Hiroyuki[1]

[1]NIED

In making national seismic hazard maps for Japan, earthquake probabilities are estimated based on past seismicity with the Brownian passage time model and the Poisson process model. With a small number of past earthquakes, unreliable model parameters produce large uncertainties of estimated values. In the present paper, we discuss a Bayesian approach to the problem for the Poisson model. When n earthquakes were observed in period T_0, a Bayesian approach gives the probability that m earthquakes are observed in period T_1 in the form of a binomial distribution. We compared Bayesian probabilities with those obtained by the maximum likelihood estimate (MLE) for n less than 5 and found the following significant differences between them. 1) When T_1 is the average interval of the past earthquakes, Bayesian probabilities of at least one earthquake increase 3 to 12% over those of MLE. 2) For a somewhat smaller T_1 than that in 1), the differences become larger. The Bayesian approach presented here could be tested by a simulation study.

Long-term probability for large earthquake along the Nankai trough estimated from an incomplete catalog

OKADA, Masami[1*]

[1]MRI, JMA

The Earthquake Research Committee of Japan published a report (the second edition) on the long-term evaluation for great recurrent earthquake along the Nankai trough in May, 2013 and newly forecasted the probability for such event in coming 30 years to be 60 - 70%. The giant earthquake may be possible, and the report was socially paid attention to very much. In the calculation of probability the BPT, Brownian Passage Time, distribution model is used in which the distribution parameters estimated with the maximum likelihood method or the time predictable model are plug in directly to the formula of conditional probability. Those are estimated from a few data, but not considered about the bias and uncertainty in them.

The committee explained that an earthquake, the Keicho event (1605) may not occur along the Nankai trough and some qualifying earthquakes are probably missed from the current catalog. In this presentation I will introduce a Bayesian new method with non-informative prior distribution to the parameters in a lognormal distribution for calculating the probability for the coming event from an incomplete catalog, and show the result of about 23 % for the event in the forthcoming 30 years along the Nankai trough

Space- temporal stability of the seismic quiescence (4) -Relation of seismic quiescence area and the main shock

YOSHIKAWA, Sumio[1*] ; HAYASHIMOTO, Naoki[2] ; AKETAGAWA, Tamotsu[3]

[1]Meteorological Research Institute, [2]Meteorological Research Institute, [3]Japan Meterological Agency

We have been continuing investigation of seismic quiescence phenomena for the purpose of application to earthquake prediction. As a result of re-investigation of the cases for the earthquakes of M7 class in Japan, we found that the distance between the hypocenter of the main shock and the center of seismic quiescence area becomes large with the earthquake magnitude to occur in the detected cases. Based on this scaling law, detectable cases could be newly found in the non-detected ones in the previous investigation.

We applied the method of 'eMAP' which was developed by Aketagawa and Ito (2008) and Hayashimoto and Aketagawa (2010) for detection of the seismic quiescence. For the study we picked up 26 earthquakes that occurred from 1987 to 2011 with the magnitude larger than or equal to 6.7 and the intensity larger than or equal to five in Japan. There were 11 detected cases and 15 non-detected cases in the past investigation (Ota et al.(2009) and Yoshikawa (2012)). In the case of the 1995 Kobe earthquake, where seismic quiescence could not be detected by 'eMAP' in the past investigation, a clear seismic quiescence has been reported by the DPRI of Kyoto University (1995) and the Japan Meteorological Agency (1995). As a result of re-investigation of this case, it became possible to treat it as a detectable case if the following things were considered. Though we have considered as the necessary condition for the precursor that the phenomenon appears in and around the focal area before occurrence of the main shock, we could not recognize as a phenomenon to be connected directly with the main shock because a seismic quiescence appeared in Tamba region approximately 30km distant from the epicenter near the Akashi Channel. And any remarkable quiescence was not detected in the epicenter, since the average seismic activity before the earthquake was too low. It is necessary to make clear the condition to treat the quiescence as a precursor. Then as we re-examined the detected cases, we found that the distance between the epicenter of the main shock and the center of the quiescence area became large with the magnitude of the earthquake to occur. We have reported that there are scaling laws in the size of the quiescence area and the duration of quiescence against the magnitude (Yoshikawa et al., 2013). As the quiescence is supposed to occur in the stress reduction area caused by aseismic slip, the main shock should occur in the periphery of the quiescence area and it is quite natural that the distance between the epicenter and the center of the quiescent area becomes larger obeying the scaling law.

We re-examined other non-detection cases and found that the precursory seismic quiescence can be detected also in the 1987 eastern off Chiba earthquake, the 1994 far-off Sanriku earthquake, the 2000 western Tottori earthquake, and the 2004 south-east off Kii peninsula earthquakes. As a result of this, 16 cases can be considered as detected and 10 cases as not- detected for 26 cases in total.

Recent anomalous groundwater temperature and water level changes and impending great earthquakes at the Nankai trough

TSUKUDA, Tameshige[1*]

[1]Japan Women's Univ.

Earthquakes are generated by the anisotropic principal stress regime in the rock medium. In the preparing process of a large earthquake, the medium would be deformed generating regions of contraction and dilatation around the nucleus of the shearing stresses. According to a hydraulic model, pore fluid flow is driven upward to the ground surface through crack systems serving as flowing pipes by high pressure pumps at a deep spot. The change in the quantity of the upwelling hot water from deep underground causes a change of groundwater temperature(Tsukuda et al., 2005).

We have groundwater observation stations for temperature at 12 sites, and for water level at two in the Tokai and Nanki regions, central and southwest Japan, respectively, where are close to the so-called Tokai and Nakai earthquakes. High precision quartz thermometers are installed at Otomi (OT) in Yaizu City and Nakajima (NK) in Shizuoka City. At other stations, platinum resistance thermometers are installed. We use semiconductor pressure sensors for water level. At OT(Yaizu) in the Tokai region, the temperature has been monotonously increasing since the measurement started in 2003. The rate of increase has clearly fallen down since the end of 2012, suggesting weekning of the contraction in the rock medium. At NK(Shizuoka), 14km northeast of OT, the temperature data presented a precursory change from increasing to decreasing trend, one year before the 2009 Suruga-bay earthquake of M6.5 (Tsukuda, 2012). The decreasing rate after the earthquake became much higher than before and had continued till 2012. The temperature changed suddenly into increasing trend since May, 2013. The dilatation of the rock medium under Shizuoka recently changed into contraction. At stations HA and WA in Shionomisaki, Nanki region, Wakayama Prefecture. The long-term trend of the water level is rising, corresponding to the ground subsidence found by levelling and GNSS data (Kobayashi, 2013). The trend of temperature is similarly rising, suggesting contraction of the rock medium under Shionomisaki, the southernmost end of Honshu. At KZ(Kozagawa) in the Nanki region, the temperature is monotonously falling since the observation started in 2002. The decreasing rate is growing during recent two years, suggesting the dilatation turned to be intensified recently.

As mentioned above, the deformations of the rock medium are accelerated under the regions close to the source regions of the great erthquakes at the Nankai trough. For prediction studies for the impending great erthquakes, we should start to conduct detailed and multidisciplinary observations.

Two questions related to short- and long-term prediction of the so-called Tokai earthquake

GELLER, Robert J.[1*]

[1]UTokyo, Earth Planet. Sci.

In the 1970s there was widespread discussion suggesting that a large subduction zone earthquake was imminent in the Tokai district (the so-called ”Tokai earthquake”), but the ”Tokai earthquake hypothesis” was not stated in a testable form. About 40 years have passed, but no such event has occurred in Tokai. Under those circumstances it seems justifiable to conclude that the hypothesis has been falsified. That does not mean that Tokai is not at risk, just that the risk is not greater than other tectonically similar regions.

Under the Large Scale Earthquake Countermeasures Act (LECA), which was enacted in 1978, an organization for monitoring possible ”precursors” and issuing short-term alarms was established. But no reliable precursors have ever been found. LECA should therefore be repealed and the monitoring organization abolished.

On the sea level changes before the 1946 Nankai earthquake on the Pacific coast of Shikoku, Japan

UMEDA, Yasuhiro[1*]

[1]Geological Survey of Japan, AIST

1. Introduction

The abnormal sea level changes before the 1946 Nankai earthquake (M8.0) were witnessed by the inhabitants, on the Pacific coast of Shikoku, Japan. From a few days before the main shock, irregular tides were witnessed. The fishing boats could not arrive at the ports, because of the low sea level. On the contrary, some boats could arrive at ports. We considered that the abnormal sea level changes were caused by the small tsunamis from a few days before the main shock. The period and amplitude of the small tsunamis seem to have been larger and shorter closer to main shock.

2. Period and amplitude of the sea level changes

At seven points in the Susaki bay, the sea level changes were observed from

2010 to 2011. The height of tsunami by the 2011 off the Pacific coast Tohoku earthquake was amplified 20 and 8 times compared to that of the Nankai trough of 2300m depth (JAMSTEC) and 100m depth, respectively. The periods of 30-40, 50 and 80 minutes of sea level changes were observed in either case of tsunami, storm or mild weather. The periods of 50 and 80 minutes would be characteristic periods of Tosa bay. We considered that the small tsunamis were generated in the Tosa bay before the 1946 Nankai earthquake.

3. Assumed sea level changes

The assumed sea level changes(f(t)) before the main shock were obtained by the summation of the sea level changes by long term crustal movements(Fl(t)), small tsunami(F0(t)) with the period of 50-80 minutes and astronomical tide(Ft(t)). That is, f(t) = Fl(t) + F0(t) + Ft(t). Fl(t) = a • ln(t) + D0 was adopted by Umeda and Itaba(2013). In view of the summaries by the testimony for the abnormal sea level changes, F0(t) was assumed as F0(t)= A • B(t)m[cos{ωln(t-tc) +ϕ}]. ω and ϕ is frequency and phase angle, respectively. A is the amplitude ratio at each fishing port when the amplitude of Susaki bay is 1.0. Assumed sea level f(t) is shown by solid line in figure. f(t) of Susaki bay is expressed well the witness testimonies, but that of Muroto is not expressed them. f(t) of Muroto will be improved by considering the short -term and small-scale crustal deformations just before the main shock in the Muroto region.

Mechanism of generating electric fields just before earthquakes

TAKAHASHI, Kozo[1*]

[1]none

1. Precursory seismic electric fields

We consider that precursory seismic electric fields are generated by the mechanism as follows:(Refer to attached Figure):

(1) Before earthquakes, micro-cracks run in the source regions (Assumption), and into these cracks pore water pours.

(2) Uranium compounds, radium compounds and radon, which exist in crystal boundaries, dissolve into the pore water.

(3) The cracks connect the pore water and spring water, and the radio active materials appear on the surface of source regions.

(4) The radio active materials ionize the lower atmosphere above the source regions, and the electric conductivity increases there locally and temporarily.

(5) The ionization increases the current along the trace of cosmic shower between the surface and the ionosphere.

(6) As the current is pulsating, it radiates wide band radio-waves, which are observed as precursory seismic waves.

For the above mechanism the precursory micro-cracks are indispensable.

2. Mechanism generating the current between the surface and the ionosphere

The top of thunderclouds has the voltage up to about 100MV, so the electrons and negative ions flow into the clouds from the ionosphere. As a result, the ionosphere has a few MV. The mechanism, which increases the voltage at the cloud top, will be as follows:

(I) At middle latitudes, in the cloud lower than -10 deg. waterdrops become crystals, and they collide with each other. Then the water film on the smaller crystal, which is negatively charged, moves to the larger crystal, and makes the smaller crystal charged positive. The smaller crystals blow up to the cloud top and make it high voltage.(1)

(II) At low latitude, in the cloud no crystal will exist, but electric fields of about 1 kv/m exist, as other areas. So, waterdrops are polarized such as the top is negative and bottom is positive. When they collide, the negative part of smaller waterdrops, which have higher speed than the larger ones, neutralizes the positive charge of the larger waterdrops, and the smaller ones become positively charged and blow up to the cloud top, resulting the high voltage.

In the smoke billowing from volcanos, the lightning is observed. The tephra collide with each, other, and are charged by frictional electricity. By the same reason shown in (II), the charge is polarized and high voltage in the upper part of the cloud is generated. If this high voltage is observed, the explanation mentioned above will be considered to be valid.

Relationship between half-graben and high-velocities area at depths of 10 km 7

OISHI, Yukio[1*]

[1]Atelier Science

There are four oval shaped high velocities areas in Kanto Area .Two of them are in the southern part of Ibaraki prefecture. (after Matsubara Makoto 2005)

These two high velocities areas in Ibaraki prefecture gets larger, the deeper you see. At the depths of about 30km, this huge high velocities mass ,whose shape is donut, almost covers the southern part of Ibaraki prefecture and reaches at the depths of about 50km.

The western half of this huge high velocities area is on The Fourth Plate under Kanto; a part of Philippine Sea Plate(Toda Shinji 2005) at the depths of about 50km.

The eastern half of huge high velocities mass rides on the low velocities and low Poisson's ratio area, that is under beneath Lake Kasumigaura and the Southern of Lake Kasumigaura.(after Matsubara Makoto 2008)

This low velocities and low Poisson's ratio area faces subducting Pacific Plate at the depths of about 70 km.

Speaking of the low velocities and low Poisson's ratio area , the similar area exists in the asperity of M9 in 2011 off the Pacific Coast of Tohoku Earthquake; the upper part of the Pacific plate and also exists in Unzen in Nagasaki prefecture from the ground to the depths of about 30km.

I pointed out the possibility that the flexibility of the existence of the felsic rock or magma developed adherence of asperity of M9. (Ohishi Yukio 2013)

From the above it seems to be necessary to examine the possibility of the major earthquake outbreak underneath Lake Kasumigaura and the Southern Lake Kasumigaura at the depths of about from 50km to 70km.

There is another view that this low velocities area is not low Poisson's area but high Poisson's area (Nakajima Junichi 2008).

I want to wait for solution.

Three-dimensional S-wave velocity structure beneath the Naruko volcanic area by ambient noise seismic interferometry

TAMURA, Jun[1*] ; OKADA, Tomomi[1] ; MATSUZAWA, Toru[1]

[1]RCPEV, Tohoku Univ.

The 2008 Iwate-Miyagi Nairiku earthquake (M7.2) occurred along a fault ranging from the south of Iwate to the north of Miyagi. The focal region of the earthquake is located in the proximity of four volcanoes: Yakeishi-dake, Mt. Kurikoma, Onikobe, and Naruko. To study the positional relationship between the fault and magmatic bodies beneath these volcanoes, several studies have been conducted. Okada et al., (2010) estimated the S-wave velocity structure up to a depth of 40 km from body-wave tomography, and revealed that aftershock regions are distributed escaping the low velocity zones beneath the volcanoes. This study attempts to elucidate the correlation between the shallow structure of the volcanic bodies and aftershock regions in detail, focusing on the Naruko volcano locating in the south of the focal region, by seismic interferometry using cross-correlation analysis from ambient noise. Seismic interferometry is a method based on the fact that a cross-correlation function calculated from particle-motion records at a pair of stations in a wave field is equivalent to a Green's function between the two stations.

In cross-correlation analysis, we used the vertical-component data recorded by an observation network, which is densely installed in the Naruko volcanic region. By spectrum and beamforming analysis, we identified the characteristic of noise dominating in 0.1-10 Hz. The main sources of the noise are due to ocean waves coming from the Pacific Ocean and the Sea of Japan. Targeting the low-frequency range in which surface waves are more dominant than body waves, cross-correlation functions are calculated for each observation day for each pair of stations, and then stacked for 18 months to obtain a Green's function with a high SN ratio. We extract group velocity dispersion curves of Rayleigh waves using the multiple filter technique proposed in Dziewonski et al., (1969). Rayleigh-wave velocity maps from the period of 3 to 10 seconds are then calculated by processing surface-wave tomography based on the method of Barmin et al. (2001). Finally, we estimate the 3-D S-wave velocity structure up to 10 km depth by S-wave velocity inversion.

The structure shows two significant low velocity anomalies in the northwest of Naruko and in the south of Onikobe Caldera between 3 and 4 km depth. These anomalies are presumably magmatic bodies or geothermal water. Compared with the distribution of aftershocks and the fault, we can see that aftershocks do not occur in the low velocity anomaly beneath the Naruko volcano, and aftershock activity stops immediately at the northeast part of the anomaly.

Three-dimensional velocity structures in the region between Hakone volcano and Tanzawa Mountains, central Japan

YUKUTAKE, Yohei[1*] ; HONDA, Ryou[1] ; HARADA, Masatake[1] ; SATOMURA, Mikio[1] ; MATSUBARA, Makoto[2]

[1]Hot Springs Research Institute of Kanagawa prefecture, [2]Earthquake Research Institute, National Research Institute for Earth Science and Disaster Prevention

Hakone volcano is located in the northern boundary zone of the Izu-Mariana volcanic arc in central Japan, where the Izu Peninsula on the Philippine-sea plate has been colliding into the Japan island arc. There has been fumarolic activity around the Owakudani area, and many intense swarm activities have occurred in the caldera of Hakone Volcano. Previous studies (e.g. Oki and Hirano, 1970; Yukutake et al., 2011) interpreted that the hydro thermal fluid derived from a deep-seated magma beneath Hakone volcano contributes to the occurrence of swarm earthquake. However, there is no evidence to show existence of the hydro thermal fluid and a deep-seated magma. To understand the mechanism of swarm earthquake occurrence and tectonic process around Izu-collision zone, we tried to estimate three-dimensional velocity structure in and around Hakone volcano, by using tomographic inversion of seismic wave velocity.

We used the data of 52 temporary stations installed in and around the caldera of Hakone volcano. We also used the data obtained by the permanent seismic station installed by Hot Springs Research Institute of Kanagawa prefecture, Earthquake Research Institute, National Research Institute for Earth Science and Disaster Prevention, and Japan Meteorological Agency. The double-difference tomography method (Zhang and Thurber, 2003) was applied to the present analysis.

Under Hakone volcano, low Vp and low Vs anomaly regions were estimated in the depth range from 6 km to 15 km. Within the low velocity zone, Vp/Vs is high (1.9) in the 10-15km depth, while that at the 6 km depth is relatively low (1.6). This result suggests that the deep-seated magma body is located in the high Vp/Vs region, and the low Vp/Vs region reflects the hydro thermal fluid or volatiles from the magma body. High Vp and high Vs regions were estimated under Tanzawa Mountains. The high velocity zone corresponds to a plutonic body of tonalite or hornblende gabbro. A low-velocity wedge was estimated between Tanzawa Mountains and Hakone volcano that corresponds to trough-filled deposits.

Continental Moho slanting upwards to the southeast beneath Kii Peninsula and middle layer earthquakes

SHIBUTANI, Takuo[1*] ; IMAI, Motohiro[1] ; HIRAHARA, Kazuro[2] ; NAKAO, Setsuro[1]

[1]DPRI, Kyoto Univ, [2]Science, Kyoto Univ

We carried out linear array seismic observations in Kii Peninsula from 2004 to 2013 in order to estimate the structure of the Philippine Sea slab and the surrounding area. We performed receiver function analyses for 14 cross-sections including four profile lines in the dipping direction of the slab and two lines in the perpendicular direction so far. We estimated three dimensional shapes of seismic velocity discontinuities such as the continental and oceanic Mohos and the upper surface of the oceanic crust. The results clearly showed that the slab top and the oceanic Moho are dipping northwestwards and that they correspond to the upper surfaces of the low and high velocity layers, respectively. Beneath northern to central Kinki the continental Moho spreads subhorizontally at 35 - 37 km deep, while beneath the Kii Peninsula it shallows southeastwards above the slab, reaching 20 km at the central part and 15 km at the southern shore.

Mizoue et al. (1983) analyzed data from permanent seismic stations which were being developed in the Kii Peninsula at that time, found that the travel time differences between the direct P waves and the Moho reflections or the Moho refractions propagating in the east - west direction became smaller from the northern part to the southern part of the peninsula, and suggested that the continental Moho slanted upwards to the south. They also found out earthquakes in the middle depth which were distinguished from both events in the upper crust and in the Philippine Sea slab, and called them as middle layer events. They pointed out that the middle layer events occurred around the slant continental Moho.

As mentioned above our receiver function analyses successfully estimated the three dimensional configuration of the continental Moho with a high accuracy. The results clearly showed that the middle layer events are located beneath the continental Moho shallowing southeastwards. Usually no earthquake occurs in the depth range equivalent to the lower crust. This is because crustal materials deform plastically at the depth and the strength of plastic flow becomes lower than that of brittle fracture. However, if the continental Moho shallows to the depth, the strength of plastic flow for mantle materials becomes larger than that of brittle fracture. This can be a cause of the middle layer events in the shallow mantle.

Seismic anisotropy within the subducting Philippine Sea slab beneath the central Japan

SHIOMI, Katsuhiko[1*]

[1]NIED

Subduction of the Philippine Sea slab (PHS) is caused recurrent megathrust earthquakes every 100 to 150 years. Knowledge of slab geometry has been increased by using the recently established dense seismograph networks, but anisotropic feature, which is related to the tectonic stress field and/or rock properties, within the slab is still unclear. To reveal depth-dependent anisotropic feature within the PHS by using teleseismic receiver functions (RFs), we select 100 stations located in the Kii Peninsula and Shikoku, southwest Japan. We choose teleseismic events (M>6.0) from October 2000 to November 2013 for RF analysis, and use seismograms with good S/N. Low-pass filters with fc = 1.0 and 1.5 Hz are applied to estimate RFs. To estimate the orientation of anisotropy symmetry axis at each station, we apply the harmonic expansion method to the RFs (Bianch *et al*., 2010; JGR). When we apply this method to the data, we focus at the Moho depth for the CCD stacking and use the seismic velocity model by Matsubara & Obara (2011; EPS).

In the depth range around the slab Moho, the plunge azimuths in the eastern Kii, central and western Shikoku are corresponds well to the dip direction of the slab Moho estimated from the radial RFs only (Shiomi *et al*., 2008; GJI). At the southern edge of the Kii Peninsula, the plunge azimuths are rotated to clock-wise from the result of Shiomi *et al*. (2008). When N-S directed anisotropic rock exists just above the Moho, this feature can be explained. In the oceanic crust, the plunge azimuths and anisotropic axes correspond well to the dip direction of the slab, and 4-lobed terms are dominant as the Moho deepens to 40 km. This feature is consistent with the NE-SW extension field estimated from the focal mechanisms of earthquakes occurred in the slab. Within the oceanic mantle, plunge azimuths and anisotropic axes are directed to E-W direction. This direction corresponds to the spreading direction of the subducting PHS beneath this area.

The receiver function analysis at the area of the Nobi earthquake (II)

IIDAKA, Takashi[1*] ; IGARASHI, Toshihiro[1] ; KATO, Aitaro[1] ; IWASAKI, Takaya[1] ; JOINT SEISMIC OBSERVATIONS, At the area of nobi earthquake[1]

[1]ERI, Univ. of Tokyo

1) Introduction

The mechanism of the inland earthquakes is related to the concentration of the strain and accumulation of the stress. It is very important to know the relationship between the stress/strain and fault plane. The 1891 Nobi earthquake is one of the biggest inland earthquakes in Japan. The joint geophysical observations had been done at the area. Based on the results of the previous survey at the Atotsugawa fault region, we found that the lower crust structure and fluid were very important factors to the cause of the inland earthquake. In the Nobi earthquake area, the seismic tomography studies figured out the existence of a low velocity region beneath the fault. The low velocity region continues to the subducting Philippine Sea slab. It can be interpreted that the low velocity region is made by water, which was dehydrated from the subducting slab. It is expected that there is some close relationship between the inland earthquake and liquid released from the subducting slab. We did receiver function analysis at the faults area of the Nobi earthquake.

2) Data

The seismic network deployed by the Japanese University Group of the Joint Seismic Observations and the seismic stations belong to the Hi-net were used.

The earthquakes with the epicentral distances from 30 to 90 degs were used. The earthquakes occurred from Aug., 2002 to Mar. 10, 2011.

3) Results

It has been suggested that the configuration of the subducting Philippine Sea plate is distorted in the southwestern Japan region. We figured out the image of the subducting Philippine Sea plate using the receiver function analysis.

The cross sections along the longitude of 137.5^{o} E and 137^{o} E suggested the negative and positive receiver function boundaries. We can trace the negative and positive boundaries from shallower part to deeper part. The boundaries are interpreted as the upper boundary and oceanic Moho of the subducting Philippine Sea plate. It was found that the Philippine Sea plate is lying in a horizontal beneath Ise bay to Wakasa bay by the previous studies. Our receiver function results also support the result. We can obtain clear image of the crust and upper most mantle of the area using the spatially high dense seismic array deployed by the joint seismic observation.

P-wave velocity structure in the forearc region of the southwestern Nansei-Shoto (Ryukyu) Trench subduction zone

NISHIZAWA, Azusa[1*] ; KANEDA, Kentaro[1] ; OIKAWA, Mitsuhiro[1] ; FUJIOKA, Yukari[1] ; HORIUCHI, Daishi[1]

[1]Japan Coast Guard

We carried out five seismic lines across the southwestern Nansei-Shoto (Ryukyu) forearc region to elucidate variation in crustal structures along the trench. The seismic experiment consists of multichannel reflection seismic (MCS) profiling using 240 ch. and 3000 m long hydrophone streamer and wide-angle seismic refraction profiling using ocean bottom seismographs (OBSs) as receivers. We present the seismic structure related to the Philippine Sea plate subduction in the forearc region of the Nansei-Shoto island arc.

Thick materials with Vp less than 4 km/s characterize the accretionary wedge at the front of the forearc basin in the oblique subduction area to the southwest of 126 E. On the other hand, P-wave velocity structure beneath the high free-air gravity region in the forearc at 126-128 E reveals that materials with a high velocity of around 4.5 km/s ascend to 2-3 km beneath the seafloor. The subducting Okinawa-Luzon fracture zone was able to be clearly imaged not only in MCS profiles but also in the P-wave velocity distribution to the northeast of 126 E. We will discuss the relationship between the variation in the seismic structure and the characteristic of the regional seismicity.

Many OBSs on the forearc region recorded several reflection signals from the subducting Philippine Sea plate. We tried mapping these signals to estimate the position of the subducting plate.

Spectral and spatial characteristics of the refined CRUST1.0 gravity field

TENZER, Robert[1*] ; CHEN, Wenjin[1]

[1]School of Geodesy and Geomatics, Wuhan University

We investigate the density structure of the oceanic and continental crust using the global crustal model CRUST1.0, which has been refined by incorporating additional global datasets of the topography/bathymetry (ETOPO1), the polar ice sheets (DTM2006.0 ice-thickness data) and the global geoid model (GOCO-03S). The analysis reveals that the average crustal density is 2830 kg/m^3, while it decreases to 2490 kg/m^3 when including the seawater. The average density of the oceanic crust (without the seawater) is 2860 kg/m^3, and the average continental crustal density (including the continental shelves) is 2790 kg/m^3. We further compile the gravity field quantities generated by the Earth crustal structures. The correlation analysis of results shows that the gravity field corrected for major known anomalous crustal density structures has a maximum (absolute) correlation with the Moho geometry. The Moho signature in these gravity data is seen mainly at the long-to-medium wavelengths. At higher frequencies, the Moho signature is weakening due to a noise in gravity data, which is mainly attributed to crustal model uncertainties. The Moho determination thus requires a combination of gravity and seismic data. In global studies, gravimetric methods can help improving seismic results, because (i) large parts of the world are not yet sufficiently covered by seismic surveys, and (i) global gravity models have a relatively high accuracy and resolution. In regional and local studies, the gravimetric Moho determination requires either a detailed crustal density model, or seismic data (for a combined gravity and seismic data inversion). We also demonstrate that the Earth long-wavelength gravity spectrum comprises not only the gravitational signal of deep mantle heterogeneities (including the core-mantle boundary zone), but also shallow crustal structures. Consequently, the application of spectral filtering in the gravimetric Moho determination will remove not only the gravitational signal of (unknown) mantle heterogeneities, but also the Moho signature at the long-wavelength gravity spectrum.

Correction of Gravity Measurements Utilizing GSI Maps and its Application in the Southern part of Uemachi Fault Zone

RYOKI, Kunihiro[1*]

[1]Hyogo Polytechnic Center

1. Summary

In Earth science research with some field work, acquisitions of geolocation of the measurement point are essential. Particularly, it is a major burden that the latitude, longitude and altitude of the measurement points are obtained for the various corrections in gravity measurements. These pieces of information can be obtained by geodetic surveying or GNSS surveying in the field. Occasionally, topographic maps of large scale are substituted for these surveying.

On the other hand, the acquisition of geographic information, that has been digitized, into a numerical value has become possible on WWW in recent years. Web browsing service map of GSI, Geospatial Information Authority of Japan, which had been put to the test, was translated to the formal opening to the public on October 30, 2013. The new browsing service is ”GSI Maps” (GSI, 2013a). According to the Agreement of GSI Tile Use, it is to be able to take advantage of this service in the academic research (GSI, 2013b). Therefore, it is created that JavaScript applications give information on the measuring position by using GSI Tiles (GSI, 2013c). If combined with some mobile digital devices, information of geolocation is readily available even in the field.

When gravity measurements have been conducted, until now, the authors have been made the most use of the large-scale topographic map as the base map in the southern part of Uemachi Fault Zone. These results were mixed up to base on Tokyo Datum and Japanese Geodetic Sytem 2000. Therefore, they are integrated with the latter in this time.

2. Target area

Survey’s line of the target has integrated the results by Ryoki (2011), Ryoki and Nishitani (2013) and recent measurements. The length of the survey line is about 9,7 Km. The line lies from Yunagi-cho Izumiotsu to Ibukino Izumi and intersects the some faults included in Uemachi Fault Zone.

3. Acquisition of geographic information

Latitude, longitude and altitude of the measuring points were used numerical information provided by GSI. These elements obtained by constructing an HTML application. A JavaScript code has been created to revise some samples of GSI Tile. In general, for the purpose of protecting the system, the string is not transferred directly to the clipboard from a Web browser. However, there is a function to be transferred through JavaScript in the specific browser. On the other hand, in some browsers which not support such a function, the ZeroClipBoard library is possible to use to transfer the information (zeroclipboard.org, 2014). Numerical information, transferred to the clipboard, is edited in a spreadsheet application or in an editor software. In this study, an application which is used at indoor after measurement in situ is coded for a batch process. If operated in tablet devices instead to a field note book, numerical information is easily got in the measurement point. Numerical site information is used for various corrections and illustrated the gravity measurement point on the map.

4. Result

Formerly, in order to obtain numerical information related to the measurement point, latitude, longitude and altitude had been read using a digitizer from topographic map. But, if using the application proposed in this paper, time required for these operations could be significantly reduced. In particular, as it becomes a constant accuracy of the reading errors of the elevations which determined by GSI Maps, homogeneity of the data could be secured.

5. Challenges for the future

It is obvious that the application, which is proposed in this paper, ensures the homogeneity of data and improves the measurement efficiency in a variety of field research that includes geosciences. Development of the system for the operation of the tablet terminal is able to challenge, and it is an aim that an application of the terrain correction have been considered in the future.

The crustal structures of the subduction of the Philippine Sea Plate in the northern Nansei-Shoto trench

OIKAWA, Mitsuhiro[1*] ; NISHIZAWA, Azusa[1] ; KANEDA, Kentaro[1] ; FUJIOKA, Yukari[1] ; HORIUCHI, Daishi[1]

[1]Japan Coast Guard

Seismic characters of convergent plate boundaries are reflected in the heterogeneity in the structural evolution, the interior regime as well as external architecture (Kopp, 2013). At the north end of the Nansei-Shoto trench the Amami plateau, which is known as a remnant arc, is subducting, and this causes a landward concave of the subduction axis. The Nansei-Shoto trench was recognized that its seismicity is rather low, but in the past few years, new scientific researches indicated the possibility of a mega earthquake is not so much low. There are needs to grasp the Philippine Sea plate's topography and crustal structure around the sea area of the Amami plateau because they might be constraint conditions how the mega earthquake could happen.

Japan Coast Guard conducted two integrated seismic experiments that combine a wide-angle refraction survey and a multi-channel reflection survey. The first line (line ECr10) was conducted in 2009 and the second line (line ECr11) was carried out in 2012. ECr10 started from the west end of the Amami plateau to the north sea area to the Amami-O-Shima island. ECr11 started from the Kikai basin to the just south of the Yaku Shima Island. A depression on the Nansei-Shoto arc between two seismic lines is well known as a major tectonic boundary of the Nansei-Shoto arc.

The southern end of ECr10 is the west edge of the large Amami plateau. Uyeda(2005) said that there is a local bouguer low anomaly and this means the crust of the Amami plateau should be thicker than the normal oceanic crust. The past seismic survey (Nishizawa et. al., 2009, 2014) reveals that the thickness of the center Amami plateau is approximately 16km, which is obviously thicker than the normal oceanic. The southern end of ECr11 is located on the Kikai basin. The Kikai basin's bouguer anomaly is rather high, this means the possibility that the crust of the Kikai basin should be an oceanic crust. The seismic survey supports the high anomaly because of its thin crust. However the composition of the crust shows the horizontal heterogeneity of its crust and an identification of the middle crust (6.0 - 6.5 km/s layer) exists (Nishizawa et. al. 2009). These characters do not support that the basin is a typical oceanic crust.

We made a comparison of the structure on the Philippine plate between ECr10 and ECr11, by using the seismic surveys results and the precise bathymetric data collected by Japan Coast Guard. Regarding topography, we found many normal faults parallel to the trench direction. Especially there are more faults on the margin of the Amami plateau than of the Kikai Basin. As for crustal structures, the crust of the Amami plateau has a middle crust. The existence of middle crust is along with the past results but not only of the Amami plateau but also of Kikai basin. This means that the subducting margin of the Kikai basin might not be a typical oceanic crust.

Seismic structure beneath Kyushu island, Japan, inferred from S-wavevector receiver functions.

UEDA, Takuya[1*] ; TAKENAKA, Hiroshi[2] ; MURAKOSHI, Takumi[3] ; OKAMOTO, Taro[4]

[1]Kyushu Univ., [2]Okayama Univ., [3]National Defense Academy, [4]Tokyo Institute of Technology

The underground structure of Kyushu region is characterized by active subduction of the Philippine Sea plate (PHS) beneath the Eurasian plate and several active volcanos, for example, Aso, Kirishima, and Sakurajima volcanos along with the volcanic front, and Unzen volcano located Beppu-Shimabara graben. And also there are very thick sediments at several plains in Kyushu. Therefore the seismic structure beneath Kyushu Island is seemed to be very complicated and it is very important to understand the detailed structure, especially around Moho and the top of PHS. There are many previous researches on seismic structure beneath Kyushu Island. Travel time tomography method is very useful tool for imaging the subsurface structures. In the previous works, a lot of characteristic structures are identified by the tomography for example, low velocity structure beneath volcanic front.

Receiver function analysis is also very useful tool to image the seismic velocity structures. We apply it to image seismic structure on Kyushu area. In this study, we use teleseismic records from Hi-net and F-net seismic stations in Kyushu, which are supplies by the National Research Institute for Earth Science and Disaster Prevention.

If those seismic stations are located at the top or in the sedimentary layer, the records include strong effect of reverberation within the sedimentary layer, which makes the image of the structure unclear. To overcome this problem, we exploit the modified S-wavevector receiver functions (SWV-RFs). The SWV-RFs are derived by deconvoluting the upgoing S-wave component with the upgoing P-wave component of the records. For suppressing the sedimentary layer effect, we apply SWV-RFs for borehole records and move virtually the seismic sensor to the top of the basement layer, and calculate the SWV-RFs at that location [Takenaka and Murakoshi, 2010]. This method needs the structure model from the surface to the sensor location. We employ the Integrated Velocity Structure Model by the Headquarters for Earthquake Research Promotion. We take several cross sections in Kyushu Island to map the calculated SWV-RFs. We then interpret the continental Moho and low velocity regions in the mapped SWV-RFs. It can be seen that characteristic low velocity regions in mantle wedge, some of which may be related to magma. We also model some SWV-RF sections by the 2.5-D finite-difference method to confirm our imaging results.

Seismic reflection survey at the Kego fault, Kyushu, Japan

MATSUMOTO, Satoshi[1*] ; SHIMIZU, Hiroshi[1] ; NAKAMOTO, Manami[2] ; MIYAZAKI, Masahiro[2] ; ABE, Susumu[3]

[1]Institute of Seismology and Volcanology, Kyushu Univ., [2]Faculty of Sciences, Kyushu University, [3]R&D Department, JGI, Inc

Kego fault is one of the active faults in Japan, which located Kyushu Island, Japan. The fault is composed of two major segments; the earthquake fault of the 2005 West-off Fukuoka prefecture earthquake and southeastern part running through central Fukuoka City. We performed reflection survey at the southeastern part of the fault in order to explore detailed structure of the fault. The experiment was carried out on the two profile. One was located at central part of Fukuoka city with length of 1 km for obtaining reflection section shallower than depth of 1 km. Another was for imaging heterogeneous structure in the seismogenic zone beneath the fault, which was deployed 35 km length across southeast end of the fault. After applying seismic reflection processing, we obtain reflection sections for two profiles. The gap of horizontal reflector was found around the depth of 0.6 km in the shallow seismic section at central Fukuoka, corresponding to the Kego fault. The hanging wall of the fault is western side of the fault as geological study suggested. The deep section at the southeastern part of the fault reveals that strong reflective layers exist in the seismogenic zone at the west of the fault. In addition, we found many reflectors at the lower crust beneath the whole area of the profile.

P-wave heterogeneous structure around the Kego fault inferred from reflection analysis for seismic network data

KAMIZONO, Megumi[1*] ; MATSUMOTO, Satoshi[2] ; MIYAZAKI, Masahiro[1] ; NAKAMOTO, Manami[2] ; SHIMIZU, Hiroshi[2] ; ABE, Susumu[3]

[1]Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, [2]Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, [3]R&D Department, JGI, Inc.

The Kego fault is one of the active fault in Japan, running through the western margin of the Fukuoka plain. On March 20, 2005 the west off Fukuoka earthquake (M7.0) occurred at northwestern extension of the Kego fault. In order to evaluate the effect on the fault by the earthquake, crustal structure is basic information to model the fault condition. This study estimated the subsurface structure around the Kego fault from artificial source used in the reflection survey.

In the survey, vibrator tracks are used as seismic sources at 8 shot points. Sweep time of the source is 24 seconds and sweep frequency range is from 6 Hz to 30 Hz. We recorded the signal from the vibrators at seismic stations deployed by Kyushu University and NIED. Seismic reflection analysis was applied to the data for detecting reflectors beneath the CMP line located between the reflection profile and the station. As simplicity, we processed observed data on the assumption that basement is homogeneous.

We obtained seismic deapth sections at CMP lines for the seismic stations. Numerous refletors in the lower crust are found in the sections; therefore the lower crust is heterogeneous. The reflective zone in the lower crust is from the depth 20 to 32 km in the section, suggesting that the lower limit of the zone corresponds to the Moho discontinuity. Since the section imaged heterogeneous structure across the Kego fault, we compared characteristics of reflectivity between footwall and hanging walls of the fault. The structure of the superficial part is different depending on the place. At the some point CMP lines, there are reflector in the western side, however in the eastern side of the fault it is not so. This difference in reflectivity depends on the cross point between the CMP line and the fault. This suggests that there isn't clear difference in east and west of the fault at other point. Consequently, there might be variation of the structure along the strike of the Kego fault.

The seismic velocity structure in the Northern Kinki District using the dense seismic observation

KAIYA, Emi[1] ; KATAO, Hiroshi[1*] ; SHIBUTANI, Takuo[1] ; IIO, Yoshihisa[1] ; MIURA, Tsutomu[1]

[1]DPRI, Kyoto Univ.

Micro-seismicity in the Northern Kinki District is active. However we don not know the cause and the relation between these seismic activities and crustal structure or active faults around there clearly. In the Northern Kinki District, we are carrying out a dense array seismic observation using 83 temporal stations since 2008. The average station interval at the center of the Tamba plateau is about 5km, so we expect to know the seismic structure beneath this region with higher resolutions than that derived from the permanent stations.

In this study, we estimate high-resolution seismic velocity structure using data from these dense observations. Based on the results of 3D seismic velocity tomography, we discuss about relations between the seismic activities and other geophysical and geological features of this area.

Seismic attenuation beneath Tateyama volcano

IWATA, Koji[1*] ; KAWAKATA, Hironori[2] ; DOI, Issei[3]

[1]Ritsumeikan University, [2]Ritsumeikan University, [3]Disaster Prevention Research Institute

Tateyama volcano (Midagahara volcano) locates in southeast Toyama prefecture. Subsurface structures beneath active volcanoes have frequently been investigated using seismic attenuation (e.g., Oikawa et al., 1994: Sudo et al., 1996), and it was reported that there are strong attenuation regions beneath some active volcanoes. The volcanic activity of Tateyama volcano is quite low, and subsurface structure beneath the volcano has not been investigated in detail. Since Hi-net was developed by NIED, the attenuation structure of whole area of Japan has been estimated (e.g., Jin and Aki, 2005; Carcole and Sato, 2009). However, local structure beneath inactive volcanoes is still in question. In this study, we investigated the seismic attenuation beneath Tateyama volcano using seismograms obtained by Hi-net.

In this study, we used seismograms of five Hi-net stations near Tateyama volcano. The seismograms were selected so that epicentral distances from Tateyama volcano were 70 km˜140 km, the magnitudes of the earthquakes were larger than 2.5, focal depths were less than 30 km, and signal-to-noise ratios were sufficiently high.

At first, we focused on the two stations which locate opposite sides of Tateyama volcano each other, and compared seismograms whose epicenters were located almost along the line of Tateyama volcano and the two stations. For the seismograms which passed beneath the volcano, S-waves were more attenuated than P-wave. In detail, S-wave attenuation was pronounced in 4˜8Hz and 8˜16 Hz bands. This feature was seen in all seismograms from northwestern or southeastern sources. On the other hand, seismograms from northeastern or southwestern sources did not show such a feature. There should be a region that preferentially attenuated S-waves beneath Tateyama volcano, and the distribution is heterogeneous.

Also, it should be noted that S-waves passing beneath Tateyama volcano showed clear peak delay, which suggested that there was a region with high scattering attenuation beneath Tateyama volcano.

Detailed velocity structure along the Nankai trough, off the Kii Peninsula, obtained from DONET data

NAKANO, Masaru[1*] ; NAKAMURA, Takeshi[1] ; TONEGAWA, Takashi[1] ; KANEDA, Yoshiyuki[1]

[1]JAMSTEC

Along the Nankai trough off southwestern Japan, the Philippine Sea (PHS) plate is subducting to the northwest below the Eurasian plate. Historically, mega-thrust earthquakes have occurred repeatedly along the Nankai trough (e.g., Ando, 1975). Future great earthquakes will cause serious and widespread damage in central and western Japan. The Japan Agency for Marine-Earth Science and Technology (JAMSTEC) installed a network of permanent ocean-bottom observation stations off the Kii Peninsula above the source region of the expected great earthquakes. This is known as the Dense Oceanfloor Network System for Earthquakes and Tsunamis (DONET). Previous studies (e.g. Nakano et al., 2014) revealed that the present seismic activity well overlaps the aftershock region of the sequence of 2004 off the Kii Peninsula earthquakes (M_{JMA} = 7.1, 7.4, and 6.5). The focal mechanisms of the earthquakes show that the axis of compressive stress in the PHS plate is oriented N?S, almost perpendicular to the direction of plate convergence, indicating a complex tectonic regime in this region. In this study, we investigate detailed seismic velocity structure in this region.

In this region, P-wave velocity (Vp) structure is well developed based on repeated seismic surveys, but S-wave velocity (Vs) structure is not well known. Therefore, we start from an initial layered velocity structure assuming Vs, and update it to well explain the travel-time of earthquakes, then obtain three-dimensional velocity structure described below.

1. Estimate average layered structure below the study area.

1.1. An initial layered structure of Vp is constructed referring to the result of seismic surveys. The Vp/Vs ratio of each layer is assumed considering oceanic structures. Using this structure, we determine the hypocenter distribution.

1.2. Using the travel-time and initial hypocenters, 3D velocity structure is computed by using the tomoDD program (Zhang and Thurber, 2003).

1.3. The 1D velocity structure is updated by averaging the velocity at each depth.

1.4. Hypocenters are re-calculated based on the updated velocity structure, and the procedures 1.2.-1.4. are repeated until the 1D velocity structure converges.

2. Construction of 3D velocity structure.

2.1. Initial 3D velocity structure representing the subducting plate and oceanic sedimentary layers is constructed based on the study of Nakamura et al. (2011). Vp is from the result in 1.

2.2. The Vp/Vs ratio of each layer is obtained by a grid search method, in which minimizes the residual between observed and calculated travel time.

2.3. Site correction is obtained for the best model.

3. Computation of detailed 3D velocity structure.

3.1 Using the velocity structure and hypocenter distribution obtained in 2. as the input, detailed 3D velocity structure is obtained by using tomoDD program. In the computation of travel time, the site correction obtained in 2.3. is included.

The obtained velocity structure shows that the velocity anomaly along the trough anomaly well corresponds to the earthquake distribution. In the oceanic crust, seismic activity corresponds to a region of low-velocity anomaly, while earthquake distribution corresponds to a high-velocity anomaly in the mantle. The obtained structure may help to understand the detailed structure in this region. However, since the used data is from earthquakes immediately below DONET, the resolution of tomography may not be good. We will investigate the resolution and dependence on the initial velocity structures in the future study.

Mechanism of large crustal earthquakes in Kanto and Chubu: Influence of structural heterogeneities

FUJISAWA, Moeto[1*] ; ZHAO, Dapeng[1] ; TOYOKUNI, Genti[1] ; KITAGAWA, Hiroki[1] ; NISHIZONO, Yukihisa[2] ; INAKURA, Hirohito[2]

[1]RCPEV, Tohoku Univ., [2]West Japan Engineering Consultants, Inc.

Large inland crustal earthquakes often cause heavy damage to human society. Therefore it is very important to clarify the generation mechanism of the large crustal earthquakes for disaster reduction. It is considered that fluids dehydrated from the subducting Pacific and Philippine Sea slabs affect the nucleation of large crustal earthquakes under the Japan Islands (Zhao et al., 2010). In this study, we focus on the Kanto and Chubu regions, and investigated the cause of large crustal damaging earthquakes (M>6) (Usami et al., 2013; Utsu, 1999) by comparing the earthquake distribution with tomographic images of the crust and upper mantle.

We used high-quality arrival-time data of local earthquakes which occurred during June 3, 2002 to June 26, 2013 complied by the Japan Meteorological Agency (JMA) Unified Catalogue and those during June 3, 2002 to November 10, 2013 compiled by the Tohoku University Data Base. The local events were carefully selected based on the following criteria. (1) All the events were recorded by more than 20 seismic stations; (2) the uncertainty of hypocentral location is smaller than 4 km; (3) to keep a uniform distribution of hypocenter locations and avoid the event clustering, we divided the study area into small blocks (5 km $\times$ 5 km $\times$ 1 km), and selected only one event in each block that was recorded by the maximal number of seismic stations. As a result, our data set consists of 824,742 P-wave and 627,664 S-wave arrival times from 21,831 events recorded by 877 seismic stations in the study area. We applied the tomographic method of Zhao et al. (1992) to our data set. The grid interval is 0.20 deg. in the lateral direction and 15?30 km in depth, which is the resolution scale of the 3-D velocity model we obtained. The final root-mean-square ravel time residual is 0.287 s for the P-wave data and 0.424 s for the S-wave data.

Our results show significant velocity variations in the crust and upper mantle. The subducting Pacific and Philippine Sea slabs are imaged clearly as high-velocity zones. In contrast, low-velocity anomalies are revealed in the crust and mantle wedge beneath active arc volcanoes, which reflect the source of arc magmatism produced by slab dehydration and corner flow in the mantle wedge. Most of the large crustal earthquakes are located in or around the low-velocity zones in the crust and/or the uppermost mantle. These results suggest that the generation of large crustal earthquakes are affected or controlled by the structural heterogeneities. In particular, fluids play an important role in the nucleation of the large earthquakes.

Seismic Reflection Surver around the Mouth of Fuji River

ITO, Shinobu[1*] ; YAMAGUCHI, Kazuo[1] ; IRITANI, Ryohei[1] ; YAMANAKA, Yoshiaki[2] ; ITO, Shun'ichiro[2] ; MURATA, Kazunori[2]

[1]GSJ, AIST, [2]Suncoh Consultants Co., Ltd

We conducted seismic reflection survey around the mouth of Fuji River in February 2014. Fujikawa-kako fault zone is identified around this area. Shimokawa et. al. (1996) conducted seismic reflection survey in this area, and identified the Iriyamase fault. Shizuoka Pref. (1996) also identified the Nakayama fault. Our purpose of the survey is that we understand structure around both the Iriyamase and the Nakayama fault in more detail than the previous studies. There are two seismic survey lines. A survey line FJK1 is located from the mouth of Fuji river toward Mukaida river along the coastline, and the length of the line is about 3.5km. A survey line FJK2 is located on the right bank of Fuji river and at about 2km north from the coastline, and cross over the Kambara Jishinyama. The length of FJK2 is a little bit longer than 1km. We used IVI Y2400 as seismic source. Sweep frequency for FJK1 and FJK2 is 10 to 100Hz and 10 to 120Hz, respectively. Sweep length is 12s, and record length is 16s for both lines. We used SG-10 (10Hz of natural frequency) and DSS-12 that is a distributed seismic data acquisition system. Temporal spread length of FJK1 is about 1km. We fixed the spread of FJK2. Geophones are set at intervals of 5 meters for both lines. Some events can be deduced as reflected waves in some samples of shot records for FJK1. However, we are afraid that they are produced by a bank. Soon, we are going to show detailed results.

Depth variation of the P- and S-wave velocities in the Kanto sedimentary basin inferred from seismic interferometry

YOSHIMOTO, Kazuo[1*] ; SUGAWARA, Yuma[1] ; KAJIKAWA, Kengo[1] ; KOBAYASHI, Manabu[1] ; MASUDA, Kei[1] ; TAKEMURA, Shunsuke[1] ; HIRATA, Naoshi[2] ; SAKAI, Shin'ichi[2] ; SATO, Hiroshi[2] ; NAKAHARA, Hisashi[3]

[1]Nanobioscience, Yokohama City Univ, Yokohama, Japan, [2]ERI, Univ. of Tokyo, Tokyo, Japan, [3]Geophysics, Science, Tohoku Univ, Sendai, Japan

Information on the seismic velocity structure of the Kanto sedimentary basin is necessary for evaluating the strong and long-period ground motions in the Tokyo Metropolitan area for future large-to-great earthquakes. However, there are few studies on the depth variation of both P and S wave velocities of the sediment, except for the vertical seismic profiling (VSP) measurements at a limited number of deep boreholes. In this presentation, we will report the characteristics of the depth variation of both P and S wave velocities of the sediment on the basis of the seismic interferometry for P and S waves of local earthquakes.

Seismic waveforms of 160 local earthquakes recorded by the MeSO-net were analyzed in this study. The autocorrelation of vertical displacement waveform of P wave and SH displacement waveform from a single event were stacked over all events available at each station, respectively, to obtain the P- and S-wave reflection responses of the Kanto sedimentary basin. We successfully found clear P- and S-wave reflections from the bedrock (seismic basement) at 266 observation points. This result indicates that the P-wave seismic interferometry is effective for the exploration of deep sedimentary basin as well as S-wave interferometry. In our dada, two-way travel time between the free surface and the bedrock of P-wave and S-wave (hereafter Tp and Ts, respectively) ranges from 0.5 s to 4.0 s and 2.0 s to 8.0 s, respectively. A graph showing Tp-Ts relation reveals that the trend of its variation is very similar to that reported at Iwatsuki deep boreholes from VSP measurement, even though there is a large scatter of data. Our results indicate that the ratio of P-wave velocity and S-wave velocity of the sediment is approximately 4 at a shallow depth ($<$0.5 km) and decreases down to 2 or less at a deep depth ($>$2.0 km) in the Kanto sedimentary basin.

ACKNOWLEDGMENTS
Data provided by the MeSO-net is gratefully acknowledged. This research was partially supported by the Earthquake Research Institute, University of Tokyo.

Seismic activity and attenuation structure in fukushima-yamagata prefectural border area

MIYAGKI, Keiichiro[1*] ; TSUMURA, Noriko[1]

[1]Faculty of Science, Chiba University

In Fukushima - Yamagata prefectural border area, seismicity suddenly became active after off the Pacific coast of Tohoku earthquake (here after we call it 2011 Tohoku earthquake). We estimated distribution and focal mechanisms of earthquakes that occurred in the time period before and after the 2011 Tohoku earthquake to clarify causes of the seismicity activation. We used seismograms which are observed at the Hi-net stations operated by National Research Institute for Earth Science and Disaster Prevention. Earthquakes with M ≧ 2.0 in the Hi-net catalogue from July 3 , 2002 to March 10 , 2011 and from April 1 , 2011 to August 31 , 2011 were analyzed in this study. As a result, hypocenters which occurred after the main shock were distributed into five clusters they were located at different region from those where earthquakes occurred before the main shock. It is known that there are active faults near the study area. A fault plane estimated from a northwestern cluster ' s hypocenters shows similar strike and dip of that of an active fault. Further, fault planes estimated from another clusters ' hypocenters seems to have a conjugate relationship with the fault plane of the active faults. In addition, we observed that hypocenters in some certain clusters moved to lateral and vertical direction with approximately constant speed. Most earthquakes have the thrust-type focal mechanisms during the study period. Q value is considered to be a sensitive parameter to temperature and existence of fluid in the crust. We estimated Qp/Qs value by taking velocity amplitude spectral ratio between P and S waves to evaluate the affection of magma or fluid to earthquake occurrence. We used 898 spectra of 152 earthquakes which were observed by 9 stations nearby source region to calculate average Qp/Qs value on the ray path by Takaoka et al. (2013) ' s method. As a result, ray paths from the hypocenters to stations within 20km showed high Qp/Qs values, while paths from the hypocenters to the far stations showed low Qp/Qs values. This result might indicate that high attenuation region exists in a shallow part nearby source region.

Crustal and upper mantle structure of East Antarctica, derived from broadband seismic deployments at the International P

KANAO, Masaki[1*] ; TSUBOI, Seiji[2]

[1]National Institute of Polar Research, [2]Japan Agency for Marine-Earth Science and Technology

Deployment of broadband seismic stations on the Antarctica continent have been an ambitious project to improve the spatial resolution of seismic data across the Antarctic Plate and surrounding regions. Several international collaborative programs were conducted in Antarctica during the International Polar Year (IPY 2007-2008). The Antarctica's GAmburtsev Province (AGAP; IPY #147), the GAmburtsev Mountain SEISmic experiment (GAMSEIS), a part of AGAP,, and the Polar Earth Observing Network (POLENET; IPY #185) were major contributions in establishing a geophysical network in Antarctica. The AGAP/GAMSEIS project was an internationally coordinated deployment of more than 30 broadband seismographs over the crest of the Gambursev Mountains (Dome-A), Dome-C and Dome-F area. The investigations provide detailed information on crustal thickness and mantle structure; provide key constraints on the origin of the Gamburtsev Mountains; and more broadly on the structure and evolution of the East Antarctic craton and subglacial environment. In addition to the PASSCAL observation system by USA, original coordinated systems were developed by Japan (at Dome-F (GM07) and GM06 stations), as well as by other groups in China and France. Regarding Japanese instrument system, the same sensor and data logger as used by US/PASSCAL were utilized, but the electric power supply system and enclosures were developed independently. Data were recorded in MiniSEED format, a commonly accepted international standard, to ease analysis. Logistical and staff support were provided by the US researchers and staff at AGAP-S camp in the installation of the Japanese stations GM06 and GM07. From GAMSEIS and POLENET data obtained, local and regional seismic signals associated with ice movements, oceanic loading, and local meteorological variations were recorded together with a significant number of teleseismic events. In this presentation, in addition to the Earth's interiors, we will demonstrate some of the remarkable seismic signals detected during IPY that illustrate the capabilities of broadband seismometers to study the sub-glacial environment, particularly at the margins of Antarctica. In future, monitoring stations inland ice plateau of Antarctic, such as Dome-F, firmly attribute a crucial role in the Federation of Digital Seismographic Network (FDSN) in southern high latitude.

Seismo-stratigraphy and structure of the Adventure Plateau (Sicily Channel): an example of old data recovery

CIVILE, Dario[2] ; ALP, Hakan[1*] ; LODOLO, Emanuale[2] ; CENTONZE, Jacques[2]

[1]Istanbul University Department of Geophysics, [2]Istituto Nazionale di Oceanografia e di Geofisica Sperimentale

We present here a seismo-stratigraphic and structural study of the Adventure Plateau, the north-westernmost sector of the Sicily Channel. This bank, where water depths do not generally exceed 150 m, is the shallowest part of the whole Sicily Channel, with relief which sometime rises up to less than 50 m. This analysis is based on a large set of multichannel seismic profiles and well information acquired mostly for commercial purposes in the 70s and 80s. Despite the general poor quality and consistency of the data used, it was possible to draw with sufficient detail the various seismo-stratigraphic sequences, calibrated with well information. The sedimentary sequence crossed by wells in the Adventure Plateau comprises deposits ranging from Triassic to Plio-Quaternary. A broad lithological distinction can be made between the sequences ranging from Triassic to Middle Miocene, predominantly carbonate, and the sequences ranging from Tortonian to Quaternary, predominantly siliciclastic. Moreover, we observe in the wells the presence of various hiatuses, particularly at the top of the Miocene and at the Early Jurassic. Three main structural domains have been identified within the Adventure Plateau: (a) a compressional belt in the N-W part of the bank, deformed during Middle-Late Miocene, and corresponding to the SW-trending offshore part of the Maghrebian Chain; (b) the Adventure foredeep of the Maghrebian Chain, located in the central part of the bank, and filled by over 2000 m of siliciclastic Late-Miocene to Quaternary deposits; (c) the Adventure foreland of the Maghrebian Chain, corresponding to the S-W part of the bank, affected from the Early Pliocene by a strong extensional phase associated to the Pantelleria Graben rifting. The eastern boundary of the Adventure Plateau is part of a broadly NS-trending, lithospheric-scale transfer zone which separates the Sicily Channel into two distinct sectors. This study shows the potential and capability of old data in areas where there is scarce geophysical knowledge. They represent an important source of information, especially for the shallow water areas of the Sicily Channel that are still poorly known in terms of geology and stratigraphy.

Possibility of timelapse survey by seismic interferometry in image domain

SHIRAISHI, Kazuya[1*]

[1]JGI, Inc.

(1) Seismic interferometry in image domain

Seismic interferometry (SI) is generally applied in a data domain by crosscorrelating the different seismic traces without information of media for a redatuming or a signal extraction. Then the synthesized virtual source records are processed for a subsurface imaging. The direct subsurface imaging of passive seismic data by interference of extrapolated wavefields based on an imaging condition can be recognized as a SI in the image domain. Although the image domain SI is based on the velocity model for wavefield extrapolation, the fact that both the passive observation data and the velocity model are required for the depth imaging is common in the data domain SI and the image domain SI.

In the SI in the image domain by combining with the principle of a reverse time migration (RTM), arbitrary time-windowed seismic record is propagated forwards from a receiver point which become a virtual source and the same time-windowed records are propagated backwards from other receiver points. If any multiple reflection waves between the surface and the reflection boundaries satisfy the imaging condition, the reflected energy will be focused on those points. Because the seismic records of all receivers in one passive observation are not independent each other, the wavefield extrapolations can be only once in forward and backward respectively. In the data domain SI, however, the forward and backward extrapolations are repeated over all receiver points in a final RTM, because the virtual source records synthesized by the crosscorrelation should be treated independently. Therefore, total computational cost of the image domain SI could be lower than the data domain SI.

(2) Applicability to a time-lapse study of passive

Passive seismic monitoring or time-lapse survey using permanent observation systems are one of recent research topics. Although high repeatability can be kept in the active seismic survey both on sources and receivers, any repeatability on sources is not guaranteed in the passive seismic survey. In this study, numerical simulation is demonstrated to evaluate the repeatability of the subsurface image and the possibility of extracting a small temporal velocity change by image domain SI with passive seismic data. In this simulation study, simple assumptions with an acoustic wavefield and a same mechanism for all sources are introduced. The passive seismic data for different condition of source distribution or/and velocity perturbation are synthesized, and then the image domain SI is applied for each data set. The repeatability of imaging and the possibility of extraction are measured by some repeatability indexes.

The passive observation records are synthesized using modified overthrust model of SEG/EAGE (15 km x 5 km) with 151 receivers on the surface due to independent 128 sources in the ground (Ricker wavelet with 10 Hz). The sources in the ground are randomly distributed for each model respectively. A velocity change with 10 percent decrease is added in an anticline structure around the center of the model with an elliptical shape (1 km x 0.1 km). A smoothed model from the true velocity model is commonly used for each RTM.

From the simulation study, the global images of the overthrust model are well reproduced in appearance for the different source distributions. However, the repeatability indexes show that the amplitude change due to the source distribution difference is too large to ignore even though the small velocity change can be extracted. Some additional techniques are required to extract only the velocity change without the influence due to the source distribution difference. In addition, there are other difficulties in a real data such as different source mechanism, elastic effects, and some kinds of noises.

Temporal changes of P and S wave velocities in NE Japan associated to the M9Tohoku-Oki earthquake from doublets analyses

PACHECO-VIVERO, Karim[1*] ; NISHIMURA, Takeshi[1] ; NAKAHARA, Hisashi[1]

[1]Geophysics, Science, Tohoku University

Application of seismic interferometry using ambient noise and coda waves of regional earthquakes have shown notable seismic wave velocity decreases associated with the occurrence of the M9.0 Tohoku-Oki earthquake. These analyses can be generally attributed to S-wave velocity changes at shallow structures because these waves are dominant in surface waves. On the other hand, analyses of doublets have also succeeded in detecting temporal changes of direct arrival times of P waves as well as those of S waves. Also, the seismic rays pass deeper portions. However as the medium changes by the M9 earthquake are widely observed in East Japan, it is difficult to separate the observed travel time differences into the effects of hypocenter parameters and the travel time differences caused by the change in the medium beneath the stations. In this study, therefore, we develop a new method to determine temporal changes of P and S wave velocities beneath stations by simultaneously determining hypocenter parameters of doublets. We relate travel time differences of doublets to site factors at each station and the differences of hypocenter parameters. We further give a constraint in which the sum of the differences in origin times of the doublets analyzed is set to be zero, since the doublets are considered to randomly occur. As a result, our inverse problem estimates the model parameters, namely the site factors for P and S waves at each station and the relative locations of hypocenters and origin times of the doublets. Seismic data at 454 stations of the Hi-net seismic network in East Japan are used. We analyze 35 doublets with magnitudes ranging from 3.7 to 4.7 and depths from 30 to 60 km located offshore in East Japan for the period from 2005 to 2013. The seismic data are band-pass filtered between 1-2 Hz and travel time differences of arrival times of P and S waves are measured by applying a cross-spectrum method. The inversion results show that hypocenters of doublets differ by about 0.05 km and 0.12 km at a maximum each other in the horizontal and vertical directions, respectively. Even when we change the data set of doublets, the relative hypocenter locations do not significantly change, which indicates our inversion method is stably determining the hypocenter parameters. For the site factors, we find significant delays of arrival times as large as 0.04 s for the S-waves and about 0.01 s for the P-waves. Time delays are observed mainly at stations located widely in Tohoku region between 37 and 40 degrees in latitude, which are west from the M9 fault zone. The observed spatial distributions of time delays seem not to be well matched with the regions strongly shaken, which are located mostly in the eastern area of Tohoku region, or the regions where seismic velocity reductions at shallow medium are detected from analyses of bore-hole and ground surface records. These discrepancies suggest that the time delays detected from doublets originate from different regions, maybe deeper portions beneath Tohoku region.

Estimation for seismic wave propagation property of soil structure based on seismic interferometry

SEIICHIRO, Kuroda[1*] ; MASUKAWA, Susumu[1] ; TAGASHIRA, Hidekazu[1]

[1]National Institute for Rural Engineering, NARO

Recently seismic interferometry was applied to estimation for seismic response of natural ground but also those of artificial structure like a building. We applied seismic interferometry concept for retrieval of seismic response of a model dike of soil structure like a fill dam. We employed deconvolution interferometry to estimate seismic response in time domain. From the waveforms obtained from deconvolution with the motion in the basement of a model dam, we estimate traveltimes of shear wave propagating through it and its mean velocity. Estimated velocity explain the normal mode of a model dike well. This approach can be applicable to monitor change in seismic response a dike caused by strong earthquakes or its internal water content change.

Temporal changes of auto-correlation functions associated with the volcanic activity in Hakone volcano, central Japan

YUKUTAKE, Yohei[1*] ; UENO, Tomotake[2] ; HONDA, Ryou[1] ; MIYAOKA, Kazuki[1] ; HARADA, Masatake[1] ; SATOMURA, Mikio[1]

[1]Hot Springs Research Institute of Kanagawa Prefecture, [2]National Research Institute for Earth Science and Disaster Prevention

Auto-correlation functions (ACFs) of ambient noise are thought to be a powerful tool for searching temporal change of crustal structure associated with strong ground motion, or volcanic activity. In this study, we investigated the velocity changes at Hakone volcano associated with an intense swarm activity.

Hakone volcano is located at the northern boundary zone of the Izu?Mariana volcanic arc in central Japan, Many intense periods of swarm activity have occurred in the caldera. It was noted, in last two decades, that seismic swarms were remarkably prevalent in 2001, 2006, 2008-2009, 2011 and 2013. During the swarm activities, except for that in 2011, crustal deformations related to volcanic activities were detected by the GNSS stations network in and around the caldera of Hakone volcano. In particular, remarkable tilt changes were also detected by the tiltmeters within the caldera in 2001 and 2013 activities. It is interpreted that the crustal deformation was caused by pressure from a Mogi point source or dike at a depth of 7 km and two shallow open cracks in the caldera (e.g. Daita et al., 2009; Harada et al., 2009).

To estimate the velocity changes associated with the 2013 activity, we used the continuous velocity waveforms recorded at the stations of Hot Springs Research Institute, National Research Institute for Earth Science and Disaster Prevention Hi-net, Japan Meteorological Agency in and around the caldera, in the period between January 2012 and December 2013. Filtered trace at the frequency band of 1-3 Hz was used to calculate autocorrelation by one-bit correlation technique. To obtain stable record of the one-day ACF, we stacked the ACFs for time intervals of one week. We obtained fluctuations of the velocity structure by using the stretching method (e.g. Wegler et al., 2009).

The velocity fluctuations at the stations in the caldera show a gradual decrease prior to the swarm activity. The velocity decreases at these stations are consistent with increases in base length detected by the GNSS stations around Hakone volcano. We also found that there was sudden velocity decrease at Owakudani station near fumarolic area just after the beginning of swarm activity and tilt changes. We interpreted the velocity decrease at these stations as a material change or a crustal deformation associated with the volcanic activity.

The roles of dispersion and nonlinear effects in the 2001 Tohoku-Oki earthquake tsunami

SAITO, Tatsuhiko[1*] ; INAZU, Daisuke[1]

[1]National Research Institute for Earth Science and Disaster Prevention

The present study aims to reveal the roles of the dispersion and the nonlinear effects in the 2011 Tohoku-Oki earthquake tsunami. Tsunami simulations were conducted based on the nonlinear dispersive equations with a high-resolution source model. The result successfully reproduced the waveforms recorded in both near shore and deep sea. The calculated inundation area showed a good coincidence with the actual inundation at the Sendai Plain, the widest inundation area during this event. Conducting sets of simulations using different equations, we obtained the followings insights. Although the dispersion was neglected in most studies, the maximum-amplitude distribution was significantly overestimated in the deep sea if the dispersion was not included. The waveform observed at the station in which the largest tsunami height (>2 m) recorded among deep-ocean stations also verified the necessity of the dispersion. It is well known that the nonlinear effects play an important role for the tsunami inside bays and harbors. Additionally, the nonlinear effects needed be considered for the accurate modeling of the later waves even at the offshore stations. In particular, including nonlinear terms rather than including the inundation was more important for the precise modeling of the waves reflected from the coast.

Numerical simulation of tsunamis due to a landslide

YOSHIKAWA, Ryo[1*] ; KAKINUMA, Taro[1]

[1]Graduate School of Science and Engineering, Kagoshima University

Numerical simulation of tsunamis due to a landslide has been performed using a MPS method, where the water surface is indicated based on the spatial gradient of number density of particles. In comparison with the water surface displacements through hydraulic experiments, the calculation results are accurate when the inflow can be assumed as a fluid. The larger the initial potential energy of the inflow is, the larger the tsunami height becomes, although the tsunami height is not large when the initial position of inflow is below the water surface since the initial relative potential energy of the inflow is lower, as well as without impact of plunging. Due to the inflows of the assumed initial values for mass, shape, and velocity caused by a sector collapse of Sakurajima Island, the tsunami height shows more than ten meters in Kagoshima Bay.

Point spread functions for earthquake source imaging

NAKAHARA, Hisashi[1*] ; HANEY, Matthew[2]

[1]Graduate School of Science, Tohoku Univ., [2]U.S. Geological Survey

Recently, various methods such as back-projection method (e.g. Ishii et al., 2005), time-reversal (TR) method (e.g. Larmat et al. 2006), and hybrid back-projection (HBP) method (Yagi et al., 2012) have been proposed and applied for earthquake source studies in addition to kinematic waveform inversions (e.g. Hartzell and Heaton, 1983) . In addition, theoretical relationships among the methods have also been clarified (e.g. Kawakatsu and Montagner, 2008, Fukahata et al., 2013). In this study, we introduce the notion of the point spread function (PSF) into earthquake source imaging, and show that the PSF clarifies the meaning of the earthquake source inversions. Under ideal circumstances in which receivers continuously surround the source, the PSF can be interpreted with seismic interferometry.

Kinematic waveform inversion methods are now standard for earthquake source studies. The observation equations (or forward modeling equations) are based on the representation theorem. According to Claerbout (2001), imaging is defined to be the mathematical process of multiplying adjoint Green's functions with both sides of the observation equation. Fukahata et al. (2013) pointed out that the process is very close to the one used in the HBP method. The source image may be blurred and degraded due to uneven distributions and insufficient number of stations. The degree of blurring and degradation can be expressed by the PSF which is often used in optics. The PSF for the source imaging can be expressed by stacked cross correlations of Green's functions between two source points with respect to receivers on a surrounding surface. If distributions of sources and receivers are discretized, the observation equation can be formulated in matrix form. Source inversion is found to remove the effect of the PSF, but other source imaging methods suffer from the PSF.

Ideal circumstances are considered here to better clarify the meaning of the PSF. It is assumed that stations are continuously distributed so as to surround the source points. For this case, we use source-receiver reciprocity of Green's functions. Then, we can consider the following reciprocal configuration in which sources are surrounding two stations. The point spread function is expressed as the stacked cross correlations of waveforms between the two receivers with respect to the surrounding sources. This configuration is exactly the same as ones in seismic interferometry and therefore we can interpret the PSF based on seismic interferometry. For single-force sources, the PSF is found to be the imaginary part of the Green's function. This fact was already pointed out in terms of TR method (e.g. Fink, 2006). For moment-tensor sources, the PSF is shown to be the imaginary part of the spatial derivative of Green's function with respect to each coordinate of the two receivers. This is a novel finding of this study. It is also suggested that the source image is the integrated version of the true source process when the interpretation based on seismic interferometry strictly holds.

In summary, kinematic source inversion methods can remove the effect of the PSF, but other source imaging methods suffer from blurring and degradation by the PSF. As a result, careful weighting of data is necessary for the source imaging methods. For ideal cases in which receivers surround the sources, the PSF can be interpreted with seismic interferometry with the help of the source-receiver reciprocity of Green's functions. This study will contribute to better understanding of the meaning of source inversion methods.

Analysis and application of wave propagation process of sweep signals in attenuative media

MATSUSHIMA, Jun[1*]

[1]Graduate School of Engineering, The University of Tokyo

The sweep signal is the most extensively used land seismic exploration technique. In conventional data processing using sweep signals, a received trace is cross-correlated with source sweep to convert the extended sweep signal into a pulse signal. For attenuation estimation, a time window is often used to compute the frequencies of the direct-arrival waveforms. Uncorrelated sweep signals are useful in the discussion of harmonics simply because the uncorrelated data are one of the few situations in which we commonly input a nearly pure frequency into the earth. Our previous study proposed a method that enables accurate measurement of ultrasonic attenuation using sweep signals under the assumptions that velocity dispersion can be ignored and the quality factor (Q) is not dependent on frequency. This method is independent of the effect of windowing while the windowing effect underestimates the attenuation results due to a spectral leakage effect. In most cases, however, the presence of attenuation is accompanied by velocity dispersion because of causality. The presence of velocity dispersion causes attenuation to be disturbed, although the proposed method is not so sensitive to the presence of velocity dispersion. The present paper elucidates the wave propagation process of sweep signals in attenuative media with velocity dispersion to develop the method which can take the effect of dispersion into account. We obtain a time-scale representation of sweep signals by using the continuous wavelet transform method to perform a time-series analysis of a seismic trace that decomposes the trace into its respective amplitude and phase components in both the frequency and time domains.

3D numerical simulation of seismic wavefield in inhomogeneous rock samples

YOSHIMITSU, Nana[1*] ; FURUMURA, Takashi[1] ; MAEDA, Takuto[2]

[1]CIDIR/ERI, The Univ. of Tokyo, [2]ERI, The Univ. of Tokyo

We focus on expanding the applicability of the transmitted waveforms obtained at laboratory experiments to examine detailed medium structure with the aid of novel numerical simulations. For this purpose, we investigate the feature of elastic waveforms in a centimeter class rock sample based on a 3D finite difference method (FDM) simulation. Previously, there were a few ways to approach the later phase of transmitted waveform in a rock sample because the propagation process of the reflected and converted waves generated in a finite-sized rock sample were not figured out. If analyses with entire waveform including the later phases will be possible, it should bring more detailed information on internal medium structure of rock samples.

First, we obtain transmitted waveforms in laboratory with cylindrical Westerly granite sample which horizontal to vertical ratio is 1 : 2. A source transducer is put on the center of the side surface and step voltage is applied to it. Vibration on sample surface is recorded as velocity waveform by laser Doppler vibrometer.

Next, we prepare the simulation model that covers the size of the rock sample. The volume is discretized into 512 x 512 x 1024 grids with an interval of 100 μm. Assuming proportional relationship with X-ray absorption coefficient obtained from micro focus X-ray CT images of the rock sample, we set the density (2.5 - 3.1 g/cm^3), P wave velocity (5.0 - 6.0 km/s), and S wave velocity (2.8 - 3.5 km/s) on each grid. Then, 3D FDM numerical simulation is performed with a single point force which is the same movement with the source transducer of the experiment. Band pass filter with a cut-off frequency of 50 kHz to 2 MHz is applied to the obtained waveforms.

The wavefield obtained from the simulation show that the reflected (PP, SS, PPP, and SSS) and converted (PS, SP, and PPS) waves are generated at the boundary of the sample. As time progresses, waves reflected at the side boundary return to the source area, and waves reflected at the top of the sample propagate through the sample at same time. Thus, we confirmed that waves trapped in the closed medium generate a very complicated shape of the later part of waveforms. Scattering and conversion at mineral grains are also observed due to the heterogeneity of medium, while they have only a limited effect on the simulated waveform in this case.

Radial component of measured and simulated waveforms recorded in the same horizontal plane at the source position are compared. Each phase shape in entire simulated waveform is matched with measured waveform. Two large amplitude phases observed in the measured waveforms are revealed as direct P wave and reflected SS wave from the simulated waveforms. Complex waveform shapes after the arrival of SS wave are indicated to as multiple reflected and converted S waves at the round boundary of the sample.

Curvilinear grid finite difference method simulation of seismic wave propagation for depth-dependent velocity structure

MAEDA, Takuto[1*]

[1]ERI, The University Tokyo

I propose curvilinear grid method on large-scale finite difference method (FDM) simulation of seismic wave propagation in depth-dependent structure. The FDM usually uses uniform-sized grid having spatial scale smaller than 6-10 of wavelength. Although it is quite straightforward method and is therefore suitable to large-scale parallel simulation, it is not economical to use homogeneous grid size under depth-dependent structure in regional scale because of wide dynamic range of wavelength. Low-velocity sediment requires fine scale grid, but such smaller grid size also requires very small time-stepping in deeper part to satisfy the stability condition of FDM. To deal with this problem, discontinuous-grid method (Aoi and Fujiwara, 1999; Lee et al., 2008) has been proposed. However, possible numerical instability at a discontinuous surface in the former method (Kristec and Moczo, 2010).

The curvilinear coordinate method can use any non-linear, non-orthogonal coordinate. The uniform-size numerical grid is used along the curved coordinate in the computation domain. On the other hand, we still uses the Cartesian coordinate for expressing physical quantities such as velocity vector and stress tensor. This method has been used to incorporate rough ground surface (e.g., Hestholm, 1999). However the recent study on staggered-grid FDM (e.g., Nakamura et al., 2012) suggest that the rough surface can be expressed by the fine-scale homogeneous grid. So, I use a coordinate whose grid-width gradually and smoothly increases with depth to make ratio between grid-size and wavelength nearly constant. My coordinate transform equation depends on vertical depth only, so that to make the computational loads in coordinate transformation and additional memory requirements relatively small. The rotated-grid staggered grid (RSG) scheme (Saenger et al., 2000) has been adopted to make central finite differentiation possible in all directions under the curvilinear coordinate.

As a test, we implemented this curvilinear coordinate FDM in 2D SH and P-SV systems, with using the Butterworth-shape grid-size increase function. This coordinate has a characteristic depth. Grid size linearly increases with depth at deeper than the characteristic depth. On the contrary, this curvilinear coordinate converges to the Cartesian at the shallow limit. This feature is preferable since one can connect the homogeneous Cartesian grid in the shallower portion to the curvilinear grid system without any boundary conditions. In the numerical experiments, I found that the method is effective and stable even for the coordinate system having large grid-size ratio of up to 10. Extension to the 3D model is quite straightforward, and it makes possible to perform broadband large-scale wave propagation simulations including slow sediment in medium-sized computers.

Waveform inversion of seismic reflection data and its application to fault structure survey

WATANABE, Toshiki[1*] ; KOBAYASHI, Masami[1] ; YAMAOKA, Koshun[1] ; ITO, Tanio[2] ; KANO, Ken-ichi[3] ; ABE, Susumu[4]

[1]Nagoya University, [2]Teikyo Heisei University, [3]Shizuoka University, [4]JGI, Inc.

Seismic waveform inversion (Tarantola, 1984) is a novel technique of imaging subsurface structures. It reconstructs a model of physical parameters that best explains waveforms of observed seismic data by incorporating a nonlinear least-squares inversion. Waveform inversion provides high-resolution model than that from traveltime tomography. Recent development of computational environment accelerates studies on practical application of the method to 2-D/3-D field data.

In this study, we investigate an application of the method, originally developed for crosswell seismic data, to reflection seismic data. The problems are (1) singular nature of sensitivity near sources and receivers at the surface, (2) attenuation of sensitivity in deeper part of the section, and (3) contamination of surface wave. We introduced a weight increasing with depth on the gradient, and near-offset trace mute to reduce the effects of the problems listed above. Using the synthetic waveform data numerically generated from a given structure model, we proved that a clear structure image was successfully retrieved after iteration.

Then, we applied the method to the field data of wide-angle reflection survey acquired in the Fujikawa-kako fault zone - ISTL seismic reflection survey conducted in 2012 (2012FIST)(Ito et al, 2013) to reveal the detailed structure of Omiya fault. Although the reconstructed velocity structure is consistent with the recent interpretation that the Omiya fault is a reverse fault, it was far from convergence due to the insufficient number of seismic sources used in the survey. Problems and requirements for future survey design will be discussed in the presentation.

Site amplification factor of the Hi-net stations

UENO, Tomotake[1*] ; SAITO, Tatsuhiko[1] ; SHIOMI, Katsuhiko[1]

[1]NIED

This study estimated site amplification factors of all the Hi-net stations. Employing the coda normalization method and analyzing more than one thousand earthquakes, we obtained the values of all Hi-net sites in the frequency bands of 0.6-1.0 Hz, 1-3 Hz, 2-4 Hz, 2-6 Hz, 4-8 Hz, 6-9Hz, and 8-12 Hz. The cite amplification factors were rather small showing that 90 % of the cite amplification factors ranged within 20 dB. The site amplification varies from station to station more largely with decreasing the frequency. A correlation between the site amplification factor and the S-wave velocity where the sensor is installed was recognized. The cite amplification factor decreases with increasing the S-wave velocity when the S-wave velocity is less than 1.5 km/s. When the S-wave velocity is larger than 1.5 km/s, the correlation disappears. Stations in southwest Japan show smaller site amplification factors, while stations in plains and around the volcanic front in the northeastern Honshu, Japan show larger site amplification factors.

Separating body and Rayleigh waves with cross terms of the cross-correlation tensor of ambient noise

TAKAGI, Ryota[1*] ; NAKAHARA, Hisashi[2] ; KONO, Toshio[1] ; OKADA, Tomomi[1]

[1]RCPEV, Graduate School of Sci., Tohoku Univ., [2]Geophysics, Graduate School of Sci., Tohoku Univ.

We develop a novel method to separate body and Rayleigh waves with the vertical-radial (ZR) and radial-vertical (RZ) components of the cross-correlation tensor of ambient noise. Furthermore, analyzing ambient noise records observed at a seismic array, we validate the method. For the separation, we utilize the difference in polarizations between the rectilinear P and the elliptic Rayleigh waves. Assuming the two-dimensional surface and three-dimensional body waves are the superposition of random uncorrelated plane waves, we derive two fundamental characteristics of the ZR and RZ correlations. One is that, between the ZR and RZ correlations, Rayleigh wave contributions have the opposite signs and P waves have the same signs. The other is that, for both ZR and RZ correlations, Rayleigh wave contributions are time-symmetric and P waves are time-antisymmetric. Accordingly, we can separate P and Rayleigh waves by just taking the sum and difference between ZR and RZ correlations and by just taking the time-symmetric and time-antisymmetric components. This method can be performed (1) without any knowledge of velocity structure, (2) using only two stations with three-component sensors on a ground surface, (3) even in the case of anisotropic wave incidence, and (4) with the quite simple procedure. We consider that the developed method can make better use of three-component observations of ambient noise for evaluating the cross-correlation tensor accurately, for improving deep velocity structure using both of extracted body and surface waves and, more fundamentally, for understanding the composition of ambient noise.

Study of high-frequency seismic wave propagation by active-source experiments

TANIMOTO, Toshiro[1*] ; OKAMOTO, Taro[2]

[1]University of California, Santa Barbara, [2]Department of Earth and Planetary Sciences, Tokyo Institute of Technology

Seismic wavefields generated by resonant shaking experiments of the Millikan Library, on the campus of California Institute Technology (Pasadena, California, USA), were analyzed. Because the resonant shaking frequencies are 1.12 Hz (the east-west direction) and 1.64 Hz (the north-south direction), this active-source experiment can provide opportunities for studying high-frequency seismic wave propagation in Southern California.

Two such experiments for each frequency were analyzed; for the north-south shaking experiments, the harmonic signals were observed up to distance 323 km in one experiment and up to 396 km in another experiment. For the east-west shaking (1.12 Hz), the maximum distance was 200 km but most observations were confined to less than 100 km.

Spectral amplitudes showed a systematic decaying trend with distance in all cases. Numerical simulations indicated that the predominant signals were surface waves. Assuming that all signals were surface waves, we obtained estimates for the parameter QU for surface waves where Q is the attenuation parameter and U is the group velocity (in km/s). There was, however, a major break in the amplitude-distance trend at a distance about 50 km; for data with distance less than 50 km, QU = 95 $\pm$16 , where U is in km/s. For data beyond 50 km, we obatined QU= 1454 $\pm$ 226. This change in trend must be related to the regions sampled by waves, as the shorter-distance data were dominated by paths in the Los Angeles basins while the longer-distance data did not contain paths in the basin structures.

Through cross correlations between MIK (station in the Millikan library) and a station in the regional network, phase information was also analyzed. For many stations, phase was stable for frequencies between 1.637 and 1.638 Hz which meant that phase is locked between MIK and a station. While it was not possible to estimate phase velocity, because the number of cycles cannot be resolved for high-frequency waves, a stacking approach for multiple-window data allowed us to estimate frequency derivative of phase and group velocity for 25 paths. Group velocity between MIK and network stations are mostly less than 2 km/s. For stations with distance less than 50 km, most group velocity results were about 0.5 km/s or less. Combined with the estimate for QU from the amplitude-distance data, Q is estimated to be 190 for distances less than 50 km. This estimate, however, contains uncertainty up to a factor of two as variations in group velocity estimates differ from station to station.

[1]JAMSTEC

Tentative ocean bottom arrays using seismometer, hydrophone and pressure gauge have recently been deployed through many scientific projects all over the world. However, in Japan, a permanent ocean bottom monitoring system, called DONET, is now working, and dense cabled-OBSs (ocean bottom seismometers) have been constructed around the Japan Trench. It seems that, compared to other countries, such environments in Japan potentially give us some advantages for investigating the Earth ' s interior, seismic activity, and wavefields under the ocean. In order to easily kickoff the use of these records, it would be better to know characteristics of wavefields observed at seafloor.

A large amplitude in the frequency range of 0.07-0.5 Hz can be often seen in the spectrum of noise record observed at seafloor, which is known as microseisms that are generated by wind propagating sea surface. This large amplitude also emerges at land observation. At frequencies longer than 0.02 Hz in the spectrum observed at typical broadband OBS, the amplitude of infragravity wave is strong in the vertical component, and that of tilt effect is dominant in the horizontal component.

In this presentation, avoiding the use of such longer period components, we focus on shorter period components than 1 Hz of records observed at OBSs. We introduce what kind of analyses we can do hereafter with permanent OBS records, which is based on the use of records observed at tentative ocean bottom arrays. In particular, we will introduce ambient noise and receiver function analyses, in which short period components are mainly used.

Nonlinear radiation of hypocenter and prevision of earthquakes

KIKUCHI, Toshiaki[1*]

[1]National defence Academy

Hypocenter vibrations have been analyzed using the analysis method based on time reversal. The dynamic model of the hypocenter vibrations based on the results was advocated. In addition, the effectiveness of the dynamic model was confirmed. The activity regions in the hypocenter are presumed using the dynamic model here.

First, the outline of the dynamic model is described. The time-reversal process was executed to the P wave signals received at the observation stations for the earthquake that occurred in the central part of Suruga Bay in August, 2009, and the pulses formed at the position of the hypocenter, that is, time reversal pulse (TRP) was obtained. The TRP corresponds to an equivalent source to which the hypocenter emits. The obtained TRP provided clear orientation dependency. To clarify the origin of the azimuthal dependence, the frequency spectrum of the TRP to azimuth was obtained. The frequency spectrum was greatly changed by the azimuth. Then, the distribution of the maximum amplitude frequency to azimuth was obtained. As a result, the maximum amplitude frequency rises greatly as azimuth moves from west to east and it has descended afterwards. This frequency rise shows the local movement of sources by high speed. The moving direction converged in the direction of Nishiizunishi, Kawazu, and Ito.

The P waves received at these observation stations exhibited a unique behavior. The head part of the wave received in Nishiizunishi was expanded. However, there was no expansion in the head part in the waves received in Ito and Kawazu near Nishiizunishi.

The head's growing in this manner occurs when the progression rate of cracks in an active fault becomes near the velocity of propagation. The pressure that occurs due to the crack is added cumulatively by moving by high speed. That is, the parametric effect occurs in the active fault. Nishiizunishi is a specific point that reflects the feature of this earthquake.

As for the waveform of the aftershock that received at the specific observation station, the head part of the P waves expanded more than that of main shock. Similarly, the expansion of the head part was observed for the precursor earthquake that occurred before the main shock. The dynamic model of hypocenter vibrations has advocated from these results. The point where the narrow beam emitted from an active fault reaches the surface of the earth is called a parametric spot. The head of the pulse to which the head expands is called a parametric head. This model was verified about four earthquakes larger than M5 that occurred from 2012 to 2009 near Mt. Fuji. The effectiveness of the dynamic model was confirmed.

The dynamic model is consistently approved for precursors, a main shock, and aftershocks. Therefore, the dynamic model may be used for the prevision of earthquake.

The precursor earthquakes of the earthquake that occurred in the central part of Suruga Bay in August, 2009 are examined. The receiving waves that accompanied the parametric head in that were observed seven times. These represent evidence that the progress of the crack began to become a high speed in the active fault. Therefore, observing the seismic waves of a slight earthquake at the peculiar parametric spot and examining the change, may foresee a big earthquake afterwards.

Frequency domain calculation of the seismic wavefield propagating along an ocean trench, with a constant Q attenuation

MITSUHASHI, Yuta[1*] ; FURUMURA, Mitsuko[2] ; MATSU'URA, Ritsuko S.[2] ; SHOJI, Masahiro[1]

[1]KKE, [2]ADEP

For shallow interplate earthquakes, large long-period later phases are frequently observed at long distance. Simulations using the finite difference, which we have performed, revealed an important effect of seawater on those later phases (e.g. Furumura et al., 2011).

However, attenuation $\exp(-\pi ft/Q)$ in the finite difference calculation is set to $\exp(-\pi ft/(Q_o f/f_o))$, meaning $Q/f=Q_o/f_o$ is set as a constant, where f_o is a target frequency of the calculation purpose, and Q_o is its corresponding attenuation factor, so it causes some problems especially for waves propagating for a long distance.

Then we calculated waves propagating in a 2.5D structure in the frequency domain with FEM to realize Q as a constant instead of Q/f, for both cases with and without seawater. We could confirm the important effect of seawater on later phases as well as the finite difference calculations. Calculated later phases have relative large amplitude for frequencies lower than f_o in the Q-constant model compared with the Q/f-constant model. It indicates necessity of estimation of difference between realistic Q and modeled one, when we use the finite difference method. In addition, the results reveal large later phases in the case with seawater, which are rarely seen in the calculated waveforms without seawater. It implies overestimation of magnitude of ocean earthquakes obtained from analysis of waves propagating through a long distance along and across an ocean trench, such as the 1911 off Kikai Island earthquake and the 1933 off Sanriku earthquake observed in Honshu.

Development and extinction of long-period ground motion in thick sediments

TAKEMURA, Shunsuke[1*] ; YOSHIMOTO, Kazuo[1]

[1]Yokohama City University

To obtain better insights of long-period ground motion in thick sediments, which often cause severe damage of large-scale man-made structures, we analyzed horizontal seismograms recorded by dense strong motion networks in the complex large Kanto basin. We found distinct large amplitude long-period ground motion around northern Kanto, which is caused by Love wave excited at the northwestern edge of Kanto basin. Amplitude of Love wave significantly developed during propagation in thick (>3 km) sediments and then suddenly weakened at region where significant change of basin structure exists.

To clarify causes of such observations, we conducted 3D finite difference method (FDM) simulation of seismic wave propagation. In simulation, we assumed plane SH-wave incident into a realistic basin structure model embedded in a homogeneous half-space background structure, to focus characteristics of Love wave excited at the basin edge. Simulation result in a realistic basin model referred from JIVSM (Koketsu et al., 2008) well reproduced observed Love wave development around the northern Kanto. Another simulation in the model, which is limited to maximum bedrock depth of 3 km, shows no significant difference of simulated waveforms compared with the previous model. Thus, development of surface waves in thick sediments is mainly caused by the deepening of shallower low-velocity layers, rather than the depth variation of bedrock.

Acknowledgement

We acknowledge the National Research Institute for Earth Science and Disaster Prevention, Japan (NIED) for providing the K-NET/KiK-net waveform data. We also use strong motion data from SK-net.

Receiver function travel time tomography

HIRAHARA, Kazuro[1*] ; YAMASAKI, Tomona[1] ; ABE, Yuki[1] ; SHIBUTANI, Takuo[2]

[1]Graduate School of Science, Kyoto University, [2]Disaster Prevention Research Institute, Kyoto University

Hirahara et al. (2006) proposed a method of Receiver Function (RF) Tomography which combines travel time tomography using travel times from local and teleseismic events with receiver function analyses. In the method, a 3-D P and S wave velocity structure is estimated together with the velocity discontinuity interfaces, where we add both data of the amplitudes and differential travel times of Ps converted phases in RFs employing Gaussian beam RF synthetics. We found, however, that it is difficult to match the amplitudes of Ps phases to estimate the velocity contrasts between velocity discontinuity interfaces with 2-D undulations.

.

Here, as a step toward RF Tomography, we are developing a method of RF Travel Time Tomography using only travel times of P and S waves from local and teleseismic events and P-Ps times of Ps converted phases obtained with the receiver function analyses. Abe et al. (2011) developed a method to estimate iteratively geometries of dipping seismic velocity discontinuities with high dipping angles of 30 to 70 degrees from common conversion point stacking of receiver functions, in which the multistage fast-marching method (de Kool et al., 2006) is applied to the ray tracing with refraction at dipping interfaces. The large amplitudes of RFs stacked in 3-D cells are interpreted to the Ps phases converted at the velocity discontinuity interfaces and the differential travel times P-Ps of the corresponding phases are additionally used for the travel time tomography of P and S waves from local and teleseismic events.

In this paper, we do not analyze the actual data but aim at developing the code of RF Travel Time Tomography based on the code of FMTOMO (Fast Marching Tomography) by Rawlinson (2007). First, for a 3-D heterogeneous structure with interfaces of a Moho and a subduction slab, we synthesize travel times of P and S waves from local and teleseismic events, and also Ps times converted at the Moho and the slab top and the oceanic Moho interfaces. Then we investigate the ability of retrieving the 3-D velocities and the undulation of the Moho and the dipping slab interfaces.

Ocean acoustic Rayleigh wave persistently excited by earthquake signals

[1]JAMSTEC

In the interferometry, the wavefield propagating between two positions can be retrieved by correlating ambient noise recorded on the two positions. This approach is useful for applying to various kinds of wavefield, such as ultrasonic, acoustic (ocean acoustic), and also seismology. Off the Kii Peninsula, Japan, more than 150 short period (4.5 Hz) seismometers, in which hydrophone is also cosited, had been deployed for 2 months on 2012 by Japan Agency for Marine-Earth Science and Technology (JAMSTEC) as a part of " Research concerning Interaction Between the Tokai, Tonankai and Nankai Earthquakes " funded by Ministry of Education, Culture, Sports, Science and Technology, Japan. In this study, correlating ambient noise recorded on the hydrophones, we attempt to investigate characteristics of wavefield observed at seafloor.

The observation period is from Sep. 2012 to Dec. 2012. Station spacing is around 5 km. For 5 lines off the Kii Peninsula, the 30 - 40 seismometers are distributed at each line. Sampling interval is 200 Hz for both seismometer and hydrophone. The instruments are located at 100 - 4800 m in water depth. In the processing for the both records, we applied a bandpass filter of 1 - 3 Hz, replaced the amplitude to zero if it exceeds a value that was set in this study. We calculated cross correlation function (CCF) by using continuous records with a time length of 600 s, stacked the CCFs over the whole observation period.

We first aligned only CCFs using two stations with a separation distance of 5 km along lines off Kii Peninsula. As a result, we could detect strong signals in the CCFs that clearly show travel time variation as a function of water depth. The group velocity of the signal gradually changes from 1.3 km/s to 0.7 km/s at water depths from 2000 to 4000 m. In addition to the wave, a relatively weak signal with a group velocity of 1.4 - 1.5 km/s can be seen in the region at water depth of 4,000 m.

We investigated the wavefield by using a numerical simulation with finite difference technique. As a result, all of these signals can be explained by acoustic Rayleigh wave, which has the energy within not only the ocean but also sediment. A case in which vertical forces are located at subseafloor generated the acoustic Rayleigh wave well, and the CCFs using synthetic waveforms match well with the observed ones. However, another one in which vertical forces are located at sea surface failed to describe the observation. This means that the observed acoustic Rayleigh wave in background wavefield would be generated by earthquake signal, not signals due to microseisms. Moreover, we will show that the amplitude of the signals possibly correlates with seismicity distribution, which also supports that the signals are excited by earthquake signals.

Modeling inclined cracks in a 2-D finite difference grid

NASUNO, Arata[1] ; KAWAHARA, Jun[1*] ; SHIINA, Takahiro[2] ; OKAMOTO, Taro[3]

[1]Ibaraki University, [2]Tohoku University, [3]Tokyo Institute of Technology

Seismic scattering due to cracks are often numerically simulated using a boundary integral equation method (BIEM), a finite element method, or a finite difference method (FDM). Among others, the FDM has a great advantage in tractability, though having a limitation that it can treat rectangular grids only. Using the rotated staggered grid that they developed, Saenger et al. (2000, Wave Motion) modeled a crack or cavity as a gather of grid points with zero elastic constants. In contrast, Suzuki et al. (2006, 2013, Earth Planets Space) modeled a 2-D empty crack as a linear array of grid points with zero traction on the basis of a standard staggered grid (Virieux, 1984, 1986, Geophysics). Using this method, these authors successfully simulated seismic wave scattering due to cracks. However, they only treated cracks parallel to grid lines.

Here we extended the method of Suzuki et al. (2006) for modeling cracks with zero antiplane shear traction to the case of cracks inclined with respect to grid lines. Using the idea of the staircase approximation to irregular free surface (Ohminato and Chouet, 1997, Bull. Seis. Soc. Am.), we modeled an inclined crack as staircase-like arrayed grid points with zero antiplane shear traction within a staggered grid. We then simulated a plane harmonic SH wave obliquely incident on the crack until the resultant oscillation of the crack became stationary. We then measured the amplitude of displacement discontinuity along the crack. We also calculated the same displacement discontinuity using a frequency-domain BIEM (Murai et al., 1995, Geophys. J. Int.). It was confirmed that the both results were consistent, irrespective of the crack inclination angle, if the grid spacing was much smaller than the crack length and hence the staircase-shaped crack plane was sufficiently smooth. This implies the validity of the present method of modeling inclined cracks.

Acknowledgments: For the BIEM calculations, we used a code of Dr. Yoshio Murai (Hokkaido University), and used the computer systems of the Earthquake and Volcano Information Center of the Earthquake Research Institute, the University of Tokyo.

The recent movement and the future plans of the JMA EEW

NAKAMURA, Masaki[1*] ; KODERA, Yuki[1] ; TAMARIBUCHI, Koji[1] ; AIZAWA, Koji[1] ; OGAMI, Yoshie[1] ; HIRANO, Kazuyuki[1] ; YAMADA, Yasuyuki[1] ; SAKIHARA, Hirokazu[1] ; URATANI, Junpei[1] ; MORIMOTO, Masahiko[1]

[1]JMA

We sometimes reported our efforts to improve the JMA EEW system and we will make a presentation about the recent movement of the JMA EEW and the future plan to improve the system.

In the case of the 2011 off the Pacific Coast of Tohoku Earthquake (Mw9.0), the warning of the EEW was disseminated 30 s after the Mw9.0 event occurrence, which was 8 s after the first detection. The estimated magnitude was 7.2 at the time and the warning was issued only for Tohoku. We could provide the warning before the arrival of S-waves for all warning areas. However, the actual magnitude was 9.0 and the wide area was ruptured. The under estimate of the magnitude and the extent of the source region caused the under estimate of intensities. Especially, in Kanto, we observed 6-upper, but we could not provide the warning for the public. The warning was provided for the public only once, but the updated information was provided only to the limited users. We issued the EEW totally 15 times for the event. Finally the EEW estimated M8.1 105 s after the first detection. Moreover, aftershocks sometimes occurred simultaneously over the wide region. Then, the system became confused and did not always determine the hypocenter parameters correctly. In 49 days after the main shock to April 28, 2011, 70 EEWs were announced to the public, but actual observed intensities did not exceed 2 at any stations in 17 cases.

To overcome those problems, we will introduce the real-time pseudo seismic intensity by Kunugi et al. (2008), by which we will be able to monitor the extent of the strong motion field (the simplest version of Hoshiba, 2013) and to evaluate the calculated hypocenter parameter. The current JMA EEW system is based on the calculated hypocenter parameter. We have the idea of a hybrid method using the conventional method and the real-time intensities (Kotera et al, 2014). Furthermore, Tamaribuchi et al. (2014) developed a new method to classify multiple concurrent events for EEW. Their approach used the particle filter method and the method estimated location, origin time and magnitude in the probabilistic framework, using trigger time, maximum amplitude, epicentral distance and incident angle of the waveform for the likelihood function. We have a plan to use the method additionally.

Moreover, JMA began to provide long period ground motion information, using the observed waveform at each station, on JMA web site March, 2013 (Aizawa et al., 2014). We have just begun to investigate the long period ground motion forecast aiming at establishing an earthquake early warning for long period ground motion (Ogami et al., 2014).

Earthquake Early Warning system combined with real-time ground motion prediction

KODERA, Yuki[1*] ; YAMADA, Yasuyuki[1] ; HIRANO, Kazuyuki[1] ; MORIMOTO, Masahiko[1] ; HOSHIBA, Mitsuyuki[2] ; NAKAMURA, Masaki[1]

[1]Seismology and Volcanology Department, Japan Meteorological Agency, [2]Meteorological Research Institute

We introduce a hybrid method which is a combined method of the current JMA EEW system and the simplest version of real-time ground motion prediction method. We also report applications of the hybrid method to some cases in which the current JMA EEW system underestimates or overestimates seismic intensity.

The current JMA EEW system (the conventional method) forecasts seismic intensity on the basis of hypocenter parameters estimated from observed seismic waveform. When accurate hypocenter parameters are determined in an early phase, forecast values of seismic intensity in all areas are calculated quickly and long lead times are available in many areas. On the other hand, if estimated hypocenter parameters are inappropriate, the conventional method leads to underestimation or overestimation of forecast values of seismic intensity.

Hoshiba (2013) proposes real-time ground motion prediction method as a method of forecasting ground motion without the use of hypocenter parameters. The real-time ground motion prediction method predicts wave field directly from observed wave field by a boundary integral equation for displacement. This method is expected to robustly forecast accurate ground motion because it utilizes actual wave field information. Forecast of JMA seismic intensity based on the real-time ground motion prediction method can be performed easily by the following algorithm:

(1) Gather real-time pseudo seismic intensities (Kunugi et al., 2013) of observation stations within a radius R from a target station.

(2) Take the maximum value of the real-time pseudo seismic intensities as a forecasted seismic intensity of the target station.

This is the simplest version of real-time ground motion prediction method. The algorithm assumes that a ground motion which causes large seismic intensity propagates within a radius R without attenuation. In this method, a lead time tends to be short because the area where actual wave field information is available is limited to a radius R.

The conventional method and the simplest version of real-time ground motion prediction method have complementary features on earliness and robustness. Therefore, appropriate combination of these methods is expected to become a hybrid method which has both earliness and robustness. We propose a hybrid method as follows:

(1) Take the maximum forecasted value of two methods in ordinary circumstances.

(2) Reject a forecasted value of the conventional method when the conventional method is not consistent with the real-time ground motion prediction method.

We set input data as real-time pseudo seismic intensities of JMA observation stations, output data as forecasted values of seismic intensity meters in Japan and radius R as 30km and apply the hybrid method to some previous earthquake events. In the case of the 2011 off the Pacific coast of Tohoku Earthquake, whereas seismic intensity scales of Kanto region the conventional method estimates are more than one degree smaller than actual, the hybrid method estimates them appropriately with an accuracy of about one degree. In the case of multiple events on April 3, 2011, the hybrid method can avoid overestimation of seismic intensity the conventional method leads to by qualify control of estimated hypocenter parameters of the conventional method. In the case of an earthquake in the northern part of Tochigi prefecture on February 25, 2013, forecasted seismic intensities of the conventional method are one or two degrees larger than actual although the conventional method estimates hypocenter parameters appropriately. The hybrid method also overestimates seismic intensity in consequence of the overestimation of the conventional method.

Achievement of Faster and More Accurate Earthquake Early Warning System - Combining JMA and Hi-net data -

YAMADA, Masumi[1*] ; TAMARIBUCHI, Koji[2]

[1]DPRI Kyoto University, [2]JMA

Earthquake Early Warning systems (EEWS) are designed to quickly determine locations and magnitudes of earthquakes and then provide predictive warnings about the arrival time and amplitude of the strong shaking. Current JMA EEWS uses data from two seismic networks: JMA accelerometer network and NIED high sensitive seismometer network (Hi-net). Currently, these two datasets are processed in the different scheme and the results are merged to issue a warning. Combining these two datasets and processing in the same framework should improve the accuracy and speed of the warning.

In this study, we tried to develop a method to use these two dataset in the same framework. A major barrier to do this is that the instrument responses are different in these networks. Hi-net seismometers are velocity-type sensor with the corner frequency of 1Hz, which means that the response of long-period components underestimates ground motions. It also saturates for very large ground motions. We need a special care to use this Hi-net data in the same framework.

We applied time-domain recursive filters to correct instrumental response of Hi-net sensors and adjust them to the response of mechanical seismometers. We successfully developed a method to produce records with the same response to the JMA acceleration data. We evaluated the saturation of the Hi-net data with the data in 2 month after the Tohoku earthquake, and found the effect of saturation was minor. Therefore, we can use Hi-net data and JMA acceleration data in the same scheme theoretically. Speed of the warning improved by 3 seconds in the average for the inland earthquake by combining these two networks.

1. Introduction

Recent installation of many ocean bottom seismometers increases the number of P and S-wave arrival times to be measured. The number becomes more than the limit that we are able to conduct picking. We have started to develop an automatic system of hypocenter location which is able to locate hypocenter with accuracy compatible to manually picking. Our previous study introduced a method of using the evaluation equation composed of many parameters based on seismological knowledge about how to pick arrival times. We have showed that the method can pick reliable arrival times of P and S waves. We also have introduced the method of hypocenter location which is able to locate hypocenters even at a period of earthquake swarm. The method makes pseudo seismograms whose amplitude become large at P and S wave arrival times and locates hypocenter with applying the semblance technique to the pseudo seismograms. In this paper, we preset the accuracy of P and S wave picking by the automatic system.

2. Method

In general, the predominant frequency of S wave is lower than that of P wave. We added the data of time variations of predominant frequency for S wave picking. The predominant frequency is calculated by the similar manner of calculating τc, which is used widely to calculate magnitude in the EEW system. Firstly, we calculate differential and double differential of horizontal component observed seismograms as follows.

V (t) = (u(t)-u(t-dt))/dt

A (t) = (u(t)-2u(t-dt) + u(t+2dt))/dt2

Then we compute 0.1 second running mean of the absolute value of V(t),and A(t) and calculate the ratio of two running means. We get time variations in predominant frequency from the time change of the reciprocal value of the ratio, though it is required to multiply a constant value. We assume dt to be 0.02 seconds. We put values of time changes of predominant frequency in the evaluation equation, which is composed of many parameters showing characteristic of seismograms; correspond to the periods between the candidates of arrival times.

3. Results

1) Remarkable drop in predominant frequency are found in almost all seismographs at times of S wave arrivals, showing the effectiveness of its usage in the arrival time picking. Same drop is found at P wave arrivals but there are many cases of increase.

2) We copied all available continuous seismic waveform data in Japan for 24 hours on September 3, 2011, and computed hypocenter automatically. Our automatic system locates 1523 events and the number by JMA catalogue is 588 in the same period. The number of automatically picked P waves is 2.6 times larger than that of manually picking by JMA, and S wave 1.6 times larger.

3) We compared P and S wave arrival times picked automatically with those by manually picking. P and S wave time differences are 0.06 and 0.16 seconds, respectively. This value is close to the difference in a case when two operators conduct picking for the same data.

4) We compared origin times estimated by two closed stations both of which have P and S wave arrivals. We select all couple of two stations with station distance less than 30km and compared origin times estimated from P and S wave arrival times. The average origin time differences by the manually picked data and those by automatically are 0.26 and 0.27sec, respectively.

We can conclude from these comparisons that we already developed an automatic system compatible to manually picking.

Real-time site correction based on evaluating relative responses to common reference station for wide area network

AOKI, Shigeki[1*] ; HOSHIBA, Mitsuyuki[1]

[1]MRI, JMA

Hoshiba (2013a, JGR) proposed a method for prediction of ground motion based on real-time monitoring, in which hypocenter and M are not required. In this method, site amplification must be corrected in real-time manner. Aoki and Hoshiba (2013, AGU) designed the recursive filters for real-time site correction according to Hoshiba (2013b, BSSA), and predicted the JMA seismic intensity of a station by applying this filter to the observed record at the neighboring station, namely exchanging the site amplification factors with each other. In their experiments, in order to consider the effects of the source and propagation in the observed records at adjacent two sites to be identical, the events whose epicentral distances were greater than 100km were selected. Consequently, they show the accuracy of frequency-dependent site correction is better than that of frequency-independent correction using the scalar value, which indicates the average difference in observed intensities at both stations.

In this study, we regard the average spectral ratio, which can be evaluated from the strong motions simultaneously observed at adjacent two stations without the assumptions of attenuation function and source information, as the relative site amplification (RSF) between these two stations. The RSF between distant two stations are estimated by least squares method, combining RSFs of adjacent stations in the network which consists of adjacent station pairs in wide area (Ikeura and Kato, 2011, JAEE). The method is applied to JMA seismic intensity meter network and NIED strong motion seismograph network (K-net and KiK-net including borehole meters), and we can get the RSFs of the stations which almost cover Honshu and Shikoku islands to the common reference station (JMA Tokyo Chiyoda-ku).

The causal digital filters having similar amplitude property to the RSFs are designed according to Hoshiba (2013b, BSSA) and are applied to the waveforms observed in the 2011 Tohoku great earthquake and 2004 Chuetsu earthquake. Site-corrected waveforms can be regarded as the waveforms simulated observing on the sites having the same amplification factor as the reference station. We compare the distribution of seismic intensity with and without site correction. In the distribution of site-corrected intensity on the ground surface, small-scale heterogeneities found on the distribution without site correction vanish and the smooth attenuation of seismic intensity with distance becomes clearer. Before the site correction, the intensity observed in the borehole generally tends to become smaller than that on the ground surface. However the distributions of site-corrected intensities in the borehole are very similar to the distribution of site-corrected intensities on the ground surface. These results indicate that our site correction method applicable to real-time processing works well.

Acknowledgements: We make use of the recordings of NIED strong motion seismograph network (K-NET and KiK-net) and JMA seismic intensity meter network.

Real-time prediction of earthquake ground motion -application of data assimilation and its application to actual data-

HOSHIBA, Mitsuyuki[1*] ; AOKI, Shigeki[1]

[1]Meteorological Res. Inst., JMA

Aiming at improvement of prediction of seismic intensity in Earthquake Early Warning, we are investigating a new technique for real-time prediction of earthquake ground motion. We have proposed to use data assimilation technique for estimation of current wavefield of ground motion, and then predict future wavefield based on physics of wave propagation. In this presentation, we will show examples of application of the technique to the actual data, such as those from the 2011 Tohoku earthquake and the 2004 Mid-Niigata earthquake.

In the proposed technique, estimation of current wavefield is important. We correct site amplification factors using recursive filtering (Aoki and Hoshiba, 2014), apply band pass filter which is used for JMA seismic intensity (Kunugi et al., 2008), and then estimate envelope of 3-component vector summation of the filtered waveforms. We apply the data assimilation technique to the envelope and then estimate the spatial distribution of strength and propagation direction of ground motion.

The strength and the propagation direction are used as an initial condition, and then wave propagation is calculated. In this presentation, as the physics of wave propagation we will use Radiative Transfer Theory in which wave propagation is simulated by energy propagation based on high frequency approximation. The theory has been used for interpretation of seismogram envelope. We will indicate examples of predictions of 10 and 20s in this presentation.

For application to the 2011 Tohoku earthquake, this method reproduces the strong ground motion which were generated from multiple SMGA, and then propagated into many directions. Strong ground motion, generated at off Fukushima much later than the earthquake origin time, propagated into Kanto region, and then around Kofu and Nagoya. The prediction of 10 and 20s reflects the spatial distribution. In the conventional method based on hypocentral location and magnitude, it was not easy to predict the ground motion for the case of the late rupture.

For case of the 2004 Mid-Niigata earthquake, this method reproduces propagation of strong ground motion from repeated aftershocks. Especially at around epicenter region, strong ground motion repeatedly arrived even when the motion of earlier events still large. In the conventional method, the case of the repeated occurrence of aftershocks was not easy.

The proposed method is expected to be useful for improvement of prediction of seismic intensity in Earthquake Early Warning.

Investigation for earthquake early warnings of long-period ground motion

OGAMI, Yoshie[1*] ; AIZAWA, Koji[1] ; SAKIHARA, Hirokazu[1] ; URATANI, Junpei[1] ; NAKAMURA, Masaki[1]

[1]JMA

Sometimes seismic intensity cannot express difficulty of action and indoor situations in high rise buildings properly when severe long-period ground motion occurs. To notify people of such situations and facilitate effective countermeasures, JMA started to provide information on long-period ground motion from March 28th, 2013. And now, we are investigating for an earthquake early warning for long-period ground motion.

There are some techniques for prediction long-period ground motion, and we investigate attenuation relationships of response spectrum because it can calculate at any given seismic parameter and calculate fast.

We investigate following three relationships that they are used for governmental studies, we can get their coefficients and detail information on amplification factors, and they have different equation format or adjustment techniques.

-Sato et al.(2010) and Sato et al.(2012)
-Morikawa and Fujiwara(2013)
-Yokota et al.(2010)

We use earthquakes that earthquake early warnings were issued, their magnitudes are bigger than 5.5, and maximum seismic intensities are 3 or larger, and we calculate absolute velocity response spectrum for seismic parameters of each earthquake early warning information and JMA seismic catalog. Prediction points are JMA seismic stations, K-net stations and KiK-net stations, and prediction element is intensity scale of long-period ground motion.

As a result, every equation represent trend properly. Especially, the probability that intensity scales fall inside the error of +/- 1 is 70 to 80 percent when we use seismic parameters of JMA seismic catalog. But there is a tendency that prediction intensity scale is bigger than one of calculated from real wave form near the epicenter because we use the shortest distance from source faults to observation stations which depend on Mw. In addition, calculated results are affected accuracy of seismic parameters of earthquake early warnings. Therefore there is need to discussion when we issue prediction information and what information number we should use.

Updating of Earthquake Early Warning for Long-Period Ground Motions

IRIKURA, Kojiro[1*] ; KURAHASHI, Susumu[1]

[1]Aichi Institute of Technology

Introduction: In the present EEW systems developed by the JMA, Japan, hypocenter and magnitude of an earthquake are determined quickly, after which ground shaking strengths such as seismic intensity are predicted based on a ground motion prediction equation and then earthquake warning are sent to public when the seismic intensity are beyond 5-lower. This method might underestimate ground motions for large earthquakes with wide rupture area because source extent produces error in estimating distance from source to site and the effects of rupture directivity prediction are not taken into account. Another problem is that the magnitude and source distance cannot be determined before the rupture terminate. Therefore, lead times of prediction become smaller in disastrous regions as earthquakes become larger. Long-period strong motions related to damage of skyscrapers and large oil-storage tanks are generated only from large earthquakes.such as mega-thrust earthquakes. It takes very long time before the rupture terminates. A new idea applying the Kirchhoff-Fresnel boundary integral equation proposed by Hoshiba (2013) will solve the above problem by predicting ground motions at front stations where ground motions do not arrive yet without estimating the hypocenter and magnitude of an earthquake. We attempt to examine the applicability of the front detection method to prediction of long-period strong motions.

Methodology: Ground motion u(P,t) in the wavefield at location P and time t inside a close region is approximated as Kirchhoff-Fresnel Integral.

Equation (1)

In the above equation, u(r,t) is ground motion at a reference point on S and G(P-r,t) is the Green's function between a reference point r and a target point P. The above equation is available for the case where the wave length is much smaller than the spatial fluctuation of absolute amplitude of u(r, t) and G(P, t?t, r , 0), i.e. in high-frequency motions.

When the distance to the source is much larger than |P ? r|, plane wave incidence can be assumed locally around P. Then, u(P,t) is approximated as a convolution between G(P-r,t) and u(r,t).

Equation (2)

When the target point is almost aligned along a line connecting the source to the reference point, the crosscorrelation of u(P,t) and u(r,t) is approximated as follows.

Equation (3)

T(P,r, t) is the transfer function between the reference point and the target point. S(t) is defined as the autocorrelation of the source time function s(t).

Equation (4)

We can estimate the transfer function when the ground motions from some small earthquakes are obtained at the target point and at the reference point at the same time from (3). The autocorrelation function of the source time function of the small earthquake is estimated in advance, e.g. from the waveform inversion of the source process. When large earthquakes such as mega-thrust earthquakes happen in the subduction zone, we can evaluate long-period ground motions at sites where large shakings do not arrive yet using ground motions at stations already observed closer to the source and the transfer functions calculated in advance.

Keywords: Earthquake Early Warning, Long-Period Ground Motions, the applicability of the front detection method

$$u(\boldsymbol{P},t) = \int \frac{1}{v(\boldsymbol{r})} \cdot (\cos\theta + \cos\theta') \cdot G(\boldsymbol{P}-\boldsymbol{r},t) * \dot{u}(\boldsymbol{r},t) dS \quad (1)$$

$$u(\boldsymbol{P},t) = G(\boldsymbol{P},\boldsymbol{r},t) * u\left(\boldsymbol{r}, t - \frac{\boldsymbol{P}-\boldsymbol{r}}{v}\cos(\theta'-\theta)\right) \quad (2)$$

$$u(\boldsymbol{P},\boldsymbol{r}_0,t) * u(\boldsymbol{r},\boldsymbol{r}_0,-t) = T(\boldsymbol{P},\boldsymbol{r},t) * S(\boldsymbol{r}_0,t) \quad (3)$$

$$S(\boldsymbol{r}_0,t) = s(\boldsymbol{r}_0,t) * s(\boldsymbol{r}_0,-t) \quad (4)$$

Current Status and Issues of the Broadcast Start Condition of Earthquake Early Warning

TAKANO, Kiyoshi[1*]

[1]III and ERI, the University of Tokyo

In-site broadcasting system is widely used as a means of transmitting of earthquake early warning. But about the current situation of the broadcast start condition, it is determined by the user who introduced it in consultation with providers. For example, if there is a hazardous material in the building, it will be broadcast starting at predicted seismic intensity 3 or more. On the other hand, in the building with no less hazardous materials, it will be broadcast starting at predicted seismic intensity lower 5 or more. The current situation of the broadcast start condition is as described above; the users have determined in consideration of the user environment.

The document, which serves as a reference in the broadcast start condition to determine appropriate, did not exist until the JMA had published guidelines in April 2011. In this guideline, in particular, for the case of in-site broadcasting towards an unspecified number of people, it has been recommended to broadcast suited to the alarm condition of earthquake early warning of JMA.

The alarm condition of earthquake early warning in JMA is, ”it is issued for areas predicted strong shaking (seismic intensity lower 5 or more) and for areas where seismic intensity 4 is predicted when if seismic wave were observed at more than two seismic stations and the seismic intensity was predicted to lower 5 or more”. And to match in this, mobile phone companies and commercial televisions have broadcast the earthquake early warning in areas where JMA issued an alarm.

At the beginning, we also have set the broadcast start condition of our in-site broadcasting system to match to this alarm condition in JMA. Furthermore, we have operated by setting the ”broadcast start condition for giant earthquakes” by using the combination of not only predicted seismic intensity but also predicted magnitude because from the fact that at the time of the Tohoku Giant Earthquake, the predicted seismic intensity at the alarm of earthquake early warning was much lower than the actual.

However in the period of one year from the start of the operation, there were three broadcasting occurred but in those case the real seismic intensity were 2 or 3 and as a result, these broadcasting became the excessive broadcast.

In this opportunity, I would like to report on the results of review for broadcast start condition of earthquake early warning. And I hope to discuss issues for better broadcast start condition and realizing it.

Jamstec-Ocean seismological database-Integrated byNetwork data (team JOIN) is started since 2012, with the purpose of developing an earthquake research information database through the integration of discrete database, such as real-time earthquake study and lithosphere structure research catalogue. JOIN is consist of three divisions, 1) seismological study using DONET (Dense Ocean-floor Network for Earthquake and Tsunamis) data, 2) sub-structural study for nankai-tonankai earthquake area, and 3) data-management and opent to public for oceanographic data acquired JAMSTEC equipment. These can lead not only scientific but practical outreach, consequently, disaster prevention of each local government.

We have developed web-based real-time monitoring system of strong motion and pressure sensor of DONET observatory network, this is user-friendly tool for servant service of disaster prevention department.

Trial operation with the monitoring system is undergoing for a few government close to nankai-tonankai area, aiming full-scale operation which will start from April 2014.

Technical summary of this system will be introduced.

Examination of the relative site amplification factor of OBS and their real-time correction: examples of Sagami Bay OBS

HAYASHIMOTO, Naoki[1*] ; HOSHIBA, Mitsuyuki[1]

[1]Meteorological Research Institute

Hoshiba (2013, JGR) proposed a method for real-time prediction of ground motion based on real-time monitoring as the next-generation EEW, in which detection of hypocenter and Magnitude are not required. In this method, site amplification is one of the important factors. Therefore, relative site amplification factor have been evaluated at KiK-net (Iwakiri and Hoshiba, 2011) and at JMA seismic intensity stations (Aoki and Hoshiba, 2013) in the frequency domain. Ocean Bottom Seismograph (OBS) will provide valuable information to grasp ground motion propagation from ocean area. However, it is necessary to correct the site amplification factor of OBS for applying real-time monitoring method. Hayashimoto and Hoshiba (2013, SSJ) reported relative site amplification factor of OBSs at Tonankai region (Tonankai OBS (JMA) and DONET (JAMSTEC)) as a preliminary result. In this study, we evaluate relative site amplification factor of Sagami Bay OBS (NIED, Eguchi *et al*., 1998, MGR) which is close to land stations, and examine the effects of real-time correction to predict ground motion of land station from OBS.

The averaged spectral ratio of a station-pair from many events can be regarded as the relative site factor when the hypocentral distances to station-pair are much larger than the distance of those stations. In this study, we use the waveform data from the Sagami Bay OBSs and adjacent land stations (K-NET and KiK-net, NIED), and select the dataset with the hypocentral distance which is greater than 100km. We compare Fourier spectra from the waveforms of S-wave portion (20s) on OBSs with those on adjacent land stations as the relative site factors. In examples of the relative site factors of OBSs to KNGH23 (KiK-net borehole station), the amplification factor of the horizontal component is greater than that of the vertical component for frequencies 1-10Hz. We conclude that the site effects of OBSs characterized by such a low velocity sediment layers causes those amplification factors.

In order to examine the effect of frequency-dependent relative site amplification factor, we compare the accuracies of predicted seismic intensity using the spectral ratio with those using the average of seismic intensity (frequency-independent factor). We design the causal digital filter (Hoshiba, 2013, BSSA) having similar amplitude property to relative site factor for the station pair. The filter parameters are estimated and applied for both horizontal and vertical components. And we use the real-time processing of seismic intensity (Kunugi *et al*., 2008, Zisin 2) to estimate seismic intensity from observed and predicted waveforms. Both of the techniques are applicable in real-time. We consider the RMS of residual between observed and predicted seismic intensities as the accuracy of site correction of each station pair. In the case of prediction of seismic intensities from OBSs data to land stations, the average RMS of frequency-dependent method are smaller than that of frequency-independent method. Similar results are also obtained at pairs of land station. These results indicate that the frequency-dependent site factor is crucial factor to predict seismic intensity from OBS data, and also show that OBS can be used as front stations in the method for prediction of ground motion based on the real-time monitoring.

Acknowledgments: Strong motion acceleration waveform data were obtained from K-NET and KiK-net of NIED.

Improvement of earthquake early warning system using the extrapolation of wavefield with apparent velocity and direction

SATO, Asuka[1*] ; YOMOGIDA, Kiyoshi[1]

[1]Global Seismology, Natural History Sciences, Graduate School of Science, Hokkaido University

The present early warning system in Japan utilizes the epicenter information preliminary estimated by P-wave arrival times at stations near an event. The present system is still not effective in the following cases, for example, (a) more than one earthquakes occur nearly simultaneously, (b) a deep event whose wave front propagates in a different manner from shallow ones, particularly with very high apparent velocity on the surface, and (c) a large event (M>8) whose finite fault area cannot be neglected. In order to deal with non-circular wave front expansion of these cases, we propose a new approach based on the extrapolation of the early observed wave field alone without determining an epicenter. The idea is similar to the migration method of exploration seismology. The conventional migration method utilizes the wave field on a given wavefront (e.g., Kirchhoff integral migration). In the early warning system, on the other hand, we can obtain the speed and direction of wave field expansion over the surface. Based on the standard representation theorem with a Green's function, we extrapolate wave field outwards or in the future with not only the observed waveform but also its spatial derivative (normal for the wavefront). This enhances the resolution and reliability in the extrapolated wave field in comparison with the conventional approach with the waveform only.

For the extrapolation of wave fields accurately and reliably, we need a reliable Green function in each case. Since the actual wave propagation of P or S waves is very complex or sensitive to details of 3-D velocity structure between a source to each target point on the surface, we shall consider it in a two dimensional manner only focusing on the practical use of the early warning system, that is, a wavefront propagates on the surface with an apparent velocity of P-wave. These apparent velocities vary for events of various depths in different regions. The velocity of shallow events in Hokkaido is about 7.1km/s while that in Nagano prefecture of central Honshuu island is about 5.5km/s. The velocity strongly depends on focal depth: 7.1km/s for the depth of 10km, and 8.9km/s for the depth 100km. The velocity also varies as a function of epicentral distance, particularly for a deep event. We make a table of apparent velocities in different depths, regions and epicenters so that we can pick up an appropriate Green function (apparent velocity) for the wave field extrapolation when an event takes place. We also explain how to estimate the apparent velocity and propagation direction with several early observed wave forms. One key to apply the wavefield extrapolation in the warning system is the good correlation among the seismograms that are observed early as input data. Nevertheless, correlations are generally poor in high-frequency (about 1Hz) seismograms recorded in Japan such as Hi-net data. To enhance the correlation of P waveforms among adjacent stations, we need to correct the site response of each station promptly. Using both shallow and deep events, we first estimated site effect as a function of frequency for Hi-net stations in Hokkaido. We used a rock site station (ONPH) as a reference station for site correction terms for other stations.

For deep earthquakes, a region of anomalous seismic intensity is seen in the Pacific Ocean side of Japan called 'abnormal seismic intensity' , due to a subducting Pacific plate of high velocity and small attenuation. For the earthquake of 590 km deep beneath Vladivostok on 18 February 2010, we examined the direction of P waves propagating in Japan. The apparent velocity is highly anisotropic: fast along the islands but slow perpendicular to them. It is about 7.5km/s in the Souya district in the north of Hokkaido while about 13km/s in the Hidaka district in the south. In our extrapolation scheme, we can model the amplification of wavesin terms of abnormal seismic intensity.

Early forecasting of aftershocks from seismic energy release rate immediately after the mainshock

SAWAZAKI, Kaoru[1*] ; ENESCU, Bogdan[2]

[1]NIED, [2]University of Tsukuba

The detection completeness of earthquakes just after a large earthquake becomes very poor because their signals are overlapped each other in seismogram records and are hidden by the large amplitude of coda waves. Currently, the JMA starts to serve the aftershock forecasting at least 24 hrs after the mainshock because long lapse times are necessary before the catalog data becomes available for the forecasting with a certain reliability. Recently, Sawazaki and Enescu (under review) succeeded in estimating temporal change in energy release rate for the mainshock and the early aftershock sequence by using the Hi-net continuous records. In their method, the energy release is not determined for each discrete event, but is estimated as a continuous process like a source time function which sums up energies from all the earthquakes occurring at the same time. Therefore, theoretically there are no missing energies in the energy release rate even just after the mainshock. The estimated energy release rate follows a power-law temporal decay like the modified Omori law from about 40 s after the mainshock, and the deviation of the energy release rate with respect to the temporal regression curve distributes according to a power-law like the Gutenberg-Richter law. Since the current aftershock forecasting is conducted based on these two statistical laws, the energy release rate would be available for the early forecasting of the aftershocks.

We examine the statistical characteristics of energy release rate in the frequency range of 8-16 Hz for three crustal earthquakes took place in Japan. From the energy release rate obtained at the first 1 hr, 3 hrs, and 6 hrs after the mainshock, we estimate the number of energy release rate larger than 10^8 J/s (about M_W4/s) occurring within 24 hrs after the mainshock. For the 2008 Iwate-Miyagi Nairiku earthquake, the ratios of the estimated/observed numbers are 24/35, 12/20, and 20/10 for the forecasting at 1 hr, 3 hrs, and 6 hrs after the mainshock, respectively. Likewise, the ratios are 1524/223, 231/99, and 113/50 for the 2004 Niigata Chuetsu earthquake, and 17/59, 8/59, and 30/21 for the 2007 Niigata Chuetsu-oki earthquake. For the Niigata Chuetsu earthquake, M_J5.9, M_J5.8, and M_J6.3 aftershocks occurred in the first 1 hr, while there are no aftershocks larger than M_J5.5 in the lapse times from 1 to 24 hrs. For the Niigata Chuetsu-oki earthquake, there are no aftershocks larger than M_J5 in the first 3 hrs, while M_J5.7 aftershock occurred 5.4 hrs after the mainshock. Such large aftershocks and their secondary aftershocks may change the pattern of aftershock activity, and causes the over- and under-estimations in the forecasting.

A method to remove non-seismic long-period pulses for improved estimations of automatic centroid moment tensor solutions

SAKAI, Takahide[1*] ; KUMAGAI, Hiroyuki[1] ; NAKANO, Masaru[2] ; MAEDA, Yuta[1] ; YAMASHINA, Tadashi[3] ; PULIDO, Nelson[4] ; INOUE, Hiroshi[4] ; MELOSANTOS, Arnold[5] ; FIGUEROA, Melquiades[5] ; PUNONGBAYAN, Jane[5] ; NARAG, Ishma[5]

[1]Nagoya University, [2]JAMSTEC, [3]Kochi University, [4]NIED, [5]PHIVOLCS

Non-seismic long-period pulse-like waveforms appear in broadband seismic records when P or S waves arrive (e.g., Delorey et al, Bull. Seism. Soc. Am., 2008). The pulse-like waveforms affect centroid moment tensor (CMT) solutions estimated from waveform inversion, but a method to remove those pulse-like waveforms yet to be established. Broadband seismograph networks were installed in the Philippine and Indonesia region to monitor earthquakes and tsunamis. The pulse-like waveforms appear in those network data frequently. Those data are used for automatic estimations of CMT solutions by SWIFT (Source estimates based on Waveform Inversion of Fourier Transformed seismograms), which was developed by Nakano et al. (Geophys.J.Int, 2008). SWIFT estimates both the CMT and moment function by the use of long-period (50-100 s) waveform data, but sometimes the long-period pulse-like waveforms affect SWIFT solutions. To monitor earthquakes and tsunamis, we have to estimate source parameters rapidly and adequately. In this study, we propose a simple and rapid method to remove long-period pulse-like waveforms from broadband seismic records.

Japan Meteorological Agency information on long-period ground motion

AIZAWA, Koji[1*] ; OGAMI, Yoshie[1] ; URATANI, Junpei[1] ; SAKIHARA, Hirokazu[1] ; NAKAMURA, Masaki[1]

[1]Japan Meteorological Agency

An earthquake generates seismic waves with various periods, and earthquakes with larger magnitudes generate stronger long-period ground motions. When the natural period of a high-rise building is close to the predominant period of ground motion, resonance happens and the building is severely shaken longer than surface of the Earth. Today, more and more people spend time in high-rise buildings especially in metropolitan areas. If great earthquake occurs, many people in high-rise buildings will be affected by long-period ground motion.

To notify people of such situations and facilitate effective countermeasures, JMA started to provide information on long-period ground motion from March 28th, 2013. Based on questionnaires to tenants of high-rise buildings, it has become clear that difficulty of people's activities depends on the velocity of floor movement, and we classified the intensity of long-period ground motion into four on the basis of velocity. To get the classification, we use wave forms observed by JMA seismic intensity meters on the surface of the Earth which are automatically sent to the JMA system. To estimate shaking at higher floors from wave forms on the surface of the Earth, we simulate the shaking of buildings by absolute velocity response spectrum of the period between 1.5 and 8.0 seconds which causes a significant resonance of buildings with 45 meters or higher. The information is available on the JMA website, with various kinds of contents such as absolute velocity and acceleration response spectrum.

Prediction of long-period ground motion intensity for earthquake early warning

DHAKAL, Yadab prasad[1*] ; KUNUGI, Takashi[1] ; SUZUKI, Wataru[1] ; AOI, Shin[1]

[1]National Research Institute for Earth Science and Disaster Prevention

The 2011 Mw 9.1 Tohoku-oki earthquake caused strong shakings of high rise buildings constructed on deep sedimentary basins in Japan. During the earthquake, many people got into difficulty with their movements inside the high rise buildings even on the Osaka basin located at distances as far as about 750 km from the epicentral area. Japan Meteorological Agency (JMA) has started to provide people with information on intensity of long-period ground motions based on the absolute velocity response spectra (1.6 to 7.8 s) of the observed records on the grounds (Aizawa et al., 2013). The intensity scale of long-period ground motions is classified into four: 1, 2, 3, and 4 having spectral values of 5 to 15 cm/s, 15 to 50 cm/s, 50 to 100 cm/s, and more than 100 cm/s, respectively. The spectra were computed at natural periods of 1.6 to 7.8 s using 5% of critical damping. The maximum value of the computed spectra among 1.6 to 7.8 s defines the class of intensity. We have recently constructed empirical prediction equations of absolute velocity response spectra in the period range of 1 to 10s aiming for earthquake early warning application (e.g., Dhakal et al., 2013). The equations use JMA displacement magnitude and hypocentral distance as basic parameters. Earthquakes having JMA magnitude 6.3 or larger and focal depths shallower than 50 km were used. One of the difficulties in empirical prediction of long-period ground motions is to effectively include the effects of local geological structure such as 3-D basin effects in the prediction equations. To simplify this problem, we obtained site correction factors at K-NET and KiK-net strong motion sites as the mean value of the logarithmic residuals. To make predictions possible at sites other than the strong motion observation sites, we derived correction coefficients based on the relationships between the average residuals and depths of deep sedimentary layers, which are available for whole Japan at Japan Seismic Hazard Information Station (J-SHIS). We found that the standard deviations are minimized by corrections using the depth of layer having Vs value of 1.4 km/s.

To define intensity at a site, we obtained the maximum value of the predicted spectra among T=1.6 to 7.8 s using the empirical prediction equations explained above. However, we found that the maximum predicted values were somewhat biased against the observed maximum values. Therefore, we applied an additional correction factor to the maximum predicted values to finally obtain the intensities. When a prediction equation was constructed using the maximum value of the observed spectra as the independent parameter, the additional correction factor was eliminated as the resulting residuals were normally distributed; also, the predicted intensities were almost identical to those obtained based on the regression analysis results for each natural period. In this study, we illustrate and discuss the application of empirical prediction equations for the prediction of JMA intensity of long-period ground motions for earthquake early warning application.

Regional Earthquake Early Warning Applications in Marmara Region Based on KOERI Seismic Network

PINAR, Ali[1*] ; COMOGLU, Mustafa[1] ; ZULFIKAR, Can[1] ; TUNC, Suleyman[1] ; ERDIK, Mustafa[1]

[1]Bogazici University, Kandilli Observatory and Earthquake Research Institute, Istanbul, Turkey

KOERI (Kandilli Observatory and Earthquake Research Institute) operates a seismic network in Marmara Sea region (NW Turkey) consisting of 40 broadband and 30 strong motion inland and OBS stations which has a good topology for regional EEW studies. Data transmission between the remote stations and the base station at KOERI is provided both with satellite and fiber optic cable systems. The continuous on-line data from these stations is used to provide real time warning for emerging potentially disastrous earthquakes.

The Virtual Seismologist in SeisComP3 and the PRESTo regional EEW (earthquake early warning) softwares are the two regional EEW algorithms that have been recently setup at KOERI data center to generate the EEW sygnal. Onsite EEW application are underway for more than a decade.

The early warning sygnal is communicated to the appropriate servo shut-down systems of the receipent facilities, that automatically decide proper action based on the alarm level. Istanbul Gas Distribution Corporation (IGDAS) is one of the end users of the EEW signal. IGDAS, the primary natural gas provider in Istanbul, operates an extensive system 9,867 km of gas lines with 550 district regulators and 474,000 service boxes. State of-the-art protection systems automatically cut natural gas flow when breaks in the pipelines are detected. IGDAS uses a sophisticated SCADA (supervisory control and data acquisition) system to monitor the state-of-health of its pipeline network. This system provides real-time information about quantities related to pipeline monitoring, including input-output pressure, drawing information, positions of station and RTU (remote terminal unit) gates, slum shut mechanism status at 581 district regulator sites. The SCADA system of IGDAS receives the EEW signal from KOERI and decide the proper actions according to the previously specified ground acceleration levels. Presently, KOERI sends EEW signal to the SCADA system of IGDAS Natural Gas Network of Istanbul.

The EEW signal of KOERI is also transmitted to the serve shut down system of the Marmaray Rail Tube Tunnel and Commuter Rail Mass Transit System in Istanbul. The Marmaray system includes an undersea railway tunnel under the Bosphorus Strait. Several strong motion instruments are installed within the tunnel for taking measures against strong ground shaking and early warning purposes. This system is integrated with the KOERI EEW System. KOERI sends the EEW signal to the command center of Marmaray. Having received the signal, the command center put into action the previously defined measures. For example, the trains within the tunnel will be stopped at the nearest station, no access to the tunnel will be allowed to the trains approaching the tunnel, water protective caps will be closed to protect flood closing the connection between the onshore and offshore tunnels.

Full moment tensor inversion for the 2013 Sea of Okhotsk deep earthquake

HARA, Tatsuhiko[1*] ; KAWAKATSU, Hitoshi[2]

[1]IISEE, BRI, [2]Earthquake Research Institute, The University of Tokyo

We performed full moment tensor inversion for the May 24, 2013 Sea of Okhotsk deep earthquake, which is the largest deep earthquake (the moment magnitude is 8.3 after the Global CMT solution). Following Kawakatsu (1991), we redefined the diagonal components of the moment tensor, and determined full six component moment tensors. In order to determine the isotropic component independently from the CLVD component, we analyzed long period signals in the period range between 550 and 1000 s following Kawakatsu (1996), and Hara et al. (1995, 1996). We retrieved VHZ channel broadband waveform data from the IRIS DMC. The duration of the time series is five hours. We used the Direct Solution Method (Hara et al., 1991, 1993) to calculate the Green's functions. We considered the 3-D velocity structures of model SAW24B16 (M*é*gnin and Romanowicz, 2000) and crust 2.0 (Bassin et al., 2000; http://igppweb.ucsd.edu/~gabi/rem.html) to calculate synthetic seismograms. We set spatial grids around the PDE hypocenter for possible centroid locations and temporal grids around the centroid time of the Global CMT solution for possible centroid times. We conducted linear moment tensor inversions for pairs of the spatial and temporal grids to investigate the dependence of solutions on centroid location and time. In the preliminary analysis, the isotropic components of the solutions with larger variance reductions and smaller correlation coefficients with the isotropic component and the other moment tensor components are in the range around 2 to 4 per cent (implosive) of the seismic moment of this event. This preliminary result is consistent with Okal (2013), who obtained the implosive isotropic component with about 2 per cent of the seismic moment by the analysis of the normal modes ${}_0S_0$ and ${}_1S_0$, although further evaluation on uncertainty of the estimates obtained in this study is required.

Estimation of Radiated Seismic Energy from Teleseismic Body Waves

KIUCHI, Ryota[1*] ; MORI, James[1]

[1]Disaster Prevention Research Institute, Kyoto University

Radiated seismic energy is a fundamental parameter for understanding source physics. Using teleseismic P waves, Choy and McGarr (2002) reported that strike-slip earthquakes in the oceanic lithosphere have high apparent stress (rigidity multiplied by the ratio of radiated energy to seismic moment). However, that estimates may have a large variation, because of the large radiation pattern of nodal arrivals. Therefore, we improved that used method to better correct for radiation pattern. From our result, we find that the strike-slip earthquakes have apparent stress values that are 5 to 8 times higher than dip-slip earthquakes with the oceanic events having slightly higher values than continental events. In addition, using our improved methods, we can estimate the apparent stresses for strike-slip earthquakes with more reliability, since the error of radiated seismic energies becomes smaller.

Seismic energy estimation of repeating earthquake sequences offshore northeastern Japan

ARA, Masamichi[1*] ; IDE, Satoshi[1] ; UCHIDA, Naoki[2]

[1]The University of Tokyo, EPS, [2]Graduate school of science Tohoku university

Repeating earthquakes are thought to occur on locked patches, which represent almost time-independent irregularity on the plate interface, to catch up with stable slip on the surrounding interface. Thus, they produce spatial and temporal stress heterogeneity around the source area, which may control the spatial and temporal patterns of seismic energy of repeating earthquakes. We estimate seismic energy for many small to moderate repeating earthquakes that occurred offshore northeastern Japan, to understand the nature of stress heterogeneity and hidden structural irregularity.

Seismic energy reflects dynamic fault motion during an earthquake, while seismic moment is determined by the difference between the initial and final states of the fault. Seismic moment is determined relatively precisely using the low frequency limit of seismic spectra. In contrast, seismic energy has large errors because it is determined from the entire frequency range of seismic spectra, after correcting path and site effects which can be significant especially at high frequencies. Another problem is the size dependence of seismic energy, which has been a matter of debate for two decades in seismological community. A typical question is whether scaled energy (the ratio of seismic energy to moment) is dependent on seismic moment. These problems have to be alleviated to discuss the spatial and temporal variation of radiated seismic energy. Seismic energy must be estimated as precise as possible.

As mentioned, the most serious problem in estimating seismic energy is removing path and site effects. To avoid this problem, the present study adopts an empirical Green's function (EGF) method. We regard the ratio of seismic spectra as the ratio of source spectra, since the seismic spectra of co-located events observed at one station share the same path and site effects. We modify an EGF method with coda waves developed by Baltay et al. (2010), to rigorously evaluate the uncertainty in corner frequencies and the effects of noise.

This method is applied to several repeating earthquakes of magnitude ˜2 to 6 that occurred offshore northeastern Japan. We estimate seismic energy for a group of events by calculating the ratios of source spectra using S-coda waves in two horizontal components of Hi-net, National Research Institute for Earth Science and Disaster Prevention. The scaled energy is almost constant or slightly increasing with seismic moment. Nevertheless, the results are still tentative because the estimation of seismic energy is dependent on the assumption of source spectral model, such as the omega-square model, which have not been constrained well.

Stress drop variations among small earthquakes in the Tohoku-oki region - implications for the 2011 megathrust event

UCHIDE, Takahiko[1*] ; SHEARER, Peter[2] ; IMANISHI, Kazutoshi[1]

[1]Geological Survey of Japan, AIST, [2]Scripps Institution of Oceanography, UC San Diego

It is important to assess the likely rupture characteristics of future megathrust earthquakes. One approach is to study the spatio-temporal variation of geophysical properties in active subduction zones. We explore this idea by examining stress drops of 1536 small earthquakes (Mw 3.0 - 4.5) shallower than 80 km in the Tohoku-oki region before the 2011 Tohoku-oki earthquake. We estimate stress drops using the spectral analysis method described by Shearer et al. [2006], which isolates source, path, and receiver terms and then applies an empirical Green's function (EGF) correction before computing corner frequencies and stress drops using the Madariaga [1976] model.

We find an overall increase in stress drop with depth, as well as lateral variations in stress drop along strike. Higher-than-average stress drops are found in East Aomori-oki and Miyagi-oki, whereas Sanriku-oki is a moderate stress-drop area. The high stress-drop zone in Miyagi-oki is located just south of the large slip area of the 2011 Tohoku-oki earthquake, and possibly acted as a barrier to further rupture propagation during the event. The Miyagi-oki high-stress-drop zone is located on west of the 1978 Miyagi-oki earthquake rupture area.

Stress drops of earthquakes in the large slip patch of the 2011 Tohoku-oki earthquake are comparable to the mainshock stress drop. Since studies [Hasegawa et al., 2011; Yagi and Fukahata, 2011] indicate that the 2011 Tohoku-oki earthquake released nearly all the stored shear stress, our findings suggest that small earthquakes prior to the mainshock also released a large fraction of the accumulated shear stress. Note that the absolute values of the stress drops of small earthquakes are not well constrained due to assumptions such as the choice of source models, whereas the relative values among the stress drops of small earthquakes are better resolved. Therefore the hypothesis of nearly complete stress drops for the small earthquakes needs to be confirmed by other approaches.

In addition, the frequency dependence of the seismic radiation observed during the mainshock, with proportionally higher frequencies coming from the deeper parts of the fault, mimics the depth dependence we see in small earthquakes in the same region.

These results imply that smaller pre-mainshock earthquakes can provide insights into the fault properties and consequent rupture processes of future megathrust earthquakes.

Broad-band source image for the 2011 Tohoku earthquake constructed by strong-motion data

KUBO, Hisahiko[1*] ; ASANO, Kimiyuki[1] ; IWATA, Tomotaka[1] ; AOI, Shin[2]

[1]DPRI, Kyoto Univ., [2]NIED

From the comparison between slip model using long-period (10s˜) seismic waves and excitation zones of short-period (0.1-10s) seismic waves, it has been suggested that the 2011 Tohoku earthquake (Mw9.1) has the period-dependent spatial variation on the seismic-wave radiation and this variation would be caused by the spatial difference of slip behavior on the plate boundary (e.g., Koper *et al.*, 2011; Lay *et al.*, 2012). However, their studies were based on the qualitative comparison of the results obtained by different methods, and the quantitative comparison between source models having different period-bands has not been made. Therefore, the construction of the source models at different period-bands by a common method is important to further understand the source characteristics of the 2011 Tohoku earthquake. Kubo et al. (2013, Fall Meeting of SSJ) estimated the spatiotemporal slip models for the 2011 Tohoku earthquake on three different period bands (10-25s, 25-50s, and 50-100s). In this study, we estimate the source models for the 2011 Tohoku earthquake on five continuously-different period bands (10-25s, 17-33s, 25-50s, 33-67s, and 50-100s) using strong-motion data, and construct broad-band source image for the 2011 Tohoku earthquake.

The spatiotemporal rupture history is estimated by the kinematic linear waveform inversion using multiple time windows (Hartzell & Heaton, 1983). The Green's functions are calculated by the 3D FDM (GMS; Aoi & Fujiwara, 1999) using a 3D velocity structure model, Japan Integrated Velocity Structure Model Version 1 (Koketsu *et al.*, 2012). Three components of velocity waveforms at 25 stations of K-NET, KiK-net, and F-net of NIED are used in this analysis. Using waveform records at the stations for the middle-size events which occurred in the source area of the 2011 Tohoku earthquake, we confirmed the adequacy 3D velocity structure model at the analyzed period-band.

The source image for the 2011 Tohoku earthquake on the period band of 10-100s is summarized as follows: (1) (1st) Deep rupture off Miyagi rupture at 0-60s toward down-dip mostly radiating relative short period (10-25s) seismic waves. (2) Shallow rupture off Miyagi at 45-90s toward up-dip with long duration radiating long period seismic wave. (3) (2nd) Deep rupture off Miyagi at 45-90s toward down-dip radiating long period (25-100s) seismic waves. The dominant-period difference in the seismic-wave radiation between twice deep ruptures off Miyagi may result from the mechanism that the second rupture is smoother than the first one because small-scale heterogeneities on the fault are removed by the first one. (4) Deep rupture off Fukushima at 90-135s.

The broad-band source model on the period band from 5-100s is under construction and we will report this.

[Acknowledgments] The strong-motion data recorded by K-NET, KiK-net, and F-net of NIED was used for this analysis.

Foreshocks implying slow slip transients leading to large earthquakes

KATO, Aitaro[1*] ; OBARA, Kazushige[1]

[1]ERI University of Tokyo

In the recent decades, a growing number of geophysical evidences has clarified that a major fault zone along plate interface hosts not only the unstable fast sliding during rupture of ordinary earthquake, but also slow slip transients without any seismic radiations. Because slow slip transients quasi-statically release the shear stress in the adjacent seismogenic regions, the slow slip transients may have caused stress loading on the nearby seismic patch and might play a role in a slow nucleation process leading to a large earthquake (Beroza and Ide, 2010; Bouchon et al., 2011; Kato et al., 2012). Therefore, it is quite important to reveal interplay between slow slip and unstable fast slip, in order to shed light on the nucleation process of large earthquake.

Here, we explored foreshock activities implying slow slip transients leading up to large earthquakes. We applied the matched filter technique to continuous waveform data around 10 days prior to the past large earthquakes in Japan (M >˜6.5), and created newly foreshock catalog for each sequence. We found out accelerating seismicity preceding some large earthquakes at plate interfaces and intraplate at time scales of days to hours. These foreshocks were located very close to the initiation point of each mainshock rupture. The increase in foreshock seismicity implies that a fault may begin to slowly slip before large earthquake, as like recognized in the foreshock sequence prior to the 2011 Tohoku-Oki earthquake.

Similar Characteristics between the earthquake source process and Vere-Jones' Branching model

ZHUANG, Jiancang[1] ; WANG, Dun[2*]

[1]Institute of Statistical Mathematics, [2]Earthquake Research Institute, University of Tokyo

Vere-Jones' branching crack model was develop in 1970s. In this model, the earthquake source is regarded as the results of the total population of crack elements in a critical or near-critical branching process, where the crack does not propagate in a single continuous movement, but through a series of steps. At each step, each crack element simply terminates or generates several other crack elements nearby. Regarding the total number of steps (generation) as the duration time and the total number of crack elements as the total energy released, the following similarities are found between earthquake sources and this model:

1. The distribution of energies is asymptotically a Pareto distribution (power law) for the critical case, or a tapered Pareto distribution (tapered power law, Kagan distribution) for the subcritical case.
2. The duration time of ruptures has a tapered inverse power distribution.
3. The number of crack elements at each generation (time step) show similar patterns of earthquake source time functions.

Figure 1 (a) and (b): Plots of the numbers of crack elements at each time step in two simulation examples. (c): Distribution of half duration times in real earthquake catalog. (d): Distribution of duration times in synthetic catalogs.

Review on Source Type Diagrams

ASO, Naofumi[1*] ; OHTA, Kazuaki[1] ; IDE, Satoshi[1]

[1]Graduate School of Science, The University of Tokyo

Force system of earthquake is expressed by a symmetric moment tensor, assuming internal forces on a point source, and it has information of characteristic directions, source size, and source type. Although we often assume double couple as the source type, significant non-double-couple component including isotropic component is reported mainly for induced earthquakes or volcanic earthquakes. It is also known that combination of double couples may produce non-double-couple components. For discussion on source types, it is helpful to display them into some visual diagrams.

Since the information of source type has two degrees of freedom, it can be displayed on a two-dimensional flat plane. Although the diagram developed by Hudson et al. [1989] (HPR diagram) is popular, it is inconsistent with the concept of scalar moment [Aki and Richards, 2002]. This problem originates in the projection of a three-dimensional point (λ_1, λ_2, λ_3) on a cubic surface, where λ_1, λ_2, and λ_3 are eigenvalues of moment tensor.

Then, Chapman and Leaney [2012] developed a new diagram by combining spherical projection and stereographic projection (CL diagram). The spherical projection overcomes the problem of the HPR diagram, and the stereographic projection keeps areal density from a spherical surface to a flat plane. This diagram has an advantage that a straight line passing through the center corresponds to the mechanism obtained by combination of an arbitrary mechanism and a double couple, but the diagram is curved shape, and it does not suit for detailed discussions on non-double-couple component when the isotropic component is dominant.

In the present study, we developed another new rectangle diagram that overcomes difficulties of the HPR diagram and the CL diagram simultaneously (AOI diagram). After projecting (λ_1, λ_2, λ_3) on a spherical surface, we project it on a cylinder, keeping areal density. This diagram is an orthogonal system of the isotropic axis (the trajectory for varying isotropic component) and the deviatoric axis (the trajectory for varying deviatoric component while keeping its scalar moment). Since isotropic component represents the information from P-wave and deviatoric component represents the information from both P- and S-waves equivalently, the AOI diagram is consistent with the concept of seismogram analyses.

Since there is no source type diagram that is the best at everything, as well as map projection, it is important to use various diagrams taking account of their advantages and disadvantages. In the present study, we also provide examples of projecting a data set on different diagrams, and point out their apparent differences and important considerations.

Stress concentration ahead of supershear rupture

FUKUYAMA, Eiichi[1*] ; XU, Shiqing[1] ; MIZOGUCHI, Kazuo[2] ; YAMASHITA, Futoshi[1]

[1]Nat'l Res. Inst. Earth Sci. Disas. Prev., [2]Centr. Res. Inst. Elect. Pow. Ind.

We report the shear strain field ahead of a supershear rupture. The strain data was obtained during the large-scale biaxial friction experiments conducted at NIED in March 2013. We conducted friction experiments using a pair of meter-scale gabbro rock specimens whose fault area was 1.5m x 0.1m. We applied 2.6MPa normal stress and loading velocity of 0.1mm/s. At the long side of the fault edge, which is parallel to the slip direction, 32 2-component semi-conductor strain gauges were installed at an interval of 50mm and 10mm off the fault. The data are conditioned by high frequency strain amplifiers (<0.5MHz) and continuously recorded at an interval of 1MHz with 16-bit resolution. Many stick slip events were observed and a unilateral rupture event was chosen in this analysis that propagated with supershear rupture velocity. By focusing at the rupture front, stress concentration was observed and sharp stress drop occurred immediately inside the rupture. We found that the stress concentration becomes mild as the rupture propagates and length of the stress concentration area becomes longer. This observation is quite interesting because the rupture propagates at a constant speed close to square root two times the shear wave velocity and thus a longer stress concentration region suggests more energy dissipation. We might speculate that such longer stress concentration area suggests longer plastic region ahead of the rupture (or longer cohesive distance). I.e. The cohesive zone length might be longer as the rupture propagates to maintain constant rupture velocity propagation.

Effects of normal stress on the evolution of AE activities and frictional properties of a fault

IIDA, Takuro[1] ; YABE, Yasuo[1*]

[1]Graduate School of Science, Tohoku University

To numerically investigate earthquake generations on a plate interface or a fault, we need to know their frictional properties. This study provides a clue to evaluate the frictional properties from spatio-temporal variations of such observations as seismicity and aseismic sliding on the interface of the fault.

We performed frictional sliding experiments using a rotary shear apparatus under a variety of normal stress from about 5 MPa to about 15 MPa. Stepwise change in the sliding rate was imposed to investigate rete dependences of AE activity and friction. Cumulative displacement up to 200 mm was achieved to elucidate their evolutions.

We confirmed similar evolutions of AE activities and friction to those shown by Yabe (2002). That is, the frictional property (rate dependence of friction) of the fault was first the velocity strengthening. The velocity strengthening became weak with an increase in the cumulative sliding. Then, the fault showed the frictional property of velocity weakening. Finally, the rate dependence of friction converged to a constant negative value, when the cumulative sliding reached a critical distance. The m-value of AE events increased with sliding, when the cumulative sliding distance was smaller than a critical distance. After the critical sliding distance, the m-value took a constant value. The critical sliding distances of the frictional property and the m-value were almost the same each other. The rate dependence of the m-value, which was negative under a small sliding distance, also converged to a constant value of about zero at the cumulative sliding distance.

The evolutions were quantitatively evaluated by applying an exponential-decay function to data that is similar to the function proposed by Wang and Scholz (1994) to express wear processes of a fault. The function well reproduced the experimental data, suggesting that AE activities and frictional properties evolved in association with the wear. The decay distances of evolutions of the AE activities and the frictional properties were equal to each other and in inverse proportion to the normal stress. The latter could be understood by taking into account that the larger the overlap volume of asperities on the fault, the larger the normal stress. Further, when the normal stress was increased, the velocity weakening became weak and the m-value was decreased.

These results imply that there exists interrelations among seismicity and frictional properties of the fault.

Determination of the coefficients of Mhdd by a grid search approach

HARA, Tatsuhiko[1*]

[1]IISEE, BRI

Hara (2007) developed an empirical magnitude formula using durations of high frequency energy radiation and maximum displacement amplitudes using tele-seismic P waves. Recently, Hara (2013), who referred to this magnitude as M_{hdd}, tried to re-determine the coefficients of the formula using a larger dataset by a linear inversion. The M_{hdd} calculated by the proposed coefficients better agree with the moment magnitudes from the Global CMT catalog. However, there is slight epicentral distance dependence for their differences. In this study, in order to reduce this epicentral distance dependence, we performed a grid search to determine the coefficients of M_{hdd} by minimizing both the differences between M_{hdd} and moment magnitudes and the dependence of their differences on the epicentral distance. The dataset is the same as that of Hara (2013). The search ranges for each coefficient can be set reasonably based on the studies of Hara (2007) and Hara (2013). The preliminary result suggests that it is possible to reduce the epicentral distance dependence using the coefficients obtained by the grid search method.

Wavelet domain inversion for examination of the frequency-dependent characteristics of the seismic wave radiation

SUZUKI, Wataru[1*] ; AOI, Shin[1] ; SEKIGUCHI, Haruko[2] ; KUNUGI, Takashi[1]

[1]NIED, [2]DPRI, Kyoto University/NIED

Frequency-dependent characteristics of the seismic wave radiation from earthquake sources are important subject for advancing the source physics and the strong-motion prediction. The 2011 Tohoku-Oki earthquake has exhibited particularly distinctive characteristics. The large slip is estimated in the shallow part of the fault from the low-frequency waveforms or geodetic data, whereas the source models derived from the analysis of the higher-frequency seismic data, such as the empirical Green's function modeling or backprojection method, suggest that the high-frequency waves were intensely radiated from the deeper portion. Our previous study (Suzuki et al., 2011) examined the contribution of the significant slip events to the waveform synthesis from the low-frequency waveform inversion results. We found that the sources of the very-low-frequency waves (<0.02 Hz) and higher-frequency waves seem different in the location even in the frequency band used in the waveform inversion. The examination on the frequency dependence in this previous study is somewhat indirect. We have therefore developed the source inversion method that utilizes the wavelet coefficients as the target to fit. This new method is based on the multi-time-window scheme and is linear inversion. The moment rate is directly related to the waveform in each octave band. We have first applied the developed method to 0.01-0.125 Hz strong-motion data of the largest aftershock of the Tohoku-Oki event that occurred in the off Ibaraki prefecture. The preliminary analysis does not suggest the clear frequency dependence for this Mw7.9 event in the analyzed frequency band. As future work, we will extend the analyzed frequency range and also apply to the Tohoku-Oki mainshock.

Tracing Rupture Process of the 2011 Tohoku M 9.0 Earthquake Using Small Seismic Arrays in China

XUELIN, Shen[1] ; WANG, Dun[2*]

[1]1.Key Laboratory of Earthquake Geodesy Institute of Seismology, China Earthquake Administration, [2]2.Earthquake Research Institute, The University of Tokyo

Back projection(BP) can trace rupture front of large earthquakes. It has been widely applied for better understanding rupture processes of recent large earthquakes. An important result/ouput from BP is rupture length, which roughly corresponds to the final size of earthquakes given geological environment. Thus it can be used for fast estimate of the size of large earthquakes for the purpose of tsunami warning and disaster evacuation.

Most studies were focused on using data recorded at distances of 30 to 85 degrees to epicenter, in which distance range the first coming wave is direct P wave which ensures a good resolution for the results from BP.

Here we applied several sub China array data to trace the rupture propagation of the Tohoku earthquake to investigate the effect of the other regional phases such as Pn. We tested the effects with seismograms recorded in sub arrays of China seismic array. The results suggest that the overall rupture length can be recovered, though there is some visible disconvergence, especially for those results derived from distant sub arrays.

Waveform correlation analysis of small repeating earthquakes using high sampling-rate seismograms

HATAKEYAMA, Norishige[1*] ; UCHIDA, Naoki[1] ; MATSUZAWA, Toru[1] ; OKADA, Tomomi[1] ; NAKAJIMA, Junichi[1] ; MATSUSHIMA, Takeshi[2] ; KONO, Toshio[1] ; HIRAHARA, Satoshi[1] ; NAKAYAMA, Takashi[1] ; TOHOKU-EQ, Group for the aftershock observations[3]

[1]Graduate School of Science, Tohoku University, [2]Faculty of Sciences, Kyushu University, [3]Group for the aftershock observations of the 2011 Tohoku Earthquake

Repeating earthquake sequence is a series of earthquakes with nearly identical waveforms which occur at the same location repeatedly and they are thought to represent repeated ruptures of small asperities on a fault plane. Since there are many unknown features about asperities such as detailed structures, reproducibility and fluctuation of rupture patterns, it is very important to reveal such features to understand the generation process of interplate earthquakes.

Numerical simulations of the repeating earthquakes with rate- and state-dependent friction laws reveal that stress disturbance caused by postseismic slip of a large earthquake near the repeater can change rupture pattern of the repeater's asperity. Actually, some observations show systematic changes in the magnitudes of small repeating earthquakes immediately after large earthquakes. Such rupture pattern changes will make difference especially in high-frequency components of the waveforms. Therefore, in order to verify the rupture pattern changes of small repeating earthquakes, we have to perform detailed analysis on the differences in high-frequency components of the waveforms.

In this study, we performed 1 kHz sampling-rate seismograph observation at permanent borehole stations along Sanriku coast, Japan for the period from April to November 2011, immediately after the Tohoku-Oki earthquake. We investigate the waveform correlations of small repeating earthquakes using waveform data. We make a pair of earthquakes belonging to the same group of repeating earthquakes and calculate their coherences. The results show that in high-frequency band, there are both high-coherence pairs and low-coherence pairs even in the same repeating earthquake group, although all the pairs show high coherence in low-frequency band. Furthermore, frequency bands in which the coherences are low are nearly the same for all the pairs. These results suggest rupture pattern changes in the asperity.

We also find that earthquakes which show low coherence in high-frequency band for all the counterparts occur immediately after events in the vicinity of the repeater's asperity. This observation implies that rupture pattern changes in the asperity, which make difference in high-frequency components of the waveforms, are caused by stress disturbance due to the nearby earthquakes.

Study on the source process of the largest aftershock of 1923 Kanto earthquake

HONDA, Ryou[1*] ; KIMURA, Hisanori[2] ; KASAHARA, Keiji[3] ; YUKUTAKE, Yohei[1] ; HARADA, Masatake[1] ; DOKE, Ryosuke[1] ; MIYAOKA, Kazuki[1]

[1]Hot Springs Research Institute, [2]National Research Institute for Earth Science and Disaster Prevention, [3]Association for the Development of Earthquake Prediction

The largest aftershock of M7.5 (Takemura, 1994) occurred at off Boso Peninsula following the 1923 Kanto earthquake. Although the hypocenter have been estimated by previous studies (e.g., Takemura, 1994; Hamada et al, 2001), precise source process have not been estimated yet.

The source region of the largest aftershock is characterized by the region of seismic and aseismic phenomena associated with subduction motion of the Philippine Sea Plate, including slow slip events (SSEs), large backslip events, and repeating earthquakes. Kimura et al. (2009) estimated fault plane of the largest aftershock from geodetic data and they concluded that the fault plane lies within the region of large backslip and the large slip area of the Boso SSE. Estimation of the source process during the largest aftershock is, therefore, important to understand earthquake preparation process around the region.

We set three point sources on the fault plane estimated by Kimura et al. (2009); shallow part (S1), middle part (S2) and deep part (S3). We calculated synthetic seismograms and evaluated the cross correlations between the observed and the synthetic waveforms. We tested the nine hypocenter-asperity combinations using S1, S2 and S3. The combination with the highest value of the average cross correlation is regarded as the best model. We obtained the best score for combination of S2 (hypocenter) and S3 (asperity). This result shows that rupture started from S2 and propagated toward S3.

The observed data used in this study were provided by Kajima Corporation. We are grateful for their kind considerations.

Earthquake source process of the 2013 Santa Cruz earthquake and the tsunami

PARK, Sun-cheon[1*] ; KIM, Satbyul[2] ; LEE, Jun-whan[1]

[1]National Institute of Meteorological Research, Korea Meteorological Administration, [2]Pukyong University, South Korea

In order to understand the characteristics of large tsunamigenic earthquakes, we analyzed the earthquake source process of the 2013 Santa Cruz earthquake and simulated the tsunami. We first estimated the fault length of about 200 km using 3-day aftershock distribution and the source duration of about 110 sec using the duration of high-frequency energy radiation (Hara, 2007). From these results, we used the initial value of rupture velocity as 1.8 km/s for teleseismic waveform inversions. Teleseismic body wave inversion was carried out using the inversion package by Kikuchi and Kananmori (1991). Teleseismic P waveform data from 28 stations were used and band-pass filter of 0.005 ˜1 Hz was applied. Our best-fit solution indicated that the earthquake occurred on the northwesterly striking (strike = 290) and shallowly dipping (dip = 15) fault plane. Focal depth and rupture velocity were determined to be 23 km and 1.3 km/s, respectively. Moment magnitude of 7.8 was obtained showing somewhat smaller than the result of previous study (Lay et al., 2013). Slip distribution of the event showed roughly two patches of large slip, one around the hypocenter and the other to the southwest.

Using the slip distribution obtained by teleseismic waveform inversion, we calculated the surface deformations using formulas of Okada (1985) which would be assumed as the initial change of sea water by tsunami. Then tsunami simulation was carried out using Cornell Multi-grid Coupled Tsunami Model (COMCOT) code and 1 min-grid topographic data for water depth. Two DART buoy data were used to verify our simulation. In the presentation, we will discuss more details on the results of source process and tsunami simulation and compare them with the previous study.

Relationship between the source process of the 2013 Sea of Okhotsk deep earthquake and the thermal structure of the slab

ENDO, Suguru[1*] ; YAGI, Yuji[1] ; NAKAO, Atsushi[2]

[1]Univ.Tsukuba, [2]Tokyo Institute of Technology

Deep earthquakes occur at depths where, due to the high normal pressures and the prominence of plastic behavior caused by high temperatures, the brittle fracture is difficult to explain. As a consequence, the mechanism of deep earthquakes has been long standing challenge in Earth Science since the early twentieth century. Some mechanisms of deep earthquakes have been suggested and these mechanisms are sensitive to the thermal structure of slabs. Accordingly, the purpose of this study is (1) to infer the source process of the Sea of Okhotsk deep earthquake (Mw 8.3, depth 608.9 km) on 24 May 2013 (UTC) by using the Hybrid Back?projection (HBP) method (Yagi et al., 2012) and waveform inversion (Yagi and Fukahata, 2011) and (2) to elucidate the relationship the source process and the thermal structure in the Kurile slab.

We found that the reactivation of the rupture occurred near the hypocenter. This means that a stress concentration near the hypocenter overcomes the fault strength and reactivates rupture at the hypocenter (Gabriel et al., 2012). We investigated the relationships between our results and the thermal structure of the Kurile slab and found that (1) the main shock started to rupture from the outer portion of the slab (2) the source region of the earthquake extended in a temperature range between 740 ℃ and 990 ℃. This study does not clearly support transformational faulting as a mechanism for occurrence of the Sea of Okhotsk deep earthquake suggested by Zhan et al. (2013) because it is unlikely that metastable olivine exists all over the slab at the depth of the main shock.

Focal mechanisms of the triggered tremor beaneath the Hinagu fault zone, southwestern part of Japan

MIYAZAKI, Masahiro[1*] ; MATSUMOTO, Satoshi[2] ; SHIMIZU, Hiroshi[2]

[1]Grad. Sch. Sci., Kyushu Univ., [2]SEVO, Kyushu Univ.

Non-volcanic tremors induced by large amplitude surface wave have been detected all over the world. Most of them are located on and near the plate boundary (Miyazawa and Mori, 2005; Nadeau and Dolene, 2005) and few of them are near volcanoes (Obara, 2012). Chao and Obara (2012, SSJ) found the triggered tremor that located beneath the Hinagu active fault zone, western part of Kyushu Island, Japan. Miyazaki et al. (2013, SSJ) reported that the tremor occurred beneath the seismogenic zone.

In this study, we attempted to estimate focal mechanisms of the tremors triggered by the surface wave of the 2012 Sumatra earthquake. We use the method developed by Hirasawa (1966) that uses the S wave polarization angles. We eliminated the data with low Signal-to-Noise ratio because the angles of waves of tremors were sensitive to background noise.

As a result, we found that focal mechanisms of the triggered tremors were roughly consistent with regional stress field. They could provide constraint for investigating dynamic triggering process of the tremor.

Spatio-Temporal Variation of Stress Drop Observed at Carthage Cotton Valley Gas Field, Texas

IIDA, Shuhei[1*] ; KIM, Ahyi[1]

[1]Yokohama City University

Understanding source characteristics of hydraulic fracturing induced microearthquakes is expected to provide a better understanding of the fracturing process and the influence of pre-existing structures controlling the distribution of events. Especially it is still controversial whether the events are associated with volumetric change or not. To address this question, we estimated the source parameters using the empirical Greens function analysis.

Collapse of intraplate earthquake, Separation of accretionary wedge, and Rotation of plate by lateral-fault type

MASE, Hirofumi[1*]

[1]none

(Refer to the chart)

”Nankai Slab” that subduct from Nankai Trough forms the slope that turned to the northwest and is soaked to the thing that heads eastward. That edge shapes to receive resistance. And, ”Nankai Slab” receives the right turning force and weak places collapse. The part that is deeper than that place crawls up and the whole might rotate right. (A),intraplate earthquake of ”Nankai Slab”, and (B), lateral-fault type earthquake that the boundary with ”Tokai Slab” causes, are the Nankai Earthquake(EQ) and the To-Nankai EQ and the Tokai EQ.(this paragraph (1)(2))

Two huge cracks that seem that they relate to the right rotation exist if seafloor topography chart(3) is seen.

Crack(a):This crack starts from the place of about 10km to the east in Cape Daio and lengthens to the south. And, this crack gets to the trough. The trough projects to the south on the west side on the boundary of this place. I think that this crack slips when the upper plate(land side plate, accretionary wedge)

greatly moves on the lower plate ”Nankai Slab”.

Crack(b):This crack is shape of the character of Y off Lake Hamana and reach the trough. ”Nankai Slab” and ”Tokai Slab” are completely separate in the north from Lake Hamana(7). And, I think in the south this crack leads to the trough while touched. This crack is the one that this plasmotomy reached bottom of the sea and that slips when the whole of lower plate moves with the upper plate put.

Earthquake(B) is the one that Crack(b) slips. It can be said that that Crack(a) slips is intermediate of earthquake(A) and (B).

Dr. Yamanaka proposed in 2004 large and clear source model of the 1944 To-Nankai EQ that eastern edge within the range gets to Omaezaki(4).

That large area of slip is equal to the area of Crack(a) and (b). The 1944 EQ was not only earthquake(A) and everything might have happened. I composed the source process by earthquake(A),(B) and Crack(a),(b) referring to Dr. Yamanaka’s (interplate earthquake) source process.

1.Earthquake(A) occurred, and it spread in the direction of northeast along the slab-contour. 2.Separation of the accretionary wedge spread to the southeast and it reached the trough. 3.The separation spread along the trough first and spread along Crack(a) next. 4.(Rotation of upper plate) Crack(a) slipped because the separation was large-scale. 5.(Rotation of lower plate) Crack(b) slipped and earthquake(B) occurred because the environment was in order. The stress occurred in the vicinity of the trough. 6.The Mikawa EQ occurred because of the influence of 4,5. 7.The 2004 EQ occurred and the stress of 5 was absorbed.

Long-term seismic quiescence and activation anomalies preceding to the 2004 Sumatra and the 2005 Nias earthquakes

KATSUMATA, Kei[1*]

[1]Inst. Seismology and Volcanology, Hokkaido University

I find long-term precursory seismic quiescence and activation anomalies before the 2004 Sumatra (M_w9.1) and the 2005 Nias (M_w8.6) earthquakes. An earthquake catalog created by International Seismological Center is analyzed between 1964 and 2004, including 1153 earthquakes shallower than 100 km with the body wave magnitude of $5.0 \leq M \leq 6.0$. A detailed analysis of the earthquake catalog using a gridding technique (ZMAP) shows that the 2004 Sumatra and the 2005 Nias earthquakes are preceded by not only a seismic quiescence anomaly started in December 1987, but also a seismic activation anomaly started in July 1989. The quiescence and activation areas are located very closely each other between 2S and 6N, which cover the area around the rupture initiation point of the 2004 Sumatra earthquake and the whole area ruptured by the 2005 Nias earthquake. The observed spatial pattern of quiescence and activation can be explained by stress perturbation due to a long-term slow slip event located on the two main shock faults, which is predicted by a numerical simulation [*Kato et al.,* 1997].

Spatial heterogeneity of the frictional property on the Pacific plate off south-east of Hokkaido, Japan

SAITO, Yu[1] ; YAMADA, Takuji[1*] ; TANIOKA, Yuichiro[1]

[1]ISV, Hokkaido Univ.

The stress drop is an indicator of the difference of the shear strength and the dynamic frictional stress. We analyzed 330 middle-size earthquakes to investigate the spatial heterogeneity of the frictional property on the Pacific plate off south-east of Hokkaido.

Large earthquakes have been occurring repeatedly off south-east of Hokkaido, Japan, where the Pacific Plate subducts beneath the Okhotsk Plate in the north-west direction. For example, the 2003 Tokachi-oki earthquake (Mw8.0) recently took place in the region in 2003. Yamanaka and Kikuchi (2003) analyzed the slip distribution of the earthquake and concluded that the area with a large slip during the 2003 earthquake was mostly overlapped with the area of the 1952 Tokachi-oki earthquake. Miyazaki *et al*. (2004) reported that a notable afterslip was observed at adjacent areas to the coseismic rupture zone of the 2003 earthquake, which suggests that there would be significant heterogeneities of strength, stress and frictional properties on the surface of the Pacific Plate in the region. In addition, some previous studies suggest that the region with a large slip in large earthquakes permanently have large difference of strength and the dynamic frictional stress level and that it would be able to predict large slip areas by analyzing the stress drop of small earthquakes (e.g. Allmann and Shearer, 2007 and Yamada *et al*., 2010).

We estimated stress drops of 330 earthquakes ($4.2 \leq M \leq 5.0$), using S-coda waves of Hi-net data. The 330 earthquakes were the ones that occurred from June, 2002 to December, 2012 off south-east of Hokkaido, Japan, with the latitude from 40.5N to 43.5N and the longitude from 141.0E to 146.5E. First we selected the closest earthquakes with magnitudes between 3.0 and 3.2 to individual 330 earthquakes as empirical Green's functions. We then calculated source spectral ratio of the 330 pairs of interested earthquakes and EGFs by deconvolving the spectra of S-coda waves. We finally estimated corner frequencies of earthquakes from the source spectral ratios by assuming the omega-squared model of Boatwright (1978) and calculated stress drops of the earthquakes by using the model of Madariaga (1976). The estimated values of stress drop range from 3.0×10ˆ(-1) MPa to 2.0×10ˆ(2) MPa independent of the seismic moment. Figure shows the spatial distribution of estimated stress drops.

We found spatial difference of estimated values. The average value of stress drop in the afterslip area at the 2003 Tokachi-oki earthquake, where the small displacement was observed, was 1.2 MPa. On the other hand, the value in the source area of the 2004 Kushiro-oki earthquake was 2.0 MPa. In addition, the average values of stress drops in the deeper and shallower parts of the source area of the 1973 Nemuro-oki earthquake were 1.0 MPa and 2.1 MPa, respectively, and the difference was statistically significant. These differences would reflect the spatial heterogeneity of the frictional property on the Pacific plate.

Acknowledgments: We used Hi-net waveform data (http://www.hinet.bosai.go.jp/) and the slip distribution of large earthquakes (EIC seismic note; http://www.eri.u-tokyo.ac.jp/sanchu/Seismo_Note/index.html)

Keywords: Pacific plate, Friction, Spatial heterogeneity, Stress drop

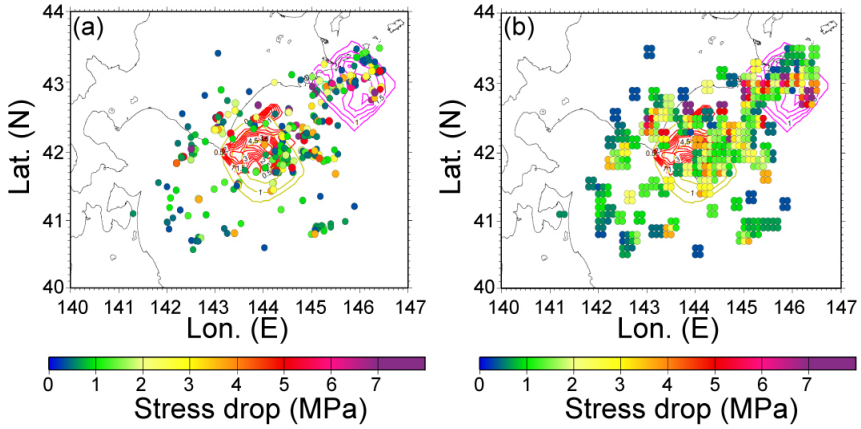

Fig. (a) Estimated stress drops of analyzed 330 middle-size earthquakes ($4.2 \leq M \leq 5.0$). Each circle shows the stress drop for each earthquake. Contours indicate slip distributions of past four large earthquakes off south-east of Hokkaido (EIC seismic note, http://www.eri.u-tokyo.ac.jp/sanchu/Seismo_Note/index.html). (b) Spatial pattern of the averaged stress drop. Individual circles indicate averaged values of stress drop for every 0.1 degree, which were calculated from the values of earthquakes in areas with 0.2 x 0.2 degrees.

Seismically inferred rupture process of the 2011 Tohoku-Oki earthquake by using 3D and 2.5D Green's tensor waveforms

OKAMOTO, Taro[1*] ; TAKENAKA, Hiroshi[2] ; HARA, Tatsuhiko[3] ; NAKAMURA, Takeshi[4] ; AOKI, Takayuki[5]

[1]Dep. Earth Planet. Sci., Tokyo Institute of Technology, [2]Dep. Earth System Sci. Okayama University, [3]IISEE, Building Research Institute, [4]Japan Agency for Marine-Earth Science and Technology, [5]GSIC, Tokyo Institute of Technology

The March 11, 2011 Tohoku-Oki earthquake (GCMT Mw9.1) generated strong ground motions and large tsunamis, and caused devastating damages in the northeastern Japan. The rupture process of this event provides important clues for understanding the geophysical condition of the generation of mega-thrust earthquakes and the mechanism of the excitation of the large tsunamis.

We analyze "seismic" rupture process of this event by using a non-linear full-waveform inversion method. We incorporate the effect of the near-source laterally heterogeneous structure on the synthetic Green's tensor waveforms because the analysis can result in erroneous solutions if the effect is not considered [1]. Also, in order to increase the resolution we use the teleseismic and the strong-motion seismograms jointly: the distribution of strong-motion station is one-sided and analysis with only the strong-motion records may result in reduced resolution near the trench axis [2]. For the teleseismic P-wave synthetics we use a 2.5-dimensional finite-difference method [3]. For the strong-motion synthetics we use a full three-dimensional finite-difference method that incorporates topography, oceanic water layer, three-dimensional heterogeneity and attenuation. Our simulation is accelerated by GPUs used in parallel [4]: we use the TSUBAME GPU supercomputer in Tokyo Institute of Technology.

In the previous study [5] we used only a single structure model (i.e., a single vertical slice of the 3D heterogeneous structure) to generate all the 2.5D Green's functions. In this paper we have updated the 2.5D structure models. That is, we extracted twenty-three vertical slices from the 3D structure model: each slice was (nearly) perpendicular to the trench axis and was taken along the nodes of the grid that formed the fault plane. By using these new models the 2.5D Green's functions and 3D Green's functions are now "consistent" with each other.

We computed Green's tensor synthetic waveforms for 31 teleseismic and 32 strong-motion components. We used 640 GPUs of the TSUBAME supercomputer for the calculation of each strong-motion synthetics. The inferred slip distribution has large slips near the JMA epicenter with the maximum slip of about 32 m. The amount of slips at the areas close to the trench axis is smaller than that of the land-ward area (i.e., near the JMA epicenter). Inversion results similar to these features have been obtained by previous study [2] but it is remarkable that our joint "seismic" inversion using 2.5D-teleseismic and 3D-strong-motion Green's tensor waveforms resulted in the solution with these features (i.e., land-ward large slips and trench-ward small slips). These features have important implications for tsunami studies because large slips near the trench axis are expected for large tsunamis. In order to verify the solution we will inspect the resolution by using simulations of inversion and the effect of the choice of the Green's tensor waveforms on the solutions.

Seismic velocity and attenuation tomography of the source zone of the 2011 Tohoku-oki earthquake (Mw 9.0)

ZHAO, Dapeng[1*] ; LIU, Xin[1] ; HUANG, Zhouchuan[1]

[1]Tohoku University, Department of Geophysics

Detailed 3-D P and S wave velocity (Vp, Vs) and attenuation (Qp and Qs) tomography of the crust and upper mantle under the entire Northeast Japan arc from the Japan Trench to the Japan Sea coast is determined (Zhao et al., 2011; Huang and Zhao, 2013; Liu et al., 2014). The suboceanic earthquakes under the Pacific Ocean and the Japan Sea are used in this work and they are relocated precisely using sP depth phases. Vp and Vs tomography is determined using a large number of high-quality arrival times, whereas the Qp and Qs tomography is obtained using a large number of t∗data measured precisely from P and S wave spectra of local earthquakes. Our results reveal the high-V and high-Q subducting Pacific slab, and significant low-V and low-Q anomalies in the crust and mantle wedge under the volcanic front and the back-arc area. Large megathrust earthquakes (M >6.0) during 1900-2013 including the great 2011 Tohoku-oki earthquake (Mw 9.0) sequence are generally located in high-V and high-Q patches which are surrounded by low-V and low-Q anomalies in the megathrust zone. The high-V/high-Q patches in the megathrust zone generally exhibit large coseismic slips of megathrust earthquakes and large slip deficit on the plate interface. We think that these highV/high-Q patches represent asperities in the megathrust zone, whereas the low-V/low-Q anomalies reflect weakly coupled areas. These results suggest that structural heterogeneities in the megathrust zone control the interplate seismic coupling and the nucleation of megathrust earthquakes.

A Study on Seismicity before and after the Tohoku Earthquake around its Southern Boundary Using Dense OBS Array Data

NAKATANI, Yukihiro[1*] ; MOCHIZUKI, Kimihiro[1] ; SHINOHARA, Masanao[1] ; YAMADA, Tomoaki[1] ; HINO, Ryota[2] ; ITO, Yoshihiro[3] ; MURAI, Yoshio[4] ; SATO, Toshinori[5]

The southern boundary of the 2011 Tohoku earthquake, the source area of the largest aftershock, and a subducting seamount are located around off Ibaraki in the Japan Trench subduction zone. It is important to evaluate the spatial and temporal distribution of seismicity which provides key information about the seismic energy release. However, the seismicity is not well constrained due to a large distance offshore from the onshore network. Therefore, estimating seismic energy release off Ibaraki by using ocean-bottom seismometer (OBS) data is essential to understand the characteristics of the main shock rupture propagation. In this study, we estimated seismicity distribution around off Ibaraki region before and after the 2011 Tohoku earthquake using dense OBS array data.

It is difficult to apply methods that have been designed for on-land seismic stations due to the large ambient noise and effects of thick seafloor sediments. Furthermore, conventional manual picking is difficult because of the occurrence of many aftershocks. We therefore applied a semblance analysis to OBS waveform data with theoretical P-wave travel-time table obtained by the construction of an original 3-D P-wave velocity structure model.

To evaluate the validity of event identification and the accuracy of the epicenter distribution, I conducted comparisons of our epicenters with the JMA epicenters and synthetic tests using theoretical waveforms with several different sets of signal-to-noise ratio and focal depths.

As results of epicenter determination by the semblance analysis, we found that a lot of earthquakes occurred in the vicinity of the frontal region of the subducting seamount after the 2011 Tohoku earthquake. Next, there exists an along-strike density contrast of seismicity, and the inactive region possibly corresponds to the seismically quiet band previously revealed by a seismic observation. Furthermore, we applied the semblance analysis to OBS waveform immediately after the main shock and estimated the spatial and temporal transition of detailed seismicity. We found that the seismicity around the subducting seamount was activated after the largest aftershock rather than between the occurrences of the main shock and the largest aftershock. It puts constraints on the southern boundary of the 2011 Tohoku earthquake.

Large shallow slip during the 2011 Tohoku-Oki earthquake: New insights from JFAST and high-velocity friction experiments

UJIIE, Kohtaro[1*] ; TANAKA, Hanae[1] ; SAITO, Tsubasa[1] ; TSUTSUMI, Akito[2] ; MORI, James[2] ; KAMEDA, Jun[3]

The Japan Trench Fast Drilling Project (JFAST), Integrated Ocean Drilling Program (IODP) Expeditions 343 and 343T were conducted to understand the coseismic deformation mechanisms and dynamics of large shallow slip during the 2011 Tohoku-Oki earthquake. The drill site is located at the toe of the frontal prism near the Japan Trench axis. Observations and analyses of recovered core samples as well as logging-while-drilling data indicate that the plate-boundary fault is highly localized in pelagic clay less than 5 m-thick. The smectite content in pelagic clay is ˜78%. The deformations in the plate-boundary fault are marked by distributed shear along anastomosing scaly foliations and localized slip along the boundary between red-brown and dark-brown scaly clays with different fabric orientations. On the microscopic scale, injection structures and mixing of clays of different colors without shear surfaces are observed along the localized slip zone, suggesting fluidization during the localized slip. High-velocity (1.3 meters per second) friction experiments on core samples taken from smectite-rich clay of the plate-boundary fault, show a small stress drop with very low peak and steady-state shear stress. The very low shear stress can be attributed to the abundance of smectite and thermal pressurization effects. Steady-state shear stress is independent of normal stress, and the microstructures after the experiments show evidence for fluidization. These features suggest that the fault material behaved like a fluid during high-velocity shearing due to thermal pressurization of pore fluid. Our results indicate that large shallow slip resulted from coseismic fault lubrication, and the similarity of microstructures between natural and experimental shear zones may represent the fluidization of fault material during earthquake faulting. Seismic slip could be promoted even in plate-boundary faults at shallow depths, as the slip propagates through the smectite-rich fault material.

The Integrated Ocean Drilling Program (IODP) Expedition 343 drilled three holes through the plate boundary near the Japan Trench to investigate the cause of very large fault slip during the 2011 Tohoku-Oki earthquake. In this paper, we report trace element and Sr-Nd-Pb isotope compositions of core samples, including plate-boundary fault rocks, recovered from Hole C0019E.

The rocks in C0019E are lithologically subdivided into seven units (Chester et al., 2013): Units 1 to 3, wedge sediments of upper plate; Unit 4, plate-boundary fault; Units 5 to 7, sediments of lower plate. The clay-rich plate-boundary fault rocks (Unit 4) are characterized by elevated concentrations of rare earth elements (REE) and some refractory metals, and are distinct from any other JFAST samples in terms of trace element characteristics. Brown mudstones of the lower plate (Unit 5) show trace element characteristics (e.g. REE pattern) roughly similar to those of the upper plate sediments (Units 1 to 3), but they are still distinguishable from each other. Pelagic sediments in the lower plate (Unit 6) show highly varied trace element compositions with a large Ce anomaly. The Sr, Nd and Pb isotope data show variations that are essentially consistent with trace element characteristics observed for each unit.

The clear relationship observed between lithological units, trace element and isotope compositions and radiolarian ages of the JFAST samples provides a key for understanding the origin of the shallow fault zone of the Tohoku-Oki earthquake and the frontal wedge at the Japan Trench. Geochemical characteristics of the JFAST samples will be discussed along with those of sediments from DSDP site 436, which is a nearby input site, for elucidating the origin of the JFAST rocks and for evaluating coseismic/interseismic processes possibly recorded in the plate-boundary fault rocks.

IODP Expedition 343, Japan Trench Fast Drilling Project (JFAST), drilled through the plate-boundary dècollement of the Japan Trench, where large slip occurred during the 11 March 2011 Tohoku-Oki Earthquake. In order to reconstruct the deformation of the sediments at the cm scale and less, we conducted paleomagnetic measurements of the core sample from the plate-boundary dècollement zone.

The plate-boundary core sample has a scaly fabric and is composed of bicolored clay layers with sharp contacts. We prepared slabs for thin sections across the contacts with typical dimensions of 3x3x5 cm^3 from the core sample. We measured remanent magnetization of 16 slabs. The slabs were subjected to natural remanent magnetization (NRM) measurements in 0.5-1 cm intervals and progressive alternating field demagnetization (AFD) up to 80 mT with a 2G755 pass-through superconducting rock magnetometer at Kochi University.

Typically, two paleomagnetic components were isolated during the AFD of slab samples up to 80 mT. One component (‘soft’ component) was demagnetized below 20-30 mT, and another component (‘hard’ component) was not demagnetized even up to 80 mT. For multiple slab samples cut from the same whole-round sample, the hard component generally has a consistent paleomagnetic direction. Contrastingly, the direction of the soft component is not so consistent between adjacent slabs, and even varies within a single slab.

The direction variation of the soft component possibly reflects the cm-scale rotation of competent phaccoids during deformation within the slab samples from the plate-boundary thrust zone. The consistency of the hard component directions implies that the hard component was remagnetization during/after the rotation, and was possibly carried by newly-formed magnetic minerals during the deformation.

Change of permeability caused by 2011 Tohoku earthquake detected from pore pressure monitoring

KINOSHITA, Chihiro[1*] ; KANO, Yasuyuki[2] ; ITO, Hisao[2]

[1]Graduate School of Science, Kyoto University, [2]DPRI

We have monitored pore and atmospheric pressures at the Kamioka mine in Gifu Prefecture, central Japan since 2005 to study relationship between groundwater and earthquake. Pore pressure decreased after the 2011 Tohoku earthquake (M9.0) occurred on 11 March 2011, which may be attributed to expansion of the crust west of the epicenter or a permeability increase. To evaluate rock permeability changes, we analyzed the Earth tide response of pore pressure before and after the earthquake. Pore pressure fluctuates associated with the meteorological effects, Earth tides and crustal deformation. We assumed that without the change of aquifer conditions tidal response of pore pressure is constant. We compared the tidal response before and after the event. We extracted amplitude and phase lag of M2 and O1 constituents from pore pressure by tidal analysis program, BAYTAP-G. These amplitudes decreased and phases changed after the earthquake. It was in accord with pore pressure decreases. We estimated the hydraulic diffusivity using the poroelastic theory and diffusion equation. If we assume that the poroelastic coefficient is constant, the hydraulic diffusivity increased from 8.9 to 65.0 m^2/s at the time of the Tohoku earthquake. We also analyzed data before and after the Noto Hanto Earthquake (M6.9) which occurred in the northwestern part of Ishikawa Prefecture, central Japan on 25 March, 2007. The epicentral distance of the Noto Hanto Earthquake from our observation site is 112 km. No hydraulic diffusivity change is detected. The causes of the hydraulic diffusivity change are potentially related to a static and/or dynamic stress change. In order to discuss the difference in hydraulic diffusivity change between the Tohoku and Noto Hanto earthquakes, we analyzed other earthquakes to relate the hydraulic diffusivity changes, and the amount of static and dynamic strain changes.

Enigmatic phase lead of pore pressure: 11+ years of ACORK monitoring at the frontal decollement of Nankai Trough

KINOSHITA, Masataka[1*] ; KANO, Yasuyuki[2]

[1]JAMSTEC, [2]Kyoto Univ. DPRI

For more than 11 years we have been conducting a continuous monitoring of downhole pore pressures at multiple sub-bottom intervals in ODP Holes 808I and 1173B situated landward and seaward of the deformation front in the Nankai Trough off Cape Muroto. We found that the pressure response to the semi-diurnal ocean tide (M2), both amplitude and phase, gradually change during the observed period. The M2 amplitudes at most depths in Hole 808I decay as their phase delay (up to 45 degrees), ONLY IF the amplitude is larger than ˜0.2 of that for the seafloor. On the other hand, we observe an anomalous phase LEAD (up to -40 degrees) if the relative amplitude is lea than ˜0.2. We hypothetize that the recorded pore pressure is a combination of two components; one with larger amplitudes and phase-delay and the other with small amplitude and phase-lead. The former can be interpreted as the decrease in formation compliance relative to that of the system, or as the decrease in hydraulic diffusivity around the sensors. The mechanism of the latter variation remain still enigmatic. Existence of gas-rich layer next to the sensor, as suggested by wang and Davis (1996), is difficult to generate such a large phase lead. The predicted earth tide at this site does not coincide with the observed phase. Thermal expansion/contraction caused by the flow within the casing, induced by tidal loading, may cause this phase shift, but a simple thermal/hydrological diffusion cannto explain both the amplitude and phase simultaneously. A complex process including some unknown mechanism may be in operating at Hole 808I.

The increase in missing waveform images of the F-net seismographs preceding the 2004 off Kii peninsula earthquake

SUE, Yoshiki[1*]

[1]No institution affiliation

1. Introduction

The F-net is a broadband seismograph network constituted of 73 STS-1 and 2 seismometers. Natural frequency of the seismometers is 120 seconds (STS-2) and longer, thus they can detect long-period ground motion. On its website, waveform images of the stations for a day or an hour are provided. The analyses on their file size have shown long-period vibrations (Sue, 2010).

2. Analysis

Variation recorded in waveform images may mean variation of ground motion. Thus operational status of the F-net is investigated. There are two sources on it.

a. Data acquisition trouble log: This is the formal information covering from instantaneous to long-lasting loss of data. Reasons for troubles are shown. While, update of the information is irregular.

b. Missing of waveform images: The website displays the message ”Waveform image does not exist”. It is surmised that this situation is caused by continuous loss of data exceeding 1 day (Daily plot) or 1 hour (Hourly plot). The reasons are not shown. While update of the information is regular.

So far, analyses on ”missing of waveform images” for the 2011 Tohoku earthquake (M=9) has been done (Sue, 2013). As a next step, the 2004 off Kii peninsula earthquake (M=7.4), which occurred on September 5, 2004 at the Nankai trough, is carried out. For details, for the period of about 3 months from June 1, 2004 to September 10, 2004, the F-net stations located in the area between Itoigawa - Shizuoka tectonic line and Okinawa island are investigated (The one in Noto peninsula is excluded).

3. Results

Fig. 1 shows the result. During June - first half of July, 2004, which is more than 1.5 month before the main shock, the most frequent number of the image-missing station is 1, and it was stable condition. From last half of July and later, the number varied.

On August 30 and 31, which are 6 and 5 days before the earthquake, there were large increases of the number. Further, arrangement of image-missing stations is mainly in southern part and east coast of the Kyushu island respectively.

On Sept. 4, which is the previous day of the main shock, there were 3 image-missing stations, located from Shikoku island to Kyushu island alongside the Nankai trough (Fig.2).

After the earthquake, number of image-missing station decreased to zero.

The major reasons for missing images are ”Network trouble” and ”Electric power supply trouble”.

4. Discussion

Number of F-net station with missing waveform images increases before an earthquake. The phenomena appear not only close to the epicenter, but wide area surrounding it. The phenomena are also observed at the 2011 Tohoku earthquake, thus they may usually appear before a large earthquake. Similar phenomena as shown in this paper might be observed at the anticipated Nankai trough earthquake.

Missing images of all 73 stations happened on 23 to 25 in July (Fig.1). Same phenomena appeared at the 2011 Tohoku earthquake, thus the phenomena may be a sign of unstableness of the F-net system.

It is assumed that increases of the missing waveform images preceding a big earthquake was because the F-net could not withstand possible long-period variation of the earth’s surface. ”Network trouble” and ”Electric power supply trouble” might be causes for such situation. Such phenomena are not observed for the Hi-net seismograph network, probably because of its characteristic (NF = 1 sec).

When the DONET (Dense Oceanfloor Network System for Earthquakes and Tsunamis) detects anomaly, malfunctioning of the F-net may appear at the same time or even earlier.

The area formed by the F-net stations with missing images may have certain relation with magnitude of the earthquake.

Acknowledgement

The author thanks NIED for using the data of the F-net.

Heat flow distribution along the Nankai Trough: Influence of the structure of the Shikoku Basin oceanic crust

YAMANO, Makoto[1*] ; KAWADA, Yoshifumi[1] ; GOTO, Shusaku[2] ; HAMAMOTO, Hideki[3]

[1]Earthq. Res. Inst., Univ. Tokyo, [2]Geol. Surv. Japan, AIST, [3]Center Environ. Sci. Saitama

The thermal structure of the Philippine Sea plate (Shikoku Basin) subducting along the Nankai Trough, one of the most important factors controlling the temperature structure around the plate interface, significantly affects physical/chemical processes in the seismogenic zone of subduction earthquakes. Surface heat flow observed on the floor of the Nankai Trough should reflect the thermal structure of the incoming Shikoku Basin. Previous surveys showed that heat flow on the trough floor is extremely high for the seafloor age between 135^{o}E and 136^{o}E (south of the Kii Peninsula), while it is comparable to the value expected from the age in the neighboring area to the east of 136^{o}E. The transition zone from high to normal heat flow lies in the vicinity of the rupture segmentation boundary between the 1944 Tonankai and the 1946 Nankai earthquakes, across which seismicity on the landward side of the trough significantly changes, implying influence of the temperature structure on subduction earthquake processes.

For further investigation of the along-strike variation in heat flow on the trough floor, we conducted heat flow measurements around the Nankai Trough off the Kii Peninsula and off Shikoku in 2011 to 2013. Most of the measurements were made in the area around 136^{o}E, where the high to normal heat flow transition occurs, and on the trough floor to the south of Shikoku, where the existing data were very sparse. 39 new heat flow data on the trough floor allowed us to delineate heat flow variation along the trough. A conspicuous change in heat flow distribution was found at around 136^{o}E. On the west of 136^{o}E, heat flow is extremely high and variable, ranging from 130 to 250 mW/m^2,while on the east of 136^{o}E, heat flow monotonously decreases eastward from 200 to 100 mW/m^2 in about 50 km with no appreciable scatter. On the trough floor south of Shikoku, west of 134.5^{o}E, no significant change was observed along the trough in spite of westward increase in the seafloor age.

The heat flow distribution described above appears to be correlated with the structure of the Shikoku Basin oceanic crust. The high and variable heat flow area between 134.5^{o}E and 136^{o}E corresponds to the youngest part of the Shikoku Basin which was formed by spreading in NE-SW direction, whereas the neighboring areas with less scattered heat flow, east of 136^{o}E and west of 134.5^{o}E are the older parts formed by E-W spreading. The thickness of the oceanic crust and the basement relief also change around 136^{o}E, in the vicinity of the heat flow transition boundary. Spinelli and Wang (2008) proposed a model for the high heat flow around 135^{o}E that vigorous pore fluid circulation in a permeable layer in the subducting oceanic crust efficiently transfers heat upward along the plate interface. We may infer that the permeability structure of the oceanic crust changes at the transform boundaries between the E-W and NE-SW spreading, which yields variations in vigor and/or pattern of pore fluid circulation, resulting in the contrasting heat flow distributions. Since heat transfer by fluid circulation in the subducting oceanic crust lowers the temperature of the plate interface, the along-strike variation in the trough floor heat flow could indicate corresponding variation in the temperature distribution in the seismogenic zone.

Reevaluation of temperature at the updip limit of locked portion of Nankai megasplay, inferred from IODP Site C0002 tem

SUGIHARA, Takamitsu[1*] ; KINOSHITA, Masataka[2] ; ARAKI, Eiichiro[3] ; KIMURA, Toshinori[3] ; KYO, Masanori[1] ; NAMBA, Yasuhiro[1] ; KIDO, Yukari[1] ; SANADA, Yoshinori[1] ; MOE, Kyaw thu[1]

[1]CDEX/JAMSTEC, [2]KCC/JAMSTEC, [3]DONET/JAMSTEC

Temperature near the updip limit of the locked zone still has large uncertainties due to lack of knowledge about thermal and hydrological properties at depth.

In 2010, the first Long-Term Borehole Monitoring System was deployed at ˜900 m below sea floor (mbsf) above the updip limit of seismogenic fault zone in the Nankai Trough off Kumano (Site C0002).Four temperature records show that the effect of drilling diminished in less than 2 years and they all reached thermal equilibrium by 2012. From in-situ temperatures and thermal conductivities measured on core samples, the temperature and heat flow at 900 mbsf are determined as 37.9 ℃ and 56.1 mW/m2, respectively. This heat flow value is in excellent agreement with that from shallow borehole temperature corrected for rapid sedimentation in the Kumano Basin. We use these values to constrain the temperature below 900 mbsf to the mega-splay and plate boundary fault zones.

To extrapolate temperature downward, we use LWD bit resistivity data as a proxy for porosity and the thermal conductivity is modeled from this porosity using a geometrical mean model. Upon integration by the 1-D thermal conduction we included the radioactive heat and frictional heat production. Estimated temperature at the megasplay ranges between 132 to 149 ℃, depending on thermal conductivities and radioactive heat. It is significantly higher, by up to 40 ℃, than previous 2-D numerical model predictions that can account for the heat flow across the deformation front. The discrepancy may be explained either by increasing the effective frictional coefficients along the fault zones or by introducing a lateral fluid flow along the permeable layers somewhere in the sedimentary layer. Revision of 2-D simulation by introducing our new boundary conditions will also be useful. Ultimately, reaching the megasplay fault and in-situ temperature measurement in the drilled hole is required to understand seismogenesis in the Nankai subduction zone.

Preliminary Scientific Results of IODP Expedition 348: Ultra-deep Riser Drilling into the Nankai Accretionary Prism

HIROSE, Takehiro[1*] ; TOBIN, Harold[2] ; SAFFER, Demian[3] ; TOCZKO, Sean[1] ; MAEDA, Lena[1] ; KUBO, Yusuke[1] ; EXPEDITION 348, Scientists[6]

[1]JAMSTEC, [2]University of Wisconsin-Madison, [3]Pennsylvania State University, [4]Chiba University, [5]The university of Tokyo, [6]IODP Expedition 348

The Nankai Trough Seismogenic Zone Experiment (NanTroSEIZE) is a multi-disciplinary scientific project designed to investigate fault mechanics and seismogenesis along subduction megathrusts through seismic imaging, direct sampling, in situ measurements, and long-term monitoring in conjunction with laboratory and numerical modeling studies. International Ocean Discovery Program (IODP) Expedition 348, the latest advance of the NanTroSEIZE project, started on 13 September 2013 and was completed on 29 January 2014. During Expedition 348, the drilling vessel *Chikyu* advanced the ultra-deep riser hole at Site C0002, located 80 km offshore of the Kii Peninsula, from a depth of 860 meters below sea floor (mbsf) to 3058.5 mbsf, the world record for the deepest scientific ocean drilling, and cased it for future deepening. The drilling operation successfully obtained data on formation physical properties from logging while drilling (LWD) tools, as well as from lithological analyses of cuttings and core from the interior of the active accretionary prism at the Nankai Trough. IODP Site C0002 is the currently only borehole to access the deep interior of an active convergent margin.

Preliminary scientific results of Expedition 348 include:

(1) Fine-grained turbiditic mudstones with coarser silty and sandy interbeds, exhibiting steep dips (between ˜60 and 90 degrees) are predominant in the prism down to ˜3000 mbsf. The biostratigraphic age of the sediments in the lowermost part of the hole is thought to be 9-11 Ma, with an assumed age of accretion of 3-5 Ma.

(2) Slickenlined surfaces, deformation bands and mineral veins are present throughout the drilled interval, while well-developed scaly clay fabrics are increasingly observed below ˜2200 mbsf. A substantial fault zone with well-developed foliation was successfully cored from the deep interior of the prism at ˜2205 mbsf.

(3) Porosity generally decreases from ˜60% to ˜20% from the seafloor to 3000 mbsf. However, physical properties including grain density, electrical conductivity and P-wave velocity suggest fairly homogeneous properties in the interior of the prism between ˜2000 and 3000 mbsf.

(4) Drilling mud gas analysis during the riser drilling indicates that a source of hydrocarbon gas shifts from microbial origin to thermogenic at around 1700-2300 mbsf.

Lithological and structural characterizations, the style of deformation, and downhole physical properties all indicate a complex structural evolution and will provide unprecedented insights into the mechanical state and behavior of the prism at depth.

Levels of frictional heat along deep to shallow parts of the megasplay fault : a Raman spectroscopic analyses of CM

MUKOYOSHI, Hideki[1*] ; HIRONO, Tetsuro[2] ; MASUMOTO, Hirokazu[2]

[1]Faculty of Education and Integrated Arts and Sciences, WASEDA University, [2]Department of Earth and Space Science, Graduate School of Science, Osaka University

Estimation of frictional heating of deep to shallow portion of ancient megasplay fault is important for understanding of weakening mechanism (e.g., thermal pressurization, melt lubrication) of present plate boundary fault and megasplay fault. In this study, we performed microstructural observation and Raman spectroscopic analyses of carbonaceous materials (CM) in the fault rock of 2.5-5.5 km depth of an ancient megasplay fault (an out-of sequence thrust in the Shimant accretionary complex) and 1-4 km depth of a thrust in the Emi group, Hota accretionary complex. We also conducted heating experiment of CM in host rock of these fault with anaerobic condition (rate of temperature increase: 20 K/min) in order to investigate the effects of fast heating rate like frictional heating during earthquake.

Raman spectrum of CM of both fault is similar to spectrum of 400∼600 ℃ heating experiment of CM. This result shows that both fault had heating history of 400∼600 ℃ by frictional heating. Further examination for effect of shearing to molecular stricter is needed for more detailed evaluation of frictional heating history.

Upper plate geology controls the rupture area segmentation -A case study of the Nankai Trough

KIMURA, Gaku[1*] ; HASHIMOTO, Yoshitaka[2] ; KITAMURA, Yujin[3] ; YAMAGUCHI, Asuka[4] ; HAMAHASHI, Mari[1] ; KOGE, Hiroaki[1] ; MORITA, Sumito[5]

[1]Dept. Earth and Planetary Science, The University of Tokyo, [2]Kochi University, [3]Kagoshima University, [4]Atmosphere and Ocean Research Institute, The University of Tokyo, [5]AIST

What controls the earthquake rupture area of megathrust is one of the most fundamental questions in geodynamic research of subduction zone. In the case of the Nankai Trough, Japan, three major controlling factors have proposed so far, surface topography of the subducting plate like seamount, locally strong rigidity of upper plate due to igneous rock composition, andfriction property of the plate boundary megathrust including abnormal pore fluid pressure distribution. Such controlling factors are applicable to other subduction zone in general. For example, the topographic high like seamount is proposed to control the location of asperity due to stronger coupling. The topographic-high worked as an asperity contacts with upper plate and rupture could be propagated when the contact breaks. The topographic-high also works as a barrier in the difficult case to be broken. From the geological point of view, plate boundary megathrust in the seismogenic zone must be composed of fault rock in brittle regime because of its temperature range from ~150 ℃ to ~350 ℃, which is cooler than the temperature for the plastic deformation of quarts, feldspar and other rock forming minerals of oceanic crust except for clayey phyllosilicates. In this temperature range, tectonic melange like fault rock with highly pressurized interstitial fluid is expected. Seismic observation showing a reflector with intensive amplitude of negative reflection coefficient suggests a plate boundary fault layer with abnormal fluid pressure. The friction behavior of the fault rock and pore fluid effect is a recent main concern in the subduction zone. The third factor is the mechanical property of the upper plate for the plate boundary megathrust in subduction zone. It is used to treat that the upper plate is a mechanical uniform media saving the elastic energy for theseismic slip along the megathrust. The mechanical property of the upper plate changes for a geological long time scale due to the growth of accretionary prism or tectonic erosion. In addition to such subduction mode of accretion vs erosion, some peculiar tectonic events (e.g. change in convergent direction, some obstacle collision, spreading ridge collision and rapid magmatic accretion etc.) modify the mechanical property of the upper plate and its heterogeneity in space. In the case of the Nankai Trough, a pultonic body is situated beneath the place of epicenter and is suggested to have been functioned as an asperitiy of 1944 Tonankai and 1946Nankaido Earthquakes. We examined the on-land geology of the Shikoku island and the Kii Peninsula, SW Japan, basement structure and composition beneath the forearcKumano Basin on the basis of recent results of ocean drilling by IODP (Integrated Ocean Drilling Project) and other investigations to infer the geologic composition of the upper plate. As a result we conclude that the key geologic event was middle to late Miocene episodic and rapid growth of forearc crust, mainly due to the magmatic intrusion and extrusion. This event was casued by the eastward migration of the T-T-T triple junction. Such ancient event now controls therupture area of the great earthquake in the subduction zone.

The research project on the extended Nankai seismogenic zones towards disaster mitigation of the mega-thrust earthquakes

KANEDA, Yoshiyuki[1*] ; FUKUWA, Nobuo[2] ; FURUMURA, Takashi[3]

[1]Japan Agency for Marine-Earth Science and Technology, [2]Nagoya University, [3]The University of Tokyo

The recurrence of Nankai trough mega thrust earthquakes and tsunamis are the very severe problem to Japan. Therefore, MEXT of Japanese government has implemented the research project during a period from FY2008 to 2012 to evaluate seismic linkage around the Nanakai trough mega thrust earthquake seismogenic zones. We have obtained many significant scientific results, such as the extended seismogenic zone, in this previous research project. In the 2013 fiscal year, a new project launched aiming mitigation of disaster caused by the Nankai trough earthquakes in the extended seismogenic zone. This new project is composed of three research fields which are the disaster mitigation research filed, observational research filed and the simulation research field. According to lessons learned from the 2011 East Japan Earthquake, the disaster mitigation research filed are progressing 5 sub-themes which are precise seismic hazard estimation, providing research results to local government/community for disaster measures, investigating recovery and revival methodologies based on social environmental changes, and constructing redundant hazard information database. The observational research field reveals structures of crust and plate, seismicity, and historical tsunami events in the Nankai trough. In the simulation research field, investigations will be conducted for recurrence cycle simulation of mega thrust earthquakes, data assimilation method that improves reliability of the simulation, seismic and tsunami wave simulations for disaster mitigation. We must surely progress each sub-theme at the beginning and finally integrate them for disaster mitigation around the extended Nankai trough sesimogenic zones. In this talk, we will introduce the outline of new project and the present progress.

Ogasawara Bending Slab and Mantle Convection

NIITSUMA, Nobuaki[1*]

[1]Inst. GeoSciences, Shizuoka Univ.

Ogasawara Slab is not only steeply dipping, but also, bending concentrically and reaching to bottom of upper mantle, which are shown with the hypocenters of 14 May 2013 M7.3 (619 km depth) and 7 February 1998 M6.4 (552 km depth).

Pacific Plate is spreading along East Pacific Rise, and subducting along Japanese Islands down to bottom of upper mantle as slab. If we consider the mass balance in upper mantle on Plate motion with accompaning beneath mantle, the mantle should convect from subduct area toward spreadin area.

The allover concentric bending within the upper mantle realizes overturn of the slab. The slab surface contacts with upper surface of lower mantle where upper mantle minerals change phase for higher pressure. The coldest slab surface in the upper mantle could not change the phase, and might float on the surface of lower mantle toward opposit direction of Plate motion. The return flow of the upper mantle, induced by the floating slab surface, might allow the high speed of the largest Pacific Plate motion.

Izu Slab, north extend of Ogasawara Slab, is bending concentrically above ca. 410km of depth and unbending blow the depth as flat slab. The geometry of the shape from Ogasawara Salb to Izu Salb should intercalate discontinuous part of the slab. Nishinoshima erupted in Nobember 2013 on the slab discontinuous part. The forcal mechanisms on the slab discontinuous part change before and after the East Japan Super Erthquake.

Rectified tidal loading: Control on earthquakes manifested by deep tremors

IDE, Satoshi[1*] ; TANAKA, Yoshiyuki[2]

[1]Deptartment of Earth and Planetary Science, University of Tokyo, [2]Earthquake Research Institute, University of Tokyo

Earthquakes occur due to plate motion, but it remains unclear as to what controls the plate motion. A clue to this problem is provided by a recently discovered cluster of deep tectonic tremors or tiny earthquakes that are occurring in western Japan. Here we demonstrate that tremor activity is strongly correlated with tide levels observed at a nearby station. The correlation is interpreted as representing a nonlinear relationship between stress and slip, which is similar to the rate-dependent friction law. An empirical relationship and observed tide records explain the temporal changes in tremor activity over a period of nine years. The nonlinear fault rheology rectifies oscillating tidal stress and amplifies small changes in tidal amplitude. This mechanism of rectified tidal loading may control temporal changes in plate motion and earthquake occurrence. Remarkably, the background seismicity in the present study area matches the predicted tremor rate obtained from tidal observations over the past 50 years. This mechanism may also explain the weak periodicity of large earthquakes, and is likely to be helpful in probabilistic forecasting of future seismicity.

Structural mechanics model of plate-interface fracture at subduction zones

EGUCHI, Takao[1*]

[1]National Defense Academy, Japan

There are unidentified and unveiled properties concerning the physical process of greater inter-plate earthquakes at subduction zones. We, here, present a stochastic fracture model of the plate-interface with dynamic discrete interaction blocks. The stochastic treatment in this study is mainly based on structural mechanics. Here, in the four-dimensional point of view, regarded as significant long-wavelength components of the mechanical inter-plate coupling, we assign several discrete lattice-like blocks being connected each other on a hypothesized plate boundary system. The representative mechanical interaction vector (or tensor) for each discrete block should be variable on the plate boundary system. The total number of the discrete blocks and their nesting pattern should also vary with time during the long-term subduction process with intermittent greater seismic events.

Hereafter, we treat the inter-plate coupling at discrete blocks, using parameters such as failure probability *(Psf)* and safe probability *(Pss)* of the total system of the plate boundary. Here, $Psf + Pss = 1$.

The system fracture for the case of parallel connecting blocks is defined as the breakdown of all parallel blocks. Whereas, for the case of a series connecting block system, the system fracture is defined as the failure of one of the series block, or more. The system failure probability of a simple mechanical system being coupled in parallel N blocks is given as a product of $p(i)$ from $i = 1$ to $i = N$. Here, $p(i)$ is the failure probability of the *i-th* block of the system. For the case of a mechanical system connected in series N blocks, the system safe probability becomes a product of $\{1-p(i)\}$ from $i = 1$ to $i = N$. For a mechanical system composed of both parallel and series blocks, the system failure probability and system safe probability can be estimated with the above definition. Then, we assume that the inter-plate shear coupling of the plate-interface progresses only at discrete blocks of brittle fracture.

We consider two different configuration models for a two-by-four matrix *(2x4)* system of discrete coupling blocks, consist of four columns in the trench-parallel direction and two rows of deep side and a shallow side in the dip direction, as follows.

Configuration model A is a series-connected system of both the shallower parallel-connected column blocks and the deeper parallel-connected ones.

Configuration model B is a parallel-connected system of the four columns of the shallower and deeper rows being directly series-connected in the dip direction.

By setting the failure probability, $p(i,j)$, of *(i,j)-th* block, we can estimate the system failure probability *(Psf)* and system safe probability *(Pss)* for the configuration models, A and B. For the configuration models A and B, the system safe probability, *Pss(A)* and *Pss(B)* can be obtained. In the case of p(i,j) less than 0.5 for all blocks, *Pss(A)* becomes larger than *Pss(B)*, indicating that the configuration model A is safer than the model B. When the representative pattern of the inter-plate coupling changes from the configuration model A to B, or vice versa, we should carefully estimate the system probabilities.

We also demonstrated the detailed hypothetical expression form of p(i,j) by considering the effect of preceding larger seismic ruptures at blocks and the subsequent healing process, etc.

Seismicity rate variations in subduction zones related to forearc topography

NISHIKAWA, Tomoaki[1*] ; IDE, Satoshi[1]

[1]Department of Earth and Planetary Science, University of Tokyo

There are clear variations in seismicity among subduction zones worldwide in terms of such as the frequency of earthquake occurrence and maximum earthquake magnitude. These variations have been attributed to differences in tectonic properties in subduction zones, such as relative plate velocity and subducting plate buoyancy. For example, Ide [2013] demonstrate proportionality between relative plate velocity and background seismicity rate — the frequency of seismic events excluding aftershocks. Given that earthquakes occur to release strain in the crust accumulated by relative plate motion, we can intuitively understand this proportionality.

The overriding plate is also an important control on earthquake occurrence in subduction zones. Seismological observations and studies of tectonics have suggested the relationship between forearc topography and frictional properties on the plate interface, such as interplate locking and pore fluid pressure. Given this relationship, variations in forearc topography may reflect differences in frictional properties on the plate interface among subduction zones worldwide. However the relation between forearc topography and variations in seismicity among subdcuction zones is still unclear. In this study, we compare forearc slope and background seismicity rate in subduction zones worldwide. The forearc slope is based on Smith and Sandwell [1997], and the background seismicity rate is estimated using the epidemic type aftershock sequence (ETAS) model [Ogata, 1988]. We show the correlation between forearc slope and background seismicity rate. Subduciton zones with steeper forearc slopes have higher seismicity rates. Furthermore, subduction zones that are outliers of the proportionality between relative plate velocity and background seismicity rate [Ide, 2013], such as Cascadia and South Chile trench, also appear to obey this correlation.

According to the critical taper theory [Davis et al., 1983; Dahlen, 1984], which explains the relationship between forearc topography and frictional properties on the plate interface, and sand box experiments [e.g., Gutscher et al., 1996], steep forearc slope is associated with high basal friction. When we take these studies into account, our results suggest that the seismicity rates are high in subduction zones with steep slopes and high basal friction. This can be explained by considering erosion and accretion processes and geometrical irregularities on the plate interface. Erosional margins tend to have steeper forearc slopes [Clift and Vanucchi, 2004]. Because of thin trench sediments in erosional subduciton zones, geometrical irregularities on the subducting plate are not smoothed. Such irregularities may cause high basal friction at the tip of the forearc wedge and steepen the forearc slope. In the seismogenic zone, these irregularities act as numerous small asperities, and these asperities result in many seismic events in the erosional subduction zone. In contrast, accretionary margins generally have gradual slopes. Thick trench sediments smooth subducted seafloor, and it results in low basal friction at the tip of the forearc wedge and the gradual forearc slope. The smoothed plate interface may act as one large asperity in the seismogenic zone, and fewer earthquakes occur in the accretionary subduction zone. Furthermore, these variations in number and size of asperities among subduction zones worldwide may cause differences in megathrust earthquake occurrence.

Our results reveal the relation between forearc topography and seismity, and suggest that the frequency of seismic events in subduction zones is controlled by not only the mechanical factors such as relative plate velocity and the strain accumulated in the crust, but also the material factors such as erosion and accretion processes, trench sediments, and geometrical irregularities on the plate interface.

Feasibility of acoustic monitoring of strength drop precursory to earthquake occurrence

KAME, Nobuki[1*] ; NAGATA, Kohei[2] ; NAKATANI, Masao[1] ; KUSAKABE, Tetsuya[1]

[1]Earthquake Res. Inst., Univ. of Tokyo, [2]Ministry of Education, Culture, Sports, Science and Technology

Rate- and state-dependent friction law (RSF), proposed on the basis of laboratory experiments, has been extensively applied to modeling of earthquake stick-slip cycles. A simple spring-slider model obeying RSF predicts a significant decrease of the frictional strength Phi (the state of contact) that is localized within a few years preceding the earthquake occurrence. On the other hand, recent laboratory experiments successfully monitored the history of the strength by simultaneously measuring P-wave transmissivity |T|across the frictional interface using a 1MHz transducer. This suggests a possibility of earthquake forecast by monitoring the strength of a natural fault by acoustic methods.

The present paper explores the feasibility of such monitoring in the field on the basis of the physics of RSF combined with the linear slip model (LSM) employed in the classical acoustic methodology for monitoring an imperfectly welded interface. The characteristic frequency f_c, around which |T|(or reflectivity |R|) has a good sensitivity to the interface strength, is shown to be proportional to the strength and inversely proportional to the representative scale of real contacts.For natural faults f_c is estimated to be 1 to 100Hz, which is practicable in the field. The changes of |T|and |R|depend on the ratio of the strength drop to the absolute strength level, the latter of which is not constrained by RSF simulations. Expected changes in wave amplitude in the preslip period would be several percent for strong faults and several tens percent for weak faults, which may be detectable by acoustic methods such as seismic reflection surveys.

Semi-quatitative analysis of change in stress state in Chelung-pu Fault, Taiwan

HASHIMOTO, Yoshitaka[1*] ; TOBE, Kota[1] ; YEH, En-chao[2]

[1]Kochi Univerisity, [2]National Taiwan Normal University

Semi-quantitative stress state before and after earthquake in Chelung-pu fault, Taiwan

Stress change caused by earthquake is important to understand size and nature of an earthquake. Detailed waveforms of the 1999 Chi-Chi earthquake were taken along the Chelung-pu fault. In the aftermath of the earthquake, Taiwan Chelungu-pu Fault Drilling Project (TCDP) was conducted to take core with the seismogenic fault. In this study, we estimated paleo-stress condition semi-quantitatively using micro-fault inversion method and stress polygon. Then we discuss the relationship between spatial and temporal changes of stress with seismic cycles.

We used Multiple inversion method (MIM) (Yamaji, 2000) and k-means clustering (Otsubo et al., 2006) to estimate paleo-stress. As a result, we obtained four solutions of stress state (c1-c4) from TCDP core. To estimate the range of stress conditions we used stress polygons on the basis of the Anderson theory of faulting as used in Lin et al. (2007). We projected our paleo-stress orientations to the directions of SHmax, Shmin and SV. In addition to that, using stress ratio and a definition that SHmax is larger than Shmin, we can restrict the stress conditions for the paleo-stress in the stress polygons.

Two stress conditions (c1 and c3) were comparable with that from Lin et al. (2007) as a present state and post-seismic condition in normal stress regime. The range of stress condition for c2 is obviously higher than others, and the stress condition is in revere fault regime. The differences of stress condition possibly indicate the change in stress magnitude in the seismic cycle. Stress drops were estimated as -7.94˜2.60MPa for c1 and c2, and 2.71˜13.68MPa for c2 and c3. The calculated stress drop is comparable with estimated average stress drop from slip distribution in Chi-Chi earthquake (Ma et al. 2000).

Fluid transport property and diagenetic microstructure of chert in the Mino Belt

YAMAGUCHI, Asuka[1*] ; TANIKAWA, Wataru[2] ; KAMEDA, Jun[3] ; SHIMIZU, Mayuko[4] ; HAMADA, Yohei[5] ; KIMURA, Gaku[4]

[1]Atmosphere and Ocean Research Institute, the University of Tokyo, [2]JAMSTEC/Kochi, [3]Graduate School of Science, Hokkaido University, [4]Department of Earth and Planetary Science, the University of Tokyo, [5]JAMSTEC/IFREE

Pore fluid pressure along plate boundary megathrust is controlled by both fluid supply and fluid transport property, and it affects on faulting and earthquake mechanics. In the case of subduction zones where relatively old (older than 50 m.y. in age) oceanic plate subducts, oceanic crust is covered with thick pelagic siliceous sediments composed of diatomic and/or radiolarian oozes. In the Japan Trench, Kimura et al. (2012) pointed out that the volume of dehydrated fluid during silica diagenesis from opal-A to quartz through opal-CT is significant compared to that from clay mineral (smectite-illite) transition. However, fluid transport property of siliceous sediments has not been well-understood yet. In this study we conducted both permeability measurement and microstructural/microchemical observation of bedded chert from Inuyama-section in the Mino belt, Jurassic accretionary complex in Japan, as an on-land analog of subduction zone where old oceanic plate subducts.

Initial porosity of chert samples at atmospheric pressure is 0.4 to 2.2 %. Permeability was measured at room temperature under isostatic confining pressures of 5 to 120 MPa, by the steady state flow method with nitrogen gas as a pore fluid. Water permeability was then obtained by using Klinkenberg equation. At effective pressure of 5 MPa converted water permeability is 10^{-17} to 10^{-19} m^2, decreases with increasing effective pressure down to the ranges of 10^{-20} to10^{-21} m^2.

Optical and electron probe microanalyzer (EPMA) analyses show that chert is composed of radiolarian fossils filled with quartz and chalcedony, and red-colored matrix. Red matrix shows ˜95 wt.% of SiO_2, whereas >99 wt.% of SiO_2 are commonly observed from inside part of the radiolarian fossils. Such high concentration of SiO_2 within radiolarian fossils indicates that dissolved silica was precipitated into cavities maintained by radiolarian tests. This process would be related with silica diagenesis, occurring as dissolution-precipitation processes.

Silica mineral precipitation onto pore spaces would contribute to construct characteristic low porosity and permeability of chert. Our result shows that silica diagenesis works as not only a fluid source but also as a process for porosity/permeability reduction in convergent margins characterized by old subducting oceanic plate.

Mechanical properties of the shallow Nankai Trough accretionary sediments

KANAGAWA, Kyuichi[1*] ; TAKAHASHI, Miki[2] ; AZUMA, Shuhei[1] ; ITO, Hidenori[1] ; INOUE, Atsuyuki[1]

[1]Graduate School of Science, Chiba University, [2]Active Fault and Earthquake Research Center, Geological Survey of Japan

We report the results of triaxial compression and friction experiments of clayey mudstone, silty mudstone, sandstone and tuff samples, which are cored from the shallow (1000-1500 mbsf) Nankai Trough accretionary prism at IODP Sites C0002 and C0009, at room temperature, and confining pressures and pore water pressures close to their in situ conditions.

Triaxial compression experiments at these conditions and an axial displacement rate of 10 μm/s reveal that the failure strength is ≈300 MPa for a sandstone sample, ≈48 MPa for a tuff sample, ≈20 MPa for a silty mudstone sample, and ≈14 MPa for a clayey mudstone sample. The sandtone, tuff and silty mudstone samples failed relatively rapidly within 20 s, while the clayey mudstone sample failed slowly for ≈40 s. Another silty mudstone sample did not fail, and deformed ductilely at a strength of ≈15 MPa. The sandstone sample is strongly lithified by being cemented by calcite, which makes this sample's failure strength very high. The ductilely deformed silty mudstone sample seems not lithified enough to fail. A probable increase in pore pressure during compression of the clayey mudstone sample due to its low porosity (≈11 %) and permeability (≈10^{-19} m^2) in addition to its intrinsic weakness due to the abundance of clay minerals (≈42 wt%) likely makes this sample weak and promotes its slow failure. Such failure in clayey mudstone is a possible source for slow slip events observed in the shallow Nankai Trough accretionary prism.

Friction experiments at these conditions and axial displacement rates changed stepwise among 0.1, 1 and 10 μm/s reveal that frictional properties of these samples change systematically according to the content of clay minerals. The content of clay minerals is ≈6 wt% in the sandstone sample, ≈17 wt% in the tuff sample, 29-34 wt% in the silty mudstone samples, and ≈42 wt% in the clayey mudstone sample. Steady-state friction coefficient at the axial displacement rate of 1 μm/s decreases with increasing content of clay minerals, from 0.87 of the sandstone sample, through 0.71 of the tuff sample and 0.53-0.56 of the silty mudstone samples, to 0.25 of the clayey mudstone sample. Slip-dependent frictional behavior also changes from slip hardening to slip weakening with increasing content of clay minerals. Although all samples exhibit velocity-strengthening behavior upon stepwise changes in sliding velocity, the ratio of $(a - b)$ value to the velocity dependence of steady-state friction decreases with increasing content of clay minerals, which implies that the friction component decreases while the flow component increases accordingly. Thus, faulting in the shallow Nankai Trough accretionary prism is likely controlled by the content of clay minerals in sediments as well as in fault zones.

Recent observations of slow earthquakes along faults within shallow part of subduction zones, for example the very low frequency earthquakes at the Nankai Trough [Ito and Obara, 2006; Sugioka et al., 2012], has demonstrated that faulting there is slow yet seismic; suggesting that frictional velocity dependence along the fault at the shallow portion must be negative. However, previous experimental results have repeatedly shown that velocity dependence of the expected fault zone material is generally estimated to be positive. Here, we present our recent experimental results showing that velocity dependence of the friction of the shallow subduction zone faults are not necessarily be positive.

We have performed a series of rotary-shear large displacement (>150 mm) friction experiments on the following shallow fault simulating material: clayey fault material form the shallow megasplay fault zone within the Nankai accretionary prism, input pelagic siliceous to calcareous sediments to the Costa Rica subduction zone, and simulated artificial gouge of montmorillonite/quartz mixtures (20-40 wt% of montmorillonite). Experimental results reveal that these material do exhibit velocity weakening behavior at a range of velocities from 0.003-0.3 mm/s. Velocity weakening of these material is mostly characterized by a small degree of the friction velocity dependence (the absolute value of (a-b) is typically <0.005.

The SSEs are often described as conditionally stable sliding of faults [e.g., Shelly et al., 2006]. High pore fluid pressure could alter a velocity-weakening fault with a small value of (a-b) to conditionally stable regions by reducing the effective normal stress [Scholz, 1998]. The presented velocity weakening property with a small value of (a-b) could be responsible for generating shallow slow seismic slip events in subduction zones. Textural observation reveals the importance of studying effects of both the clay content and shear-induced deformation textures on the frictional velocity dependence.

Frictional properties of simulated faults containing amorphous silica/calcite mixtures

NAMIKI, Yuka[1*] ; TSUTSUMI, Akito[1]

[1]Graduate School of Science, Kyoto University

Various seismic behaviors such as large earthquakes, episodic slow slip events, or silent earthquakes are observed in subduction zones. Knowledge of the frictional properties of input material to subduction zones would help to understand the complicated seismic behaviors. On the Cocos plate, which subducts beneath the Caribbean Plate at Middle America Trench offshore Costa Rica, input sediments containing clay, silty clay sediments and silicic to calcareous ooze were collected during the IODP expedition 334. We have been studying the frictional properties of the collected input material to the Costa Rica subduction zone. In order to better understand frictional processes of a fault in silicic to calcareous ooze, we have performed a series of friction experiments on a simulated fault gouge containing mixtures of amorphous silica and calcite.

Frictional experiments were performed at a constant slip velocity of v = 0.28 mm/s, and also under a velocity-stepping condition. The silicic to calcareous ooze sample showed the following characteristic behavior. The friction coefficients at 0.28 mm/s showed initial peaks at 0.4?0.6 and subsequent little decrease, followed by a gradual increase to attain a constant friction value at 0.6?0.8. The analogue gouge containing 40?80 wt% of calcite reproduced such frictional behavior well. The experimental samples of the input ooze material required only about 40 mm of displacement to attain constant steady-state friction level. However, the calcite/amorphous silica mixtures needed larger displacement to attain steady-state friction. Furthermore, the calcite/amorphous silica mixtures could not reproduce friction velocity dependence observed for the collected ooze samples. The result suggests the importance of studying effects of grain size distribution and the grain morphologies on the frictional properties of the silicic to calcareous ooze material.

Effect of temperature on frictional behavior of smectite and illite: Implication for the updip limit for seismogenic zon

KUBO, Tatsuro[1*] ; KATAYAMA, Ikuo[1]

[1]Department of Earth and Planetary Systems Science, Hiroshima Univercity

Introduction: Along plate boundary subduction thrusts, the transformation of smectite to illite within fault gouge at temperatures of ˜150C is one of the key mineralogical changes thought to control the updip limit of seismicity. Saffer and Marone (2003) reported illite shale exhibited only velocity-strengthening behavior, opposite to the widely expected, potentially unstable velocity-weakening behavior of illite. They concluded transformation of smectite to illite is not responsible for the seismic-aseismic transition in the updip limit of subduction zones. However, their experiments were limited at room temperature although the updip limit of seismogenic zone is thermally controlled that occurs at temperature around 150oC. Therefore, in this study, we determined the effect of temperature of frictional properties of smectite and illite and discuss whether the smectite-illite transition accounts for the updip limit of seismogenic zone along subduction thrust.

Experimental methods: Frictional experiments were performed using a biaxial frictional testing machine at Hiroshima University. The powder materials of clays were placed on the simulated fault surface and two side blocks were placed together to produce a double-direct shear configuration. Normal stress was applied via a hydraulic ram on the side block with 15, 40, 60 MPa, and then, shear stress was applied by advancing the central block downward at a constant velocity. The sample assembly was heated by an external furnace up to 200oC that is monitored by thermocouples located close to the central block. Mechanical data were recorded continuously with a sampling rate of 10 Hz and the frictional coefficient was calculated from the shear force divided by the normal force assuming zero cohesion.

In the frictional experiments, we determined the velocity dependence of sliding friction, which is a key parameter for stable or unstable sliding (e.g., Dieterich, 1979). After steady-state sliding, the loading velocity of 3 μm/s was abruptly changed to 30 μm/s in each frictional experiments to determine the velocity dependence of these clay minerals. We calculated the velocity dependence of sliding friction as follow:

$$(a-b)=d\mu(d \ln V)$$

where a,b is the frictional parameter and V is sliding velocity. The velocity dependence is important to show seismic slip, in which negative values of (a-b) reflect velocity-weakening behavior, whereas positive values of (a-b) reflect velocity-strengthening behavior and thence stable (aseismic) sliding.

Results and Discussion: In comparison of steady-state fictional strength of clay minerals, the value of frictional strength of smectite is nearly half as large as that of illite. The effect of temperature on the frictional strength is rather weak, and the steady state friction is slightly increased at high temperatures. Our results suggest that the shear stress required to initiate sliding is much lower for smectite than illite, and smectite could not accumulate much strain energy.

The velocity dependence at room temperature shows always positive at normal stress higher than 40 MPa, which is similar to the results of Saffer and Marone (2003). However, at temperature of 200C, illite shows negative values of (a-b), suggesting that illite exhibits unstable velocity-weakening behavior. This results explains smectite is potentially aseismic for stable sliding at the subduction thrust, whereas illite becomes seismic due to a negative velocity dependence and unstable sliding at high temperatures. These experimental results indicate that the smectite-illite transition potentially account for the updip limit of seismogenic zone along subduction thrust, which is opposite to the previous results at room temperature.

Frictional properties of basalt-derived fault rocks and implications for subduction earthquakes

SAITO, Tsubasa[1*] ; UJIIE, Kohtaro[1] ; TSUTSUMI, Akito[2]

[1]Life and Env. Sci., Univ., Tsukuba, [2]Sci., Kyoto Univ.

Recent seismic reflection surveys in subduction zones such as Nankai Trough suggest that subduction earthquakes mostly occurred along the upper part of oceanic crust composed of basaltic rocks (e.g., Bangs et al., 2009). Hence, frictional properties of basalt appear to be keys for understanding earthquake nucleation and rupture propagation during subduction earthquakes, yet they remain poorly understood. In the Upper Shimanto accretionary complex of eastern Shikoku, basalt and tectonic melange are repeated by thrusts, representing duplex structure associated with underplating (Ikesawa et al., 2005). Underplating-related thrusts develop in basalt and consist of basalt-derived foliated cataclasite and ultracataclasite. Fluidization of comminuted material and mineralogical signatures of frictional heating were reported from a few centimeters-thick ultracataclasite (Ujiie et al., 2007; 2008; Kameda et al., 2011). We examined the frictional velocity dependence at slip rates of 0.0028-0.28 mm/s and high-velocity (1.3 m/s) frictional properties of disaggregated pillow basalt and basalt-derived foliated cataclasite and ultracataclasite. The samples from pillow basalt show velocity-weakening behavior, while those from foliated cataclasite and ultracataclasite exhibit velocity-strengthening behavior. All samples show slip weakening behavior during high-velocity friction experiments, with the samples from ultracataclasite marked by smaller stress drop, slip weakening distance, and fracture energy. The compositions of materials and preliminary microstructural observations suggest that velocity-weakening samples show lower clay content (21 wt.%) and grain-size reduction, while velocity-strengthening samples exhibit relatively high clay content (29-50 wt.%) and clay foliations. Our results suggest that earthquake nucleation likely occurs in subducting basalt, but slip tends to be stable when clays and clay fabrics are formed by hydrothermal alteration and shear deformation, respectively. The results of high-velocity friction tests suggest that earthquake rupture propagates easily through ultracataclasite rather than foliated cataclasite and pillow basalt, which is consistent with the fact that the geological evidence of earthquake faulting was found from the ultracataclasite.

Amorphization of clay minerals by wet and dry grinding

FUJIMOTO, Koichiro[1*] ; FUKUCHI, Rina[2]

[1]Tokyo Gakugei University, [2]Tokyo University

Nanoparticles in fault zones are recently paid much attention since they give significant influences on the frictional properties (Ma et al., 2006). Nanoparticles are considered to be formed not only by mechanical grinding but also by mechanochemical processes. Amorphous nanoparticles were found in Iida-Matsukawa fault, Central Japan (Ozawa and Takizawa, 2007). It is well known that clay minerals are easily transformed into amorphous phase by mechanochemical processes. We conducted pulverization experiments of some clay minerals under both dry and wet conditions to clarify the characteristics of the pulverized materials and the mechanism of amorphization.

We used kaolinite saponite and sericite as starting materials. Pulverization experiments were conducted using planetary ball mill and characterization of run products were conducted by XRD, FT-IR, TG-DTA and FE-SEM. Three minerals were completely transformed into amorphous materials by dry grinding. XRD peaks were weakened but still remain after one day wet drying as for kaolinite and sericite. On the contrary, as for saponite, XRD peaks do not show remarkable change under wet condition. Probably amorphization rate is reduced because impact energy in the ball mill is decreased in the presence of water. Presence of interlayer water affects on the behavior of saponite.

Fluid inclusion as fossil fluid in seismogenic zone, trap mechanism and interpretations for fault science

SAKAGUCHI, Arito[1*] ; YANAGISAWA, Kazumichi[2]

[1]Yamaguchi Univ./JAMSTEC, [2]Kochi Univ.

A fluid inclusion, fluid-fill capsule within rigid crystal, preserves density and chemical composition of fluid in deep crust. This records pressure, temperature and other information of the fluid when the fluid trapped. Pore fluid pressure drop due to rapid fluid ejection along the fault was discussed in Kodiak accretionary complex (Vrolijk et al., 1988). CH4-H2O fluid inclusions are reported at pseudotachylyte bearing Nobeoka Thrust, Shimanto accretionary complex (Kondo et al., 2005). Thermal stretching of fluid inclusions due to seismic frictional heating were found at seismogenic Mugi Melange, Shimanto accretionary complex (Ujiie et al., 2008). Though fluid inclusion tells us fluid condition in deep crust, trapping mechanism within crystal is still uncertain. The fluid inclusion is one of crystallographic defect, but general size from sub-micron meter to several mm is much greater than crystal lattice. A crystal tend to growth without large defect, and it seems irregular process to be formed a fluid inclusion. The trap mechanism is significant to interpret the fluid inclusion data.

We succeeded to make artificial fluid inclusion in calcite during hydrothermal experiment. A calcite crystals are nucleated and grown with temperature decrease in autoclave. Fluid inclusions were never formed in simple cooling procedure, but many large fluid inclusions were found at the overgrowth zone formed by re-heating process. Surface condition of artificial calcite of re-heating and overgrowth process were observed using SEM. Etched pattern covers the surface of re-heated calcite crystal. Some depressions are wide shallow and others are small deep. Many growth steps were found on surface of over-growth calcite. The calcite surface may have been advanced with lateral motion of growth steps. This growth step covers most of the etched depressions except small deep one. These small deep depressions are surrounded by new grown surface and became increasingly deep. Some depressions may make large pore within overgrowth zone in this process.

This observation shows that the fluid inclusion were made during overgrowth after surface etching, and this requires temporary solubility change in crystal growth process. The fluid inclusions may record pore-fluid condition after the event of pressure, temperature and/or chemical change in deep crust.

New fluid flow mechanism at seismogenic depth in subduction zone

TAKE, Kotaro[1*]

[1]Dept. of Geosphere. Yamaguchi Univ.

Since pore fluid pressure may concern with seismogenesis, large amount of articles are published for fluid flow research, and -previous researches have been focused only crack flow in deep crust. In general, a pore between sedimentary grain decreases with depth, and fluid flows only within crack in deep crust. This study shows new fluid flow mechanism that doesn't depend on crack in the rocks. This produces new perspective of fluid flow of seismogenic depth in subduction zone.

The Shimanto accretionary complex at SW-Japan, formed at seismogenic depth suffers pressure solution deformation and generally includes brittle failure of web structure and crack-filled veins. The carbonate matrix is lacked in the sediments due to deposition below CCD.

Some sandstones in the late Cretaceous Nonokawa Formation, includes spotted carbonate deposit. This carbonate deposit occurs limited area less than several meters square within sandy layer without crack-filled vein. Microscopic observation shows following features as below.

The spotted carbonate minerals overprint with embayment structure in pressure-solution deformed sandy grains, and these are cut by web structure and crack-filled veins. The fluid may have dissolved the sandy grains, and carbonate minerals were deposited at latest stage of lithification process between pressure solution deformation and brittle failure. These occurrences suggest that fluid can flow with dissolution of rock-forming grains in rigid crust without crack.

Generation of high-temperature fluid and its spatial distribution in an ancient megasplay fault

MASUMOTO, Hirokazu[1*] ; HIRONO, Tetsuro[1] ; ISHIKAWA, Tsuyoshi[2] ; TANIKAWA, Wataru[2] ; MUKOYOSHI, Hideki[3]

[1]Department of Earth and Space Science, Graduate School of Science, Osaka University, [2]Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology, [3]Faculty of Education and Integrated Arts and Sciences, Waseda University

An ancient megasplay fault outcrop is identified within Kure region of the Shimanto accretionary complex and has been formed at 2.5 – 5.5 km depth. Recent works show pseudotachylyte produced by frictional melt, fluid-rock interactions at high temperatures (>350 ℃) and enrichment of incompatible element concentrations on the fault. However, spatial distribution of pseudotachylyte and high-temperature fluid is not investigated. These informations are important to understand an earthquake is able to produce extensively high-temperature fluid and thermal pressurization. Accordingly, we performed deformation structures analysis and obtained 46 rock samples from the outcrop and analyzed these samples by vitrinite reflectance measurement, powder X-ray diffraction-RockJock mineral composition analyses and trace elements compositions measurement. Therefore, analyses of black gouge samples from the slip zone indicate fluid-rock interactions at high temperatures, whereas footwall sandstone samples that are close to fault gouge indicate enrichment of quartz and decrease of rare-earth element concentrations. These contrasts may be regarded as mobilization of elements derived from seepage of yielded high temperatures fluid within the slip zone.

Multiple damage zone system of an exhumed subduction zone megasplay fault

HAMAHASHI, Mari[1*] ; KAWASAKI, Ryoji[1] ; FUKUCHI, Rina[1] ; SAITO, Saneatsu[2] ; HASHIMOTO, Yoshitaka[3] ; HAMADA, Yohei[2] ; KITAMURA, Yujin[4] ; YAMAGUCHI, Asuka[1] ; KIMURA, Gaku[1]

[1]The University of Tokyo, [2]Japan Agency for Marine-Earth Science and Technology, [3]Kochi University, [4]Kagoshima University

More than 90% of the major earthquakes and tsunamis are known to occur at plate convergent margins, along plate boundary faults and megasplay faults. Investigating the mechanical properties and deformation patterns of these megathrusts are important to understand the generation of earthquakes and the dynamics on the subduction plate interface. Large displacement faults contribute to the reduction of steady-state strength at mid-crustal levels, and cause the frictional-viscous deformation at depth. As the candidate for such weak faults, foliated, phyllosilicate-rich fault rocks have been prevalently recognized in many tectonic settings. However, whether foliated fault rocks behave as weak structures in the longer terms and their roles in the strain localization and fault evolution, are poorly understood.

Exhumed fault zones are helpful to constrain fault strength and deformation process of foliated cataclasites formed at upper-midcrustal depths over geological time. One of the well-studied exhumed major fault zones in subduction settings is the Nobeoka Thrust, a fossilized megasplay fault in Kyushu Shimanto Belt, southwest Japan, which exposes foliated fault rocks that were formed under the temperature range of ~180-350 ℃ (Kondo et al., 2005). During the Nobeoka Thrust Drilling Project in 2011, core samples were retrieved containing both consolidated fault rocks and less consolidated, brecciated fault rocks, preserved from surface weathering and less likely to be drilling-induced. The core samples are expected to provide a different aspect on fault rock strength from previous geological studies on exposed, consolidated outcrops. In the current study, given the unique opportunity to determine the coexistence of cohesive and less cohesive fault rocks in a single fault system, we conduct macroscopic and microscopic structural observation and physical property measurements on the core samples, synthesizing with geophysical logs obtained from the drilling of the Nobeoka Thrust to characterize the damage zone architecture of the fault rocks formed in the frictional-viscous regime along the megasplay fault.

The hanging wall consists of the shale-dominant intervals of dense development of phyllitic cleavages, the sandstone-dominant intervals of disturbed foliations, and the damage zone above the fault core characterized by cataclastically broken phyllite with thick abundant sandstone blocks. The observed density of brittle fractures, breccias, and mineral veins is increased at the sandstone-dominant intervals and near the fault core, whereas brecciated and less brittle/ductile structures are abundant within the shale dominant intervals. The brittle deformation near the fault core may have caused the wearing away of the shale-rich zones by abrasion, and as a result, the sandstone-rich zones that have relatively larger strength, remained and deformed cataclastically near the fault core. On the other hand, the footwall in the drilled range consists of six sets of fracture zones, all of which include a ”brecciated zone” intensively broken in the center, sandwiched by a ”surrounding damage zone” with abundant cohesive faults, mineral veins, and sandstone blocks. The surrounding damage zone is characterized by the increase in fault and fractures with distance from the fault core, and interestingly associate with the increase in resistivity, P-wave velocity, and density and decrease in porosity. The deformation in the surrounding damage zone is inferred to occur in a strain-hardening manner, strengthening with distance from the fault core. Shear localization may initiate more easily in the sandstone-rich area later forming the surrounding damage zone, and eventually develop an intensively deformed fault core in the center. These insights would enable to reinterpret the deformation processes and weakening mechanisms that occur in foliated fault rocks along the megathrust in subduction zones.

The Enpo Boso-Oki earthquake of November 7th, 1677 occurred in the sea area of the south east offing of Boso peninsula, Kanto district, Central Japan. The shaking of the earthquake was weak, and no damage occurred due to the shaking. The shaking was felt only on the Boso Peninsula and at Edo (Tokyo). Though the shaking was small, but a huge tsunami hit the coasts of Boso peninsula, and north to Iwanuma city about 20 kilometers south of Sendai. Detailed house and human damage was recorded in "Gyokuro-So", one of the fundamental chronologies of the Tokugawa Government. In Katsuura city on the coast of Boso Peninsula, at Kawazu, Sawakura, and at Shinga villages 47 houses were destroyed, and 7 people were killed in total. Inundation heights of the tsunami at those three villages are estimated at 8.0, 8.5 and 6.3 meters, respectively. At Onjuku fishery village, 30 houses were destroyed and 57 people were killed, and tsunami height was estimated at 9.7 meters. At Yasahido village, where total number of houses was about 30, 25 houses were swept away and 13 people were killed, and tsunami height was 12.8 meters. In Choshi city, sea water rushed into Obata Ike pond. We measure the height of the saddle point separating the pond from the open sea, and we found out that tsunami height was 13.5 meters there. The tsunami height at Iwaki City, Fukushima Prefecture was 4.8 to 6.9 meters. On Hachijo Island, about 300 kilometers south of Tokyo, the residential area of Yato behind Yaene port was flooded by sea water and the inundation height is estimated at about 10 meters. The tsunami wave affected west to Ise Bay, Nagoya City. At Utsumi port in Minamichita town about 25 ships were wrecked due to the tsunami. Tsunami also recorded at Owase city on the south east coast of Kii peninsula. The authors of the present study wish to express their thanks to JNES for its financial support in promoting our research.

A Reproduction of 1707 Hoei Tsunami with long rupture duration, referring to 2011 East Japan Pacific Ocean Earthquake

MATSU'URA, Ritsuko S.[1*] ; ANJU, Akira[2] ; SHOJI, Masahiro[2]

[1]ADEP, ERC, [2]Kozo Keikaku Engineering Inc.

Hoei earthquake in 1707 was the largest earthquake in the Edo period that gave the tsunami damage to a wide area along the Pacific Ocean, from the Izu Peninsula to the Southwest Japan. It was assumed that in Hoei earthquake, the source areas of Ansei Tokai and Nankai earthquakes ruptured subsequently within a very short time [e.g. Usami (2003)], or the source areas of the two earthquakes of Ansei were broken at a time [e.g. Ishibashi (2004)]. However, the recent detailed study of historical records revealed that the crustal deformation and the seismic intensity distribution tell that the western and eastern margins of the Hoei source region did not overlap with the two earthquakes in Ansei [e.g. Matsu'ura (2012)]. Hoei earthquake was the exceptionally huge earthquake, which should be called "Western Japan Pacific Ocean Earthquake" in Edo period.

In order to explain very high tsunami of Hoei in the Western Japan, Aida (1981) set the doubled slip to the source area off the cape Ashizuri. Furumura et al. (2011) even expanded the source area further west towards Kyushu. However, their models cannot match the intensity distribution in Kyushu and arrival times of tsunami to villages along the east coast of Kyushu. We suspect that the commonly used tsunami simulation method does not work for a M9-class huge tsunami like Hoei. The theoretical calculation program of crustal deformation of a rectangular fault in a semi-infinite medium [e.g. Sato and Matsu'ura (1973)], which is widely used for the tsunami simulation, inevitably produces singular margins. When the source area was huge, the singularity should affect coastal areas. When the shallow part near the trench is included in the source area, using the same elastic constants as the deeper part should result in an unrealistic deformation solution for a tsunami simulation.

To avoid these limits to applications of the theory used, we put aside obtaining crustal deformation of the sea floor from a dislocation source model, and calculate tsunami from the model of sea floor upheaval and subsidence, which evolve in time. For a test, we first examine the case of the East Japan Pacific Ocean Earthquake of 2011. In order to avoid the detailed topography along coasts, we only used data from GPS buoys and pressure gauges located offshore. We used the ocean bottom upheaval and subsidence obtained by Saito et al. (2011) as the final crustal deformation of the 2011 huge quake. From the known epicenter, the deformation spreads gradually, with the intermittent of 20 seconds, which was observed by GPS as the stop of movement. Paying the attention for the physical plausibility, the movement starts when the rupture reaches, and continues moving until the rupture reaches the edge of a source area. Since the small smooth subsidence spreads over wide area around the major large upheaval area in Saito's model, most tsunami waveform features were reproduced only from the major upheaval area and the smaller upheaval zone protruding toward Japan Trench.

Then we did for Hoei tsunami. As the source of upheaval, we use the source region proposed by Matsu'ura et al. (2011). The topography in Hoei period, we stripped down claimed lands like the islands of Kansai International airport, and Tenpozan, which are apparently made after Hoei period. We also increased the depth of Sakai port, which had been buried by depositions carried by Yamato River since 1704. Examining tsunami for two cases of hypocenter, one at the east end of the source area near Zenisu, and the other at Kumano-nada, we realized that it is impossible to distinguish a hypocenter from limited tsunami information obtained for historical earthquakes. Even with our rough model, Hoei tsunami can go up to canals in Osaka and in the Lake Ryujin in Hazako, Oita. Our experience tells that we shall leverage the recent high power of ordinary computers for a tsunami simulation and molt to go beyond the 40-year-old theoretical crustal deformation.

Close examination of universality of matter off Miyagi that earthquakes advanced toward the east

MASE, Hirofumi[1*]

[1]none

I explained how the surrounding of the plate boundary is always compressed(1). I reproduced the Off-Miyagi by the easy experiment(2). I understood earthquakes off Miyagi gradually climbed the slope of the plate boundary. The head within range where small earthquakes occur advanced toward the east gradually and went beyond the hypocenter of 3.11 in November, 2010.(3)

Therefore, the model of off Miyagi is the following. The earthquake of M7 class occurs in several decades by one degree. In every case the hypocenter of it moves east. And, the rear side of it slips to a deep point. The moderate quake guides the earthquake of M7. And, the front of crack is formed. Slip-all-together occurs if the front of crack arrives at a proper place. The feature of this model is to be able to give the answer to the following three large problems at a time. (a)A lot of people think that it is generated repeatedly within the specific range. (b)The cause of the swerve that causes large slip in every case is not discovered. (c)Finally happening is that a shallow part is destroyed at a time.

I want to think about (IC)Off Iwate-Chubu,(IH)Off Iwate-Hokubu,(AT)Off Aomori-Toho,(TK)Off Tokachi referring to (MY)Off Miyagi(Fig.1). The 1968 Tokachi-oki earthquake and the 1994 Sanriku-Haruka-Oki earthquake occurred in (IH)(AT). The co-seismic slip distributions on the map of (4) is interesting. Though the rupture starting point and the main rupture zone can be understood of those relation of upper-lower part on slope, both are considerably away. This is a feature and it is necessary to be clarified. I interpret that a main rupture zone is the peak of slip nearest the trench. The 1968 earthquake has two large slip zone. The main rupture zone in the south is located in lower part of the main rupture zone of the 1994 earthquake on slope. I want to pay attention to that. I think the 1968 earthquake went with the earthquake that had to happen ahead of the 1994 earthquake. The earthquakes that occurred in the vicinity in the past(5) have the possibility that there were rupture zones in lower part of the 1968 earthquake or the earthquake that had to happen ahead of the 1994 earthquake on slope. Therefore, I think that (IH)(AT) walks on the road similar to (MY). And, that a shallow part can slips and timing is only waited for. We should think that the earthquake similarly climbs the slope also in region (TK).

Range (39N-40N,143E-144E) in region (IC) is the earthquake-prone zone of small and medium-sized earthquakes after 1923. It is seen that there are a lot of intraplate earthquakes(12). The lower plate always collapses due to the earthquakes and the material overflows up and accretionary wedge will be made. The upper plate relatively becomes long and swells because the lower plate shortens. And, the vicinity of the surface comes into a expansion field. And, steep cliffs are formed and fall because the upper plate surges to the trough. This will explain the geographical features of (IC) shown by (9) and the cause. The expansion field in the vicinity of the surface causes the occurrence of the lateral-fault type(10). The structure of the cliff where the sudden falls easily happen reacts sensitively to peripheral earthquakes. In addition, it has the possibility that is an efficient tsunami generator. This harmonizes with the result of (11).

Diversity of outer-rise earthquakes: As an example of the Off-Fukushima earthquake on 26 October 2013

YOMOGIDA, Kiyoshi[1*]

[1]Graduate School of Sciences, Hokkaido University

Earthquakes occurring in the outer-rise of a subducting plate are associated with the ruptures of the subduing plate itself, that is, intra-plate earthquakes. Such outer-rise earthquakes have been considered to excite much larger high-frequency than earthquakes in the plate boundary of the subducting and overriding plates, because the outer-rise earthquakes should break a lithospheric part where no peculiar weak zones exist.

A M7.1 earthquake occurred off the coast of Fukushima on 26 October 2013, which was probably associated with the 2011 great Tohoku-oki earthquake. We analyzed broadband seismic waveform data of this event recorded by F-net and other seismic networks. Compared with other large outer-rise earthquakes, the high-frequency component (>1Hz) of all the stations along the Pacific coast of eastern Japan is not abundant although slightly larger than plate-boundary earthquakes of low-angle thrust faulting. In contrast, there was the excitation of several impulsive wave packets of several seconds in period. Since only high-frequency waves are abundant at common stations for aftershocks of this outer-rise earthquake, the above features should not be originated by either propagation path or site effect.

Unlike the other outer-rise earthquakes, the rupture process of this earthquake was unique, relatively smooth with several strong patches on a rather homogeneous fault. The breakout of these patches should have been connected without any complex unbroken areas on the fault in the end, in order to explain the observed waveforms. Although we do not deny the break of a virgin (without any peculiar weak planes) lithosphere in this case, several distinguished large strong patches are likely to characterize the heterogeneity in the fault region of this outer-rise earthquake.

Among recent large outer-rise earthquakes along subduction zones near Japan, we have found another example similar to the Fukushima-oki earthquake: for the M7.0 outer-rise event on 14 March 2012 at the junction between Kuril Trench and Japan Trench, several impulsive waveforms with minor high-frequency waves. The state stress of this subducting Pacific plate should be very complex, which might lead to its non-standard rupture process. We shall need to investigate broadband frequency excitation patterns carefully for large outer-rise earthquakes.

In summary, there should be a wide variety of heterogeneities and/or stress state within a subducting lithosphere, which may be important to consider not only the source process of outer-rise earthquakes but also their tsunami generations.

High resolution seismic profiling in the northern Japan Trench axis area

NAKAMURA, Yasuyuki[1*] ; KODAIRA, Shuichi[1] ; MIURA, Seiichi[1] ; YAMASHITA, Mikiya[1] ; FUJIE, Gou[1] ; SHIMOMURA, Norio[1] ; IWAMARU, Hikaru[1]

[1]Japan Agency for Marine-Earth Science and Technology

Marine geological and geophysical surveys and analysis of their results have revealed that the ruptured area of the 2011 Tohoku earthquake extended up to the vicinity of the trench axis along the plate boundary fault. To investigate the geological structure, especially the faults and the deformation of the sediments, we have conducted reflection seismic surveys in the trench axis area of the Japan Trench off Miyagi and Iwate prefectures. Three seismic cruises have been carried out in 2011 and 2013 along 81 E-W (dip) lines and 17 N-S (strike) lines. We have used 320 or 380 inch^3 cluster air guns and a 1200 m long streamer cable to obtain high resolution seismic data. Surveyed area covers the trench axis area along the trench strike from seaward of the hypocenter of the Tohoku earthquake around 38 N at south, to ˜40 N at north. Seismic profiles around 38 N show that the trench axis is located on a graben with sediments which have been deformed by reverse faulting. Similar deformation structure is observed around 40 N, but the trench axis is located on a horst not a graben there. The thickness of the incoming sediments on the Pacific plate typically ranges ˜0.3 ? 0.5 s in two way time, however it is reduced down to $<$0.2 s around 39.5 N where the basement of the oceanic crust shows higher relief and trench inner wall is significantly steep. The thickness variation of the incoming sediments can be traced seaward and corresponded with along strike variation of the structure in the outer rise. These high resolutions seismic data served for the site selection of the JFAST drilling project by IODP and also contributes to the JTRACK proposal for future drilling in the Japan Trench following success of the JFAST.

Seismic surveys in the ruptured area of the 2011 Tohoku earthquake

NAKAMURA, Yasuyuki[1*] ; KODAIRA, Shuichi[1] ; KAIHO, Yuka[1] ; NO, Tetsuo[1] ; FUJIE, Gou[1] ; SATO, Takeshi[1] ; YAMAMOTO, Yojiro[1] ; KASAYA, Takafumi[1] ; OBANA, Koichiro[1] ; MIURA, Seiichi[1] ; TAKAHASHI, Narumi[1]

[1]Japan Agency for Marine-Earth Science and Technology

We have conducted seismic surveys in the ruptured area of the 2011 Tohoku earthquake off Miyagi prefecture in 2011 and 2013 using JAMSTEC's R/V Kairei. Three multi-channel reflection seismic (MCS) surveys were conducted in 2011 with R/V Kairei's 7800 inch^3 tuned air gun array and ˜6 km long streamer cable. The MCS profiles along 14 E-W (dip) lines and two N-S (strike) lines were acquired during these surveys. Another seismic survey was carried out in 2013 around the JFAST drill site along one dip line and two strike lines. Time migrated sections demonstrated characteristic structure in the Japan Trench subduction zone; the Pacific plate deformed by normal faults (horst and graben structure), frontal prism with seismically transparent or chaotic feature, strong landward dipping reflections corresponding to the backstop interface, "deep sea terrace" in the upper landward trench slope covered with younger sediments mainly deformed with normal faults. Our survey area covers ˜150 km in the trench strike direction around the epicenter area, which is rather small compared with the entire rupture zone (400 ? 500 km in the strike direction) of the Tohoku earthquake, however the structure is considerably variable from south to north. We have selected 6 dip lines, including the JFAST dip line, to apply pre-stack depth migration (PSDM). The PSDM sections provide higher quality profiles and interval velocity models in depth domain which are suitable for understanding the structural framework of the Japan Trench subduction zone. In 2013 survey, we also used four ocean bottom seismographs (OBSs) in addition to the MCS system. The P to S converted wave was clearly observed in the horizontal component seismograms, and the Vp/Vs in the sediment layer around the JFAST drill site was estimated at $>$4.5.

Determination of Three Thermal Properties in Japan Trench Fast Drilling Project (JFAST)

LIN, Weiren[1*] ; TADAI, Osamu[2] ; FULTON, Patrick[3] ; HARRIS, Robert[4] ; TANIKAWA, Wataru[1] ; KINOSHITA, Masataka[1]

[1]Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology, [2]Marin Works Japan LTD, [3]University of California, Santa Cruz, USA, [4]Oregon State University, USA

The 2011 Mw 9.0 Tohoku-oki earthquake produced a maximum coseismic slip of >50 m near the Japan Trench. Japan Trench Fast Drilling Project (JFAST) as the Integrated Ocean Drilling Program (IODP) Expedition 343 and 343T drilled through the plate boundary fault ruptured during the Tohoku-oki earthquake at site C0019 approximately one year after the earthquake. The most highlighted objective is to detect residual positive temperature anomaly induced by the coseismic frictional heat. To interpret measured temperature anomaly and to calculate coseismic shear stress on the ruptured fault from the temperature anomaly, the full three thermal properties (thermal conductivity, thermal diffusivity and specific heat; only two thermal properties among the three are independent) are necessary. We measured the three thermal properties using four whole round core samples retrieved from borehole C0019E at 177, 697, 802 and 828 mbsf (meter below seafloor), respectively by a transient plane heat source method (also called Hot Disk method). Independently with Hot Disk method, thermal conductivity were also measured by a line heat source method for 45 half core samples using a TEKA half-space probe onboard the D/V Chikyu and by a divided bar technique using 38 crushed core samples (particle samples) in onshore laboratory. The thermal conductivities determined independently by the three methods were consistent each other. Also, the Hot Disk measurements revealed very little anisotropy in thermal conductivity and thermal diffusivity.

Acknowledgments: This research used core samples provided by IODP. We thank all Expedition 343 and 343T scientists and the drilling and logging operation staff on board the D/V Chikyu during expedition 343 and 343T.

Modeling slow and seismic slips off Tohoku considering low to high speed friction behavior of the shallow plate boundary

SHIBAZAKI, Bunichiro[1*] ; IKARI, Matt[2] ; NODA, Hiroyuki[3]

[1]International Institute of Seismology and Earthquake Engineering, Building Research Institute, [2]Marum, Center for Marine Environmental Sciences, [3]Japan Agency for Marine-Earth Science and Technology

Ikari et al. (2013) examined low to high speed frictional properties of fault zone material from the shallow plate boundary in the Tohoku region obtained by the IODP Expedition 343 (JFAST). They found velocity-weakening frictional behavior at slip velocities slower than 10^{-6} m/s and velocity-strengthening at higher slip velocities. This frictional property is considered to be a mechanism that causes slow slip events and stress accumulation during the period between slow slip events. We investigate the effects of this frictional property on generation of slow slip events and megathrust events.

We use a rate- and state-dependent friction law with cut-off velocity to an evolution effect to represent this frictional behavior. Based on the experimental results (Ikari et al., 2013), we set the cut-off velocity at 10^{-6} m/s. We also consider dynamic weakening due to thermal pressurization at high slip velocity. We perform three-dimensional quasi-dynamic modeling of slip processes. Numerical results show the occurrence of slow slip events at intervals of several ten years at the shallow plate boundary. During the period between slow slip events, stress accumulation proceeds. When an earthquake nucleates at the deeper region, coseismic slip propagates into this region, which results in larger slip compared to the case where a simple velocity-strengthening friction law is considered.

Ito et al. (2012) detected slow slip events in the Japan subduction zone before the 2011 Tohoku-Oki earthquake. Shallow very low frequency earthquakes off Tohoku were detected by Matsuzawa et al. (2012). In addition, along the shallow plate boundary off Tokachi, sequential activity of very low frequency earthquakes occurs at intervals of several years (Asano et al., 2008). These observations suggest that the transitional friction behavior investigated by Ikari et al. (2013) occurs along the shallow plate boundary off Tohoku.

Friction properties beneath the frontal wedge near the Japan Trench: deduction from topographic variation

KOGE, Hiroaki[1*] ; KODAIRA, Shuichi[2] ; FUJIWARA, Toshiya[2] ; SASAKI, Tomoyuki[3] ; KAMEDA, Jun[7] ; KITAMURA, Yujin[6] ; HAMAHASHI, Mari[1] ; HAMADA, Yohei[4] ; YAMAGUCHI, Asuka[5] ; ASHI, Juichiro[5] ; KIMURA, Gaku[1]

[1]The University of Tokyo, [2]Institute for Research on Earth Evolution Japan Agency for Marine-Earth Science and Technology, [3]Ocean Engineering & Development Corporation, [4]Japan Agency for Marine-Earth Science and Technology, [5]Atomosphere and Ocean Research Institute, The University of Tokyo, [6]Kagoshima University, [7]Hokkaido University

The 2011 Tohoku-oki earthquake (Mw 9.0) produced a fault rupture, extending to the Japan Trench. Deformation and frictional properties beneath the forearc are the keys to elucidate this unusual event.

In this study, to obtain frictional properties (μ_b'; the coefficient of effective basal friction), we extracted shape-related parameters from the cross sections of the frontal wedge which are obtained from surveys across the trench that span sporadically along the axis of the Japan Trench. The following two methods were adopted for this study; Critical Taper Theory (CT) and Critical State Theory (CS). Both of the theories are based μ_b' From the Critical Taper Theory. Near latitude 36.1, the taper angles (slope angle + decollement dip angle) has been developed . A possible seamount subduction may differentiate this area. However, near the latitude 38.15 where the largest slip was reported with the 2011 earthquake, the taper angle has also been large without any seamounts. The calculated [or estimated] value of μ_b' in this area is larger than that of the other area, suggesting that the larger strain energy was accumulated in comparison with the other wedges.

From the Critical State Theory, the value of ω (angle between the basal decollement and backstop interface) becomes smaller toward the north. The results of CS show the increase of the ω associate with the increase of the μ_b', suggesting that strain energy is more stored toward the North.

Both results show that the μ_b' has decreased after the earthquake. The change in μ_b' may be due to the earthquake.

It is possible to know friction properties of before the earthquake and that of after the earthquake with bathymetry.

Long-term crustal movement in the Rikuzentakata area, southern Sanriku coast, based on geomorphological/geological featu

NIWA, Yuichi[1*] ; TODA, Shinji[1]

[1]International Research Institute of Disaster Science, Tohoku University

In the northeast Japan forearc, strain rate estimated based on by geological feature is different from that by geodetic feature. Thus, marine terrace suggests that the Sanriku coast has uplifted at the rate of 1 mm/yr since the late Quaternary. On the other hand, this area has subsided at the maximum rate of 10 mm/yr during the past 100 years based on geodetic data. This disaccord indicates the possibility that the giant mega-thrust earthquake causes the Sanriku coast to uplift. However, the 2011 Tohoku-Oki Earthquake (Mw9.0) was accompanied by subsidence along the Sanriku coast. This fact led us to reexamine long-term crustal movement.

We conducted geomorphological/geological analyses in the Sanriku coast, especially the southern part of the coast, where long-term crustal movement is unknown because of lack of widely distributed Pleistocene marine terrace. In this presentation, we will report preliminary results of consideration of long-term crustal movement in the Rikuzentakata area, southern part of Sanriku coast.

Large-scale simulation of coseismic and postseismic crustal deformation using a high-fidelity finite element model

AGATA, Ryoichiro[1*] ; ICHIMURA, Tsuyoshi[1] ; HIRAHARA, Kazuro[2] ; HYODO, Mamoru[3] ; HORI, Takane[3] ; HORI, Muneo[1]

[1]The University of Tokyo, [2]Kyoto University, [3]Japan Agency for Marine-Earth Science and Technology

Postseismic crustal deformation of a subduction zone earthquake is an essential factor in such studies as interseismic slip deficit rates and stress-field change of the focal area of inland earthquakes. The viscoelastic behavior of the asthenosphere largely affects postseismic crustal deformation. Several studies have used analytical models or three-dimensional (3D) finite element (FE) method to simulate postseismic crustal deformation, considering the viscoelasticity. Yet because of the large computational cost, simulations using a realistic model of crustal structure have not been carried out, despite that detailed crustal data are available. Based on the technique of high performance computing, we performed large-scale finite element simulations using 3D FE models of higher-fidelity (High-fidelity model: HFM) to available crustal data. We used the data of JTOPO30, which was constructed in a 900 m resolution by MIRC (JTOPO30, 2003), for modeling the ground surface and CAMP standard model (Hashimoto et al. 2004) for the interplate boundaries. By using this data, we constructed a one-kilo-meter-resolution HFM with the size of 1700 x 2600 x 400 km, which includes the whole of the Japanese Islands. The model has 30km thick crust and the underlying viscoelastic mantle wedge, where the Philippine Sea and the Pacific plates are subducting beneath the Eurasian and the North American plates. Because the target area was large, we also took into consideration the curvature of the earth. We expect a large degrees-of-freedom in our HFM. Therefore, to compute the time history of the crustal deformation with such a large-scale model, we used the K computer, the fastest supercomputer in Japan.

In the session, we will show the simulation of the 200-year time history of postseismic crustal deformation using the HFM. In addition, by comparing the results of various sizes of temporal and spatial discretization, we will demonstrate that our method can compute the solution with discretization fine enough for numerical convergence.

Keywords: postseismic crustal deformation, high-fidelity finite element model of crustal structure, large-scale simulation

Tsunami simulation in the Western Pacific Ocean and East China Sea from the hypothetical M9 Nankai earthquake models

HARADA, Tomoya[1*] ; SATAKE, Kenji[2] ; FURUMURA, Takashi[1]

[1]CIDIR/ERI, the University of Tokyo, [2]Earthquake Research Institute, the University of Tokyo

We computed tsunamis in the Western Pacific Ocean and East China Sea from the hypothetical models of the giant Nankai earthquake proposed by the Cabinet Office of Japanese government (2012). The maximum tsunami heights on the New Guinea coasts, Philippine Islands coasts, and Shanghai coasts in China are about 1.0-5.0 meters, 1.0-7.0 meters, and 0.5-2.0 meters, respectively. They are up to twice large as those computed from the 1707 Hoei earthquake (the largest earthquake along the Nankai trough in Japanese history). The simulation also shows that tsunami heights on the coasts in this area depend on the slip amounts on the Nankai fault.

Responding to the unexpected occurrence of the 2011 Tohoku earthquake, the Cabinet Office of Japanese government (2012) assumed 11 models of the giant Nanakai earthquake (Mw 9.1), computed tsunami heights along the Japanese coasts, and estimated the human and economic disasters. The tsunami heights exceed 10 m on the coasts of 13 prefectures, with a maximum height of 34.4 m.

Tsunamis from such a gigantic earthquake may impact the coasts in the Western Pacific Ocean and East China Sea. Harada and Satake (2012, AOGS; 2013, "Tsunami Events and Lessons Learned", Springer) performed numerical tsunami simulations in these oceans by using various fault models of the past Tokai and Nankai earthquakes.

In this study, we carried out the same simulations from the 11 fault models of the M9 Nankai earthquake. Tsunami propagations were computed by the finite-difference method for the non-linear long-wave equations with Corioli's force (Satake, 1995) in the area of 115-155 deg. E and 8 deg. S to 40 deg. N using the GEBCO 30-second bathymetry data. Initial tsunami heights computed by the Cabinet Office were used. A Manning's roughness coefficient of 0.025 $m^{-1/3}s$ was assumed for the friction and a computation time step of 1 s is used to satisfy the stability condition of the finite-difference method. We simulated tsunamis for 24 hours after the earthquakes.

We thank the Cabinet Office of Japanese government for providing the hypothetical models of the giant Nankai earthquake.

Stress concentration in the C0002 borehole of the NanTroSEIZE Project, Nankai Trough

WU, Hungyu[1*] ; KINOSHITA, Masataka[1] ; SAITO, Saneatsu[1] ; LIN, Weiren[1] ; SANADA, Yoshinori[1]

[1]Japan Agency for Marine-Earth Science and Technology

Wellbore instability is a major challenge for the engineer evaluating borehole and formation conditions. Instability is especially important to understand in areas with high stress variations, significant structure anisotropy, or pre-existing fracture systems. Borehole (in)stability is influenced by rock strength, structural properties, and near-field principal stresses. During drilling, the borehole conditions also impact borehole integrity. Factors that we can measure in the borehole during with logging while drilling (LWD) to understand these conditions include Mud Weight, mud loss, ROP (Rate of Penetration), RPM (Rotation Per Minute), WOB (Weight on Bit), and TORQ (Power swivel torque value). By observation the resistivity images, we can utilities the significant features under the interactions of effective stresses and formation.

We conducted stress analysis for Site C0002F of the Nankai Trough transect based on riser and riserless drilling data during IODP Expedition 338. Rock strength and basic physical properties, including velocity, density and porosity are obtained from core samples. The borehole shape, determined from LWD resistivity images, indicates that most of drilling occurred in stable environments, however, in a few instances the bottom hole assembly became stuck. We used our stress profile model to evaluate the mud weight required to drill a stable borehole for the measured rock strength and physical properties. Based on our analysis, we constrained the stress magnitude and possible orientation during IODP Expedition 338 by the drilling parameters. The enlargement and collapse in the borehole indicated that mud weight plays the essential role in the drilling.

Preliminary results of lithology examined during IODP Expedition 348 in the accretionary wedge of the Nankai Trough

FUKUCHI, Rina[1*] ; SCHLEICHER, Anja[2] ; MAIA, Ana[3] ; SONG, Chen[4] ; YANG, Kiho[5] ; EXPEDITION 348, Scientists[6]

[1]The University of Tokyo, [2]University of Michigan, [3]Cardiff University, [4]University of Missouri-Columbia, [5]Yonsei University, [6]IODP Expedition 348

International Ocean Discovery Program (IODP) Nankai Trough Seismogenic Zone Experiment (NanTroSEIZE) Expedition 348 took place from 13 September 2013 to 29 January 2014. This expedition was primarily designed to extend riser Hole C0002N to 3600 mbsf (in the event, C0002N sidetrack Hole C0002P was drilled to 3058.5 mbsf). We collected cuttings, core samples, mud gas, and logging data. Here we report the preliminary shipboard lithological results of IODP Expedition 348.

Four lithologic units were identified at Site C0002 based on geological and geochemical characteristics of core and cuttings samples: Unit II (475-512.5 mbsf in Hole C0002M), Unit III (875.5-975.5 mbsf in Hole C0002N), Unit IV (975.5-1665.5 mbsf in Hole C0002N), and Unit V (1665.5-2325.5 mbsf in Hole C0002N, and 1965.5-3058.5 mbsf in Hole C0002P).

Lithologic Unit II is dominated by fine-grained turbiditic deposits. Silty claystone is the main lithology, with subordinate fine-grained sandstone and sandy siltstone. Lithologic Unit III is dominated by silty claystone with trace amounts of very fine loose sand, containing common glauconite grains. Those units are interpreted to be the Kumano forearc basin sediments. Lithologic Unit IV is dominated by silty claystone, with sandstone as a minor lithology. Sandstone cuttings in this unit are generally very weakly consolidated, and occur as disaggregated loose sand. Lithologic Unit IV is divided into five subunits based on sand content and interpreted as the upper accretionary prism sediment. Lithologic Unit V is dominated by silty claystone. Fine-grained and moderately cemented sandstone was a minor component. In Hole C0002P, clay-size content in the silty claystone increases at the depth up to 2625.5 mbsf. The fine silty claystone becomes the dominant lithology from 2625.5 mbsf. This unit is possibly interpreted to be the trench or Shikoku Basin hemipelagic deposits.

Physical properties of Nankai accretionary prism sediments at Site C0002, IODP Expedition 348

KITAMURA, Manami[1*] ; KITAJIMA, Hiroko[2] ; HENRY, Pierre[3] ; VALDEZ, Robert[4] ; JOSH, Matthew[5] ; EXPEDITION 348, Scientists[6]

[1]Hiroshima Univerisity, [2]Geological Survey of Japan National Institute of Advanced Industrial Science and Technology, [3]Aix-Marseille University, [4]Pennsylvania State University, [5]The Commonwealth Scientific and Industrial Research Organization, [6]IODP Expedition 348

Integrated Ocean Drilling Program (IODP) Nankai Trough Seismogenic Zone Experiment (NanTroSEIZE) Expedition 348 focused on deepening the existing riser hole at Site C0002 to ˜3000 meters below seafloor (mbsf) to access the deep interior of the Miocene inner accretionary prism. This unique tectonic environment, which has never before been sampled in situ by ocean drilling, was characterized through riser drilling, logging while drilling (LWD), mud gas monitoring and sampling, and cuttings and core analysis. Shipboard physical properties measurements including moisture and density (MAD), electrical conductivity, P-wave, natural gamma ray, and magnetic susceptibility measurements were performed mainly on cuttings samples from 870.5 to 3058.5 mbsf, but also on core samples from 2163 and 2204 mbsf.

MAD measurements were conducted on seawater-washed cuttings (”bulk cuttings”) in two size fractions of >4 mm and 1-4 mm from 870.5 to 3058.5 mbsf, and hand-picked intact cuttings from the >4 mm size fractions within 1222.5-3058.5 mbsf interval. The bulk cuttings show grain density of 2.68 g/cm3 and 2.72 g/cm3, bulk density of 1.9 g/cm3 to 2.2 g/cm3, and porosity of 50% to 32%. Compared to the values on bulk cuttings, the intact cuttings show almost the same grain density (2.66-2.70 g/cm3), but higher bulk density (2.05-2.41 g/cm3) and lower porosity (37-18%), respectively. The grain density agreement suggests that the measurements on both bulk cuttings and intact cuttings are of good quality, and the differences in porosity and density are real, but the values from the bulk cuttings are affected strongly by artifacts of the drilling process. Thus, the bulk density and porosity data on handpicked cuttings are better representative of formation properties. Combined with the MAD measurements on hand-picked intact cuttings and discrete core samples from previous expeditions, porosity generally decreases from ˜60% to ˜20% from the seafloor to 3000 mbsf at Site C0002.

Electrical conductivity and P-wave velocity on discrete samples, which were prepared from both cuttings and core samples in the depth interval of 1745.5-3058.5 mbsf, range 0.15-0.9 S/m and 1.7-4.5 km/s, respectively. The electrical resistivity (a reciprocal of conductivity) on discrete samples is generally higher than the LWD resistivity data but the overall depth trends are similar. On the other hand, the P-wave velocity on discrete samples is lower than the LWD P-wave velocity between 2200 mbsf and 2600 mbsf, while the P-wave velocity on discrete samples and LWD P-wave velocity are in a closer agreement below 2600 mbsf. The electrical conductivity and P-wave velocity on discrete samples corrected for in-situ pressure and temperature will be presented.

The shipboard physical properties measurements on cuttings are very limited but can be useful with careful treatment and observation.

Effects of frictional heating and comminution on coal maturation

FURUICHI, Hiroyuki[1*] ; UJIIE, Kohtaro[1] ; SAITO, Tsubasa[1] ; SAKAGUCHI, Arito[2] ; TSUTSUMI, Akito[3]

[1]Life and Env., Sci., Univ. Tsukuba, [2]Sci., Yamaguchi Univ., [3]Sci., Kyoto Univ.

The detection of friction heating on faults is crucial to estimate frictional heat during earthquakes. Recently, vitrinite reflectance (Ro) has been used to detect friction heating along faults. However, the factors controlling increase in Ro on faults remain poorly understood. Moreover, the application of the commonly used kinetic model to the estimation of temperature rise during short-lived thermal events such as frictional heating on faults has not been convinced. Here, we conducted friction experiments on a mixture of 95 wt% clay-rich material from the host rock of the megasplay fault gouge and 5 wt% coal grains from the forearc basin in the Nankai subduction zone at slip rates of 0.15 mm/s-1.3 m/s under dry (room humidity) and wet (water-saturated) conditions. After the experiments, we examined microstructures, Ro and size of coal grains and then compared with those obtained from in and around the megasplay fault gouge. The results show that Ro does not increase by rapid heating alone; grain-size reduction due to comminution is required for increase in Ro. The combination of comminution and heating is the most effective for increase in Ro, possibly due to enhanced mechanochemical reaction associated with an increase in surface area of coal grains. The application of the results to the Nankai megasplay fault gouge is that increased Ro in the fault gouge results from frictional heating and comminution, while that in adjacent to the gouge are mainly derived from comminution. The Ro calculated from the chemical kinetic model is higher than that measured after the experiments. Ro is an useful tool to detect past frictional heating on faults, but the estimation of temperature rise from Ro is problematic; the new kinetics model considering the effects of frictional heating and comminution is necessary to estimate amount of frictional heat.

Receiver function analysis using OBS data: modeling 3-D structure of the Philippine Sea plate off the Kii Peninsula

AKUHARA, Takeshi[1*] ; MOCHIZUKI, Kimihiro[1]

[1]Earthquake Research Institute, University of Tokyo

Megathrust earthquakes have repeatedly occurred beneath the southwestern Japan, on the subducting Philippine Sea plate, in cycles of 100-150 years [Ando, 1975]. The rupture boundary of the latest two megathrust earthquakes, the 1944 Tonankai and 1946 Nankai earthquakes, is located at the south of the Kii Peninsula. Although some structural heterogeneity was proposed as factors of the rupture boundary [Mochizuki et al., 1998; Kodaira et al., 2006], the question of why rupture propagation stops there is still open in light of our little knowledge about 3-D geometry of the subducting Philippine Sea plate at offshore region.

In this study, we aim to construct 3-D structure model of the subducting Philippine Sea plate by receiver function (RF) analysis, using data of ocean-bottom seismometers (OBSs) deployed from 2003 to 2007 off the Kii Peninsula [Mochizuki et al., 2010; Akuhara et al., 2013]. These OBSs have three-component velocity sensors with natural frequency of 1 Hz, and their orientations were determined in this study from particle motion of regional P-wave. The difficulty of our RF analysis using OBS data is summarized by the following two factors. The first is that noise is dominant within a low-frequency band (1 <Hz), the most stable band for estimating RFs. The second is that the number of teleseismic events is limited because of short observation periods and low S/N ratio.

To overcome these problems, we calculated RFs with the aid of multi-taper correlation (MTC) method [Park and Levin, 2000]. The method is resistant to spectral leakage and able to estimate frequency-dependent uncertainties for RF, which is suitable for noisy OBS data and for high-frequency analysis. We binned resultant RFs by back azimuths, and computed time-domain uncertainties of the RFs from the frequency-dependent uncertainties estimated by the MTC method, using jackknife resampling within each back azimuth bin [Leahy and Collins, 2009]. This uncertainty estimation makes the following phase identification more reliable, even though the number of teleseismic events is limited.

Our preliminary results show some coherent peaks throughout all back azimuth bins, whose amplitude is larger than one-sigma uncertainties. Some of them have moveout, implying existence of dipping layers, and have arrival times roughly corresponding to the depth of the slab mantle. Although more detailed identification process for these peaks is largely left for our future work, these peaks might be converted phases from the slab mantle.

Three-dimensional velocity model for the Nankai Trough seismogenic zone based on structural studies

NAKANISHI, Ayako[1*] ; TAKAHASHI, Narumi[1] ; YAMAMOTO, Yojiro[1] ; TAKAHASHI, Tsutomu[1] ; OBANA, Koichiro[1] ; KODAIRA, Shuichi[1] ; KANEDA, Yoshiyuki[1]

[1]JAMSTEC

Coseismic rupture area of the great interplate earthquake concerned about its occurrence along the Nankai Trough presumed by government of Japan is now wider to the west, north and south than the former assumption. Although the new estimation is based on seafloor topography, source area of the past largest megathrust event, present seismic activity and so on, structural information has not always been enough reflected yet. In order to estimate precise coseismic rupture area of the Nankai megathrust earthquake, it is necessary to improve a physical model of the Nankai Trough seismogenic zone based on the geometry of the subducting plate and velocity structure model.

Japan Agency for Marine-Earth Science and Technology had conducted the large-scale high-resolution wide-angle and reflection seismic survey and long-term observation from off Kyushu to Tokai between 2008 and 2012. Layered velocity structure models are now obtained along grid two-dimensional seismic profiles from the Hyuga-nada to the Kii channel area. A three-dimensional seismic tomography using active and passive seismic data observed both land and ocean bottom stations had been also performed for the western Nankai Trough.

In this study, we constructed a three-dimensional velocity model of the Nankai Trough with the procedure as follows;

1) Sampling the velocity structural information along each seismic profile with interval of ˜1km in horizontal, and ˜100m in vertical directions

2) Preparing the geometry model of each interface included in layered models, e.g., basement, plate boundary, Moho, etc.

3) Setting minimum and maximum velocities of each layer based on the velocity models along two-dimensional seismic profiles

4) Interpolating sampled velocity information considering layered structure

(Landmark DecisionSpaceDesktop is used for constructing 3-D modeling)

Previously published layered models are also used to make up for insufficient structural information for the eastern Nankai Trough.

Reliability of the three-dimensional model was confirmed by comparing calculated travel-times with observed travel-times along each seismic profile. We will also try to evaluate the reliability of the model by comparing the hypocenter distribution using three-dimensional velocity model obtained in this study with that determined by three-dimensional seismic tomography using active and passive source data. We will plan to revise our 3D model with additional structural information and construct more precise and detailed model for the entire Nankai Trough area so that the model can be applied to more realistic numerical simulation.

This study is part of 'Research concerning Interaction Between the Tokai, Tonankai and Nankai Earthquakes (FY2008-2012)' funded by Ministry of Education, Culture, Sports, Science and Technology, Japan.

[1]JAMSTEC

In the Nankai Trough subduction zone, megathrust earthquakes of M 8 class occur repeatedly. There are three main seismogenic segments (Tokai, Tonankai and Nankai earthquake regions), and these segments have ruptured sometimes simultaneously and sometimes individually. To understand the control factor of the seismic linkage among these segments and Hyuga-nada segments, Japan Agency for Marine-Earth Science and Technology has been carried out a series of wide-angle active source surveys and local seismic observations from 2008 to 2012, as a part of Research concerning Interaction Between the Tokai, Tonankai and Nankai Earthquakes' funded by Ministry of Education, Culture, Sports, Science and Technology, Japan. In this study, we show the results of two local seismic observations off Kii peninsula, the one is in the Kii channel and the other is in the Kumano-nada. The boundary of the Tonankai and Nankai segments is located in this region (Baba and Cummins, 2005), and the existence of the high velocity plutonic rock in the landward plate just beneath Shionomisaki is considered as the control factor of historical rupture variation (Kodaira et al., 2006). Japan Meteorological Agency (JMA) catalogue also indicates the spatial relationship between the seismic activity and seismogenic segments; shallow microseismicity seems to be more active in the Nankai region than in Tonankai region.

The observation in the Kii channel has been performed in FY2010 and was composed of 155 short-tern (about 1.5 months) ocean bottom seismographs (OBSs) and 19 long-term (about 10 months) OBSs. First, we relocated the JMA catalogue earthquakes by using three-dimensional velocity model obtained by active source surveys and adding the first arrival time data at OBSs. As a result, the earthquakes near the trough axis were generally relocated 10-20 km shallower than JMA location. Then, we attempt to detect the earthquakes by using long-term OBS records and found the active intraslab seismicity, especially in the up-dip part of the subducted seamount (Kodaira et al., 2000). The observation in the Kumano-nada has been performed in FY2011 and was composed of 150 short-tern (about 2.5 months) OBSs and 14 long-term (about 8 months) OBSs. Now we perform the first arrival picking of these data with the seismograph data of Dense oceanfloor network system for earthquakes and Tsunamis (DONET), according to the JMA catalogue earthquake list. We will show the preliminary results of hypocenter distribution in the Kumano-nada at the presentation.

Seismic observation and active-source seismic surveys on southern Ryukyu arc

TAKAHASHI, Tsutomu[1*] ; KAIHO, Yuka[1] ; ISHIHARA, Yasushi[1] ; YAMAMOTO, Yojiro[1] ; NAKANISHI, Ayako[1] ; OBANA, Koichiro[1] ; KODAIRA, Shuichi[1] ; KANEDA, Yoshiyuki[1]

[1]JAMSTEC

The Ryukyu arc is an island arc located on southeast of the Eurasian plate. The Philippine Sea plate is subducting northwestward at Ryukyu trench. Many large earthquakes (M7˜8) occurred on this arc, and some of them generated tsunamis. The 1771 Yaeyama earthquake (M7.4) caused a large tsunami of which a maximal height is 30m. For detailed examinations of fault rupture zones and mechanisms of large earthquakes in this arc, it is important to know the seismicity, lithospheric structures and plate geometry. In 2013, Japan Agency for Marine-Earth Science and Technology (JAMSTEC) launched a series of seismic observations and active-source seismic surveys at the Ryukyu arc as a part of research project funded by Ministry of Education, Culture, Sports, Science and Technology, Japan. In FY2013, we conducted refraction and reflection wide-angle seismic surveys and seismic observation on southern Ryukyu arc.

Active source seismic data were acquired on two survey lines. The one is a 480km-long line across the island arc from the south of Ryukyu trench to Okinawa trough. The other is a 100km-long line in Okinawa trough at northwest of Iriomote island. We conducted a refraction survey on the former survey line with 60 ocean bottom seismographs (OBS), and multichannel seismic reflection (MCS) surveys on both lines. Retrieved data shows clear wave trains propagating in the Philippine Sea plate and island arc. Normal faults in Okinawa trough were clearly observed in MCS data.

For seismic observation, we deployed 36 seismic stations including 30 OBSs and 6 onshore stations. All OBSs are equipped with short period geophones. Onshore stations are deployed at Miyako, Tarama, Ishigaki, Iriomote, Kuroshima and Hateruma islands. They are composed of broadband and/or 2Hz seismometers. We also retrieved seismic data from 60 OBSs that was deployed for the active source refraction survey. Observed seismic waves of small earthquakes show path dependences of waveforms that suggest spatial variations of random inhomogeneities and attenuation. For example, OBSs in Okinawa trough did not record clear S-wave for most of earthquakes. However, they observed clear S-wave and long-lasting coda waves for some shallow earthquakes occurred at north of Iriomote and Yonaguni islands. These waveforms suggest strong random inhomogeneities at the shallow part and high apparent attenuation (due to scattering and intrinsic attenuation) at deeper part underneath the Okinawa trough. In this presentation, we outline our observations and notable features of obtained data.

A plate boundary earthquake model with consideration on submarine active faults

NAKATA, Takashi[1*] ; WATANABE, Mitsuhisa[2]

[1]Hiroshima University Professor Emeritus, [2]Toyo University

Active faults observed on seafloor along Japan Trench are resultants of repeated large earthquakes. We discuss on the relation between large earthquakes and their source faults based on a detailed active fault map along Japan Trench. Judging from the location and continuation of active faults in the earthquake source area, we consider that one of the extensive thrust faults which extends from off-Sanriku to off-Ibaraki for about 500km, is directly related to the source fault of the 2011 off the Pacific coast of Tohoku Earthquake.

The 2011 off the Pacific Coast of Tohoku Earthquake (Mw9.0) generated large tsunami with massive pulsating pattern of waves (Maeda et al. 2011). A leading hypothesis believed among many seismologists is that rupture of two extensive asperity patches surrounded by stable sliding area on the plate boundary generated the earthquake. One of the asperity patches in depth caused the strong motion and the other near the surface caused fault rupture along the axis of Japan Trench and generated gigantic tsunami. Large displacement ˜50m eastward and ˜7 to ˜10m upward was estimated from comparison of data obtained before and after the earthquake in 2004 and 2011 by multi-narrow beam bathymetric surveys across the trench (Fujiwara et al. 2011). Satake et al. (2011) explained the large tsunami height by simultaneous faulting on two different fault planes that fit with the above-mentioned asperities. Since most of the workers hypothesized without any doubt believed that the earthquake was caused by the fault ruptured up to the trench axis, existence of submarine active fault is rather overlooked so far. However, we consider the large displacement is due to landslide and do not find any extensive fault scarp on the trench axis.

We simulated pattern of seafloor deformation associated with the earthquake using a simple dislocation model for a single fault plane with uniform slip that dips 14 degree in depth and 33.6 degree beneath the tectonic bulge related to the extensive active fault. A result shows that an area of large uplift agrees more or less with the location of tectonic bulge with width of about 20km.

The record of tsunami first wave obtained by the GPS wave gage set on about 200m deep seafloor off Kamaishi on southern Sanriku Coast (Port and Airport Research Institute, 2011). The record suggests that after gradual sea-level rise of 2m during 6 minutes, acute sea-level rise of 4m took place within 4 minutes, and then sea-level abruptly dropped by 4m within 2 minutes. The length of pulsating tsunami wave is estimated about 17km from tsunami propagation velocity at 200m deep sea and total duration of pulsating pattern of tsunami, i.e. 7 minutes. This tsunami wave pattern resembles the pattern of seafloor deformation we calculated above.

We also simulate crustal movement and tsunami height along the Tohoku coast by an earthquake source fault model based the location of the submarine fault with fault-slip deduced from tectonic scarp height that is regarded as cumulative fault-slip. Our simulation explains the observed co-seismic subsidence and large tsunami height along the coast better than many other simulations based on various inversion models.

Based on these observations, we propose active fault model for plate boundary earthquake that large earthquakes are characteristically caused from submarine active faults in the island arc crust that overlap each other above the plate boundary in the narrow sense.

The last 6000 years record of tsunami events in the Kaniga-ike pond along the Nankai Trough

MATSUOKA, Hiromi[1*]

[1]Kochi Univ.

In order to reveal pre-historic record of Nankai Trough earthquakes, we collected 46 vibrocore samples from the Kaniga-ike pond. Stratigraphical study and radiocarbon dating of these samples revealed that sediment of Kaniga-ike pond recorded 17 tsunami events during the last 6000 years. These 17 events repeated almost constant intervals through 300 years. A 2000 years ago event formed remarkable thick tsunami sequence, and also shows an exclusive event in the past 6000 years.

Estimate of the contact state of microcrack from the elastic wave velocity measurement

TAMAI, Hayata[1*] ; MUTO, Jun[1] ; NAGAHAMA, Hiroyuki[1] ; ISHIKAWA, Masahiro[2]

[1]Depertment of Geology, Graduate School of Science, Tohoku University, [2]Geological institute, Graduate School of Environment and Information Science, Yokohama National Univ

Birch (1960) studied about the relationship between the confining pressure and the elastic wave velocity. It was indicated that the elastic wave velocity increases with the increasing confining pressure because the microcrack is closed at high pressure. The velocity includes the effect of microcracks at low pressure. We must the elastic wave velocity without the effect of microcrack to know the elastic constants of a rock. To do that, it is necessary to know the process of closing microcracks and the contact state of microcrack.

The power-law relation between the elastic wave velocity and confining pressure is expressed with pressure exponent of μ (Kobayashi and Kozumi, 1976). They assume that the microcrack has single contact in this model. It is necessary to take account in multiple contacts because the microcracks of a rock have multiple contacts. We applied the single contact model to multiple contacts model with the previous study (Archard, 1953). The microcrack has the point contact, ball contact and plane contact when μ is 2/3, 3/5 and 1/2 respectively. The microcrack contacts plastically if μ is $<$1/2. We measured the elastic velocity of rocks with gas medium high pressure apparatus to discuss the effect of the confining pressure.

We measure the velocity with the pulse transmission technique. We set the assembly, composed of a sample between two metal jig pasted piezoelectric transducers, in the pressure vessel. The sample height is about 15-40 mm and diameter is 20 mm. The frequency of transmission wave is 2 MHz. We recorded it 10^{-9}s rate. We measured Vp and Vs of the gabbro and granite during pressurization and depressurization to a maximum confining pressure of 200 MPa. The velocity increased drastically with the increase in the confining pressure up to 100 MPa. When confining pressure is lower than about 100 MPa, μ of the gabbro and granite is about 2/3, indicating that the contact state of microcrack is point contact. However, under pressure higher than 100 MPa, μ becomes under 1/2, indicating that all microcracks are closed plastically in the experiment with gas medium high pressure apparatus. So the velocity at pressure higher than 100 MPa does not include the effect of microcracks. Furthermore, we estimated μ of several rocks from previous studies (Birch, 1960, Zimmer et al., 2002). Although μ depends on rock type at low pressure, it converges to values smaller than 1/2 at high pressure. This indicates that all microcracks are completely closed at high pressure and this result conforms to our experiment. If fluid exists in rocks, the value of μ is less than 1/2 even at low pressure. Therefore the microcrack with fluid acts as having plastic contact. We revealed the process of closing microcracks with the increasing confining pressure from the elastic wave velocity measurement.

Frictional properties of the shallow Nankai Trough accretionary sediments

HOSHINO, Koki[1*] ; OOHASHI, Kiyokazu[2] ; KANAGAWA, Kyuichi[2]

[1]Faculty of Science, Chiba University, [2]Graduate School of Science, Chiba University

We have conducted friction experiments on sandstone, tuff, silty mudstone and clayey mudstone samples cored from the shallow Nankai Trough accretionary prism, using a triaxial apparatus recently installed at Chiba University, at a confining pressure of 37 MPa, a pore pressure of 29 MPa, a temperature of 42 degrees C, and an axial displacement rate of 1 micrometer/s. These pressure, pore pressure and temperature correspond to those supposed at the depth of 1 km below seafloor at IODP Site C0002. The results reveal that frictional properties of these samples change systematically according to the content of clay minerals, in particular of smectite. The content of clay minerals is 6.0 wt% in the sandstone sample, 17.2 wt% in the tuff sample, 34.1 wt% in the silty mudstone sample, and 42.0 wt% in the clayey mudstone sample. Except for the sandstone sample in which smectite is absent, smectite is the most abundant clay mineral in all the other samples, occupying 68-76 wt% of total clay minerals.

Steady-state friction coefficient decreases with increasing content of clay minerals, from 0.83 of the sandstone sample, through 0.74 of the tuff sample and 0.34 of the silty mudstone sample, to 0.27 of the clayey mudstone sample. Slip-dependent frictional behavior also changes according to the content of clay minerals; the sandstone sample exhibits slip hardening, while the other samples exhibit slip softening, which becomes more pronounced with increasing amount of clay minerals.

We will also report the velocity dependence of steady-state frictional strength at this condition as well as how frictional properties of these samples change at deeper conditions up to 5 km below seafloor.

Effects of shear displacement and fault zone structure on the frictional be havior of montmorillonite-quartz gouge

KAWAI, Tomoaki[1*] ; TSUTSUMI, Akito[1]

[1]Graduate School of Science,Kyoto University

Recent observation of the low frequency earthquakes in the shallow part of the Nankai subduction zone has demonstrated that faulting there is slow yet seismic; suggesting that frictional velocity dependence along the fault would be negative. However, in a widely accepted model, sediments there is expected to exhibit velocity-strengthening frictional behavior. We have reported that the fault material along the megasplay fault in the Nankai Trough exhibited both velocity-strengthening and velocity-weakening frictional behavior [Tsutsumi et al., 2011]. Fault zone structures may be important to understand why the samples exhibited different velocity dependence. In this study, we have conducted frictional experiments on artificial gouges composed of montmorillonite and quartz mixtures, in order to understand the relationship between the fault zone structures and velocity dependent frictional behavior.

We examined frictional behavior and fault zone structure of the artificial gouge samples composed of montmorillonite/quartz mixtures. All of the experiments were conducted under water-saturated conditions at 1 to 5MPa of normal stress, with shear displacement of 30 mm to 14 m, using a rotary-shear friction testing machine. Velocity step tests were conducted in a range of velocities from 0.003mm/s to 30 mm/s, in order to examine velocity dependent frictional behavior.

Results of these experiments reveal influences of normal stress and displacements on frictional behavior. Velocity weakening behavior was observed for the mixtures of montmorillonite/quartz = 20/80 and 40/60 wt%, respectively, at large displacement. In velocity-weakening samples, montmorillonite becomes to be finer-grained and is well mixed with quartz in the gouge layer after long shear displacements and at high normal stresses. These observation demonstrates that frictional behavior of the montmorillonite/quartz gouge changes with the development of the deformation structures. It is suggested that fault zone structure is one of the important factors of describing the frictional behavior along faults at the Nankai Trough.

Keywords: montmorillonite, frictional experiment, fault zone structure

Friction constitutive properties of shallow subduction zone material as estimated from rotary shear friction experiments

NAKANO, Ryuji[1*] ; NAMIKI, Yuka[1] ; TSUTSUMI, Akito[1]

[1]Graduate School of Science, Kyoto University

In order to understand the dependence of constitutive parameters, a, b, and Dc, on slip velocity, V, we conducted experiments by using a rotary shear high velocity friction apparatus. Samples used in this work were collected from the Nankai accretionary prism, offshore from Kii Peninsula, Japan, at Site C0004 during Integrated Ocean Drilling Program (IODP) Expedition 316 [Expedition 316 Scientists, 2009; Tsutsumi *et al*., 2011], and from the Costa Rica subduction zone, Cocos Ridge, at Site U1381 during IODP Expedition 334 [Expedition 334 Scientists, 2012]. All of the samples from the Nankai accretionary prism are clayey silt, whereas those from Costa Rica can be divided into 2 groups with respect to their composition: one is clayey silt (hereinafter referred to as ”Costa Rica Unit I”), the other is silicic to calcareous ooze (”Costa Rica Unit II”). All experiments were carried out at 5 MPa normal stress and 0.0028-2.8 mm/sec slip velocity under wet condition (0.5 g samples with 0.5-0.9 ml distilled water). Moreover, we created a simulation program, which can estimate the values of constitutive parameters and system stiffness, k, with Levenberg-Marquardt method, supposing the spring-block model.

The results are summarized as the following: (1) a, b and/or Dc increase with slip velocity; (2) the values are the highest at V = 0.028-0.28 mm/sec; (3) the values are the lowest at V = 0.028-0.28 mm/sec. The reason is not clarified yet, but it is remarkable that, despite the composition, the result of the clayey megasplay fault material from the Nankai accretionary prism resembles the result of Costa Rica Unit II. This implies that, as expected, constitutive parameters depend on not only material but also other conditions. Another remarkable point to be noted is that the values of system stiffness of Costa Rica Unit I decrease by a factor of 10 when compared with the measured apparatus stiffness value. This implies that the mechanical property of the material of Costa Rica Unit I may be more flow-dominated than others. This implies that the mechanical property of the material of Costa Rica Unit I may be more flow-dominated than others. Considering that the samples of the Nankai accretionary prism and Costa Rica contain 20-30 wt%, 60-70 wt% clay, respectively, it is possible that total clay content reflects the gouge behaviour.

Physical properties of sediments in reference sites and Frontal prism off Costa Rica: IODP Expedition 344

SAIKI, Ayaka[1*] ; HASHIMOTO, Yoshitaka[1]

[1]Kochi University

Comparing physical properties in reference and frontal prism sites is key to understand dewatering and lithification processes in subduction zone. Furthermore, it can be evidence for identifying the location of decollement and the underthrusting materials into seismogenic depth. In this study, we examined the physical properties of sediments in reference sites and frontal prism site both from on-board data and from laboratory experiments for velocity and porosity measurements with variation of effective pressure. Finally, we converted on-board porosity to fluid pressure using laboratory experimental data for reference sites and frontal prism site.

We focused on reference sites, U1381 and U1414, and frontal prism site, U1412 in the Integrate Ocean Drilling Program Expedition 344 off Costarica. Laboratory experiments for velocity and porosity measurements were conducted with variation of effective pressure. We kept 1MPa of pore pressure and changed confining pressure stepwise to control effective pressure. We calculated in-situ effective pressure using sample depth, bulk density and assumption of hydrostatic pressure of pore pressure. We obtained velocity and porosity data by 5 steps up to the in-situ effective pressure and 5 steps more up to 10 times of the in-situ effective pressure. Porosity change during experiments was calculated using volume change in pore water volume. We assumed on-board porosity under atmospheric pressure condition. 4 samples from sites U1381 and U1414 were measured so far.

Porosity ranges from about 77% to about 53% during experiments. P-wave velocity ranges from about 1.4 to 1.6 km/s. Velocity-porosity relationships from on-board data and from laboratory experiments are comparable nicely and also represents a good agreement with global empirical model. Because both laboratory data and on-board data shows a similar trend in the velocity-porosity relationship except for data from U1381 Unit II, the physical properties of sediment except for sediments from U1381 Unit II is similar in velocity-porosity-effective pressure relationships. Therefore, the porosity-effective pressure can be applied on most of sediments, implying that we can convert the porosity to effective pressure using laboratory results. We estimated fluid pressure from on-board porosity with depth using porosity-effective pressure relationship obtained from laboratory experiments.

For U1381 Unit I, hydrostatic fluid pressure was estimated although the error was large. Because U1381 is located in reference site, the hydrostatic pressure is expected in U1381. On the other hand, for U1414, lower fluid pressure than hydrostatic pressure was estimated in ˜10m intervals in the upper part of Unit II. Hydrostatic pressure was estimated in other interval in U1414. Therefore, fluid pressure was recovered to hydrostatic pressure below the over-consolidated layer. In the over-consolidated layer, porosity decreases quickly with constant grain density, which is comparable with the over-consolidation state. Below the over-consolidated layer, porosity increases with decrease of grain density, although the hydrostatic pressure is estimated. In the interval with increase of porosity, because sediments possibly have different physical property, further laboratory experiments on the sediments are needed. Finally, for U1412, over-consolidated sediments were estimated, which may be due to quick dehydration by frontal accretion.

A structural traverse across the Shimanto belt in western Shikoku, Japan

OOHASHI, Kiyokazu[1*] ; KANAGAWA, Kyuichi[1]

[1]Graduate School of Science, Chiba University

The Cretaceous and Tertiary Shimanto accretionary complex is largely characterized by imbricated thrust slices of trench-fill and ocean-floor sediments, and is thought as an ancient analog of the Nankai accretionary prism. Recent studies on a thermal structure and fault rock analysis for the Shimanto accretionary complex in the central and eastern Shikoku revealed that it has suffered earthquake faulting along the out-of-sequence thrusts associated with tectonic uplift. However, special distributions of thermal and tectonic structures are remaining unclear since those in the western part of Shikoku are poorly understood. In the presentation, we demonstrate the distributions and details of deformed rocks (e.g. melange and brittle faults), geological structure, and vitrinite reflectance across the Shimanto belt in western Shikoku.

Stress estimation of Kure OSTs, Shimanto accretionary complex

KOMETANI, Yusuke[1*]

[1]yamaguchiuniversity

Stress must be concentrated at front of seismogenic fault during rupture propagation. The level of this stress concentration depends on rupture propagation velocity, fault length, thickness of process zone and strength of host rock. However, few quantitative analysis was reported in natural fault due to difficulty of stress estimation. The calcite-twin piezometer, enables stress estimation from elastic rebounded rock, was proposed based on discrete element method simulation and tri-axial rock experiments (Sakaguchi et al., 2011).

The Shimanto accretionary complex is ancient subduction zone and some fossil seismogenic faults were reported.

Among them, pseudotachylyte bearing Kure OSTs cuts Cretaceous Shimotsui, Nonokawa Formation and Kure Melange. This Kure OSTs is composed of echelon formed small faults with thin damaged zone, and burial depth of the host rock is estimated as below 3 km in depth. We obtained three rock samples, applicable for calcite-twin piezometer. The highest value of estimated stress was approximately 420MPa. This is much higher value than the other seismogenic fault in Shimanto accretionary. The Okitsu Fault, formed deeper depth of approximately 4 km, have suffered lower stress of 350 MPa at fault center (Sakaguchi et al., 2011). This indicates that much higher stress was concentrated at shallow Kure OST than deep Okitsu Fault. We propose two models to make high stress at shallow portion. Long crack length from deep to surface causes high stress concentration at shallow portion. Other model causes high stress due to narrower fault zone than the Okitsu Fault. Stress may tend to concentrate at narrower process zone of Kure OSTs than wide process zone of Okitsu Fault.

Paleostress analysis of a subduction zone megasplay fault - An example from the Nobeoka Thrust, Japan

KAWASAKI, Ryoji[1*] ; HAMAHASHI, Mari[1] ; FUKUCHI, Rina[1] ; HASHIMOTO, Yoshitaka[2] ; YAMAGUCHI, Asuka[3] ; KAMEDA, Jun[4] ; HAMADA, Yohei[5] ; KITAMURA, Yujin[6] ; OTSUBO, Makoto[7] ; KIMURA, Gaku[1]

[1]Dept. Earth and Planet. Sci., Univ. Tokyo, [2]Kochi Univ., [3]Atmosph. Ocean Res. Inst., Univ. Tokyo, [4]Hokkaido Univ., [5]Japan Agency for Marine-Earth Science and Technology, [6]Kagoshima Univ., [7]AIST, Geological Survey of Japan, Inst. Geology and Geoinformation

The megasplay faults in subduction zones, branching from plate boundary thrusts, are thought to have a potential to generate earthquakes and accompanying tsunamis. It is therefore important to understand the fault mechanism of megasplay faults for earthquakes and tsunamis occuring in subduction zones. Paleo-splay faults exposed on land often preserve clear deformation features of the seismogenic zone and provide information on the fault mechanisms at depth. One of the important informations that can be obtained from exhumed faults is paleo-stress field. Here we investigated the Nobeoka Thrust, a fossilized megasplay fault in the Shimanto Belt in Kyushu. The hanging wall is Eocene Kitagawa Group, composed of phyllitic shales. The footwall is Eocene to early Oligocene Hyuga Group, composed of foliated cataclasite originated from sandstone-shale melanges. The thrust has been active during the period of 48-40 Ma [Hara and Kimura, 2008]. The hanging- and the footwall have experienced maximum burial temperatures of approximately 320^{o}C and 250^{o}C, respectively [Kondo et al., 2005]. The existence of klippes apart from the Nobeoka Thrust shows that the Nobeoka Thrust is nearly horizontal in regional scale [Murata, 1991, 1995]. Kondo et al. (2005) described two orientations of slickensides from the outcrop, suggesting the existence of flexural gentle fold in kilometer scale. In addition to the previous studies focusing on outcrops, scientific drilling has performed in 2011 penetrated through the Nobeoka Thrust, and core samples and geophysical logging data are obtained. The cores provide important information for investigating geological features under the ground and have an advantage without surface weathering.

In this study, we analyzed paleo-stress from slip vectors on small faults observed in the cores. Small faults are expected to be less-reactivated. The number of small faults is much larger than that of large faults, accordingly, high statistical reliability is expected. Multiple inverse method (MIM; Yamaji, 2000; Otsubo and Yamaji, 2006) was applied to the small faults. K-means clustering (Otsubo et al. , 2006) was applied to stress tensors detected by the MIM for estimating optimal solutions. Preliminary results indicate the presence of solutions with three maximum horizontal stress axes: N85.24^{o}E, N30.07^{o}W and N65.47^{o}E. We examined the formation process of the Nobeoka Thrust based on the results and slickensides on the outcrop. Our results would provide potential insights to the fault evolution of a megasplay fault in subduction zone.

3D micro structural observation of pseudotachylyte

HAMADA, Yohei[1*] ; KIMURA, Gaku[2] ; KAMEDA, Jun[3] ; YAMAGUCHI, Asuka[4] ; HAMAHASHI, Mari[2] ; KITAMURA, Yujin[5] ; FUKUCHI, Rina[2] ; KAWASAKI, Ryoji[2]

[1]Kochi institute for Core Sample Research, JAMSTEC, [2]Department of Earth and Planetary Science, The University of Tokyo, [3]Earth and Planetary System Science Department of Natural History Science, [4]Atomosphere and Ocean Research Institute, The University of Tokyo, [5]Department of Earth and Environmental Sciences,Graduate School of Science and Engineering Kagoshima

Pseudotachylyte, molten fault rock due to dynamic frictional heating, is a strong evidence of seismic fault slip [Sibson 1975]. Recent research reveals pseudotachylytes can be related with dynamic weakening mechanism such as melt lubrication [DiToro et al., 2006]. However, observations of internal structure of pseudotachylyte have been confined to 2D observations with optical-electron microscope. Here we performed X-ray 3D structural observation of natural pseudotachylyte developed close to the Nobeoka thrust which is a major Out of sequence thrust in fossil accretionary prism (Shimanto-belt).

The Nobeoka thrust located in Kyusyu Island, south west Japan, bounding northern and southern Shimanto belt of Cretaceous-Tertiary accretionary complex. The thrust is considered to have been active during 40-48Ma at seismogenic depth of ˜11kmbsf, experienced maximum temperature of which is 320 Cin the hanging wall and 250 C in the footwall. Thus, the Nobeoka thrust is examined that it was major OST in seismogenic zone of accretionary prism (Kondo et al., 2005; Hara and Kimura, 2008; Raimbourg et al., 2009). The pseudotachylyte bearing fault develops in the hanging wall of the Nobeoka thrust with 1 mm of width. Okamoto et al. (2007) reported that carbonate-matrix implosion breccia fill tensile cracks and inner periphery of the fault, interposing pseudotachylyte, based on optical microscopic observation. Though pseudotachylyte cut the implosion breccia, the fault jog consists only of the carbonate-matrix breccia. It may show the fault experienced dynamic pore water pressurizing accompanied by pseudotachylyte generation at its first frictional slip. Therefore, the fault is appropriate to structural investigation of dynamic fault weakening mechanism.

We performed structural observation of this pseudotachylyte with scanning electron-microscope and 3D X-ray microscope. In the electron microscopic observation, we found that fragments of host rock unevenly distributed in the pseudotachylyte. The number of fragments is larger at lower part (footwall-side) than within the center of the pseudotachylyte. We also found open cracks along the fragments arrangement. It is considered to be cooling crack generated due to rapid cooling of molten rock. The 3D x-ray microscopic observation was performed with cylinder sample of 8 mm diameter. The spatial resolution of the x-ray microscope is 1 micro meter, and detailed 3D fault structure was imaged. We focused four planes, A: lower plane of lower fault filling vein, A': lower plane of pseudotachylyte, B: upper plane of upper vein, B': upper plane of pseudotachylyte. The surfaces configurations were extracted and its roughness was evaluated as calculated average roughness, Ra (theta), in each direction. We found that Ra has minimum value in the same direction in each plane, and the lineation strongly develops at the lower planes (A, A').

From the above results, we discussed the faulting process as:

1) Start faulting. strain concentrated in the footwall side and pore pressure was raised at the part.
2) Hydraulic fracturing by high pore pressure, tensile cracks formation and fluid migration.
3) Strength (friction) recovery by draining and formation of pseudotachylyte.

Basement structure beneath the Tokyo metropolitan area as revealed with the MDRS method

HORIKAWA, Haruo[1*] ; ABE, Shintaro[1] ; YAMAGUCHI, Kazuo[1] ; NODA, Katsuya[2] ; ABE, Susumu[2]

[1]AIST/GSJ, [2]JGI

We applied the multi-dip reflection surfaces (MDRS) method to seismic data originally acquired by the Tokyo Metropolitan Government, and successfully revealed the shape of basin floor and geological structure above the basin floor. The resultant seismic image is interpreted as rift geometry with imbricated normal faults. Moreover, the active Tachikawa fault seemingly has a high dip angle.

The Kanto region that includes the Tokyo Metropolitan area is located near the boundary between the northeastern Japan and the southwestern Japan, and has complicated tectonic history. Moreover, the region is covered with thick sediment of Neogene to Quaternary. Seismic profiling has contributed to revealing the structure such as concealed half-graben and tectonic history.

The MDRS method is an improvement on the common reflection surface stacking (CRS) method in that the MDRS method can deal with conflicting dipping events. The CRS method can detect subtle reflection events by stacking the data along a specific reflection surface. However, complex geological structure often yields a seismic wave field that contain events from various surfaces with different geometry, and the CRS method has difficulty in resolving such complicated reflection events. The MDRS method seeks subtle reflected events, repeatedly applying the CRS method with various sets of parameters that govern the character of reflection surfaces, and superimposes the derived seismic images with high values of semblance. Consequently, the MDRS method can provide a clear image of such complex geological structure.

Seismic data reprocessed in this study was acquired in the Tokyo metropolitan area. The seismic survey was conducted in order to clarify the depth of the top of pre-Neogene basement and the sedimentary structure above the basement. data processing with the conventional common mid-point stacking was performed in the original survey, and provided an image with vertical offset of the top of the basement that corresponds to the active Tachikawa fault, but it generated a poor image for the overall shape of the basin floor; we can only recognize that the basin floor is not flat.

On the contrary, the MDRS method successfully generated a clear image of the basin floor and the stratification of sediments just above the basin floor. The sediments are in a wedge shape, and contain reflectors with a fanning and upward shallowing of dips. The wedge-shaped sediments are aligned horizontally. We interpret this structure as rift system with imbricated normal faults. In fact, rift system has been recognized beneath the Kanto region that is believed to be formed during the Miocene associated with opening of the Sea of Japan. Moreover, we have newly found that the top of the basement extends further beneath the Tachikawa fault. This suggests that the Tachikawa fault has high dip angle.

Seismic velocity structure in Ou backbone range by using a dense seismic array

AOYAGI, Yasuhira[1*] ; KIMURA, Haruo[1]

[1]Central Research Institute of Electric Power Industry

Ou backbone range is a strain concentration zone with E-W contraction along NE Japan arc, hence forms one of the most active reverse-faulting zone in Japan. Some destructive earthquakes, such as the 1896 Rikuu earthquake (M7.2) and the 2008 Iwate-Miyagi nariku earthquake (M7.2), have occurred there for this century. Fault rupture of the 1896 Rikuu earthquake which occurred along the eastern margin of the Yokote Basin fault zone did not reach all over the fault zone but limited to its northern part. The purpose of this study is to find some crustal structures which could control a termination of fault rupture. In this presentation, we will discuss a property of seismic velocity structure which might terminate the fault rupture of some historical earthquakes based on seismic tomography using a dense arrayed micro-earthquake observation data.

Seismicity around the Hakone volcano was activated just after the arrival of surface waves caused by the 2011 off the Pacific coast of Tohoku Earthquake. Most of these triggered earthquakes had similar distribution to prior occasional swarm activities. In order to image electrical properties around such seismic events, we carried out audio-frequency magnetotelluric (AMT) measurements at 39 sites in December 2011 (Yoshimura et al., 2012). In this study, we conducted 3D modeling of dense AMT (Yoshimura et al., 2012) and MT (Ogawa et al., 2012) data, to figure out electrical characteristics around the triggered seismicity. In spite of careful treatments for noise reduction, the effects of noise were still seen on the longer parts of the responses ($<$1 Hz) at the several measurement sites. Thus we determined to have use of the frequency range from 320 Hz to 1.02 Hz. The full components the impedance tensors at 51 sites in total were inverted using the code developed by Siripunvaraporn et al. [2005]. The model space consists of 64(x-)$\times$46(y-)$\times$36(z-direction; including 7 air layers) blocks. The minimum horizontal size of blocks was 400m$\times$400m. Significant characteristics of the obtained three-dimensional resistivity model are: (1) the most of the triggered earthquakes, which occurred shallower than a depth of 4km, seem to align along edges or areas just inside the relatively resistive block; (2) surface conductive blocks, in which there were very few earthquakes, were observed beneath not only fumarolic areas but geothermal non-active regions.

Three-dimensional seismic velocity structure around the Neodani fault

NAKAJIMA, Junichi[1*] ; KATO, Aitaro[2] ; IWASAKI, Takaya[2] ; THE JAPANESE UNIVERSITY GROUP OF THE, Joint seismic observations at the are[3]

[1]Graduate School of Sci., Tohoku Univ., [2]ERI, Univ. of Tokyo, [3]The Japanese University Group of the Joint Seismic Observations at the Area of Nobi Earthquake

The joint research project started in 2007 to enhance our knowledge on the deep structure around the Neodani fault, along which the largest crustal earthquake, the Nobi earthquake (M8.0), occurred in 1891. As a part of the project, 73 seismograph stations were installed around the fault, resulting in a dense seismograph network with a spatial separation of ˜10 km.

We performed a travel-time tomography to reveal a detailed 3D velocity structure around the Neodani fault. The tomographic method of Zhao et al. (1992) was applied to arrival-time data of earthquakes (N=3027) that occurred from 2002 to January 2013. The total number of arrival-time data was 248,354 for P waves and 215,034 for S waves. Horizontal grid nodes spaced at intervals of 0.1 degrees were set in the study area and vertical grid nodes were set at intervals of 5?30.

The obtained results show interesting features in terms of heteroegensou structures beneath the source area of the Nobi earthquake.

1. The lower crust beneath the Nobi plain shows low Vp and Vs compared to surrounding areas.
2. A low Vp and Vs area is imaged continuously from the Philippine Sea slab and the mid crust beneath the Nobi earthquake.
3. The lower crust beneath the Neodani fault shows an along-fault variation in seismic velocities, with moderate- to high-velocity crust to the southeast and low-velocity crust to the northwest.

Stress tensor inversion in the Nobi fault area, Central Honshu, Japan

KATSUMATA, Kei[1*] ; KOSUGA, Masahiro[2] ; KATAO, Hiroshi[3] ; YAMADA, Takuji[1] ; KATO, Aitaro[4] ; THE JAPANESE UNIVERSITY GROUP, The joint seismic observations[4]

[1]Inst. Seismo & Volcano, Hokkaido Univ., [2]Earthquake and Volcano Observatory, Graduate School of Science and Technology, Hirosaki University, [3]Research Center for Earthquake Prediction, Disaster Prevention Research Institute, Kyoto University, [4]Earthquake Research Institute, University of Tokyo

A stress tensor inversion method was applied to 702 focal mechanism solutions in the Nobi fault area, Central Honshu, Japan, which are obtained by using HASH (Hardebeck and Shearer, 2002) that is a method using a first motion polarity of P-wave as data. The study area, 35.3-36.1N and 136.0-137.0E, is gridded with 0.1 X 0.1 spacing in the east-west and north-south directions, respectively. The focal mechanisms are divided into three groups according to the depth of hypocenter: 2-7 km, 5-10km, and 8-13km. From each group the focal mechanisms are selected that the epicenters are located within a radius of 15 km centered at each grid. The SATSI is applied to the data at each group of depth, which is a stress tensor inversion method developed by Hardebeck and Michael (2006). The spatial pattern of stress is obtained at each depth: 2-7 km, 5-10km, and 8-13km. We find that (1) the maximum principal stress (σ_1) is oriented east-west direction almost all over the study area, and (2) the σ_1 direction rotates clockwise by some tens degrees around the Nobi fault.

Strain concentration zone recognized from GNSS data in the San-in region

NISHIMURA, Takuya[1*]

[1]Disaster Prevention Research Institute, Kyoto University

Introduction

In the San-in region, southwest Japan, there were many large earthquakes including the 1943 M7.2 Tottori and the 2000 M7.3 Western Tottori prefecture earthquakes in the shallow crust. It is well-known that an active zone of microseismicity exists parallel to the coastline of Sea of Japan. On the other hand, recent geodetic data acquired by the GEONET (GNSS Earth Observation Network) suggest that a rate of contemporary deformation is small in the Chugoku district including the San-in region (e.g., Sagiya *et al.*, 2000). We study a detailed pattern of crustal deformation using the GEONET data to clarify a relation between contemporary deformation and microseismicity.

Method

We used daily coordinates of the GEONET GNSS stations published by the Geospatial Information Authority of Japan (F3 solution). We fit a function of linear, annual, and semi-annual components to time-series of site coordinates relative to site 950462 (Fukue) to estimate secular site velocities. We also estimate strain distribution at grid points (Shen *et al.*, 1996) and in Delaunay triangles using the site velocities.

Result

We identify a concentration zone of deformation corresponding to the active zone of microseismicity in an eastern part of the San-in region during April 2005 and December 2009. Distribution of maximum shear strain rate shows that an eastern inland part of the Chugoku district has the lowest strain rate (10^{-8} yr^{-1}) in the Japanese Islands and that the high strain rate (10^{-7} yr^{-1}) is distributed in a band along the coast of Sea of Japan. High strain rate is also observed in a vicinity of the source area of the 2000 Western Tottori prefecture earthquake, which suggests postseismic deformation of the 2000 earthquake is still continuing.

Velocity profile across the active zone of microseismicity shows a velocity component parallel to the active zone (N80^{o}E) has an offset of 2 mm/yr in and around the active zone. Movements across the offset suggest a right-lateral strike slip, which is consistent with a typical focal mechanism of shallow crustal earthquakes in the zone. The 2011 Tohoku-oki earthquake affects crustal deformation in the San-in region. In a postseismic period from January 2012 to December 2013, the strain rate in the San-in region became twice as large as that before 2011.

The deformation can be roughly explained by a right-lateral block motion across the active zone of microseismicity. The used GNSS network is too sparse to estimate a locking depth of a fault between the blocks. A dense GPS array is necessary for more detailed analysis.

Concluding remarks

Analysis of the GEONET data identifies a strain concentration zone corresponding to the active zone of microseismicity along the coast of Sea of Japan in an eastern part of the San-in region. This zone with a width of ˜10 km accommodates right-lateral strike-slip movement of 2 mm/yr, which is concordant with a focal mechanism of shallow earthquakes. The observed strain rate doubled after the 2011 Tohoku-oki earthquake. More detailed distribution of deformation in the strain concentration zone is important to clarify the deformation mechanism. We need to study with both observation and model calculation.

HV frictional strength of wet Longmenshan fault gouge and its comparison with the temperature anomaly in WFSD drill hole

TOGO, Tetsuhiro[1*] ; SHIMAMOTO, Toshihiko[1] ; MA, Shengli[1] ; YAO, Lu[1]

[1]Institute of Geology, China Earthquake Adiministration

Estimation of frictional strength from temperature anomaly along coseismic fault in a drill hole after a large earthquake has received much attention recently (e.g., J-FAST project in Japan Trench after the Tohoku-oki earthquake. Surface ruptures more than 250 km long formed along existing Yingxiu-Beichuan fault, a major fault in the Longmenshan fault system, during the 2008 Wenchuan earthquake (Mw = 7.9). Drilling was conducted at Hongkou in Dujiangyan city, a western part of the fault, as a part of Wenchuan Earthquake Fault Scientific Drilling (WFSD). Temperature monitoring is an important task in the project, and WFSD-1 hole was drilled within one year after the earthquake (fastest drilled hole after a large earthquake in the world). Drilling revealed a large scale fault zone for the depth range of 580˜760 m, consisting of cataclasites (about 10 m wide), many thin fault gouge zones and fault breccia (Li et al., 2013, Tectonophysics). Temperature anomaly of only 0.15 degrees Centigrade was recognized at a depth of 590 m along a presumed coseismic slip zone (evidence for coseismic slip zone is not so strong though). Mori et al. (2010, AGU) report friction coefficient less than 0.03 from this temperature anomaly. This friction coefficient was even lower than low friction coefficients (typically 0.05˜0.2) at high slip rates, reported in the last two decades.

We have conducted wet gouge experiments on foliated fault gouge containing 25 wt% of water with Teflon sleeve at slip rates to 1.3 m/s and at normal stresses of 1.0˜4.8 MPa, and compared the results with those on dry gouge with room humidity. Sample was collected from the Hongkou outcrop (see Togo et al., 2011a, EQS), only several hundred meters from the WFSD-1 drill site. Wet gouge has peak friction coefficient of 0.1˜0.36 and steady-state friction coefficient of 0.03˜0.14, as compared with 0.65˜0.8 and 0.15˜0.2 for dry gouge (Togo et al., 2011b, EQS). Wet gouge is substantially weaker than dry gouge, but its frictional strength is still somewhat greater than expected from the near absence of temperature anomaly. However, normal stress expected at the depth of temperature anomaly is expected to be more than twice as high as those of our experiments (experiments could not be done at higher normal stresses due to gouge leak). Both peak and steady state friction coefficients of wet gouge tend to decrease by a power low with increasing normal stresses and the extrapolated steady state friction coefficient at the drilling depth reached from 0.028 to 0.022, which results are consistent with the result by Mori et al. (2010). Thus wet gouge has frictional strength fairly close to that expected from the temperature anomaly.

Wet and dry gouges have completely different deformation textures. Deformed dry gouge is characterized by ultrafine-grained slip zones (typically several to a few tens of microns thick) and weakly deformed gouge. Overlapped slip-zone structures are very common in sheared dry gouge. On the other hand, slight grain-size refinement occurs in wet gouge, and the whole wet gouge zone remains only weakly deformed. We consider that the build-up of pore pressure due to compaction induced and/or thermal pressurization separated grains and suppressed grain crushing in wet gouge.

Numerical simulation of shear bands formation in ground due to strike-slip fault

NODA, Toshihiro[1*] ; YAMADA, Shotaro[1] ; ASAOKA, Akira[2] ; SAWADA, Yoshihiro[2] ; KAWAI, Yuta[1]

[1]Nagoya University, [2]Association for the Development of Earthquake Prediction

When a strike-slip fault occurs, flower structures denoting petaloid patterns of shear bands appear inside the ground above the fault, and also the Riedel shear structures showing en-echelon shear bands appear on the surface of the ground. Ueda[1)] conducted model experiments accounting a strike-slip fault and showed evolution process of shear bands inside the model ground using X-ray CT scan system. Also, Sawada and Ueda[2)] numerically simulated evolution of flower structures etc., using a large-deformation analysis where an elasto-perfectly plastic model with the Mohr Coulomb failure criteria was used.

In this study, referring the research work by Sawada and Ueda[2)], evolution of shear bands was numerically investigated by using a soil-water coupled finite deformation analysis code ***GEOASIA***[3)] on which the SYS Cam-clay[4)] was mounted as an elasto-plastic soil model. In the analysis, since the rate-type equation of motion is precisely time-integrated, progressive failure will be analyzed as a nonlinear dynamic problem, and then generation and/or propagation of waves induced by shear bands formation[5)] will also naturally be developed in the analysis. The constitutive model used is capable of describing a wide variety of soils within the same theoretical framework. Here are shown numerical examples in which soil is taken as a non-coupled material with liquid.

First considered was a 3D FE mesh with one element in strike direction of a fault (i.e. y-direction) shown in Fig.1. The right-lateral strike-slip fault was assumed to be located below the three elements at the mid bottom of the ground. As for the boundary conditions, periodic boundary was taken directly above the fault on the x-z planes of the ground, and displacement was applied to the y-direction on the other parts of the x-z planes with a constant rate of 10^{-6}m/s on the opposite side across the fault. Also, x-z and y-z planes were frictionless. In this case, the ground exhibited localization of deformation and the shear bands grow from the bottom in a logarithmic spiral manner (“ flower structures ”). Then, the formation was attributed to plastic swelling behavior of soil element.

Next used were the other 3D meshes with forty elements in the strike direction (Fig.2) so as to investigate evolution of shear bands and effect of homogeneity/initial-imperfection in ground on the evolution. Here, as the boundary conditions, periodic boundary was assumed on the mutually opposite x-z planes and displacement was applied to the nodes located at the bottom with the same rate on the opposite side across the fault, while the same material constants were used. The imperfection was given to some elements directly above the fault by slightly altering a material constant of them. In the imperfection case, flower structures occurred inside the ground, thereafter Riedel shear structures appeared on the surface. The parts of the Riedel shear exhibited more significant upheavals than its surroundings. Furthermore, in the other numerical cases, angle between the Riedel shear and the strike varied with the different material constant.

Spatially inhomogeneous stress field in the source area of the 2011 Fukushima Hamadori earthquake sequence

YOSHIDA, Keisuke[1*] ; HASEGAWA, Akira[1] ; OKADA, Tomomi[1]

[1]Research Center for Prediction of Earthquakes and Volcanic Eruptions, Tohoku University

After the 2011 great Tohoku-Oki earthquake, many earthquakes occurred near Iwaki, Fukushima Prefecture, including Mw6.8 event of April 11. This 2011 Fukushima Hamadori earthquake sequence is characterized by normal faulting, with T-axis oriented in the NW-SE, E-W and NE-SW directions for events in the northern, central and southern parts of the source area, respectively.

In order to understand the cause of such a remarkable spatial variation of focal mechanisms, we investigated the stress field in the source area of this earthquake sequence. First, we relocated hypocenters of events that occurred during the period from 1997 to 2012 by the double-difference location method. Relocated hypocenters show that events near the 3/19 Mw 5.8 earthquake in the southern area, those near the 3/23 Mw 5.7 earthquake in northern area and those near the 4/11 Mw 5.9 earthquake in central area are aligned along planes dipping westwards corresponding to one of nodal planes, respectively.

Then, we estimated the stress field in the source area of the sequence by a stress tensor inversion of focal mechanisms reported by the National Research Institute for Earth Science and Disaster Prevention and Japan Meteorological Agency. Results show that the stress field is very heterogeneous in space with normal fault stress regime after the occurrences of the main-shock of each part of the source area. In the northern, central, southern and east parts of the source area, the minimum principal stress ($\sigma 3$) axes are oriented in the NW-SE, E-W, NE-SW and NNE-SSW directions, respectively. As a whole, $\sigma 3$ axis shows the concentric circle-like distribution. In contrast, before the occurrence of the main-shock of each part, $\sigma 3$ axis is oriented homogeneously in space in the E-W direction.

This observation suggests the possibility that the remarkable heterogeneity in stress field is caused by the static stress change of large earthquakes. We estimated the static stress changes caused by the 2011 Fukushima Hamadori earthquake sequence. A slip model estimated by Hikima (2012) using strong motion waveforms was used for the Mw6.8 earthquake. Furthermore, we made fault models of the 3/19 Mw 5.7, 3/23 Mw 5.8 and 4/12 Mw 5.7 events using hypocenter locations and the scaling relation between moment magnitude, fault length, width and slip amount for estimating their static stress changes.

Spatial distribution of $\sigma 3$ axis direction of the static stress change is approximately the same as that of the observed stress field after the occurrences of the main-shock of each part of the source area. This strongly suggests that $\sigma 3$ axis rotated after the 2011 Fukushima Hamadori sequence and the stress magnitude in the focal area before the sequence was smaller than the static stress change ($<$˜several MPa). We estimated the differential stress magnitude assuming that the difference in the stress tensor before and after the earthquakes is equal to the static stress change associated with the large earthquakes. Estimated magnitude of the differential stress was $<$20 MPa.

To what degree can rocks become weak during deformation?: Fracturing-dissolution-mass transfer-precipitation creep

TAKESHITA, Toru[1*] ; OKAMOTO, Ayumi[1]

[1]Hokkaido University

The megaquake underneath the pacific ocean off the northeast Japan revealed important facts on crustal dynamics of the Japanese island. Among them, a new suggestion on the magnitude of differential stress in the crust is important. After the megaquake, peculiar earthquakes occurred in places, where earthquakes do not frequently occur. A typical example was an earthquake caused by normal faulting near the Iwaki-city, northeast Japan, where the stress field of a weak E-W compression was changed to that of an E-W extension. Based on the facts, Yoshida et al. (2012) estimated that the magnitude of differential stress was on the order of 1 MPa in upper crust. In this presentation, we will discuss the newly arising problems of crustal dynamics in Japanese islands, and also whether or not rocks can be deformed by such low differential stresses (i.e. *c.* 1 MPa), if this estimate of flow stresses is in fact correct.

We have been studying deformation processes and mechanisms in rocks at brittle ductile transition conditions, which seem to control the strength of upper crust, based on microstructural analyses in naturally deformed rocks. Deformation behaviors at the conditions of brittle-ductile conditions can be observed in metamorphic rocks formed at great depths, because these are elevated from ductile to brittle regions across the depth of brittle-ductile transition. For example, pervasive semi-brittle micro-faulting occurred in quartz schist from the Sambagawa metamorphic rocks at brittle ductile transition conditions. Here, although quartz layers were truncated by micro-faults, very-fine grained dynamically recrystallized quartz grains were also formed along them (i.e. micro-shear zone), suggesting components of ductile deformation. Further, very-fine-grained white mica was formed along the micro-faults, suggesting fluid percolation. With increasing deformation, the density of micro-faults increased, accompanied by the widening of micro-shear zones and associated decrease of the volume fraction of undeformed lenses. Perhaps, dissolution-precipitation creep dominated in micro-shear zones, having led to stress concentration in undeformed lenses, which were subsequently fractured. It is inferred that the rocks became softened with the increasing volume fraction of micro-shear zones.

Similarly, broken and displaced quartz detrital grains are observed in meta-sandstones deformed at brittle-ductile conditions from the Kamuikotan metamorphic rocks, northern Japan. Fibrous overgrowth of quartz occurred between the broken and displaced fragments of quartz, which appears as if these grains themselves restore the original shape. On the other hand, embayment occurred toward quartz grain sides at the boundary between quartz and white mica grains, suggesting dominant dissolution of quartz at this type of boundaries. Further, cataclasites formed along the Median Tectonic Line at the conditions of brittle-ductile conditions in the Cretaceous, and new minerals precipitated from fluids in the space created by fracturing and displacement of protolith forming minerals. The fracturing is accompanied by element migration via fluids, thus the degree increases with increasing degree of fracturing. In conclusion, deformation occurred by dissolution-mass transfer-precipitation assisted by fracturing under the conditions of brittle-ductile transition, by which significant weakening can be generated in rocks.

Detecting the stress condition at a fault from focal mechanism: application to the 2013 Awaji Island earthquake (M6.3)

MATSUMOTO, Satoshi[1*] ; KATAO, Hiroshi[2] ; IIO, Yoshihisa[2]

[1]Institute of Seismology and Volcanology, Kyushu Univ., [2]Disaster Prevention Research Institute, Kyoto Univ.

One of the approaches used to evaluate potential of an earthquake occurrence is the detection of stress concentration at an earthquake fault. Stress fields in stages for pre- and post-seismic event will be different from one another. However, this change cannot provide information regarding the potential for an earthquake to occur. Here, we propose a detection method for stress conditions that uses focal mechanism data. The condition can be defined both by background stress and by a moment tensor equivalent to the stress concentration. We apply this method to actual focal mechanism data from the Awaji Island earthquake (M6.3), Japan, and show the presence of stress concentration around the earthquake fault before the mainshock. In addition, the regional shear stress is shown to be ∼25 MPa in the area, implying that the stress level is still high, thus the potential for further seismicity in the area could be high.

A friction to flow constitutive law and its application to a two-dimensional modeling of earthquake cycles

SHIMAMOTO, Toshihiko[1*] ; NODA, Hiroyuki[2]

[1]Institute of Geology, China Earthquake Administration, [2]JAMSTEC

Establishment of a constitutive law from friction to high-temperature plastic flow has long been a task for solving problems such as modeling earthquakes and plate interactions. A linear combination of friction and flow laws disagrees with experimental data. Here we propose an empirical constitutive law that describes this transitional behavior with good agreements with experimental data on halite shear zones. A complete spectrum of properties including steady-state and transient behaviors can be predicted if friction and flow parameters are known. We show numerical models of seismic cycles of a fault across the lithosphere as an application. Our friction-to-flow law merges brittle-plastic Christmas-tree strength profiles of the lithosphere and rate-dependency fault models used for earthquake modeling on a unified basis. Conventionally strength profiles were drawn assuming a strain rate for the flow regime, but we emphasize that stress distribution evolves reflecting the fault behavior. Previous fault models are revised based on our earthquake modeling. Seismic fault motion is followed by fault creep in the transitional regime and this explains pseudotachylytes overprinted by mylonitic deformation, reported at various places in the world.

A consideration about computation of tectonic stress field for inland thrust earthquake

MIYATAKE, Takashi[1]*

[1]ERI, The Univ. of Tokyo

In the case of pure thrust earthquake, the driving stress system is expected to have been as shown in Fig.1a. The stress in this figure is tectonic stress; thus, the lithostatic pressure σ_V(=ρgh) must be added. The tectonic system (Fig. 1a) can be decomposed into two systems (Fig. 1b): A and B. The functional forms of σ_X and σ_Y are unknown. The assumption that that σ_X is uniform in system A causes almost uniform shear and normal stresses on the fault. Strength (peak stress) and dynamic friction can be estimated when σ_V (=ρgz) is added to the fault normal stress and the resultant normal stress is multiplied by static and dynamic frictional coefficients. Under these conditions, we found a large stress drop in the shallower parts and minimum strength excess at the free surface. This suggests that the earthquake rupture must have started at the surface and that the stress drop must have been the highest at the ground surface. These results can be avoided if the stress σ_X is assumed to increase with depth. The depth dependency is related to variations in elastic constants. The stress field in this region likely originated primarily from plate motions. Therefore, we selected the displacement boundary condition $u_X=u_0$, which correspondings to system A' in Fig. 1c. It should be noted that other displacement components were not fixed, but free stress conditions (except the σ_{xx} component) were imposed according. After solving the stress field imposing the above boundary condition, the resultant stress component σ_{xx} was added on the boundary of $x=\pm L_X$ as a further boundary condition. The solution is the same as the problem in which the boundary condition is imposed. Taking the linear elasticity into account, the target solution can be estimated by superposing solutions A and B in Fig. 1b. System A is equivalent to system A'. The effect of system B on fault normal and shear stress is expected to be negligible, because these stresses are exactly zero for a uniform structure. We estimated such effects in a heterogeneous structure by assuming that the value of σ_Y=σ_{yy} (z) on the boundary of $y=\pm L_y$ is the same as σ_{xx} (z) on the boundary of $x=\pm\pm L_x$. We found system B to exert little effect (less than 5%) on the stress components of σ_{zx}, σ_{xx}, and σ_{zz}. Thus, B had little effect on fault normal and shear stress on the fault plane, where σ_{xx} (z) is the averaged stress component along the y-axis on the corresponding boundaries. Based on the condition of thrust earthquake that $||\sigma_X|>|\sigma_Y|>|\sigma_Z|$(Fig. 1a), the above mentioned σ_{zx}, σ_{xx}, and σ_{zz} were overestimated in our study. Thus, we can ignore the effects of system B.

Aftershock activity of the 2008 Iwate-Miyagi inland earthquake suppressed by stress shadow of the 2011 Tohoku earthquake

SUZUKI, Yuhei[1*] ; TODA, Shinji[2] ; YOSHIDA, Keisuke[1] ; OKADA, Tomomi[3]

[1]Department of Geophysics, Graduate school of Science, Tohoku university, [2]International Research Institute for Disaster Science, Tohoku university, [3]Research Center for Prediction of Earthquakes and Volcanic Eruptions, Tohoku university

The 2011 Tohoku-oki M9 earthquake has increased seismicity rates in many areas in eastern Japan. Several papers already sought the triggering mechanism to static stress change (Toda et al., GRL, 2011), dynamic stress change (Miyazawa et al., GRL, 2011) and pore fluid pressure change (Terakawa et al., EPSL, 2013). In contrast, areas where seismicity rate evidently dropped are restricted to the vicinity of the 2011 rupture zone (Kato & Igarashi, GRL, 2012), the 2004 Chuetsu aftershock zone (Hirose & Toda, SSJ fall meeting, 2011) and the 2008 Iwate-Miyagi inland earthquake aftershock zone (Suzuki & Toda, AGU fall meeting, 2013). Suzuki and Toda (2013) claim that the cause of seismic quiescence is Coulomb failure stress (CFF) decrease due to the 2011 event. However, a small quantity of focal mechanisms prevents them to confirm the mechanism.

In this study, we determine 4106 newly focal mechanisms in the area and develop a model to explain spatio-temporal seismic evolution. To estimate the focal mechanisms, we employ the method of Hardeback & Shearer (BSSA, 2002) using first motion of P-wave, provided by the campaign data by the Group for the Aftershock Observations of the 2008 Iwate-Miyagi inland Earthquake and Japan Nuclear Energy Safety Organization (JNES) in addition to the stationary data from Hi-net and F-net by NIED. Besides, we use F-net moment tensor solutions (VR?80%) and JMA focal mechanisms together with our estimates. Most of the focal mechanisms are strike-slip or thrust fault type and the distribution of ratio of strike-slip type to thrust type is spatially heterogeneous. We find several distinctive seismic clusters from all the distribution. Seismicity in two clusters in southern rupture zone of the 2008 event has been clearly decreased by the 2011 event. We calculate △CFF on all nodal planes as a proxy for background faults using a Tohoku-oki coseismic slip model given by Iinuma et al. (JGR, 2012) in an elastic half-space of Okada (BSSA, 1992). Apparent friction coefficient, μ' , is assumed to be 0.0, 0.4 or 0.8. In the case of μ' =0.0, 80% of △CFF resolved on all nodal planes are negative and over 50% △CFF are negative in the case of μ' =0.8. In the distinctive clusters mentioned above, ratios of the negative △CFF far exceed above overall average.

Seismic response to △CFF is formulated by Dieterich (JGR, 1994) based on the rate-and state-dependent friction law. The physics-based model can reproduce the empirical Omori's aftershock decay after a stress step controlled by several parameters. In this study, we estimate reference seismic rate from an average number of earthquakes from 2000 to the 2008 mainshock, △CFF associated with the 2008 mainshock, stressing rate, product of constitutive parameter and normal stress on a fault plane ($A\sigma$) estimated from the aftershocks occurred until the Tohoku-oki earthquake. Using these parameters, we calculate seismic time series from all the calculated △CFF by the Tohoku-oki earthquake, and then compare the observation with the average of all time-series curves. As a result, the models increase seismicity rate at the Tohoku-oki earthquake, which is inconsistent with the observation. We seek that reasons for mismatch between our model and observation to (i) the paucity of aftershock hypocenter data because of detectability decrease immediately after the Tohoku-oki earthquake, (ii) change in stressing rate due to the post-seismic deformation of the Tohoku-oki earthquake, (iii) reduction of friction coefficient due to fluid injection and/or pore pressure change on fault planes.

Acknowledgments. We are grateful to JMA and NIED for hypocenter list and fault plane solutions. We also thank the regional campaign data given by the Group for the Aftershock Observations of the 2008 Iwate-Miyagi inland Earthquake and JNES.

Improvement of gas medium triaxial apparatus derived from thermal fluid analysis

SAOMOTO, Hidetaka[1*] ; SHIGEMATSU, Norio[1]

[1]Active Fault and Earthquake Research Center, AIST

A huge amount of effort has used to be required for trial productions during the development of experimental apparatus. Since such trial productions generally consume vast time period and cost, the reduction of them is now a significant issue. Numerical modeling such as the finite element simulation (FE) is widely used to reduce them in various engineering fields.

Gas medium triaxial apparatus is widely used to determine the mechanical properties of rocks precisely at higher temperature. However, there has been a limitation for the use at the higher temperature in Japan due to the thermal design. In this presentation we plan to improve the gas-medium triaxial appratus derived from thermal fluid analysis based on the finite element simulation.

Here, the governing equations for thermal fluid analysis consist of the heat conduction equation, the Navier-Stokes equation and the equation of state. By solving those equations simultaneously, we obtain important physical quantities such as temperature distribution, fluid velocity field, delay of heating, etc. The knowledge derived from the computer simulations are: (1) The argon gas flow hardly has any relation with the temperature distribution on solid materials. (2) The temperatures of adiabatic materials placed near the heat sources are below the maximum operating temperature. (3)A large thermal gradient is observed close to the plastic O-ring.

Based on above results, we have attained valuable improvement policies such as replacement of meterials, improvement of radiation factor on the copper jig, etc.

The crustal structure beneath northern Mino region, central Japan revealed by seismic reflection survey

EMOTO, Tomoko[1*] ; TSUMURA, Noriko[1] ; FUJIWARA, Akira[2] ; ABE, Susumu[2] ; KOJIMA, Satoru[3] ; KANO, Ken-ichi[4] ; OMURA, Kentaro[5] ; TAKEDA, Tetsuya[5] ; ASANO, Youichi[5] ; OBARA, Kazushige[6] ; ITO, Tanio[7]

[1]Chiba University, [2]JGI, Inc., [3]Gifu University, [4]Shizuoka University, [5]NIED, [6]ERI, The University of Tokyo, [7]Teikyo-Heisei University

The Nobi earthquake, the largest inland earthquake in Japan, occurred in 1891 in northern Mino district, central Japan. In that region, most active faults run nearly parallel to the NW-SE trending hinge of megakink structure of the Mino belt (Kano et al., 1990). It is remarkable that the upper surface of the subducting Philippine Sea Plate (PSP) also shows a NW-SE trending broad anticlinal form whose axial zone is deeply situated almost below the hinge of the magakink. However we don't have sufficient information about seismic structure of whole crust and the uppermost mantle beneath this region to discuss influence of subducting plate on surface deformation.

To elucidate the seismic structure, a seismic reflection survey was carried out in October in 2009 (Komada et al.,2010). The survey line intersected at high angle with Neodani faults zone. We applied the seismic reflection method to the shot records of this survey and got seismic profiles of whole crust and the uppermost mantle.

We found reflectors having 2 s duration around 10 s two way travel time (TWT) in the seismic profiles. These waves occurred at TWT 9 - 11 s in the southwestern part of the study area, and at TWT 10 - 12 sec in the northeastern part. Applying depth conversion, the reflectors are located in the depth of 28 - 37km in the southwestern part, and of 32 - 39km in the northeastern part. We can clearly see that the depth of the reflection waves in the southwestern side of the Neodani fault zone are shallower than that in the northeastern side. Further the depth varies just beneath the Neodani fault zone. These feature correspond with the result of velocity analysis in the study area (Emoto et al., 2012).

Those reflection waves are interpreted as a lower crustal lamination by comparing with the result of previous seismic profiles. The geometry of laminated lower crust is consistent with the trend of the displacement on Nodani Fault Zone of Nobi earthquake. The fact might show that the difference of the reflectors depths between the southwestern and the northeastern side is caused by fault displacement and it might reach the whole crust. In southwestern part of study area, the depth of top boundary of the Philippine Sea plate (PSP) was estimated from travel time tomography in the previous studies. Its depth is equivalent in the lower limit of the lower crustal lamination. Then it might show that the crust of the land plate contacts on the subducting PHP beneath the northern Mino district.

Temporary observation of micro earthquakes in the northern Ibaraki prefecture by using commercially-supplied IC recorder

SAITO, Keisuke[1*]

[1]KEISUKE SAITO, [2]KEI KATSUMATA

In case of estimate focal mechanism solutions by using P-wave first-motion polarity data, a dense seismic observation network is required. In this study we propose a new seismic observation system to record a P-wave first-motion polarity. The system consists of a seismometer with a vertical component that price is approximately ten thousand yen and a commercially-supplied IC recorder that price is approximately ten thousand yen. According to the specification of the IC recorder, the recordable frequency band is from 60 to 3400 Hz. We compare frequency characteristic of waveforms recorded in stations of National Research Institute for Earth Science and disaster Prevention (NIED Hi-net) and those recorded by using IC recorder. As a result we find that the IC recorder is able to record seismic waves that frequency band is from about 20 to 3400 Hz.

In this study, we conducted a temporary observation of micro-earthquakes for one month from August to September 2012 in the northern Ibaraki prefecture where many normal-faulting type events occur, and we addressed the effectiveness of the seismic observation system. The 29 seismic stations were deployed along a road so that it allows a deployment of many stations for a short time. After collecting the temporary stations, based on the P-wave first motion polarity, we estimated the focal-mechanisms by using HASH program (Hardebeck and Shearer, 2002). As a result, we obtain the 87 focal-mechanisms for micro-earthquakes occurred in the study area.

To test the accuracy of the focal mechanisms obtained in this study, we compared those with focal-mechanisms determined by Earthquake Research Institute, The University of Tokyo (ERI) temporary stations. We compared focal-mechanisms determined by ERI and Hi-net stations and focal-mechanisms determined by using IC recorder and Hi-net stations. We compare P axis and T axis for focal-mechanisms determined by ERI and Hi-net stations and determined by using IC recorder and Hi-net stations. As a result, nothing is difference of accuracy about focal-mechanisms between determined by ERI and Hi-net stations and determined by using IC recorder and Hi-net stations, because of P axis T axis has almost same distribution on the focal sphere. We conclude that focal mechanisms determined by using IC recorder stations has almost same accuracy as those determined by a traditional three component seismometer.

Modeling the viscoelastic deformation of the NE Japan arc after the 2011 Tohoku-oki earthquake

SHIBAZAKI, Bunichiro[1*] ; NAKAI, Yoshihiko[1] ; MUTO, Jun[2] ; IINUMA, Takeshi[3]

[1]International Institute of Seismology and Earthquake Engineering, Building Research Institute, [2]Department of Earth Sciences, Tohoku University, [3]International Research Institute of Disaster Science, Tohoku University

The rheological structure of the Northeastern Japan arc crust and the upper mantle is heterogeneous along and transverse to the arc. Shibazaki et al. (2014) developed a model of the stress state of the Northeastern Japan island-arc crust using a finite element method with viscoelasticity and elastoplasticity. They reproduced several elongated low-stress regions transverse to the arc with viscous deformation that corresponds to hot fingers (high-temperature regions in the mantle wedge). The viscous relaxation process after the 2011 Tohoku-oki earthquake could be affected by the existence of low-viscosity regions caused by hot fingers. A three-dimensional (3D) finite element model was developed to investigate the viscoelastic deformation processes with heterogeneous viscosity distribution after the 2011 Tohoku-oki earthquake. The model considers the realistic crustal and mantle structures, viscoelasticity (Maxwell or Burgurs rheology), and coseismic fault slip distribution obtained by Iinuma et al. (2012). For simplicity, only the elastic crust and viscoelastic mantle structure were considered. The westward movement near the trench and eastward movement in the inland region due to viscoelastic relaxation were reproduced, which are consistent with the observations. We also consider the local low viscosity region in the Northeastern Japan arc crust. In this case, extensional viscous strain concentrates on this region. We report the numerical results that take into account the realistic 3D heterogeneous viscosity distribution in the crust and the upper mantle beneath the Northeastern Japan island arc.

[1]TRIES, [2]Ritsumeikan Univ., [3]Kagoshima Univ.

The 2011 Tohoku earthquake was a huge earthquake. We can understand again its magnitude by large dynamic-strain observations. In general, fresh rock rupture will relieve 10^{-4} strains at the source. On the other hand the 3.11 had unleashed more than 10^{-5} dynamic strains to almost all of Japan. After these strain state changes, it activated seismic swarm events of Japan. On the other hand, more than 10^{-7} dynamic strains had been also observed at the South Africa Republics distant from 14,000 km epicenter. Ritsumeikan university takes initiative of the projects 'Grant-in-aid : Multidisciplinary monitoring of preparation and generation of earthquakes at M2 sources in South African gold mines' and 'SATREPS: Observational Studies in South African Mines to Mitigate Seismic Risks'. In the project, we can come, we can see, we can observe at proximity micro-seismicity and/or strain field at 1-3 km depths of gold mine.

In this study, we analyzed dynamic strain records of 'Cooke4' mine, which caused by the 2011 Tohoku earthquake. Although static strain changes may be disturbed by mining activity, dynamic strain variations such as teleseismic waves and surface waves have been recorded clearly. We have estimated the strain field variations vicinity of zebra fault from two strain meter combination, and we obtained the result that dilatational strain in the fault and shear strain of both size of fault have changed by passing through the seismic waves. In presentation, we will discuss inactive fault vibration caused by teleseismic waves.

Relationship between ESR signal intensity and grain size distribution in shear zones within the Atotsugawa fault system

FANTONG, Emilia bi[1*] ; TAKEUCHI, Akira[1] ; KAMISHIMA, Toshio[1] ; DOKE, Ryosuke[2]

[1]Graduate School of Science and Engineering, University of Toyama, 3190 Gofuku, Toyama 930-8555., [2]Hot Spring Research Institute of Kanagawa Prefecture, 568 Iriuda, Odawara, Kanagawa 250-0031, Japan

Shear zones are zones of strong deformation within active faults and constitute significant sources of information on the seismogenic behavior of faults. The Atotsugawa fault system, which is in the Northern margin of the Hida Highland lies within a complex tectonic zone consisting of the Pacific plate, the Philippine Sea plate, the Amurian plate and the Okhotsk plate. This system consists of the Ushikubi fault, the Atotsugawa fault and the Mozumi-Sukenobe fault. The study of deformational fabrics and features within these shear zones can give more clarification on geodynamics of faults. Moreover, seismogenic behavior of a fault depends greatly on fault zone internal structure and fault rock constitutive properties. Although there are many studies on shear zone descriptions and deformational mechanisms, only few relate the description of cataclastic rocks (fault gouge) with Electron spin resonance (ESR) signals, which is based on the detection of paramagnetic defects in minerals produced by natural radiation that have accumulated for a long time and produces a characteristic signal detectable with an ESR spectrometer. By measuring the intensity of these trapped electrons, the rate of comminution and displacement of a fault can be clarified or envisaged. This study therefore focuses on the relationship between grain size distribution (sieve method) and ESR analysis, and rate of deformation with proximity to a slip plane.

Three shear zones from both the Atotsugawa and the Ushikubi fault were investigated. Sieve analysis and photomicrographs from thin sections revealed that grain size becomes coarser away from the slip plane (e.g. Fig.1a and Fig.2) indicating that the effect of displacement is more close to the slip plane. However, an irregular pattern in the grain size distribution was equally observed in some of the shear zones. This could be due to multiple phases of deformation. ESR analysis showed a decreasing trend in the intensity of signals toward the fault plane (Fig. 1b and Fig. 2) indicating that the rate of comminution was more intense towards the slip plane. However, the decreasing trend in ESR signal intensity with proximity to the slip plane was not observed in some of the shear zones probably due to multiple phase of deformation as indicated by the anatomizing faults in the shear zone II of the Ushikubi fault.

Results from ESR analysis suggest that samples closest to a slip plane will have low signal intensity than those further away while grain size distribution analyses indicates that samples closest to a slip plane become finer due to intensive crushing that is always associated with large displacement during fault activities.

Keywords: Active fault, Shear zones, ESR signal intensity, Grain size distribution, Atotsugawa fault system

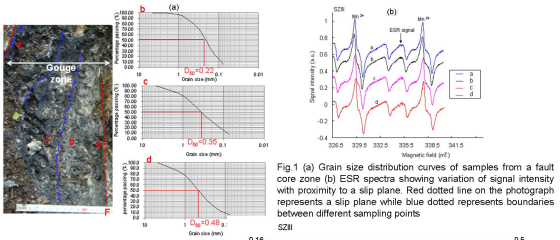

Fig.1 (a) Grain size distribution curves of samples from a fault core zone (b) ESR spectra showing variation of signal intensity with proximity to a slip plane. Red dotted line on the photograph represents a slip plane while blue dotted represents boundaries between different sampling points

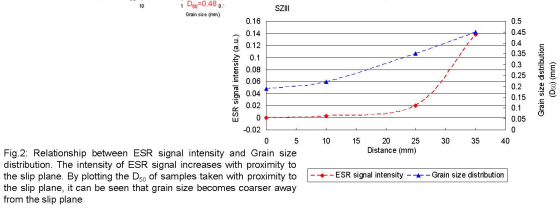

Fig.2: Relationship between ESR signal intensity and Grain size distribution. The intensity of ESR signal increases with proximity to the slip plane. By plotting the D_{50} of samples taken with proximity to the slip plane, it can be seen that grain size becomes coarser away from the slip plane

Physico-chemo-mechanical processes in a slip zone during the 1999 Taiwan Chi-Chi earthquake

HIRONO, Tetsuro[1*] ; KAMEDA, Jun[2] ; KANDA, Hiroki[1] ; TANIKAWA, Wataru[3] ; ISHIKAWA, Tsuyoshi[3]

To investigate the physicochemical processes of minerals during and after slip of the 1999 Taiwan Chi-Chi earthquake, we analyzed the mineral assemblages in the Chelungpu fault by using quantitative X-ray diffraction together with scanning and transmission electron microscope observations. In the primary slip zone, we found markedly low contents of quartz and clay minerals and large amounts of amorphous particles ranging in size from submicrometer to several tens of nanometers. Milling and heating experiments with host-rock samples indicated that these mineralogical changes are due to comminution and frictional heat during slip. Moreover, the changes may affect slip behavior through a mechanism such as thermal pressurization assisted by clay-mineral dehydration. In addition, preservation of a high amount of amorphous fine particles can potentially be used to identify the slip zone of the latest earthquake on not only the Chelungpu fault but also on other faults.

Characterization of carbonaceous materials in the Taiwan Chelungpu fault by micro FTIR-Raman spectroscopies

MAEKAWA, Yuka[1] ; HIRONO, Tetsuro[1*] ; YABUTA, Hikaru[1]

[1]Department of Earth and Space Science, Graduate School of Science, Osaka University

Coseismic slip during an earthquake induces frictional heating in fault zone. Determination of the temperature recorded in the fault is important for estimating the dynamic shear stress and displacement during the earthquake. Here we performed micro FTIR-Raman spectroscopic analyses of carbonaceous materials from the Taiwan Chelungpu fault, which slipped at the 1999 Chi-Chi earthquake. We also conducted heating experiments and friction experiments and analyzed by FTIR-Raman spectroscopies in order to investigate the effects of fast heating rate like frictional heating during earthquake. Based on the results of analyses, we discuss the capability as new temperature proxy during the earthquake.

Frictional properties of ground dolerite gouges at low to high slip velocities

WADA, Jun-ichi[1] ; KITAJIMA, Hiroko[2] ; TAKAHASHI, Miki[2] ; OOHASHI, Kiyokazu[1] ; INOUE, Atsuyuki[1] ; KANAGAWA, Kyuichi[1*]

[1]Graduate School of Science, Chiba University, [2]Active Fault and Earthquake Research Center, Geological Survey of Japan

We investigated how frictional properties of ground dolerite gouges change according to grinding time. We have ground crushed and sieved grains (smaller than 500 microns) of dolerite using an automated agate mill for 10 minutes, and 6, 12, 24, 36, 48 and 60 hours. Quantitative XRD analyses indicate that amorphous phase is absent in the gouge ground for 10 minutes, but its amount increases up to 40 wt% with grinding time. Gouges ground for more than 6 hours contain abundant spherical grains composed of amorphous nano-particles. Such spherical grains are likely formed by accretion of amorphous nano-particles through their electrostatic attraction and moisture-induced binding, as accretionary lapilli. In fact, thermogravimetric analyses reveal that the amount of water adsorbed increases up to 14 wt% with grinding time in accordance with the amount of amorphous phase.

We have then conducted friction experiments on the ground dolerite gouges using a rotary shear apparatus at room temperature, a normal stress of 2 MPa, and constant slip velocities ranging from 20 micrometers/s to 1.3 m/s. At slip velocities slower than or equal to 1.3 cm/s, temperatures of gouges were lower than 70 degrees C, and steady-state friction coefficients range from 0.59 to 0.75, which tend to be higher for gouges with longer periods of grinding time at the same slip velocity. At the slip velocity of 4 cm/s, temperatures of gouges were over 100 degrees C, and steady-state friction coefficients range from 0.60 to 0.66, the difference of which among gouges with different periods of grinding time was relatively small. At slip velocities faster than or equal to 13 cm/s, however, temperatures of gouges reached higher than 180 degrees C, and steady-state friction coefficients dramatically decreased with increasing slip velocity. In addition, steady-state friction coefficients at the same slip velocity tend to be lower for gouges with longer periods of grinding time.

Such frictional properties of ground dolerite gouges depending on grinding time can be explained by the amount of water adsorbed in amorphous gouge. At slip velocities slower than or equal to 1.3 cm/s, temperatures of gouges were lower than 100 degrees C so that water adsorbed in amorphous gouge was retained. Thus, gouges ground for longer periods of time with larger amounts of adsorbed water likely became stronger in steady-state friction due to capillary bridging between amorphous gouge particles. At the slip velocity of 4 cm/s, temperatures of gouges became higher than 100 degrees C so that dehydration occurred from the amorphous gouge, which resulted in a small difference in steady-state friction among gouges with different periods of grinding time. At slip velocities faster than or equal to 13 cm/s, the moisture production rate from the dehydrated amorphous gouge was likely faster than its leak rate, which resulted in an increase in pore pressure in the gouge layer and hence a decrease in frictional strength. Thus, gouges ground for longer periods of time with larger amounts of adsorbed water became weaker in steady-state friction due to larger increases in pore pressure.

Modelling of the postseismic deformation of the 2011 Tohoku Earthquake based on land and seafloor geodetic observations

IINUMA, Takeshi[1*] ; HINO, Ryota[1] ; KIDO, Motoyuki[1] ; SUN, Tianhaozhe[2] ; WANG, Kelin[3] ; OHTA, Yusaku[4] ; OSADA, Yukihito[1] ; FUJIMOTO, Hiromi[1] ; INAZU, Daisuke[5]

[1]International Research Institute of Disaster Science, Tohoku University, [2]Victoria University, [3]Geological Survey of Canada, [4]Graduate School of Science, Tohoku University, [5]National Research Institute for Earth Science and Disaster Prevention

On 11 March 2011, the 2011 off the Pacific coast of Tohoku Earthquake (M 9.0, hereafter Tohoku Earthquake) occurred on the plate boundary between the subducting Pacific and overriding continental plates. Terrestrial and seafloor geodetic observations on and around the Japanese Islands has been clearly detecting postseismic deformation associated with the Tohoku Earthquake, although three years have passed since the main shock. Iinuma et al. (2013, IAG Scientific Assembly) reported that just considering elastic response to the interplate coupling and postseismic slip on the plate boundary is insufficient to investigate the mechanical process of the postseismic deformation. We must take the inelastic deformation such as viscoelastic relaxation into account.

To tackle this problem, we estimated the displacement due to the viscoelastic relaxation by using a FEM model that includes subducting oceanic slab, difference of the viscosity between the continental and oceanic mantle, and high viscosity at the mantle wedge. The coseismic slip model based on the terrestrial and seafloor geodetic data (Iinuma et al., 2012) is used to initialize the viscoelastic relaxation process. After subtracting displacements due to the large aftershocks and viscoelastic relaxation from the original displacement time series data that are measured not only with the terrestrial GPS but also GPS/Acoustic ranging and vertical displacements observed by using Ocean bottom pressure gauges, we estimated the spatial and temporal evolution of the postseismic slip distribution on the plate interface by applying a time-dependent inversion method devised by Yagi and Kikuchi (2003).

The result of FEM calculation shows that westward displacements at seafloor sites are accounted for by viscoelastic relaxation process. However, eastward movements larger than the observed displacements at the most terrestrial GPS stations are predicted by means of the FEM model. Therefore, postseismic slip (or recovery of the interplate coupling) needs account for onshore westward displacement.

One of two areas where normal-fault-type slip distributes is estimated by applying the time dependent inversion analysis to the displacement time series as well as the result of the inversion when we assume a spherical layered structure to calculate the displacements due to the viscoelastic relaxation. But, the locations of the normal-faulting areas are different. When we use the layered structure, the area is mapped inside the main rupture area of the M9 main shock. On the other hand, normal-fault-type slip at a portion of the plate boundary deeper than the coseismic main rupture area is estimated when we calculate displacements due to the viscoelastic relaxation by means of our FEM model. Since such normal faulting areas can be regarded as the patches on the plate boundary where interplate coupling occur, it is essential to estimate the locations and rates of the slip accurately to consider the frictional character on the plate interface. Therefore we need reduce and exclude the dependency of the postseismic slip distribution with respect to the estimation of crustal deformation due to the viscoelastic relaxation. We will examine and improve rheological structure that is included in the FEM model, and will present results of further investigation at the meeting.

Scale dependency of rock friction strength revealed by large scale biaxial friction experiment

YAMASHITA, Futoshi[1*] ; FUKUYAMA, Eiichi[1] ; MIZOGUCHI, Kazuo[2] ; TAKIZAWA, Shigeru[3] ; KAWAKATA, Hironori[4]

[1]NIED, [2]CRIEPI, [3]Tsukuba Univ., [4]Ritsumeikan Univ.

In order to bridge a scale-gap between natural earthquakes (~10^3 m) and laboratory experiments (~10^{-2} m), we carried out biaxial friction experiments using meter-sized rock specimens. We used a pair of Indian gabbro, whose nominal contact area was 1.5×0.1 m^2. The experiments were conducted under conditions with loading velocities from 10^{-4} to 3×10^{-2} m/s and with normal stress of 1.3, 2.7 and 6.7 MPa. The normal and shear loads were measured with load cells. Hereafter, we refer the shear load divided by the normal load as the friction coefficient. It is well known that the rock friction has dependency on slip velocity at high slip velocity. We observed a similar tendency in the present experiments; the friction coefficient is almost constant (~0.75) at low loading velocities (10^{-4} to 10^{-3} m/s), whereas it falls suddenly at the loading velocity of 10^{-2} m/s approximately. This feature is consistent with the results using small rock specimens whose dimension is on the order of 10^{-2} m (e.g. Di Toro *et al*., 2011, Nature). It should be noted that the velocity weakening characteristics of rock friction is first confirmed on meter-sized rock. However, we found that the measured friction coefficients show weak dependency on normal stress, which suggests that the slip velocity is not a unique factor controlling the rock friction strength. On small sized rock specimens, dependency of the friction coefficient on work rate was reported; the friction coefficient is almost constant at low work rates, whereas it becomes smaller with approaching to natural conditions (e.g. Di Toro *et al*., 2011; Mizoguchi and Fukuyama, 2010, Int. J. Rock Mech. and Min. Sci.). We investigated this relationship using the present data, and found a sudden and clear reduction of the friction coefficient at the work rate higher than 10^{-2} MJ/m^2s. The clear dependency of the friction on the work rate indicates that the weakening property of rock friction is governed by the work rate rather than the slip velocity. Di Toro *et al*. (2011) suggested that the work rate is proportional to a rate of temperature increase on a fault and the heating causes various transitions of rock mineral properties, which leads to the frictional weakening. In the present experiments, similar mechanisms should work and weaken the fault strength. However, we found that the meter-sized rock friction starts to decrease at the work rate one order of magnitude lower than that of the small gabbro specimens. This difference may come from the heterogeneity of the shear stress on the fault. From the point of view, we calculated heterogeneous stress distribution on the simulated fault produced by the present apparatus, and then, we estimated the weakening property of macroscopic friction depending the work rate under the estimated stress condition. We further estimated the weakening property in the case that additional stress heterogeneity was given on the fault surface. The results reveal that stronger stress heterogeneity can make more decrease in the macroscopic friction, which suggests that the rock friction has scale dependency, because such spatial heterogeneity will become strong in larger scale.

Graphite-bearing pseudotachylytes in metasediment: Implication for CO2 degassing by oxidation of graphite

NAKAMURA, Yoshihiro[1*] ; MADHUSOODHAN, Satish-kumar[2] ; TOYOSHIMA, Tsuyoshi[2]

[1]Graduate School of Science & Technology, Niigata University, [2]Department of Geology, Faculty of Science, Niigata University

Graphite in fault rocks has important role in controlling the redox states in COH fluid, and many researchers have pointed out that the behavior of fluid in pore water or hydrous minerals dramatically change the physical and chemical property of fault rocks. Recently, the CO_2 degassing, form possible biogenic sources, along the faults is monitored in various active faults (e.g. Lewickie and Brantley, 2000). It is expected that the behavior of graphite in fault rocks play a key role about the fluid composition and the physicochemical properties. Here we present a detailed analysis of graphite found in pseudotachylyte and discuss the relationship between graphite and fluid during earthquake activity.

Graphite-bearing pseudotachylyte in Hidaka metamorphic belt, Hokkaido, Japan was examined using SEM, EMPA, and XRD. In pseudotachylyte-bearing cataclasite, melt-induced textures such as biotite microlites, shell textures of Fe-oxide, flow textures, spherulites and vesicles in Fe-oxide are observed. On the basis of microtextures, mineral assemblages of melted and survived minerals, pseudotachylytes are divided into two types; Pst I and Pst II. The matrix of Pst I is composed of sanidine, hematite and vesicles in Fe-oxide, and plagioclase and quartz are remained. These observations suggest that they are solidified from silicate melts by dehydration of biotite at around 700 - 1150 degree Celsius based on the experimental data. In addition, we can also deduce the stability of biotite and graphite in silicate melts of Pst I from the reaction of biotite equilibria on the T-fO_2 plane at 200MPa based on the experimental data of graphite and biotite. Mineral assemblages of sanidine, hematite and volatile in vesicles are stable only in high fO_2 fields, suggesting fO_2 in the range of over 10^{-11} at around 700 degree Celsius by frictional melting of Pst I phase. In this phase, graphite in Pst I is unstable and will be converted to COH fluid in silicate pseudotachylyte melts. On the other hand, in Pst II matrix, these phyllosilicates but also quartz, plagioclase and apatite are found to be melted or have formed embayment textures, whereas only zircon has survived. These data indicate that the Pst II has formed at a peak temperature of around 1200 - 1400 degree Celsius by the breakdown of plagioclase, sulfide and apatite. The graphite content in Pst II decrease from 1.5 wt.% to 0.9 wt.% with increasing degree of frictional melting and alter the δ^{13}C values, which shows wide range of δ^{13}C values between -20.9 and -33.1 permil, when compared with the δ^{13}C values of graphite from associated fault rocks and host metamorphic rocks (-24.8 +/- 0.67 permil). These data suggest that the host graphite has been converted to the COH fluids and then a part of fluid deposited graphite are re-precipitated from COH fluid during isobaric cooling and other carbon expelled as COH fluid due to the oversaturated melt.

Thus it is evident that frictional melting and dehydration of sheet silicates during coseismic slip generates CO_2 gas by the oxidation of carbonaceous materials. During the transformation of cataclasite to pseudotachylyte the total carbon content has decreased by about 0.5 wt.%. Assuming a rock density of 2.7g / cm^3, the fusion of 10^{-3} m^3 (i.e. 1mm thickness $\times$ 1m^2 fault plane) of cataclasite into Pst II releases 50g of excess CO_2. The estimation of CO_2 degassing in this study is comparable to those reported by Famin et al. (2008). Thus, not only carbonates but also organic matters, including graphite and carbonaceous materials in crustal rocks, are potential to be a source of CO_2 by frictional melting, and the release of CO_2 into fault planes may drastically change the dynamic properties of flash fluid pressure and frictional properties of fault planes during seismic activity.

Friction on the fault plane controls the behavior of faulting during seismic slip. Recent studies suggest that the frictional process on faults shows scale dependency. It is critically important to observe structures on the fault planes in various scales, especially in smaller scale in the sub-micron range. The roughness on fault planes has long been thought to hold fractal property, however, a recent work observed that a mirror fault plane, when examined up to nanometer-scale, does not obey self-affine roughness. Their observation revealed that the fault surface is coated by grains of several ten nanometers in diameter. In this abstract, we show a detailed observation of a glossy fault plane with striations sampled from drilled core of the Nobeoka Thrust taken by a scientific drilling project, the Nobeoka Thrust Drilling Project (NOBELL).

The NOBELL recovered cores with a total depth of 255 m penetrating the Nobeoka Thrust at 41 m below ground surface. The visual observation of the cores and the wireline log of the borehole clearly differentiate the hanging wall and the footwall. In this study, we analyzed a fault plane just below the Nobeoka Thrust main fault core on which gloss and striation develop using an integrated apparatus of Confocal Laser Scanning Microscope (CLSM) and Atomic Force Microscope (AFM). We also analyzed the sample surface applying Raman spectroscopy, Auger electron spectroscopy (AES) and organic component analysis using CHN coder (Yanaco MT-6).

The sample surface was imaged by the CLSM and AFM in various scale and its topography was obtained. The grains of several tens of nanometers in diameter were observed under the AFM image. This surface shows very flat surface with a hight difference of ˜80 nm in the imaged square ten micrometers on a side. The X-Z measurement by CLSM revealed an interface of around 1 micrometer below the surface. The interference fringe was observed at the rim of dark area. These facts suggest that the fault surfece is covered by a thin film approximately 1 micrometer thick. The result of the Raman spectrometry indicates that the glossy fault plane material is rich in carbon. The organic component analysis of handpicked samples reported carbon fraction. Applying the AES, we recognized carbonaceous material on the true surface.

In conclusion, the questioned sample here appears to have been polished with fault frictional process so intensely that the surface grains comminuted to sub-micrometers and then a thin carbonaceous film developed. Such nanoscale structure observations in combination with the geometrical fractal property and chemical and surface analysis could provide further details of dynamic weakening during seismic slip.

Dynamic backthrust branching: role of barriers, and implications

XU, Shiqing[1*] ; FUKUYAMA, Eiichi[1] ; BEN-ZION, Yehuda[2] ; AMPUERO, Jean-paul[3]

[1]NIED, [2]University of Southern California, [3]California Institute of Technology

Increasing evidence indicates that backthrusts may become active during or after megathrust ruptures in subduction zones, such as in Chile and Sumatra (Melnick et al., 2012; Singh et al., 2011). Previous studies of relevant mechanisms mainly focused on the interaction between forethrusts and the megathrust. Here we investigate through dynamic rupture simulations how backthrusts may be activated by megathrust ruptures in subduction zone environments. Assuming a single backthrust branch that is backward inclined to the compressional side of a continuous main fault, our results show that (1) fast speed and long propagation distance of the main rupture favor the activation of backthrust; (2) the outward propagation of the activated branch rupture interacts with the main fault mainly in the backward direction, while the tapered slip towards the branch end at the junction affects the main rupture behavior around the junction. We further assume an effective barrier for the main fault at the junction, motivated by the previous studies that barriers of various types (e.g. sharp fault bend, fault end, and transition region with increased basal friction) can also generate backthrusts during the long-term quasi-static process. Compared to the case without barrier, one prominent effect of the barrier is to arrest or delay the forward propagation of the main rupture, such that a resultant backward stress lobe as discussed in Xu and Ben-Zion (2013) can load the backthrust branch over a considerable time. This is particularly important for rupture activation along relatively immature backthrusts within sediments, where the nucleation time leading to the spontaneous propagation phase could be long, due to the large effective Dc, low frictional strength drop, or surface roughness. Indeed, our additional results confirm that the barrier model, although not always necessary, is more favorable for the activation of backthrusts with increased dynamic friction.

Our study has several implications: (i) it agrees with the quasi-static model based on the critical taper theory and limit analysis (Cubas et al., 2013) that an increase of basal friction towards the toe may statistically favor the activation of backthrusts near the up-dip limit of megathrust ruptures; (ii) there are also possibilities that backthrusts can still be activated by a propagating rupture, therefore the dynamic critical taper theory developed by Wang and Hu (2006) needs to be improved. In fact, not only the region near the up-dip limit of the seismogenic zone can be pushed into a critical state, successive region around the propagating rupture front within the seismogenic zone can also be temporarily stressed to failure and may even sustain a failure propagation along preexisting branches; (iii) it provides a specific example of compressional-side antithetic branching that can support the early speculation of fault behavior at junctions (King, 1986; Andrews, 1989).

A possibility of a CM fault thermometer Part 1: Reflectances

OKAMOTO, Shiori[1] ; HOSHINO, Kenichi[2*]

[1]Fac. Sci., Hiroshima Univ., [2]Grad. Sch. Sci., Hiroshima Univ.

The chemical kinetics of thermal maturation (coalification) of carbonaceous matters (CMs) in the oil and gas windows was well investigated by Burnham and his coworkers (e.g., Braun and Burnham, 1987). Burnham and Sweeney (1989) and Sweeney and Burnham (1990) introduced an activation energy distribution model for their rate law of dehydration and degassing of CMs and presented the correlation between the reflectance of CM in oil (%Ro, in percent) and the extent of the reaction (F) calculated from the rate law. They also noted that the rate law can be applied for heating rates ranging from laboratory conditions (1C/week), igneous intrusions (1C/day), and geothermal systems (10C/100 yr) to burial diagenesis (1C/10 m.y.).

On the other hand, Huang (1996) demonstrated that %Ro increased after a few days heating experiments and estimated a power rate law with t (second) to the power of 0.078. Muirhead et al. (2012) also examined that R1 ratios of Raman spectra of CMs increased after a few tens-seconds pyrolysis and proposed a power rate law with the power depending on T (K). However, those power rate laws were obtained from the experiments with bare CM fragments extracted from rocks. The power rate laws may not be applied to CMs in rocks, since we confirmed that the R1 ratios of CMs on surfaces of heated rock samples are larger than those inside the samples (details will be shown in the following presentation, Part 2).

Chips of pelitic rocks collected from the Shimanto accretionary complex were heated in an Ar-purged capsule in an oven. Since the oven takes 18-21 minutes to achieve pre-set steady temperatures and a few minutes for cooling down after heating, the following heating durations are regarded as those of constant temperatures during heating runs. The chips were heated at temperatures, 300, 350, 450, 550, 600 and 750C for 2, 5, 13 and 34 minutes.

Reflectance measurements and Raman spectroscopic analyses were taken for CMs in the chips of which surfaces were scraped off before polishing. The reflectances in air (Ra, not in percent) of CMs of unheated and heated chips and standards (SiC, GGG, YAG, sapphire and spinel) were obtained by analyzing gradations of G color of 24 bit color microphotographs taken by a reflecting microscope.

Averages of Ra of CMs in two unheated chips are 0.093 and 0.106, while an average of measured %Ro of the former is 1.99 of which F (extent of reaction) calculated from the correlation of Sweeney and Burnham (1990) is 0.618. Ra values of CMs in chips heated below 450C show no significant difference with those in unheated ones. This is consistent with that F simulated along the T-t paths of the 300C, 350C and 450C for 34 minutes runs are 0.618, 0.618 and 0.622, respectively.

On the other hand, averages of Ra of CMs heated at 550C, 600C and 750C for 34 minutes are 0.121, 0.127 and 0.151, respectively, and their respective F values simulated are 0.742, 0.811 and 0.850. It is interesting that the averages of Ra for the runs at 750C for 2, 5 and 13 minutes are 1.47, 1.50 and 1.50, respectively. The all simulated F values for the last three runs are 0.850, the maximum extent of reaction of the rate law.

Although additional heating experiments of rocks with CMs of various initial maturities are needed, we may say from the above results that the CM fault thermometer is quite possible for high temperature faulting.

CM maturations due to heating indicated by Raman spectra will be shown in the following presentation (Part 2).

A possibility of a CM fault thermometer Part2: Raman spectra

OKAMOTO, Shiori, KOUKETSU, Yui, SHIMIZU, Ichiko, HOSHINO, Kenichi

Key words: carbonaceous matter, thermometer, fault, Raman spectra

Parameters of Raman spectra of carbonaceous matters (CMs) have been widely used to estimate geological temperatures (e.g., Beyssac et al., 2002). Huang (1996) and Muirhead et al. (2012) proposed empirical power rate laws for CM maturation represented by reflectances in oil (%Ro) and R1 ratios of Raman spectra, respectively, from pyrolysic experiments of bare CM fragments extracted from rocks and meteorites, respectively.

To investigate a possibility of a fault thermometer by thermal maturations of CMs indicated by their Raman spectra, we conducted heating experiments of pelitic rock samples taken from Aki Group of the Shimanto accretionary belt in Kochi Prefecture, whose diagenetic temperature is estimated as ˜180C by vitrinite reflectances (Kitamura et al., 2014). The samples were heated at temperatures, 300, 350, 450, 550, 600 and 750C for 2, 5, 13 and 34 minutes (see details in the previous presentation, Part 1).

It was indicated by comparing the spectra of CMs on surfaces of heated samples and those inside the sample that maturations of the former proceeded faster than the latter during heating. Therefore, in order to apply the thermal maturation of CM to a fault thermometer, it is needed to analyze CMs inside the samples.

It should be mentioned that micro-XRD analyses of CMs after the highest and longest heating run show no graphite peak. Hence, the maturation process during the present experiments is not graphitization but coalification.

Raman spectra of CMs show two major peaks, so-called G-band and D1-band peaks. Analytical results of the peaks indicate that certain parameters of Raman spectra of CMs remarkably vary even after low temperature (300 - 450C) heating runs, whereas reflectances of CMs do not increase (see Part 1). The positions of G-band peak (Gp) and D1-band peak (Dp) tend to shift toward higher wave numbers with increasing heating durations in the all temperature runs. However, they do not shift monotonically with heating temperatures. Their wave numbers increase with the heating temperatures up to 450C, then decrease at 550C, and again increase up to 750C.

Differences between Gp and Dp (Gp-Dp) also vary with heating temperatures and durations. Although they become smaller as the temperature is higher for the longest runs (34 minutes), this temperature dependency could not be seen for the other heating durations.

The ratio of intensity to full width at half maximum of the G-band peak (Gif) and that of the D1-band peak (Dif) decrease with increasing temperatures from 300C to 450C and from 550C to 750C, but increase from 450C to 550C. The both Gif and Dif do not show monotonic change with the heating durations.

As stated in the above, a simple indicator varying monotonically with heating temperatures and durations has not been found yet. However, we conceive that the sensitivities of the above indices of the Raman spectra to the thermal maturation of CM may show their potentials as a fault thermometer. Size dependencies of variations in some of the above indices with heating temperatures and durations and similarities of those of small-grained CMs and rims of large-grained ones also show a possibility to estimate both heating temperature and duration simultaneously by a size dependent thermometer, that is, a thermo-chronometer.

The rupture and slip of the 2011 Tohoku-oki earthquake (Mw9.0) propagated along the plate-boundary megathrust and caused a huge tsunami. In order to elucidate the physical mechanisms responsible for such unexpectedly large slip of the fault, the IODP Exp. 343, the Japan Trench Fast Drilling Project (JFAST) was carried out one year after the earthquake. It succeeded in recovery of material from the plate boundary shear zone. We have examined how mineralogical properties vary through a depth-section including the plate boundary fault rock.

At the drill site (C0019E) where the large fault slip (>50m) occurred, a plate boundary shear zone was identified around 820 mbsf. X-ray diffraction (XRD) analysis revealed that abundance of smectite is markedly higher within the fault (60?80 wt.%) than in the surrounding host rocks, suggesting the shear zone material had a low intrinsic friction coefficient. Laboratory experiments on these materials demonstrated very low frictional state under various sliding conditions (Ujiie et al., 2013; Ikari et al., submitted)

In comparison, we also examined the mineralogy of reference material recovered on the outer rise of the Japan Trench (Site 436) during DSDP Leg 56. XRD analyses on the continuous series of cores found a marked anomaly in smectite abundance in the topmost ~5m section in the pelagic clay layer. Such a mineralogical feature compares well to that observed in the JFAST cores, and the smectite-rich horizon in the incoming sediments is inferred to be the localized deformation zone (decollement) when it arrives at the Japan Trench.

Shock compression experiment of olivine- Part 3: pulverization occurred before frictional melting

OBATA, Masaaki[1*] ; MASHIMO, Tsutomu[2] ; CHEN, Liliang[2] ; ANDO, Jun-ichi[3] ; YAMAMOTO, Takashi[3] ; UEDA, Tadamasa[1]

Seismic waves may be generated by a rapid slip accompanied by a rapid drop of shear stress at or near the rapture tip that propagates rapidly. It is an important subject of seismology to identify the material changes occurring at the fracture tip. The inferred slip weakening has been ascribed to (1) frictional melting and lubrication, (2) thermal pressurization, (3) flash heating and melting, (4) powder lubrication, and the combinations of those above. High-speed rotary shear friction apparatus has played important roles in formulating the above hypothesis in the past, but in these experiments fault planes are already prepared and the formation of new fault planes cannot be studied. Moreover normal pressure cannot exceed few tens of mega-Pascal because of the instrumental limitation.

We performed a series of shock compression experiments using a keyed powder gun at Kumamoto University in order to investigate the focal mechanics of deep earthquakes. We used a single crystal of forsterite (Fo 94; shaped in a diskette of diameter 12 mm and thickness 3 mm nearly perpendicular to the olivine c-axis). The olivine disk is mounted in a steel capsule. Flyer speed was 1.5 km/s; applied pressure, 31 GPa; and shock wave velocity, ca. 7 km/s; particle velocity, ca. 1 km/s. After the shock experiment the capsule is recovered from the gun and cut perpendicular to the disk plane and polished thin sections were prepared for optical, SEM an TEM observations.

Many shear planes were generated. Olivine shows wavy extinctions and locally cataclastic texture. Shear planes (i.e., fault) are typically sharp and show up to 0.5 mm displacement. The TEM observation of the fault wall where 'spongy material is attached' revealed that the wall has a zonal structure as follows. Well inside the wall are developed densely spaced and tangles [001] screw dislocations. Outer 2-5 micron zone is polycrystalline olivine of average grain size 200-300 nm. The outermost rim is an aggregate of semi-rounded small olivine particles (ca. 200 nm) mounted in a matrix of glass of olivine composition, indicating that melting of olivine occurred here. It is important to note that the same dislocation structure remained in these olivine nano-particles. It is inferred from these structure that polygonization and pulverization of olivine has occurred before melting began near the fault wall (within a few microns). Such pulverization is possible at running fracture tip, where stress and strain rate are the highest (Reches and Dewer, 2005). The whole process occurred in a short duration of the order of 0.5 microsecond. The fracturing was probably propelled by the rapid sweep of shock waves running through the sample in our experiment. Apart from the role of the shock waves, the situation is considered to be analogous to natural earthquakes. Present experimental result sheds light on the long-lasting controversy on the formation of pseudotachylytes.

High-velocity frictional behaviors of dolerite under controlled pore-water pressure

TOGO, Tetsuhiro[1*] ; SHIMAMOTO, Toshihiko[1] ; MA, Shenli[1] ; YAO, Lu[1]

[1]Institute of Geology, China Earthquake Adiministration

High-velocity friction experiments on rocks with or without gouge have been conducted mostly under dry conditions and demonstrated dramatic weakening of faults at high velocities (e.g., Di Toro et al., 2011, *Nature*). Recent experiments under wet conditions (e.g., Ujiie and Tsutsumi, 2010, *GRL*; Faulkner et al., 2011, *GRL*) revealed very different behaviors from those of dry faults, but those experiments were done under drained conditions. Experiments with controlled pore pressure Pp are definitely needed to determine mechanical properties of faults under fluid-rich environments such as those in subduction zones. Thus we have developed a pressure vessel that can be attached to our rotary-shear low to high-velocity friction apparatus (Marui Co Ltd., MIS-233-1-76). With a current specimen holder, friction experiments can be done on hollow-cylindrical specimens of 15 and 40 mm in inner and outer diameters, respectively, at controlled Pp to 35 MPa, at effective normal stresses of 3-9 MPa, and at slip rates of 60 mm/year to 2 m/s. An effective normal stress can be increased by about 10 times by replacing a 10 kN pneumatic actuator with a 100 kN hydraulic actuator. We report an outline of the experimental system and preliminary high-velocity experiments with controlled pore pressure on Shanxi dolerite.

High-velocity friction experiments were performed on hollow-cylindrical specimens of Shanxi dolerite at effective normal stresses of 0.13-1.07 MPa and at slip rates of 1, 10, 100 and 1000 mm/sec. Nitrogen gas and water were used of the pore fluid and compared the frictional behavior. In the N^2 tests an axial force was kept at 1 kN and the nitrogen gas pressure was increased in steps from 0 to 5 MPa to change an effective normal stress. In the wet tests the specimens were soaked in distilled water in the vessel and Pp was applied by nitrogen gas in a similar manner as in the dry tests. Nitrogen gas acted as buffer to prevent an abrupt change in the pore-water pressure during experiments. The steady-state friction coefficient of dry dolerite increased from 0.3-0.35 at 10 mm/s to 0.55-0.8 at 100 mm/s and then decreased down to 0.2-0.6 at 1000 mm/s. The results are quite similar to those of dry granite tested under similar conditions (Reches and Lockner, 2010, *Nature*). However, the steady-state friction coefficient of dolerite under a pore-water pressure decreased monotonically from 0.4-0.8 at 1 mm/s to 0.3˜0.5 at 1000 mm/s, and the strengthening from 10 to 100 mm/s disappeared with a pore-water pressure. We plan to conduct more experiments with controlled pore-water pressure and to do textural and material analysis of specimens to gain insight on the weakening mechanisms.

Re-evaluation of frictional heat recorded in the dark gouge of a megasplay fault at the Nankai Trough

MASUMOTO, Hirokazu[1*] ; HIRONO, Tetsuro[1] ; ISHIKAWA, Tsuyoshi[2] ; KAMEDA, Jun[3] ; YABUTA, Hikaru[1] ; MUKOYOSHI, Hideki[4]

[1]Department of Earth and Space Science, Graduate School of Science, Osaka University, [2]Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology, [3]Graduate School of Science, Hokkaido University, [4]Faculty of Education and Integrated Arts and Sciences, Waseda University

Because a megasplay fault branching from the deep subduction boundary megathrust in the Nankai Trough is thought to be the source of large tsunamis associated with past Tonankai earthquakes, investigation of the heat signal due to frictional slip recorded in the fault is important for estimating the earthquake slip parameters. We performed X-ray diffraction and infrared spectroscopic analyses of a megasplay fault-rock sample and re-examined previously reported trace-element and isotope compositions, but observed no specific change related to high temperature (≥250 ℃). In addition, although a qualitative increase of the illite content in illite/smectite mixed-layer minerals within the slip-zone sample was previously reported, our kinetic evaluation of illitization, taking into consideration the coseismic temperature change due to frictional heating and heat conduction, revealed that the illitization reaction hardly progresses at temperatures under 250 ℃. Alternatively, we suggest that the illite content in mixed-layer minerals might increase progressively via a comminution – dissolution – recrystallization process during multiple past slips. Accurate assessment of the slip behavior of the megasplay fault could be efficiently obtained by drilling to penetrate the fault zone at a deeper depth of approximately 1.5 km, where records of high temperatures would be detectable.

Roughness of fault surfaces over a length-scale range from nano- to milimeters.

KISHIDA, Minori[1*] ; MIZOGUCHI, Kazuo[2] ; TAKAHASHI, Miki[3] ; HIROSE, Takehiro[4]

[1]Hiroshima University, [2]Central Research Institute of Electric Power Industry, [3]Geological Survey of Japan, AIST, [4]Kochi, JAMSTEC

Geometric complexities of faults are first-order effects that complicate the mechanics of earthquakes and faulting. Here we report on the topographic roughness measurements on two natural fault surfaces with a continuous length-scale range from 1 nm to 3 mm. The fault surfaces observed in this study include (1) the Corona Heights fault in the Castro Area of San Francisco, that has been studied mineralogical and microstructural in detail, and (2) the Itozawa fault in Fukushima prefecture, a normal fault moved just after the 2011 Off the Pacific Coast of Tohoku earthquake. Both fault surfaces exhibit shiny slickensides on which various length and width of slickenlines are observed.

In order to measure fault surface topography with a scale range from 1 nm to 3 mm, we performed line-measurements both parallel and perpendicular to the slickenlines using two scanner devices; a confocal whilte-light scanning microscope (measurable range: 0.15 ˜3000 μm) and a scanning probe microscope (1 ˜50000 nm). The topographic properties of the measured surfaces were expressed either as a Hurst exponent (H) which are calculated from power spectrum density (PSD) of topography data. As a result, the Corona Heights fault and the Itozawa fault exhibit a consistent geometrical property, a linear behavior on a log-log plot where axes are PSD and spatial length scale. A slope of the log-log plot, H, of the Corona Heights fault and the Itozawa fault shows H_N = 0.73 $\pm$0.010 perpendicular to the slickenslide and H_P = 0.81 $\pm$0.012 parallel to it, and H_N = 0.87 $\pm$0.013 and H_P = 0.94 $\pm$0.014, respectively. Smaller H_P than H_N is often reported, that interpreted as surface roughness in the slip direction becomes less pronounced selectively with progressive displacement (e.g., Sagy et al., 2007). Therefore, almost no difference between H_P and H_N in the observed fault surfaces could imply that both faults may be relatively immature due to less total displacement, or otherwise H_P and H_N are undifferentiated with displacement in the length-scale range from 1 nm to 3 mm. Candela et al., (2012) measured roughness of thirteen earthquake fault surfaces and suggested that the fault geometry can be expressed as a single geometrical description (i.e., single H) over a range of scales from 50 μm to 50 km. Our data, at least H_N = 0.81 perpendicular to the slickenlines, is consistent with their universal H_N = 0.81 $\pm$0.04 even for lower length-scale range. Hence, the geometric complexiity of fault surfaces in nature can be maintained over length-scales from nano- to kilometer and be described as the sigle Hurst exponent.

Evolution of fluid transport property by diagenesis in basaltic rocks from the Shimanto belt, Southern Shikoku

TANIKAWA, Wataru[1*] ; YAMAGUCHI, Asuka[2] ; KAMEDA, Jun[3] ; TADAI, Osamu[4] ; HATAKEDA, Kentaro[4] ; KITAMURA, Manami[5]

[1]JAMSTEC/Kochi, [2]Atomosphere and Ocean Research Institute, The University of Tokyo, [3]Graduate School of Science, Hokkaido University, [4]Marine Works Japan Ltd., [5]Hiroshima University

Large slip displacement was observed at shallow portion of the plate boundary fault during 2011 Tohoku earthquake, and this slip has contributed to cause large tsunami. The large displacement was probably caused by dynamic fault weakening at shallow boundary fault, or reduction of fault strength at middle to deeper portion by pore pressure generation. Pore pressure can be generated by chemical dehydration, fluid influx from deeper crust or pore volume reduction associate with permeability reduction at a large subduction plate boundary. In this study, we investigate the change of fluid transport property for basalt during diagenesis process at Nankai Subduction zone.

We collected basalt brocks in the Cretaceous Shimanto accretionary complex of Japan from Okitsu-Kozurutsu site and Kure site in Kochi, Japan. Porosity and P-wave velocity of each basalt at atmospheric pressure are 1.4 % and 2.1%, and 6.4 km/s and 5.9km/s, respectively. We found a slight difference of S-wave velocity for basalts. Permeability was measured by using N2 gas as a pore fluid, and calculated by steady state gas flow method. Permeability was measured at room temperature and under confining pressure that were increased from 1 to 160 MPa in steps.

Gas permeability was decreased with an increase of differential pore pressure at a same confining pressure. This pore pressure dependence implies the Klinkenberg effect, therefore we converted gas permeability to water permeability using the Klinkenberg equation. We did not find a variation of permeability at the lowest effective pressure of 1MPa, and permeability shows from 10^{-15} to 10^{-16} m^2. Permeability in all basalts decreased with an increase of effective pressure, and reaches from 10^{-18} to 10^{-21} m^2. Basalt from Kure site shows the lowest permeability of 10^{-21} m^2 at 100 MPa, and permeability of basalt from Okitsu site shows the largest value of 3×10^{-19} m^2. Permeability reduction with an increase of effective pressure in most samples is described by the power law equation where exponent ranges from -2 to -3. The permeability reduction for the highest permeable basalt was expressed by the theoretical relation that is based on the Hertzian contact theory (Gangi, 1978). Fractures are apparently developed in this sample, therefore the reduction in permeability is influenced more by fracture asperity rather than pore structure.

The permeabilities of basalts in this study are smaller than permeability of basalt in fault zone at Okitsu site (Kato et al., 2004), Juan de Fuca and Tonga-Kermadec (Christensenan and Ramananantoandro, 1988). At present, we did not see clear relationship between the permeability and diagenesis. Most of basalt rock shows very low permeability, therefore they have higher potential to generate a pore pressure by dehydration reaction or influx from depth during subduction at Nankai Trough.

Effects of thermal cracking on elastic wave velocities and Poisson's ratio of basalt, gabbro and granite

NISHIMURA, Kaya[1*] ; UEHARA, Shin-ichi[1] ; MIZOGUCHI, Kazuo[2]

[1]Faculty of science, Toho University, [2]Central Research Institute of Electric Power Industry

Marine seismic refraction studies have found that there are high Poisson's ratio regions (>0.35) in oceanic crust at subducting plate. Christensen (1984) performed laboratory measurements of compressional and shear wave velocities (Vp and Vs, respectively) of basalt, which is one of major rocks in oceanic crust, and estimated Poisson's ratio, and suggested that observed high Poisson's ratio can be explained by high pore pressure. This distribution of high pore pressure have been concerned because it should influence fault mechanism of plate boundary at subduction zones. Christensen (1984) used intact rock for the measurements. But there are probably dense cracks near faults in nature. Therefore, to investigate Vp, Vs and Poisson's ratio for fractured rock is important to evaluate distribution of high pore pressure regions by using seismic studies. This study reports the results of measurements of Vp and Vs, and estimations of Poisson's ratio for thermally cracked gabbro, basalt and granite, which are major rocks in oceanic crust and continental crust. Rock specimens were heated at 100 ℃, 300 ℃, 500 ℃ and 700 ℃ to thermally crack them. We performed measurements at atmospheric pressure and dry condition. We also measured Vp and Vs for water-saturated specimens of gabbro and basalt heated at 700 ℃, and compared the results with those under dry condition to investigate the effect of pore fluid on Vp and Vs.

As results, specimens heated at higher temperature tended to have slower Vp and Vs. Density of the specimens was also decreased as heating temperature was increased, and especially the density change was clear from 500 ℃ to 700 ℃. This imply that clack density of specimens was increased with increasing temperature, and this might be the reason why Vp and Vs were decreased. Poisson's ratios obtained in this study (0.05-0.25) were lower than the observed high Poisson's ratio. Vp and Vs for water-saturated specimens were generally faster than those for dried specimens, but output signals tended to be smaller and therefore improvements of the measurements systems and methods to analyze the signals should be necessary.

Frictional property of rocks in the Izu-Bonin-Mariana Forearc under high temperature and pressure conditions

HYODO, Geni[1*] ; TAKAHASHI, Miki[2] ; SAITO, Saneatsu[3] ; HIROSE, Takehiro[4]

[1]Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University, [2]Geological Survey of Japan-Advanced Industrial Science and Technology, [3]Japan Agency Marine-Earth Science and Technology, [4]Kochi Institute for Core Sample Research, Japan Agency Marine-Earth Science and Technology

The Kanto region lies atop of three tectonic plates: the North American Plate, the Pacific Plate, and the Philippine Sea Plate. In addition, the collision and subduction of the Izu-Bonin-Mariana (IBM) arc into the Kanto region results in a characteristic tectonic setting as compared with other convergent margins. Due to such complicated plate configuration, the different type of earthquakes including seismic slip (e.g., the Kanto earthquake) and aseismic creep (i.e., slow earthquake of Boso peninsula) occurs at the intra-plate and plate boundaries beneath the Kanto region. Moreover, the different type of events seems to take place side by side at almost same depth (probably nearly same P-T conditions). Although many factors including pore fluid pressure and fault topography can control earthquake generation, this study focus on frictional property of incoming materials to be subducted into the Kanto region in order to examine a hypothesis that the different types of slips arise from different input materials. Thus, we have performed friction experiments on rocks that constitute the IBM forearc using a high P-T gas medium apparatus at AIST.

We sampled five rocks (marl, boninite, andesite, sheared serpentinite and serpentinized dunite) recovered from the IBM forearc by Leg 125, Ocean Drilling Program (ODP Site 784, 786). The rocks were crushed and sieved into 10˜50 μm in grain size. Then, the rock powders were sandwiched between saw-cut alumina cylinders and sheared at temperature of 300^{o}C, confining pressure of 156MPa, pore pressure of 60MPa and axial displacement rates of 0.1 and 1 μm/s. The sheared serpentinite and serpentinized dunite exhibit steady-state friction of 0.55 and 0.35-0.41, respectively and their velocity dependence of friction is positive (velocity strengthening behavior). On the other hand, for marl, boninite and andesite, a periodic stick-slip behavior appears at 1 μm/s. However, contrary to a stick-slip behavior at room temperature in general, rise time of the stick-slip behaviors are quite long (3.9, 9.3 and 10.8 sec, respectively), that could be called as a “ slow stick-slip ” . Similar slow stick-behavior were observed in halite and serpentinite slipped at high temperatures (Noda and Shimamoto, 2010; Okazaki, 2013), but this is first time to recognize this unique slip behavior in sedimentary and igneous rocks. Although it is difficult to discuss the diverse slip behaviors observed at the Kanto region based on our limited experimental results, we will examine the conditions where the transition between stable and unstable sliding appears using the input materials and explore the generation mechanisms of earthquakes at the Kanto region.

Temperature-dependent frictional strength of dolerite in a nitrogen atmosphere and its relation to amorphous material

TANAKA, Nobuaki[1*] ; WADA, Jun-ichi[1] ; KANAGAWA, Kyuichi[1]

[1]Graduate School of Science, Chiba University

Noda et al. (2011, JGR) revealed by rotary shear experiments on dolerite at a normal stress of 1 MPa, a sliding velocity of 1 cm/s and controlled temperatures from room temperature to 1000 ℃, that its frictional strength has a negative correlation with the amount of amorphous phase in wear materials as well as a positive correlation with the amount of iron oxides which increases with increasing temperature by oxidation of the iron-bearing minerals. However, oxidation of iron-bearing minerals as observed in their experiments is unrealistic in fault zones at depths due to the paucity of oxygen there.

We therefore conducted rotary shear experiments on the same dolerite at the same normal stress, sliding velocity and temperature conditions with Noda et al. (2011) in a nitrogen atmosphere with the oxygen content of 0.1 %, and compared the results with those of Noda et al. (2011). We collected mechanical data during stable sliding of 20 m after the presliding of 100 m at each experimental condition. Sieved wear materials smaller than 250 μm were then used for quantitative X-ray diffraction analyses.

Steady-state friction coefficient was ~0.47 at room temperature and 200 ℃, ~0.7 at 400 and 600 ℃, and ~0.9 at 1000 ℃. Steady-state was not reached at 800 ℃ due to intense fracturing of samples. The amount of amorphous phase in wear materials shows a change with increasing temperature similar to that for experiments in the air (Noda et al., 2011); ~65 wt% at room temperature, ~70 wt % at 200 ℃, ~70 wt% at 400 ℃, ~45 wt% at 600 ℃, ~15 wt% at 800 ℃, and 0 wt% at 1000 ℃. In contrast, the amount of iron oxides does not show a noticeable change with increasing temperature.

Experiments by Noda et al. (2011) in the air showed a negative correlation between frictional strength and the amount of amorphous phase at temperatures lower than or equal to 800 ℃. Our experiments also show an overall tendency of increasing frictional strength and decreasing amount of amorphous phase with increasing temperature. However, steady-state friction coefficient differs by more than 0.2 between room temperature and 400 ℃, while the amount of amorphous phase differs by only ~5 wt% between these two temperatures. In addition, the amount of amorphous phase differs by ~15 wt% between 400 and 600 ℃, whereas steady-state friction coefficient is almost the same at these two temperatures. This implies lack of a direct relationship between frictional strength of dolerite and the amount of amorphous phase in wear materials. Study on what controls the temperature-dependent change in frictional strength of dolerite is now in progress.

Pre-slip was expected to occur prior to large earthquakes, since a pre-slip model was proposed by Ohnaka and Kuwahara (1990) based on their rock frictional experiments. The pre-slip accelerates toward an unstable sliding event. However, such phenomena have never been clearly observed for natural earthquakes. Ohnaka and Kuwahara (1990) observed a 1-D strain distribution along a sample surface, and estimated the apparent rupture propagation speed. In addition, the fault was narrow, and the rupture growth might be affected by free surfaces at the edge of the sample, though the free surface effect is not so common for natural earthquakes. Therefore, we closely observed two-dimensional rupture propagation on a wider fault during rock frictional experiments.

We carried out meter-scale rock frictional experiments (Fukuyama *et al*., 2013), and investigated rupture propagation of stick-slip events and some of their characteristics, using AE (acoustic emission) and strain records. The fault consisted of an interface of two Indian gabbro blocks. Their width and height were 0.5 m, and the length of upper and lower blocks were 1.5 m and 2.0 m, respectively. The arrays of strain gauges and AE sensors were installed within the lower block in order to understand two-dimensional rupture propagation. Twenty four sets of AE sensors and biaxial strain gauges were attached 60 mm below the sliding surface at intervals of 150 mm parallel to the slip direction and at intervals of 75 mm perpendicular to the slip direction. We analyzed time series of strain and AE data, and found stick-slip events accompanied with slow and accelerating strain decrease that propagated at a speed much slower than elastic wave speed.

This study was supported by NIED research project ”Development of monitoring and forecasting technology for crustal activity” and JSPS KAKENHI Grant Number 23340131.

The experimental study about frictional instability of fault gouges in terms of Rowe's energy ratio

HIRATA, Momoko[1*] ; MUTO, Jun[1] ; NAGAHAMA, Hiroyuki[1]

[1]Dept. Earth Science, Tohoku University

1. Introduction

The stress-dilatancy relationship for granular materials in a dense packing state was introduced by Rowe (1962). He used the energy ratio (K), which was the ratio of rate of energy dissipation in the direction of minimum principal stress to energy supply in that of maximum principal stress. According to the concept, K shall be a minimum and constant value (Rowe, 1962). However, there are many questions about the physical meaning of K. Therefore, the Rowe's low has not been applied much for fault mechanics until now. Nevertheless the stress-dilatancy relation is related to the onset of frictional instability, it has not been clear yet. So, we conducted friction experiments using simulated fault gouges in order to confirm whether Rowe's law can be applied to fault situation or not.

2. Methods

The friction experiments using simulated fault gouges were conducted in a gas-medium apparatus. The confining pressure was ranging from 140 to 180 MPa. We used a cylindrical gabbroic forcing blocks (20 mm in a diameter, 40 mm in a length, and cut by a 50 degree from their cylindrical axis) and quartz gouges were sandwiched by them. The sample sustained loading initially and holding at several values of axial stresses at 190, 450, 640 and 800 MPa. The strain rate was 10^{-3} /s. In order to measure strain, three strain gauges were glued onto a gouge layer through the Teflon jacket. Another one was placed to a forcing block in a vertical direction and far from a gouge layer. Data were recorded at 2 MHz.

3. Results and Discussion

From our friction experiments, we obtained K of gouges at different confining pressures. K is given by the ratio of rate of energy dissipation in σ_3 direction to energy supply in σ_1 direction, so it can be represented by the ratio of output energy to input one. We obtained strain of σ_3 direction from three strain gauges glued onto a gouge layer. Similarly, σ_1 and strain of σ_1 direction were obtained from another gauge. σ_3 was the confining pressure. Our results showed that the output energy was the linear function of input one. K increased with confining pressure and showed a certain constant value at each loading and holding stage. Moreover, the change in K was remarkable at the final loading stage. In other words, the output energy increased suddenly because gouge particles began to slip. So, the change in K is large under high stress, including just before unstable slip. It matched shear localization (e.g. Logan et al., 1992; Marone, 1998).

Because K is represented by a function of internal friction angle, we suggest that the change reflects the process of microstructural development. It implied that the statistical particle arrangements of gouges changed at each stress level. After gouges become a closest packing state at the peak stress, the grain size reduction (GSR) of gouges occurs leading to the development of shear structure. Under GSR occurrence, K became a new state. From previous study, it is known that the microstructural development has a close relation with frictional instability (e.g. Logan et al., 1992; Marone, 1998; Onuma et al., 2011). During progressive shear, the angle of R1-shear developed in gouges decreases with cumulative slip (Gu and Wong, 1994). Hence, the change in K, that is to say the change in internal friction angle must be connected with not only microstructural development but also frictional instability.

4. Summary

From our experiments using simulated fault gouges, we obtained relationships among microstructural development, frictional instability and energy ratio of it. We confirmed that the Rowe's law could be applied to simulated fault gouges. Therefore, we can assess frictional instability in terms of the energy ratio based on Rowe's law. Systematic laboratory observation provides better understanding on energetical or microstructural consideration on the shear localization and seismogenic process.

Temporal evolution of slip event probability -Case study of slow slip off the Boso Peninsula and the Yaeyama Islands

MITSUI, Yuta[1*]

[1]Grad. Sci., Shizuoka Univ.

Spatially-isolated slip events (earthquakes and slow slip events) have occurred quasi-periodically especially at plate interfaces (e.g., Nadeau and McEvilly [1997], Matsuzawa et al. [2002], Rogers et al. [2003]). This fact suggests that the concept of simple elastic rebound at the plate interfaces is true at a certain level.

Of course, the recurrence intervals of the slip events have no periodicity in a strict sense. Probably it is because the slip events never repeat in the same pattern. Earthquakes with dynamic processes especially tend to have this trend. In fact, an earthquake event occurred beyond the expected period from the previous earthquake sequence (Bakun et al. [2005]). Moreover, seemingly spatially-isolated events can be strongly affected by nearby huge earthquakes (e.g., Uchida and Matsuzawa [2013]). Thus it is difficult to discuss the event recurrence quantitatively based on deterministic physical models. Reseacheres alternatively used probability distribution to evaluate the recurrence intervals.

When we examine the event recurrence by the probability distribution approach, one of the most important point is actual event probabilities at the time of event occurrences. There has been little discussion on this point. We address it, focusing on slow slip events with shorter recurrence intervals. We select the Boso-oki slow slip events (Hirose et al. [2012]) and the Yaeyama-oki slow slip events (Heki and Kataoka [2008]). The probability distribution of the event recurrence intervals is the Poisson distribution. We evaluate the event probability as the subtraction of cumulative probability of zero occurrence from 100%. The cumulative probability reverts back to 100% at the time of an event. The mean recurrence interval as a parameter of the Poisson distribution is the sample average from the forepassed events. The above settings allow us to calculate the temporal evolution of the event probabilities off the Boso Peninsula and the Yaeyama Islands. **We can validate the calculated results** by comparing with the actual event occurrences.

In the result off Yaeyama Islands, the event numbers that occurred at a stage with the smaller probability than 50% are five out of the total numbers twenty six. About 80% of the events occurred with the event probability $>$50%. Besides, off the Boso Islands, the event numbers during a stage of the smaller probability than 50% are two out of the total numbers five. The two events followed the 2011 Tohoku earthquake. This fact may reflect the effect of the stress perturbation due to the Tohoku earthquake, as suggested by Hirose et al. [2012]. In summary, few slow slip events occur with the event probability $<$50%, in the probability evaluation based on the Poisson distribution. We additionaly find that the event probability at the time of an event off the Yaeyama islands has increased gradually.

Numerical modeling of concurrent occurrence of shallow very low frequency earthquakes and long-term slow slip events

MATSUZAWA, Takanori[1*] ; SHIBAZAKI, Bunichiro[2] ; OBARA, Kazushige[3] ; HIROSE, Hitoshi[4]

[1]National Research Institute for Earth Science and Disaster Prevention, [2]Building Research Institute, [3]Earthquake Research Institute, University of Tokyo, [4]Research Center for Urban Safety and Security, Kobe University

Concurrent occurrences of shallow very low frequency earthquakes (VLFEs) and long-term slow slip events (SSEs) are found in the Bungo channel (Hirose et al., 2010, Science). This region is located at the western rim of the area where a large slip of megathrust earthquake is expected. Thus, the understanding of such behaviors will help us to reveal the preparation process of megathrust earthquakes. We aim to numerically reproduce the concurrent slip at the shallow VLFE and the long-term SSE region.

In our numerical model, a subducting plate interface is modeled as a flat plane within a semi-finite elastic medium. Frictional stress on the plate interface is given by a rate- and state-dependent friction law with cut off velocities (e.g., Matsuzawa et al., 2010, JGR). To reproduce long-term SSEs, a region with a cutoff velocity of $10^{-6.5}$ m/s and low effective normal stress is assumed below the depth of 10 km. In terms of shallow VLFEs, result of rock experiments shows that velocity-weakening and strengthening behaviors are found at low and high slip velocity, respectively (Saito, et al., 2013, GRL). In addition, it is estimated that a radius of shallow VLFEs is 5-10km from seismic data analysis (Ito and Obara, 2006, GRL). Based on these results, we assume circular regions for VLFEs with a cutoff velocity of 10^{-4} m/s and a radius of 6 km. In addition, we pose a stable sliding region beside the long-term SSE region, as more stable sliding behavior is expected in the Hyuganada region where shallow VLFEs frequently occur even in the period without long-term SSEs. In this study, some cases are calculated to examine the effect of the distribution of frictional parameters. Model 1 is a model based on the above assumptions. Model 2 is a model without a stable sliding region beside the long-term SSE region. In Model 3, the top of the long-term SSE region is set to the depth of 18 km.

In the numerical results of these three models, recurring slip at shallow VLFE and long-term SSE regions are reproduced. Concurrent occurrence of shallow VLFEs and long-term SSEs are reproduced in Model 1 and 2, while the concurrent occurrence is not clear in Model 3. In addition, slip events at the VLFE region are also found during the period without long-term SSEs in Model 2, while most of slip events at the VLFE region are found with long-term SSEs in Model 1. Our results suggest that the top of the long-term SSE region are close to the VLFE region, and the model with stable sliding region beside the long-term SSE region (Model 1) is more preferable to reproduce observed results than the model with fully locked surrounding region (Model 2).

Spatio-temporal afterslip distribution of the 2011 Tohoku-Oki earthquake considering visco-elastic response

SUZUKI, Syota[1] ; ITO, Takeo[1*] ; SATO, Kachishige[2] ; HYODO, Mamoru[3]

[1]Graduate School of Environmental Studies, Nagoya University, [2]Faculty of Education, Tokyo Gakugei University, [3]Japan Agency for Marine-Earth Science and Technology

1. Introduction

The 2011 off the Pacific coast of Tohoku Earthquake with a moment magnitude (Mw) of 9.0 occurred at 5:46 (UTC) on March 11, 2011 along the boundary between the subducting Pacific Plate and the overlying plate. Since large earthquake are likely to produce stress concentrations in neighboring region along the plate boundary, the mainshock might have been trigger afterslip. It is very important to determine the detail of spatio-temporal distribution of afterslip, in order to understand the characteristic of friction relationship on the plate boundary. In this study, we estimate spatio-temporal afterslip distribution using visco-elastic Green's function (GF).

2. Method

We make GF using 3D finite element method (FEM) with a grid model for the Hokkaido and Tohoku regions. The model space and assumed subsurface structure for the 3D-FEM have a dimension of 2600 km (in the ESE direction) x 1500 km (in the NNE direction) x 400 km (depth) and typical subsurface structure consist of four sub-regions, i.e., upper crust, lower crust, upper mantle, and Pacific plate. The numbers of node and cell of 3D-FEM mesh are 3,205,950 and 3,121,200, respectively. For the calculation, we use the Pylith version 1.9.0, which is designed for simulating lithospheric deformation. In order to estimate the distribution of afterslip, we assume subfaults on the plate interface in and around the co-seismic slip zone of the 2011 Tohoku-Oki event. In inversion, we impose the smoothness constraint on the slip distribution. We estimate co-seismic and spatio-temporal distributions at the same time, considering visco-elastic response, derived from GEONET and seafloor observations.

3. Results and discussion

We obtain the co- and post-seismic slip distributions. The maximum slip of the 2011 event is about 60 m close to the Japan Trench. Estimated afterslip distribution is complementary to co-seismic slip distribution and also historical source regions. Amount of afterslip is about 2m, and the cumulative seismic moment is 8.06, considering visco-elastic response during 2.5 years after event. In case of only considering elastic response, amount of after slip is about 4m. There is no slip off Fukushima prefecture only considering visco-elastic response. And, our result can explain seabottom observations. i.e., Miyagi-Oki1 site move to west about 38 cm during 2 years after event. The effect of visco-elastic response is too large. In inversion for afterslip distribution from geodetic data, it must be consider to visco-elastic response due to relaxation in upper mantle.

Vertical displacement in Naruko Volcano area following the 2011 Tohoku earthquake deduced from precise leveling survey

TSUKAMOTO, Yuya[1*] ; SUGIYAMA, Kenichi[1] ; FUJITA, Wakana[1] ; WATANABE, Keitaro[1] ; WATANABE, Kosui[2] ; TAKAHATA, Akihiro[2] ; MATSUOKA, Moe[2] ; GOTO, Akio[3] ; OHTA, Yusaku[2]

[1]Fac. Sci., Tohoku University, [2]Grad. School Sci., Tohoku University, [3]CNEAS, Tohoku University

Large subsidence accompanied the 11 March 2011 Great East Japan Earthquake along the Pacific coast. GEONET data have indicated that the subsidence goes down westward (http://www.gsi.go.jp/common/000059956.pdf). In a summer field seminar by the Division of Earth and Planetary Material Science, Tohoku University, we made precise leveling survey for 10km on the second-order leveling route along the National Route 47 (from benchmark number 047-064 to 047-074; hereafter indicated as BM64, BM74 etc.) which locates along the east to west in Naruko area, Miyagi prefecture, to detect the vertical crustal deformation of this area. We performed the leveling twice (23-28 August, 2011 and 19-25 August, 2013) using bar-code leveling rods (Leica CPCL3) and an electronic digital level (Leica DNA03). By comparison with the data by Geospatial Information Authority of Japan in 2009, we acquired the change of difference in elevation at each benchmark against the westernmost BM64. We conducted round-trip survey between each benchmark and re-measured when the residual error did not meet the first-order leveling, except the segments between BM66 and BM68 in 2011 and between BM72 and BM74 in 2013 due to the fixed seminar schedule.

Contrary to our expectation before the leveling, we found all benchmarks subsided against BM64 and the degree of subsidence increases westward. At the 2011 leveling 5 months after the earthquake, benchmarks BM66, 68, 70, 72, and 74 subsided 13.0mm, 21.4mm, 81.7mm, 91.1mm and 113.9mm, respectively. This subsidence continued further with decreasing the amount, 8.5mm, 16.2mm, 23.7mm, 41.9mm and 46.2mm between 2011 and 2013, respectively. Obtained displacement pattern along the leveling survey between 2011 and 2013 is almost similar pattern with the 2009 and 2011 one.

Ozawa and Fujita (2013) and Takeda and Fukushima (2013) showed local depressions on some major volcanic areas in Tohoku region by In-SAR analysis. They explained the depressions by the east-west extension of hot and soft medium under the volcanoes. Our research route locates on one of that volcanic area and our leveling result is consistent with their previous studies. In contrast, their analysis just focused on the coseismic displacement. In our analysis, we found not only subsidence during the coseismic stage but also the subsidence in the postseismic stage. Particularly, it is worth noting that the subsidence increases remarkably between BM68 and BM70, which is inferred to cross the rim of Naruko caldera.

Acknowledgement
We appreciate Ryohei Kobayashi and Emi Hara who joined the leveling survey in 2011.

Postseismic gravity changes after the 2011 Tohoku earthquake recorded by superconducting gravimeters

IMANISHI, Yuichi[1*] ; TAMURA, Yoshiaki[2] ; NAWA, Kazunari[3] ; IKEDA, Hiroshi[4]

[1]ERI, The University of Tokyo, [2]NAOJ, [3]AIST, [4]University of Tsukuba

Continuous gravity monitoring by means of superconducting gravimeters is revealing significant effects of the 2011 Tohoku Earthquake on surface gravity in Japan. Two stations of superconducting gravimeters, Matsushiro and Kamioka, both in the main island of Japan (Honshu), are indicating gravity decreases at similar rates of approximately 10 microgal per year after the 2011 event, and this trend is still going on. Since Matsushiro and Kamioka are relatively far from the earthquake source region (epicentral distances being 420 km and 490 km, respectively), the postseismic crustal uplifts of the stations recorded by GPS are too small to account for the observed gravity decreases. Therefore, the observed gravity changes are likely to reflect ongoing changes in the density of the earth material, maybe associated with a viscoelastic flow of the asthenosphere. Data from Mizusawa, another SG station in Honshu, will also be presented in the paper.

Pressure Source Model Inferred from Crustal Deformaton Preceeding Seismic Swarm in 2013 beneath Tarumae Volcano

KOSHIROMARU, Takuma[1] ; MURAKAMI, Makoto[1*]

[1]ISV, Hokkaido University

Tarumae-volcano is an active volcano with an altitude of 1,041 m located in the southwestern part of Hokkaido. In past 350 years, three major magmatic eruptions occurred, i.e. Plinian eruptions in 1667 and 1739 and dome forming eruption in 1909. Volcanic activity in recent years is restricted to gas emission or volcanic earthquake activity at the shallow part of the volcano. A spherical source model for inflation/deflation sequence is inferred at shallow depth beneath the summit dome by campaign GPS observations by the Meteorological Agency. No sign of crustal deformation is found at the deeper depth of the volcano by continuous GPS observation in a regional scale either by the Geographical Survey Institute nor the Meteorological Agency. Thus, until now, a crustal deformation which suggests fluid activity beneath the Tarumae-volcano at deeper depths had not been detected.

In July, 2013 swarm seismic activity started at the depths of between 2-5 km about 2 km to the west of summit dome. In addition a crustal deformation preceding the swarm was identified at several observation sites. The size of the change was at about 1 micro radian or micro strain level. Because the change appeared commonly at several stations around the volcano, it is highly likely that the strain and tilt change is resulting from a activity of a source at a depth beneath the volcano. A spherical inflation source was inferred from the observation data. The estimated position is at the m.s.l. depth of 4.2 km and about 1.3 km to the NNW of the summit horizontally with inflation volume of 3.4×10^5 m^3.

Since the position and time of activation of the source are close to those of seismic activity, it is likely that there is some geodynamic relationship between swarm seismicity and crustal deformation. In our presentation we also discuss possible relationship between them.

Campaign GPS for detection of the volcanic deformation on and around Mt.Meakan and Mt.Tokachi

WADA, Sayaka[1*] ; MORI, Hitoshi, Y.[1] ; OKUYAMA, Satoshi[1]

[1]Hokkaido University, Institute of Seismology and Volcanology

Mt. Meakan is an active volcano located in the eastern Hokkaido, Japan. It made phreatic eruptions in 1996, 1998, 2006 and 2008. Mt. Tokachi is one of the famous active volcanoes sits in the central Hokkaido. In the recent 100 years, three major magmatic eruptions took place in 1926, 1962 and 1988-1989.

In this presentation, we will discuss the results of the campaign GPS on and around Mt. Meakan and Mt. Tokachi. Each broad area GPS observation had begun at Mt. Meakan in 2006 and at Mt. Tokachi in 2007, respectively. The campaign GPS observations have made for several days to weeks in each year for Mt. Meakan at 8 sites, and that for Mt. Tokachi at 12 sites.

We used the data of our campaign observations after the 2008 eruption for Mt. Meakan and since 2007 for Mt. Tokachi. We also used the data of several sites operated by JMA (Japan Meteorological Agency) at the same time. Analyzing these data, annual movements at those points were estimated. These movements included deformations of the regional tectonic moving, and of the coseismic step of Tohoku-oki earthquake on March 11, 2011. For making corrections of these non-volcanic deformations, we used the continuous data of GEONET sites by Geospatial Information Authority of Japan (GSI) around the volcanoes. Using the GEONET data from 2007 to 2013, the regional tectonic and the seismic deformations were estimated by linear approximation in space. To elucidate the volcanic deformation, seasonal variations should be taken into consideration. The discussion about estimated volcanic deformation will be made, with the corrections about the regional deformation, the coseismic step and the after slip of 2011 Tohoku-oki earthquake, and the seasonal change.

Acknowledgements

In this study, JMA, Sapporo District Meteorological Observatory furnish their observation data to us. We would like to express our gratitude to them. Also, we used the data of GEONET sites of GSI with thanks.

Crustal deformation associated with the unrest of Zao Volcano

MIURA, Satoshi[1*] ; NISHIMURA, Takeshi[1] ; OHTA, Yusaku[1] ; YAMAMOTO, Mare[1] ; DEMACHI, Tomotsugu[1] ; TACHIBANA, Kenji[1] ; OHMI, Katsuya[2] ; SHINOHARA, Eiichiro[2]

[1]Graduate School of Science, Tohoku University, [2]Sendai District Meteorological Observatory

Mt. Zao (1,841 m) is an active volcano located in northeastern Japan and having histories of phreatic or phreato-magmatic eruptions in the last 2 ka. Unrest of Zao volcano started in January, 2013 with a volcanic tremor (JMA, 2013) followed by activated seismicity mainly in the lower crust and very ?long-period seisimic events (VLP) up to today. Since the number of volcanological observatories within a distance of 10 kilometers from the volcano was limited at the time of beginning of the unrest; two continuous GPS sites and two sites equipped with borehole seismometers and tiltmeters, Tohoku University has built up 4 sites with broadband seismometers, 5 sites with continuous GPS, 1 site with shallow borehole tiltmeter, and 2 sites with a Proton magnetometer.

Using the new broadband network, we detected some VLPs with dominant period of about 10 sec, and revealed the source of the VLPs is located at a depth range of 2?4 km beneath the crater lake, from where the recent eruptions occurred since ˜600 years ago. There were, however, no significant surface phenomena such as steam explosion, ash effusion, and so on associated with the VLPs, except for precursory tilt signals about 5 minutes preceding a few major events.

We deployed dual-frequency GPS receivers at 5 new stations and the data are transmitted to the university using cellphone network for continuous observation (Demachi et al., 2011). The data are processed using the precise point positioning strategy (Zumberge et al., 1997) of GIPSY-OASIS II ver. 6.1.2 with IGS08 precise ephemerides and GMF mapping functions (GMF, Boehm et al., 2006). Since the wide area of northeastern Japan still suffers the long lasting postseismic deformation following the 2011 Tohoku-oki earthquake (M9.0), we try to extract volcanic deformation related to the unrest of the volcano using spatial and temporal filtering. Even though no distinct deformation has been recognized in the continuous GPS and tiltmeters at present, we may detect cm level variation of the shape of the mountain.

The acceleration episode of the back-arc rifting in the Izu-Bonin Arc possibly triggered by a remote earthquake in 2004

ARISA, Deasy[1*] ; HEKI, Kosuke[1]

[1]Department of Natural History Sciences, Faculty of Science, Hokkaido University

The Izu-Ogasawara (Bonin)-Mariana Island arc lies along the convergent boundary between the subducting Pacific plate (PA) and the overriding Philippine Sea plate (PH) in the western Pacific. Nishimura (2011) found that the back-arc rifting goes on behind the Izu arc by studying the horizontal velocities of GNSS stations on the Izu Islands. Here we show that this rifting has accelerated in 2004 using GNSS data at stations such as Aogashima, Hachijojima, Mikurajima, Shikinejima, and Nijima (we excluded stations in the Miyake Island because of the volcanic deformation).

The back-arc rifting behind the Izu islands can be seen as the increasing distance between stations in the Izu Islands (they are located to the east of the rifting axis) and stations located in the stable part of PH, e.g. Minami- and Kita-Daito islands. We found that their movement showed clear acceleration around the third quarter of 2004. Such an accelerated eastward movement could be interpreted not only as the acceleration of the back-arc rifting, but also as the trenchward movement of the arc due to a slow slip episode at the PH-PA boundary.

We first rule out the second possibility by constraining the onset time of the acceleration episode, and by correlating it with other inter-plate earthquakes in the PH-PA boundary. There was an inter-plate earthquake occurred on May 29, 2004 (M6.5) at the PA-PH boundary just to the south of the Boso-oki triple junction. However, the time series clearly lacked the jump which should mark the onset of the eastward slow movement. Moreover, the additional velocity vectors do not converge to the epicenter, and the onset time that minimizes the post-fit residual is significantly later than May. We therefore conclude that the accelerated eastward movement started in 2004 was not due to the afterslip of the interplate earthquake in May.

We found that the onset time coincides with the occurrence of the September 5, 2004, Kii-Hanto-oki, September 5, 2004, earthquake (M7.4), which occurred in the PH slab subducting at the Nankai Trough off the Kii Peninsula. We found that the accelerated movement vectors of these islands are almost parallel with each other, and perpendicular to the rift axis. We hypothesize that the seismic wave radiated from the epicenter of this earthquake dynamically triggered the acceleration of the back arc opening in the Izu Arc.

Subsurface structure and slip pattern of the Median Tectonic Line, SW Japan inferred from GPS displacement rate field

EDAGAWA, Nobuko[1] ; TABEI, Takao[1*] ; ICHITANI, Shozui[2] ; NAKAMURA, Yasuhiko[2]

[1]Fac. Science, Kochi Univ., [2]Grad. School Int. Arts Sciences, Kochi Univ.

The Median Tectonic Line (MTL) is the longest arc-parallel fault system in southwest Japan. Its right-lateral strike-slip motion is originated from oblique subduction of the Philippine Sea plate at the Nankai Trough, separating the Nankai forearc sliver (the outer zone) from the inner zone of southwest Japan. The deformation of the forearc sliver is characterized by interseismic contraction in the direction of the plate convergence (NW-SE) and long-term westward block movement along the MTL. In addition the MTL itself has a potential to generate a large inland earthquake in the future. Therefore it is important to understand subsurface structure and current slip/locking pattern of the MTL fault plane.

From dense GPS campaign measurements along a traverse line across the MTL, we have made it clear that a transition zone of the relative motion between the outer and inner zones is located 20-30 km north of the surface trace of the MTL (Tabei et al., 2002). To interpret the transition zone, we used a northward-dipping MTL fault plane which was revealed by seismic reflection survey (Ito et al., 1996) and assumed that its upper part was locked and a stationary right-lateral slip was occurring at depth. However, the concept of a pure strike-slip on an inclined fault plane seems somewhat unrealistic. In addition linear distribution of earthquakes aligned 20-30 km north and parallel to the MTL seems inconsistent to the hypothesis of the dipping MTL fault plane because most of them show a right-lateral slip on a nearly vertical fault plane. Unfortunately station distribution of the nationwide continuous GPS network is rather sparse in the north of the MTL because of the existence of the Seto Inland Sea. In this area we have deployed supplementary three GPS stations and collected continuous data since November 2010.

We propose a kinematic model of the transition zone. The model consists of several vertical right-lateral faults in a hanging wall above the northward-dipping MTL fault plane, which are close and parallel to each other. Distributed slip deficits on this parallel fault system may block the relative motion between the outer and inner zones and act as s broad shear zone as a whole. In this study we assume four parallel faults with different widths and depths from surface. Integrated displacement field from relative block motion and slip deficits on these faults is consistent with that derived from a strike-slip on an inclined fault.

We check the effect of the 2011 Tohoku-Oki earthquake on the deformation field of southwest Japan. We compare two displacement rate fields before (Jan. 2006 - Dec. 2009) and after (Mar. 2011 - July 2013) the earthquake. After the earthquake, additional wide-area displacements of 1-4 cm/yr trending to the source region (extension) have been superposed on the original compressional deformation field due to the subduction of the Philippine Sea plate. No significant change has been recognized in the latter.

Continuous GPS observation in northern part of Nansei Islands

NAKAO, Shigeru[1*] ; YAKIWARA, Hiroshi[2] ; HIRANO, Shuichiro[2] ; GOTO, Kazuhiko[2]

[1]GSSE, Kagoshima Univ., [2]NOEV, Kagoshima Univ.

GEONET, which is a nationwide GPS observation in Japan cover on all over Japan. However, there is a GEONET site in Toshima-mura which is located in northern part of Nansei Islands. This region is defined the boundary between Northern and Central part of Ryukyu arc (Nishimura et al., 2004). It is not clear that where is the boundary because there is almost no GPS site. Goto (2013) concluded that the great earthquake occurred in 1911 is the interpolate event in this region. We set up the continuous GPS in islands of this region due to observe crustal deformation in this region.

In Akuseki Island (AKSK), Takarajima (TAKR) and Kuchinoshima (KCHI), continuous GPS (CGPS) observation started in March 2007, July 2007 and September 2010, respectively. CGPS set up on Gajyajima (GJYA) and Ujishima (UJIS), where is a deserted island, in May 2009. CGPS in Yokoatejima (YKAT) started in September 2013. Data is recorded at CGPS sites. Electric power system at GJYA, UJIS and YKAT is composed of batteries and photovoltaic cells.

Bernese GPS Software ver. 5.0 are used with IGS precise ephemerides and IERS rotation parameters. We also estimated tropospheric delays every hour and their horizontal gradients every six hours.

The short-term repeatabilites are from 1.6 to 3.0 mm in horizontal component and from 6.5 to 7.9 mm in vertical components. These observation is expected to make contribution to resolve rigid movement and crustal deformation in this region.

The detection of crustal deformation associated with earthquake swarm in Tanzania observed by SAR

HIMEMATSU, Yuji[1*] ; FURUYA, Masato[1]

[1]Graduate School of Science, Hokkaido University

The East Africa Rift Valley is one of the divergent plate boundaries can be seen on the land surface. The area undergoes middle-class earthquakes and eruptions due to the existing faults and volcanoes.

An earthquake swarm occurred in the Northern Tanzania in July 2007 including the largest earthquake with Mw5.9 and lasted for approximately two months. According to the Global CMT solution, eight M>5 earthquakes occurred during the earthquake swarm and all of them were reported to be caused by normal fault. One week after the start of the swarm, an effusive eruption began at Mt. Oldoinyo Lengai located near the epicentral region, and a major ash eruption was observed by the time when swarm was terminated.

Biggs et al. (2009, 2013) also detected the crustal deformation associated with the earthquake swarm and Mt. Oldoinyo Lengai eruption, using mainly ENVISAT/ASAR C-band SAR data. In these interferograms, however, the ground displacements at some deforming areas were uncertain because of the difficult of phase-unwrapping. Also, these datasets were acquired only along the descending track, and the 3D deformation fields were unclear. Therefore, we used the L-band ALOS/PALSAR data obtained at both ascending and descending track to detect the detailed crustal deformation.

The purpose of this paper is to elucidate the mechanism of crustal deformation associated with the earthquake swarm in Tanzania in 2007 by interferometric synthetic aperture radar (InSAR).

By using InSAR data for ascending and descending track and the azimuth-offset data, we determined the 3D displacement. The results show a subsiding region along the NE-SW direction that are sandwiched by two horizontally deforming regions toward NW and SE directions. These spatial variation patterns are consistent with the expected direction, where the East Africa Rift Valley is expanding. In addition, the azimuth-offset data reveals slightly southward displacement in sediment area.

The ground at the subsiding region indicated ˜62 cm subsidence and ˜33 cm horizontal displacement toward SSE. The two-lobe pattern in eastern and western half each moved several centimeter upward and ˜50 cm in NW-SE direction horizontally.

In order to describe the ground displacement in detail, we estimated a fault source model assuming slip distribution in a homogeneous elastic half-space. Considering the complexity of the fault geometry, we derive a non-planar fault source model with triangular dislocation elements. Based on the result captured by InSAR and the observed area is in tension field, we propose two fault segments. The model indicates dip-slip and strike-slip displacement with maximum slip of about 1 m and 75 cm at 2-4 km depth.

Derived slip distribution can well explain the spatial variation pattern acquired by InSAR. The amount of moment release inferred from the model (Geodetic Moment: GM) exceeds that of the earthquake swarm (Seismic Moment: SM), and the ratio (SM/GM) is 37.2 percent. The ratio indicates that significant aseismic crustal deformation contributes to GM.

Some interferograms also detected the crustal deformation associated with Mt. Oldoinyo Lengai eruption during the earthquake swarm. We will also discuss the relationship between the earthquake swarm and the volcanic eruption of Mt. Oldoinyo Lengai.

Coseismic Deformation Detected by SAR and Fault Source Modeling of the 2009 Cinchona Earthquake (Mw6.1), Costa Rica

UMEMURA, Shutaro[1*] ; FURUYA, Masato[1]

[1]Department of Natural History Sciences, Hokkaido University

A shallow earthquake with magnitude 6.1 (Mw) occurred in Costa Rica, Central America, on 8 January 2009. This earthquake, called Cinchona earthquake, accompanied with many landslides and caused around 20 fatalities. In the proximity of epicenter, there is the Angel-Vara Blanca fault that has a strike NNW-SSE. Montero et al. (2009) inferred the fault as the earthquake source fault. After 4 days of the earthquake occurrence, Poas volcano located 6 km to the west of the epicenter erupted (Volcanic Explosivity Index 1) after a quiescence of one year. This volcano had remained dormant for a decade after 1996 and became active since 2006. As the 1st step to study the possible relationship between earthquake and volcanic eruption, we detected the coseismic deformation by using the ALOS/PALSAR data and created fault models to explain the data.

In this study, we used ascending (path 162, frame 190) and descending (path 465, frame 3410) data of ALOS/PALSAR. To correct for the topography effect, we used the digital elevation model of ASTER GDEM. We analyzed the SAR data with GAMMA software. In the interferogram processing, we removed the atmospheric noise. We calculated the Green's function by triangular dislocation elements using Meade (2007) scripts.

The detected interferogram indicated that the maximum coseismic LOS (Line of Sight) changes were 20cm for ascending and 22cm for descending track, respectively. We derived the fault source model that could explain the LOS changes by trial-and-error approach. The estimated strike/dip angle of the fault were 133/65, and the rake angle at the center of fault was -163 degree. The difference of fault parameter from Angel-Vara Blanca fault suggested that the previously unknown fault worked. We calculated the pressure change caused by fault movement. This indicated positive change (compression) under the Poas volcano.

An acceleration event of creeping slip detected by precise leveling survey at the central part of the Longitudinal valle

MURASE, Masayuki[1] ; MATSUTA, Nobuhisa[2*] ; LIN, Cheng-hong[3] ; CHEN, Wen-shan[4] ; LIN, Jui-jen[3] ; NISHIKAWA, Yuka[4] ; WADA, Erika[1] ; KOIZUMI, Naoji[5]

[1]Department of Geosystem, College of Humanities and Sciences, NIHON University, [2]Graduate School of Environmental Studies, Nagoya University, [3]Institute of Earth Sciences, Academia Sinica, [4]National Taiwan University, [5]The National Institute of Advanced Industrial Science and Technology

Precise levelling surveys were conducted across the central Longitudinal Valley Fault, eastern Taiwan, to understand the deformation of the transition zone between the stable fault creep area and the locked area, which maybe correspond to an asperity. In order to investigate the surface relationship between the fault creep area and the geological condition of the transition zone, we established levelling routes in the Yuli, and Chike-san areas. The Yuli area forms the geological boundary of the Lichi Melange Formation, which is composed of chaotic mudstones containing numerous exotic blocks of various sizes and lithologies. Along the Yuli route, located on the Lichi Melange, an uplift rate of 30 mm/yr was detected during the period 2010-2013, suggesting that aseismic fault creep might be continuing with long-term stability. Along the Chike-san route, located on no Lichi Melange, a vertical deformation rate of 8 mm/yr, 40mm/yr, and 20mm/yr were detected in the period 2010-2011, 2011-2012, and 2012-2013, respectively.

The creep slip distribution was estimated by using a two-dimensional single-fault model proposed at Chike-san in the period 2012-2013. Large slip rates were estimated at 4-5 km of the fault plane. At the previous periods 2010-2011 and 2011-2012, relatively large slip rates were estimated at two parts of the fault plane-one at a depth of about 1.5 km and another at a depth of 4-5 km-. We believe that the acceleration event of creeping slip was continued at the depth of 4-5 km in the period 2012-2013. The northern limit of the stable creep area may be the Yuli area. The episodic creep event occurred in the transition zone between the stable fault creep area and the asperity area. The boundary between the stable creep area and the episodic creep area is consistent with the geological boundary of the Lichi Melange Formation.

Internal stress changes due to point dislocations in a spherical earth

TAKAGI, Yu[1*] ; OKUBO, Shuhei[1]

[1]Earthquake Research Institute, The University of Tokyo

A simple and complete theory about internal deformations due to point dislocations in a homogeneous half-space was proposed by Okada (1992). This theory has been used by many researches to estimate Coulomb stress changes due to an earthquake and has contributed to understanding of seismology. Although a homogeneous half-space is a first approximation of the earth, global deformation like broad stress changes due to a great earthquake have to be calculated in a more realistic earth model, spherically symmetric earth model. Sun and Okubo (1993) succeeded in calculating surface displacements and gravity changes due to point dislocations in a spherically symmetric earth model. However, internal stress changes and displacements have never been calculated because there exist some difficulties to realize the calculation in spite of early proposal of a fundamental method (Takeuchi and Saito, 1972). In this research, we propose a strategy to realize the calculation of internal deformations and present some computational results.

We shall

i) outline the strategy to calculate internal deformations,

ii) compare the stress changes in a homogeneous sphere with those in a half-space which were already solved and

iii) show the results in a stratified earth model such as PREM.

Our study shows that significant difference between a homogeneous sphere and a half-space model occurs when epicentral distance exceeds several hundreds kilometers. For example, epicentral distances at which difference of radial stress changes in two models reach 10% are 4, 5 and 6.5 degrees at observation depth at 10, 20 and 30, respectively (Figure). Angular distance of 4 degrees, which is 400km, roughly equals the length of fault that is thought to have slipped in the 2011 Tohoku-Oki earthquake.

Figure. Difference of radial normal stress changes due to a vertical-strike slip at depth of 32km in two models, a homogeneous sphere and a half-space.The horizontal axis is epicentral distance and vertical axis is difference between the two models in percentage. Red, green and blue points indicate observation depth of 10, 20 and 30km, respectively.

Continuous measurements of ocean bottom crustal movements based on GPS-acoustic system using GPS buoy

IMADA, Naruyuki[1*] ; TERADA, Yukihiro[2] ; SAKAUE, Hiromu[3] ; TADOKORO, Keiichi[4] ; KATO, Teruyuki[5]

[1]Hitachi Zosen Corporation, [2]Kochi National College of Technology, [3]None, [4]Graduate School of Environmental Studies, Nagoya University, [5]Earthquake Research Institute, the University of Tokyo

We report the results of experiments of continuous measurements of ocean bottom crustal movements using GPS buoy and acoustic system.

We have developed a GPS buoy system for the early detection of tsunami. The system uses a buoy that is freely floating on the sea, tied to the sea bottom using an anchor, equipped with a GPS sensor at the top of the buoy. The system enables us to estimate the position of the buoy in a few centimeter accuracy.

On the other hand, Spiess (1985) and other researchers have developed the GPS-acoustic system for estimating the ocean bottom position in sub-decimeter accuracy. However, these systems have used owned or chartered vessels to measure the position of ocean surface, so that the measurements have been only intermittent. After the 2011 Tohoku-oki earthquake of Mw9.0, it has been recognized that continuous monitoring of ocean bottom crustal deformation is very important. Thus, we got an idea in that the GPS buoy could be used for the continuous monitoring of the ocean bottom crustal movements, if an acoustic system is equipped at the GPS buoy.

Based on this idea, we started experiments using our GPS buoy, which is located off Muroto Peninsula, western Japan, in the year of 2013. After a preliminary experiment in March 2013, we made an experimental observation from August to October of 2013. Three transponders were placed around the buoy and the equipment of sound sender/receiver at the side surface of the buoy. The water depth of the site is about 700meter and the ocean bottom transponders are placed so that the distances among these are in the same scale. We will report the results including noise characteristics of data, daily repeatability of estimated ocean bottom position, effects of swinging buoy, etc.

Currently, 15 GPS buoys have been established around the Japanese coasts. Augmentations of the acoustic system in these GPS buoy network will provide a powerful tool of monitoring ocean bottom crustal movements as well as tsunamis. Further requirements to GPS buoys are to be placed farther offshore, say, more than 100km from the coast. Recent developments of the GPS buoy system, including a newly developed algorithm, PPP-AR (precise point positioning with ambiguity resolution), clarified this requirements. However, still another problem of how data at the buoy placed far offshore is transmitted to land in real-time manner is still to be solved. For such problem of a newly designed high capacity data transmission system using a dedicated satellite system will be necessary. Our current experiment will provide an important data for designing a specification of such satellite system.

Movement of a fault arised by a pumping or a spring water and its understanding by poroelasticity -a case of NNW fault-

ISHII, Hiroshi[1*] ; ASAI, Yasuhiro[1]

[1]TRIES, ADEP

Tono Research Institute of Earthquake Science (TRIES) has developed a borehole stress meter for continuous observation and multi-component borehole instruments. At the present time about 15 borehole stations are in operation. We have investigated crustal movements and behavior of underground water by using data obtained from borehole observations. The depth of the deepest borehole is 1030 m.

Near TRIES, JAEA (Japan Atomic Energy Agency) is constructing deep boreholes with diameters of 4m and 6.5m. And depth is about 500m at the present time. The boreholes are 40m apart and connected by stages. NNW fault is running beside the 6.5m borehole. We are investigating a relationship between water flow and geophysical observations by using experiments of pumping water and spring water.

The main results obtained are as follows:

1. Water level of TGR350 borehole station decreases by pumping water and spring water. Data of the strain meters installed at 350m depth indicate right lateral movements of NNW fault.
2. Data of the strain meters installed at 350m depth indicate left lateral movements of NNW fault in case of recovery of water level.
3. Strain meters installed shallower depth (165m) and extensometers installed in sedimentary layer do not indicate such fault movements.
4. We have considered a mechanism explaining the phenomena by using poroelastic understanding.

We will present the details of observations and analyses.

Construction of Syobasama crustal activity observatory ?Installation of Ishii-type borehole stressmeter?

ASAI, Yasuhiro[1*] ; ISHII, Hiroshi[1]

[1]Tono Research Institute of Earthquake Science, Association for the Depvelopment of Earthquake Pred.

Large changes in the pore pressure in Toki granite have produced by the excavation of underground facilities of Mizunami Underground Research Laboratory (MIU) and drilling well for hydraulic tests in MIU (e.g. Asai and Ishii, JpGU2013). We have observed remarkable stress/strain/tilt variations associated with the pore pressure changes at borehole observation site TRIES, STG300 (on the north-east side of the fault), Togari(TGR350/TGR165), STG100, STG200 (south-west side), respectively within 500m of the MIU.

In this area the NNW trending sub-vertical (normal) fault is exists (e.g. JNC, 2003 and 2004). Pore pressure changes occurs in the south-west side of the fault, its impact were observed in water level/pressure record of the same side, and were also observed in stress, strain and tilt record. On the other hand, its impact were not seen in the water level/pressure record of the north-east side of the fault, but its impact were observed on stress, strain and tilt record. Pore pressure change occurs in the north-east side of the fault are similar to those of the south-east side. This observation results indicate that fault has impermeability and elastic deformation of the rock caused by pore pressure change extends over the fault.

In order to clarify the relationship of groundwater level changes to crustal strain changes at Syobasama observation site which is located approximately 1km northwest of MIU, Tono Research Institute of Earthquake Science has constructed the new borehole depth of 110 m and installation of Ishii-type borehole stress meters is scheduled in February 2014. We will present the details of construction of Syobasama observatory, and result of continuous stress observation with groundwater records.

Post-seismic crustal movements of the 11 April Mw6.6 Fukushima Hamadori earthquake based on GPS observations

HORI, Kayako[1*] ; AOKI, Yosuke[2] ; KATO, Teruyuki[2] ; MIYASHITA, Kaoru[1]

[1]Graduate School of Science, Ibaraki University, [2]Earthquake Research Institute , The University of Tokyo

Tohoku earthquake on March 11, 2011 (Mw9.0) was accompanied by a vigorous aftershock activity. One of the aftershocks occurred on April 11, 2011, nearby Iwaki city, Fukushima Prefecture, and was called as Fukushima-Hamadori earthquake (Mw6.6; Depth=5km). The focal mechanism of the earthquake was a normal fault. Co-seismic crustal movements due to the earthquake observed by GPS observation was amounted to about 30cm to northeast direction at Iwaki site.

Crustal deformations associated with the Fukushima-Hamadori earthquake is obtained by InSAR and the data were used to construct detailed fault slip models by the previous studies (Kobayashi et al.,2013 : Fukushima et al.,2013). However, it has not been possible to measure the postseismic deformations using the SAR because the ALOS satellite has terminated its operation in immediately after the Fukushima-Hamadori earthquake. Thus, the postseismic crustal movements has been observed only by the GPS observations. Therefore, we aim to elucidate the mechanism of postseismic deformations due to the Fukushima-Hamadori earthquake using the GPS data in this study.

In this study, it was assumed that postseismic crustal deformations were caused by a slip in the vicinity of the fault. We used earthquake fault geometries employed by previous studies (Kobayashi et al.,2013 : Fukushima et al.,2013). As the GPS data is including large postseismic displacements due to the main shock since the March 11, first, we removed the postseismic transient displacements from GPS data using a postseismic slip model of the main shock (Fukuda et al., 2013). The obtained residual displacements after April 11, 2011, are considered as postseismic displacements due to the Fukushima-Hamadori earthquake. We, then, estimated slip distribution on the fault plane based on the residual displacement field. We will discuss estimated results in our presentation.

Coseismic slip distribution for the 2011 Tohoku-Oki earthquake with topographic corrections

GOSHIMA, Hitoshi[1*] ; MIYAZAKI, Shinichi[1]

[1]Graduate School of Science, Kyoto Univerisy

Seismological study (Ide et al., 2011) revealed that the rupture of the 2011 Tohoku-Oki earthquake extended to the Japan Trench (i.e. free surface). Since the depth of the trench is about 8km, it is not appropriate to use green functions for elastic half-space media as given by e.g., Okada (1992). When we employ green functions for the half-space, it is not possible to satisfy the following two conditions simultaneously; (1) the updip limit of the rupture is ˜8km deeper than the ground surface, and (2) the rupture extends to the free surface (i.e. the trench). If the condition (1) is satisfied, the rupture extends to ˜8km at depth, not to the free surface. On the other hand, if the condition (2) is satisfied, the depth of the trench must match to the ground surface. The maximum discrepancy in between predicted ground displacements for the condition (1) and (2) is 5% in horizontal, and 15% in vertical component. Thus, it may be important to take the topography into account in green functions.

In this study we applied the topographic correction on green functions as proposed by Williams and Wadge (2000). Segall (2010) suggests that this method is applicable to approximately incorporate the earth sphericity into green function for observation sites within about 600km from the dislocation. Combining those two corrections, we are able to calculate corrected green functions for spherical earth with topography. Although this method gives only approximate green functions, it helps us to investigate the dependence of green functions on topography and fault geometry.

Then we use the corrected green functions for the inversion of coseismic slip distribution for the 2011 Tohoku-Oki earthquake. In the invsersion we use the following data set: GEONET F3 solutions obtained by the Geospatial Information Authority of Japan (GSI), the ocean bottom deformation data by the Japan Cast Guard (Sato et al., 2011), and that of Tohoku University (Kido et al., 2011; Ito et al., 2011). Then the inversion result is compared with the half-space solutions.

Secular change of permeability estimated by using the variations of groundwater discharge

MUKAI, Atsushi[1*] ; OTSUKA, Shigeaki[2]

[1]Faculty of Informatics, Nara Sangyo University, [2]Faculty of Humanities and Sciences, Kobe Gakuin University

Secular change of permeability causes the variation of the atmospheric pressure admittance of groundwater discharge. We estimated the permeability of the surrounding crust by using the groundwater discharge observed at Rokko-Takao station during 12 years from 2001 to 2012. The estimated secular change of permeability contained the short term variations for about a year as well as the gradual decrease. It is considered that the gradual decrease of permeability was caused by the closure of the cracks, which were opened in the 1995 Hyogoken Nanbu earthquake, due to the accumulation of mud and the crustal stress. On the other hand, the short term variations of permeability suggest the temporary re-open of the cracks due to the earthquake ground motions.

The Rokko-Takao station is located in Kobe, the southern Hyogo prefecture, and passes through the fracture zone of Manpukuji fault. At this station, the significant increase of groundwater discharge was observed just after the 1995 Hyogoken Nanbu earthquake (Fujimori et al., 1995). This suggested that the many cracks were opened in the fracture zone around the station by the ground motion of the earthquake. Mukai and Otsuka (2009) estimated the elastic properties by using the tidal strains observed at the station and reported that the Young's modulus of the surrounding crust showed the secular increase. This suggested that a part of cracks were closed by the crustal stress and the accumulation of mud and the strength of the fracture zone had been recovering.

Mukai and Otsuka (2013) estimated the variations of permeability due to the 2011 Tohoku earthquake by using the atmospheric pressure admittances of the groundwater discharge observed at the station under the assumption of one-dimensional model about groundwater migration. The permeability just after the earthquake increased by about 1.9 times just before the earthquake and decreased to the level about 1.3 times just before the earthquake in 10 months. This suggested that even the small ground motions due to the teleseismic waves could cause the outflow of the mud and the temporary re-open of the cracks in the fracture zone.

In this study, we estimated the secular change of permeability around the station during 12 years from 2001 to 2012 by using the procedure of Mukai and Otsuka (2013). The permeability estimated by using the atmospheric pressure admittances of the groundwater discharge showed the secular decrease by about 50% in 12 years. This result agrees to the secular increase of Young's modulus estimated by using the tidal strain and is considered that the gradual decrease of permeability was caused by the recovering of the fracture zone, in which the cracks were opened in the 1995 Hyogoken Nanbu earthquake.

Vertical crustal deformation in Boso Peninsula from 1966 to 2001 deduced from leveling and sea level data

KOBAYASHI, Akio[1*]

[1]Meteorological Research Institute

Leveling data and sea level data for the period from 1966 to 2001 in Boso Peninsula, Japan, were investigated to characterize unsteady vertical deformation. We estimated the steady vertical deformation rate at each GEONET GNSS station using the daily coordinates for the periods from January 1997 to January 2011 avoiding the period of the large earthquakes.

First-order leveling surveys have been conducted repeatedly every one or several years since 1966 in Boso Peninsula. We determined crustal displacements by comparing leveling data from successive surveys. We subtracted subduction-related steady component derived by the GNSS from the distribution of vertical crustal displacements during periods between leveling surveys. If any episodic events have not occurred, they should show little spatial variation around zero vertical displacement. Unsteady vertical deformation was not seen in the period from 1966 to 2001 except the land subsidence by pumping industrial water and natural gas brine.

2014 Boso slow slip

OZAWA, Shinzaburo[1*]

[1]Geospatial Information Authority of Japan

Introduction

The GPS network detected transient crustal deformation on the Boso peninsula in 1996, 2002, 2007, and 2011. The detected transient displacements subsided for approximately 10 days. Rupture process and slip area are similar among the past four Boso SSE. The recurrence intervals of Boso SSE are 6.4, 4.9, 4.2 years from 1996. Under this circumstance, the anticipated slow slip event started from January 1 2014. This recurrence interval of 2.2 years is the shortest one compared with the previous 4 slow slip events. In this research, we estimate spatio-temporal evolution of the 2014 Boso slow slip and compare it with those in 1996, 2002, 2007, 2011.

Data and analytical procedure

Trend and annual components which are estimated for the period between 2009 and 2011 are removed from the raw time series. The detrended crustal deformation in 2014 shows southeastward movments with 1 cm maximum movement in the Pacific coastal area.

We employed time dependent inversion to the detrended crustal deformation associated with the 2014 Boso SSEs. We used EW, NS, and UD components of crustal deformation at approximately 40 GPS sites relative to Yasato station. The plate geometry of the upper surface of the Philippine Sea plate is based on Nakajima and Hasegawa [2006]. The fault geometry is composed on the B-spline and slip on the fault is also composed of superposition of B-spline function. As a boundary condition, we set 0 slip on the edge of the fault geometry.

Results and Discussion

The results show that the slow slip started offshore of the Boso peninsula and expanded to the south over time. The estimated moment magnitudes are 6.4, while those area 6.4 in 1996, 6.5 in 2002, 6.5 in 2007 and 6.6 in 2011. The 2014 Boso SSE ruptured an area similar to those of the four Boso SSEs. The recurrence interval is 6.4 year from 1996 to 2002 events, 4.9 years from 2002 to 2007 events, 4.3 year from 2007 to 2011, and 2.2 years from 2011 to 2014 events. The five events do not seem to be slip predictable nor time predictable. Though the 2011 event shows the largest magnitude among four cases, recurrence interval from 2007 event is the shortest. We cannot rule out a possibility that the Tohoku earthquake may have affected the occurrence of the 2011 event. In fact, dCFF increased near the rupture area of the Boso peninsula from the Tohoku earthquake [Hirose et al. 2012]. However, it remains unclear the reason why recurrence interval change drastically from 4.2 to 2.2 years for the 2011 and 2014 events, since dCFF does not change so much from 2011 and 2014. Another interpretation of shortening of recurrence interval is based on a scenario proposed by several simuylation studies in which recurrence interval of slow slip events become shorter as occurrence of large earthquake nears. If this is the case, it is quite important to monitor crustal deformation on and around the Boso peininsula..

Estimation of frictional parameters in afterslip areas by assimilating GPS data :The 2003 Tokachi-oki earthquake

KANO, Masayuki[1*] ; MIYAZAKI, Shinichi[2] ; ISHIKAWA, Yoichi[3] ; HIYOSHI, Yoshihisa[3] ; ITO, Kosuke[3] ; HIRAHARA, Kazuro[2]

[1]ERI, Tokyo Univ., [2]Kyoto University, [3]JAMSTEC

Seismological and geodetic observations have revealed that various aspects of fault slips are determined by frictional properties on the interface. Kano et al. (2013) developed an adjoint data assimilation method to estimate frictional parameters from synthetic in-situ slip velocity data and found by numerical experiments that all frictional parameters are constrained if both acceleration and deceleration phases are observed. Additionally, we found that synthetic surface displacement data also have the ability to constrain frictional parameters in the areas where slip is well resolved. Following their study, we then applied the method to an actual case of the 2003 Tokachi-oki earthquake. Given reasonable initial conditions of simulation variables, estimated frictional parameters are well constrained if two conditions above are satisfied. Our results imply that the adjoint method we developed is useful to investigate and understand fault frictional properties.

Crustal deformation of the northeastern margin of the Izu Collision Zone inferred from GPS observations

DOKE, Ryosuke[1*] ; HARADA, Masatake[1] ; SATOMURA, Mikio[1] ; MIYAOKA, Kazuki[1]

[1]Hot Springs Research Institute of Kanagawa Prefecture

Izu Collision Zone is characterized by the collision between Izu Peninsula and Tanzawa Mountains, and Philippine Sea Plate also subducts beside this zone. Because of these complicated plate geometries, a number of historical earthquakes occurred in the northeastern margin of this zone. Additionally, there are a lot of active faults in the marginal area of the collision zone.

It is important to describe the steady state of crustal deformation in the Izu Collision Zone, in order to clarify mechanisms of earthquakes occurring in this area. In this study, we examined crustal deformation of the northeastern margin of Izu Collision Zone by using the datasets of GEONET sites (coordinate F3) and our original GPS sites.

Based on the displacement velocity vector diagram and profile, we can point out the following characteristics of crustal deformation there.

1) Remarkable northward crustal displacement vectors were observed in the eastern area of the Kita-Izu fault zone.

2) A shear zone with North-South trend was detected in the area between Kita-Izu fault zone and Ashigara Plain. Width of its zone was estimated about 15-20 km. Average shear strain rate in this zone was about 0.47 micro-strain per year.

3) Such remarkable crustal displacement vectors were not observed in the western area of the Kita-Izu fault zone.

This shear zone may be a transition zone between the collision and the subduction blocks on the Philippine Sea Plate, caused by the displacement gap between the blocks.

The wind velocity correction of the precipitation to use for the rainfall correction of the volumetric strainmeter

KIMURA, Kazuhiro[1*]

[1]Meteorological Research Institute

The rainfall correction of the volumetric strainmeter has the sensitivity that can judge quality of the precipitation data.(Kimura et al., 2013) In the observation of the rain gauge, it is well known that a capture rate of the rainfall decline at the time of a strong wind. We try the ranfall correction of the volumetric strainmeter in consideration of wind velocity dependence. As a result, the strainmeters at the slope of the big mountain or near the river where had a long basin area is improved the rainfall correction. This is not influence of the capture rate of the rain gauges, it is caused by the fact that altitude dependence of the precipitation is remarkable as a strong wind.

For the rainfall correction of the crustal movement data such as the volumetric strainmeter, it is necessary to consider it about the rainfall at high altitudes in addition to the precipitation around the observation station.

The change except the sudden contraction of the Higashiizu staraimeter with the seismic activity east off Izu Peninsula

KIMURA, Kazuhiro[1*] ; KIMURA, Hisao[2]

[1]Meteorological Research Institute, [2]Japan Meteorological Agency

The sudden contraction strain change of the Higashiizu staraimeter with the seismic activity east off Izu Peninsula is well known. These changes were clear for anyone, but the Higashiizu staraimeter couldn't detect the long-term change that Murakami(2006) pointed out by the GNSS data until now. However we became able to remove the seasonal change by the rainfall from the strainmeter data by using the rainfall correction(Kimura et al., submitted). After reviewing the Higashiizu strainmeter data using the rainfall correction, this data detect the interesting change with the seismic activity east off Izu Peninsula.

Characteristic strain distribution following the 2011 Tohoku earthquake based on the kinematic PPP analysis

HIRATA, Yuichiro[1*] ; OHTA, Yusaku[1] ; OHZONO, Mako[2] ; MIURA, Satoshi[1]

[1]Gradual School of Science, Tohoku University, [2]Faculty of Science, Yamagata University

The 2011 off the Pacific coast of Tohoku Earthquake (March 11, 2011, M 9.0) generated widespread coseismic deformation. The slip on the plate boundary is larger than the 10 m in widely (e.g. [1]). Ohzono et al [2] found inhomogeneous strain distribution caused by the coseismic step of the 2011 Tohoku earthquake. They extracted the residual strain distribution, which is estimated by comparison between the expected coseismic displacement by a simple rectangular faults model and the observed coseismic displacement in the Tohoku area. Ozawa and Fujita [3] found the local deformation around the Akita-Komagatake, Kurikoma, Zao, Azuma, and Nasu volcanoes caused by the 2011 Tohoku earthquake based on the ALOS/PALSAR and GPS data. They suggested that the coseismic extensional deformation concentrates in the soft medium under a volcano and that this deformation has caused local deformation with subsidence based on the FEM modeling. These previous studies , however, used the daily coordinates time series of the GPS observation. Thus, these previous studies result might be contained early postseismic displacement following the 2011 Tohoku earthquake. Based on these backgrounds, we tried to extract the pure coseismic deformation by the kinematic Precise Point Positioning (kPPP) approach.

We estimated every 1 seconds coordinates time series of the 1,208 GEONET by the GIPSY-OASIS II software version 6.1.2. We defined the " pure " coseismic displacement, which is coordinate difference between just before the origin time and 600 seconds after the event. We averaged from 500 to 700 seconds after the event for eliminating short-term fluctuation of the time series. Based on the estimated " pure " coseismic displacement, we estimate the dilatation strain distribution by method of the [4]. We also estimated strain distribution in the early time period after the 2011 Tohoku earthquake, which estimated coordinate difference between coseismic displacement by the daily coordinate (e.g. difference between 10 to 12th March, 2011) and " pure " coseismic displacement by the kPPP analysis.

As a result, we found the characteristic local expansion in and around the Mt. Gassan, which located in Yamagata prefecture. We also found the characteristic contraction in and around Mt. Zao even though this obtained strain amount is smaller than the noise level determined by the kPPP time series. We also estimated strain distribution of early postseismic between mainshock and 15th March for the understanding the spatiotemporal development of strain distribution. The area of the expansion is clearly larger than the 12th March in and around the Mt. Gassan. Furthermore, the contraction area around the Mt. Zao clearly changed to expansion between just after the mainshock and 15th March.

In the presentation, we will discuss more detail characteristics and its interpretation of the obtained strain distribution.

Convergence of the Philippine Sea Plate in Mindanao, the Philippines

NAKAMURA, Yasuhiko[1*] ; TABEI, Takao[2] ; OHKURA, Takahiro[3] ; KIMATA, Fumiaki[4] ; TERESITO C., Bacolol[5] ; ENDRA, Gunawan[6]

[1]Grad. School Int. Arts Sciences, Kochi Univ., [2]Fac. Science, Kochi Univ., [3]Aso Volcanological Laboratory, Kyoto Univ., [4]Tono Research Institute of Earthquake Science, [5]Philippine Institute of Volcanology and Seismology, [6]Grad. School of Environmental Studies, Nagoya Univ.

Tectonics of the Philippines Archipelago is characterized by westward subduction of the Philippine Sea plate at the Philippine Trench in the east (5.8 - 7.0 cm/yr), eastward subduction of the Sunda plate at the Manila Trench in the west (3.3 - 3.6 cm/yr), and left-lateral strike-slip movement of the Philippine fault inland. Under the SATREPS project ”Enhancement of earthquake and volcano monitoring and effective utilization of disaster mitigation information in the Philippines” we have conducted yearly GPS campaign measurements in the eastern part of Mindanao since March 2010. The main purpose of the observation is to make clear the plate locking distribution at the Philippine Trench and slip/locking pattern of the Philippine fault in order to estimate earthquake generation potential in Mindanao.

We occupied 15 sites in the eastern Mindanao and collected continuous data for successive three to six days on March 2010-2013. Collected data were processed with Bernese software ver.5.0 together with the data from global IGS station (PIMO near Manila) to obtain coordinates and displacement rates based on ITRF2008. The displacement rates were then converted to those with respect to the Sunda plate. Moreover we used previous displacement rate data obtained in the central and western Mindanao from the 1997-2003 campaign measurements to cover the whole of Mindanao.

The resulted displacement rate filed shows that west-northwest motions are dominant due to the convergence of the Philippine Sea plate from the east but their spatial decay with increasing distance from the trench is not significant. Even the full locking of the Philippine Trench plate interface down to the depth of 80 km can explain only 29 percent of the observed displacement rate at the maximum. Thus we need to introduce remarkable rigid block rotations to interpret the deformation pattern of Mindanao. As a result of the estimate of pole position and angular velocity of the block rotation, deformation field of Mindanao cannot be reproduced by a rotation of single block. Considering the Philippine fault as a block boundary, it is natural to introduce multiple blocks into Mindanao. Unfortunately current station coverage and density are not enough to resolve elastic deformation due to plate locking at the trench and rigid motions due to multiple block rotations.

Slip deficit rate distribution and its temporal changes along the Japan islands

HIGUCHI, Shun[1*] ; KOKETSU, Kazuki[1] ; YOKOTA, Yusuke[2]

[1]Earthq. Res. Inst., [2]Japan Coast Guard

The Japan islands are located along several plate boundaries, where the oceanic plates are subducting beneath the continental plates. Due to this subduction, slip deficits are being generated and strain is being accumulated in coupled zones of the plate boundary so that many large earthquakes have occurred. Therefore, in order to reveal the generation mechanism of large earthquakes at the plate boundaries, it is necessary to clarify slip deficit rate distributions. In addition, as seen in long-term slow slip events, there are significant temporal changes in the slip deficit rate distributions. In this study, we determined the slip deficit rate distribution along the whole Japan islands for each year from 1996 to 2010 (the observation period of GEONET operated by GSI before the 2011 Tohoku earthquake) using the inversion method, and compared each other to investigate their temporal changes.

For calculating the deformation fields in Japan, we used the daily coordinates of F3 solutions. We obtained daily time series data considering the movements of the continental plates against reference frame and removing the offsets and postseismic effects due to nearby earthquakes. We then derived horizontal rate fields in Japan for each year by least-squares fittings. For reflecting the geometry of the plate boundaries, we used the plate model (Baba et al., 2005) incorporated in JIVSM (Koketsu et al., 2012). The Green's functions were calculated using the frequency-wavenumber method (Zhu and Rivera, 2002). We performed slip deficit inversions using the method of Yoshida et al. (1996).

The slip deficit rate distributions derived from the inversions were consistent with the previous study and the plate convergence rates. In addition, known long-term slow slip events were found in the temporal changes of the slip deficit rate distributions. Furthermore, we can see the temporal changes in the Hokkaido and Kanto regions, which suggest variations of plate coupling in these regions. The zones of large slip deficit rate in the distributions look corresponding to the source regions of past megathrust earthquakes. These correspondences are significant not only in Earth science but also in seismic hazard assessments.

[1]Fukada Geolog. Inst., [2]Pacific Consultant, [3]Kubiki Techno., [4]Alpha Hydraulic Eng. Consultant, [5]JNES, [6]IRIDeS, Tohoku Univ.

A large earthquake occurred in the sea area between Aomori coast, most northern district of Honshu, and Hidaka coast, Hokkaido, on 23rd August, 1856 (3rd year of Ansei era) . This earthquake is a one of the series of the plate boundary earthquakes at the joint point of the Japan and the Kuril trenches, where the 1968 Tokachi-Oki earthquake occurred. The 1677 Enpo North Sanriku-Oki earthquake is considered also as the same typed one. The tsunami of the 1856 North Sanriku-Oki earthquake hit the coasts of Sanriku districts, the north east part of Honshu, and the pacific coast of Hokkaido. As the total number of victims of the tsunami was only 38 people in all, and it was considered not to be a large natural hazard. So it did not become a lecture for tsunami hazard in the time of the 1896 Great Meiji Sanriku tsunami. The diary kept by a priest of Kokutaiji Temple at Akkeshi in east Hokkaido records that human disturbance broke out there, and tsunami height was estimated at 2.0 m. At Saru-Kaisho office in Monbetsu town, Hidaka district, a strong tide came in front of the building of the office, where sea water rose up to the height of 11.2 meters. At Etomo village in Muroran city, sea water invaded into the residential area (height: 5.6m). On the pacific side of Hakodate peninsula, sea water flooded up to the fort of Tsugaru Clan ”Tsugaru-han Jin’ya” where the ground height is 8.6 m. At Same fishery port in the central area of Hachinohe city, residential area was flooded up to 7.3 meters height. At Kanehama village in Miyako city, which is located at the innermost point of the V-shaped bay, inundation height was 5.7 meters. As for the coasts of south part of Iwate Prefecture Tsuji et al.(1995) conducted survey. Together with this result,we have the distribution map of the tsunami height as the figure. The authors of the present study wish to express their thanks to JNES for its financial support in promoting our research.

Reexamination of 1945 Mikawa earthquake disaster (1) Detailed distribution of earthquake victims

KIMATA, Fumiaki[1*] ; MATSUTA, Nobuhisa[2]

[1]Tono Research Institute of Earthquake Science, Association for the Development of Earthquake Predict, [2]Earthquake and Volcano Research Center, Graduate School of Environmental Studies, Nagoya University

Iida (1978) organized the Mikawa earthquake disaster under the cooperation of Aichi prefecture, and clarify the whole picture of the disaster. However, he could not discuss the disaster in community level precisely. For example, 46% of 1200 houses were collapsed in Hukuji village, Hazu-gun in 1944 ToNankai earthquake, and additionally 67% of left 650 houses were also collapsed in 1945 Mikawa earthquakes one month later. The reason of strong damages in Hukuji is not discussed enough until now.

It is very important to make clear whole picture of the earthquake disaster in history and in near future as national government. As the earthquake disaster remains a rare event, detailed research of the historical earthquake disasters needful to understand the following disasters. In the presentation, we would like to discuss the disaster of the Mikawa earthquake in local community level.

1. Discussion on characteristic disaster based on earthquake victim distribution

Earthquake fault shaped S was appeared in the ground surface at the Mikawa earthquake. However recent researches of fault geomorphology and ground deformation based on geodesy point out two main faults striking with NNW-SSE direction, and an E-W striking fault is tear fault caused by slips on two faults. Additionally, dominant rupture should be occurred at Fukodu fault located in east. The total Mo estimated by ground deformation is the earthquake moment of 1.6x1019Nm(Mw6.7), and the third four of the released one is by slip of Fukodu fault. In our presentation, we discuss earthquake disaster with the local community level based on two N-S striking earthquake faults.

1) Katahara: compact cluster of dead located close to Fukodu fault

Katahara town of Hoi-gun (then-9300 people and 1887 houses) located just on Fukodu fault, lose 227 people and 319 completely destroyed houses (15.2% collapse rate). In the town, the damages are different in each street corner. Numbers of dead and completely destroyed houses within the town are shown as bar charts and color scale in 59 neighborhood blocks. The dead are limited in the narrow zone of 1 km wide along the earthquake fault. There are some communities with no collapsed house, which are located 1 km distance from the fault. Dead are corresponding to 73 % of completely-destroyed houses, and some blocks closing the fault show the rate over 90%. Precisely, people are attacked by strong seismic waves during the hours of sleep, and they had no time to evacuate to outsides from houses. There are many blocks to have no dead and no collapsed houses, which are locating more 1 km far from the fault.

2) Fukuji: Decentralized dead far from fault in river plain

On the one way, Fukuji village (then-673 houses), Hazu-gun locating 5 km southwestward from the Yokosuka Fault, one of main faults, lost 162-350 peoples and 400 houses completely. In one month before, the village also attacked by 1944 ToNankai earthquake, lost 21 people and 550 houses completely. They lost 1000 houses by earthquakes in 1200 houses for one month. The numbers of the dead are shown in each block in Fig.1B.

The dead distributions are obviously different with that in Katahara. They lost many people in almost all blocks in the village. The collapse rate of ToNankai earthquake is by far the worst in Aichi prefecture, because, second worst is 21.3% in Tomiki village, Chita-gun. The Fukuji village is just located in river plain with Yahagi and old-Yahagi rivers. An exist of thick alluvial formation caused the large damages in Fukuji.

The dead by Mikawa earthquake are caused by two reasons. One is there are very strong shaking at the blocks located immediately above the fault, and second is amplitude shaking by alluvial formation in river plain. The former is a case of Katahara and later is a case of Fukuji.

Interpretation of an illegible old stone inscription by SfM image analysis at Itsukushima shrine, Nojimazaki

SUZUKI, Hinako[1*] ; UCHIYAMA, Shoichiro[1] ; INOUE, Hiroshi[1]

[1]National Research Institute for Earth Science and Disaster Prevention (NIED)

This study shows that interpretation the illegible old stone inscription by structure from motion (SfM) image analysis. The stone monument built in 1927 for memorial on the 1923 Taisho Kanto Earthquake, the inscribed capitals can hardly read. We captured 158 photographs on the surface of the stone, and processed by SfM to generate 3 D model of it. As a result, illegible capitals became clear on the 3 D model, so visible coated contamination removed by SfM. It is effective method to archive stone inscriptions.

The Evidence of the Uplift associated with the Kanto Earthquakes inferred from the Marine Terrace in the Alluvial Valley

KIM, Haeng yoong[1*] ; MANNEN, Kazutaka[1] ; SASAGE, Kazuo[2] ; KUMAKI, Yohta[3] ; MATSUSHIMA, Yoshiaki[4]

[1]Hot Springs Research Institute of Kanagawa Prefecture, [2]PASCO, [3]Senshu University, [4]Kangawa Prefecture Museum of Natural History

Recurrent giant earthquakes at the plate boundary along the Sagami Trough have been considered as one of the greatest thread of the Tokyo Metropolitan area. At the southwestern tip of the Miura Peninsula, in south of Tokyo, the tide gauge station records the coseismic uplift amount of 1.4 m and the interseismic subsidence amount of 0.3 m in and after 1923 earthquake, respectively. It is effective to reveal evidences of the past coseismic uplift to know the future earthquake.

Wave-cut benches which emerged in 1923 are widely distributed along the rocky coast. Higher wave-cut benches, good indicators of coseismic uplift prior to 1923, are also recognizable. It is, however, often difficult to spatially compare one another due to the erosion.

We investigated the distribution of the tidal-flat deposits and the 1923 wave-cut benches at two small bays in the southwestern and southern parts of the Peninsula. The aggradation of the coastline associated with the 1923 uplift was identified by the comparison between the 1:25,000 topographic maps before and after the 1923 earthquake. Observations of outcrops and drilling cores at the 1923-formed marine terrace showed that the tidal-flat deposits consist of shelly sand and gravels. The elevation of tidal-flat deposits indicates the coseismic uplift in 1923 and the interseismic subsidence after 1923. The uplift amount was estimated approximately 0.9 m and 2.1 m at the southwestern and southern parts of the Miura Peninsula, respectively. The uplift amount inferred from the tidal-flat deposits is concordant with that inferred by the wave-cut benches.

Coseismic uplifts of the southern Izu Peninsula and the coastal area of Shimizu Plain

KITAMURA, Akihisa[1*] ; KOBAYASHI, Konatsu[1] ; OHASHI, Yoko[2] ; YOKOYAMA, Yusuke[2] ; MIYAIRI, Yosuke[2]

[1]Shizuoka University, [2]The University of Tokyo

We examined coseismic uplift events in the coastal area of the Shimizu Plain, and at the southern end of the Izu Peninsula. On the basis of lithologies, fossil contents, and radiocarbon dating, we identified geological and paleontological evidence for abrupt changes in depositional environments related to coseismic uplift associated with the AD 1854 Ansei-Tokai earthquake. We estimated a maximum coseismic uplift of 1.2 m and post-earthquake gradual subsidence of ca. 0.6 m. Radiocarbon dating of the emerged sessile assemblages at the southern end of the Izu Peninsula, central Japan suggest that at least four coseismic uplift have occurred in the area, during 3387-2485 cal yr BP, AD 570?820, AD 1000?1270, and AD 1430?1660.

Former shoreline height and Active Faulting around Obama Bay, Fukui, Central Japan

WATANABE, Mitsuhisa[1*]

[1]Toyo Univ.

I examined the distribution of marine terrace surface assigned to the oxygen isotope stage 5e along the coast around Obama Bay, Fukui Prefecture, central Japan. The marine surface is recognizable on the western and southern coast of Obama bay, which indicates only southwestern coast has progressively uplifted. There is no marine terrace surface along the NE coast of the bay. This strongly suggests that an active fault divides the bay just on the extension of the FO-A fault and the Kumagawa fault. The FO-B and FO-A fault are left-lateral active fault trending NW-SE direction. The Kumagawa fault trending WNW-SES direction display the same vertical displacement as them and SW hanging-wall uplift. These active faults composing of an extensive active fault ca. 65-km long across Obama bay displaying distinct trace jog close to the mouth of the bay (Nokogiri-zaki point). Height distribution of the former shoreline on the marine terrace surface shows the uplift pattern in this area. Comparing the uplift pattern with calculated displacement based on the dislocation theory, the fault model mentioned above explains the general features of the crustal deformation.

Comparison of the fault zones of the fault activity terminated until the Early Pleistocene and the active fault

OHTANI, Tomoyuki[1*] ; KONO, Masahiro[1] ; KOJIMA, Satoru[1]

[1]Gifu Univ.

In the active fault surveys without younger sedimentary layers, it is desired that the new method is developed to assess the fault activity using the fault rocks in the basement rocks. To achieve this, it is important to understand the characteristic features of the fault zones not only active faults, but also the faults terminated their activity recently. We studied the fault zone of the Median Tectonic Line (MTL) in Yoshino, Nara, and compare its results with those of active faults.

The MTL is the active fault in the west of the central part of the Kii peninsula, in which the fault activity is terminated recently in the east. In this eastern area, Okada and Togo (2000) show the fault which terminated its activity until 300 ka in the active fault maps. Sangawa and Okada (1977) reported an exposure of fault zone that makes a border of the Early Pleistocene Shobudani Formation and the Cretaceous Izumi Group, and that is covered by the Middle Pleistocene Gojo Formation unconformably. Based on the sedimentary ages of their formation, the MTL in this area is terminated until 1 to 1.2 Ma. The fault exposure reported by Sangawa and Okada (1977) is covered by concrete presently, we studied the fault exposure 13 km east away from the previous exposure.

In this exposure, the fault gouge zone with ca. 1 m thickness strikes E-W. The Izumi formation is in the northern side of the fault zone, in which no exposure in the southern side. The Izumi Formation in this exposure is mainly mudstone. Bedding plane is subholizontal in the host rock, in which foliation is subvertical in cataclasite near the fault gouge. Composite planar fabric in foliated cataclasite indicates the uplift of the southern side.

The powder X-ray diffraction and X-ray fluorescence analyses were performed using the samples from this fault exposure. The results of the powder X-ray diffraction analysis shows disappearance of mica and formation of chlorite in the foliated cataclasite close to the fault gouge, and decomposition of plagioclase and formation of calcite in foliated cataclasite and fault gouge. The altered minerals indicate a remarkable alteration in foliated cataclasite rather than fault gouge. Smectite is not detected in fault gouge and cataclasite.

The results of the X-ray fluorescence analysis show the increase of TiO2, Al2O3, MgO, K2O and P2O5 toward the fault gouge and the decrease of CaO, Na2O and MnO in foliated cataclasite and fault gouge. The decrease is especially in foliated cataclasite rather than fault gouge.

The studied feature is compared by that of the active faults. In the active fault zone, the latest fault gouge is characterized by the formation of smectite and concentration of Mn. Smectite is the mineral formed under lower temperature. Mn deposits under the oxidized condition. These are consistent with recent near-surface condition of the active fault zone. The studied fault zone would be displaced in the deeper part because its activity has been terminated and present surface exposure should be exhumed from 1 to 1.2 Ma to present. Mn is difficult to concentrate in the deeper reduction condition.

The Atera fault is an active fault extended 70 km along southern — central Gifu Prefecture, Japan, which is considered to slip at 1586 Tensho earthquake based on the field outcrop and trenching survey by previous researches. However, the seismic slip behavior along the fault has been understood. In this study, we performed the field observation on the Tase outcrop of the Atera fault, microscopic observation, X-ray diffraction, trace element analysis by using ICP-MS for investigating the deformation structure, mineral assemblage, and geochemical anomaly in the Atera fault. We will present their preliminary results.

Deformation simulations by the discrete element method controlling basement motions by the dislocation solutions

KUSUMOTO, Shigekazu[1*] ; ITOH, Yasuto[2]

[1]Grad. Sch. Sci. Eng. Res., Univ. Toyama, [2]Grad. Sch. Sci., Osaka Prefecture University

In previous studies on deformation of sedimentary layer due to fault motions within the basement by means of the discrete element modeling, the basement has been treated as rigid body. In this study, we attempted to control motions of the basement by dislocation analytical solutions based on the elasticity in order to discuss the deformation field of the sedimentary layer in connection with fault parameters.

As a result, we found tilt of deformed sedimentary layer which did not appear in the rigid basement model. And, shapes of deformed sedimentary layer around the fault tip were different from rigid basement model, and even in the elastic basement model it was shown that their shapes will be varied by the fault parameters selected in the modeling.

Since sedimentary layers deform by following to shape of deformed basement, and the basement controlled by the dislocation analytical solutions deforms by the fault parameters, it was shown that not only shape of deformed sedimentary layers but trishear and its propagation processes will be able to be discussed in connection with the fault parameters. In the future, we will accumulate some know-how on practical analyses method by applying our modeling procedure to interpretations of topography, geological structures and seismic survey data, and we would like to hasten quantitative discussions on tectonics and/or forming processes of geological structures.

The reproductive experiments of stratum deformation on the trench for the Kushibiki fault using numerical experiments

ANDO, Koichi[1*]

[1]Tokyo Metropolitan University Department of Geography

Introduction

The Quaternary regional stress field in eastern-central Japan tend to be east and west compaction force. Therefore, a number of thrust faults develop in this area. These faults sometimes indicate complex features, such as back thrusts or branches above 3 km depth.

It is considered that seismic waves are generated by fault activity below 3 km depth. Therefore, indirect earthquake surface faults which branch off from a earthquake source fault not generate seismic waves. Additionally, earthquake surface faults which directly connect to a earthquake source fault specify crustal movements around these faults. Therefore, we must distinguish between indirect earthquake surface faults and faults which directly connect to a earthquake source fault.

According to the approach of foam rubber models and dynamic lattice model simulations, it is known that a fault slip velocity accelerates toward a ground surface (e.g., Oglesby *et al.*, 2000; Ma and Hirakawa, 2013). According to numerical calculations which base on dynamic models, peak slip velocities of thrust faults with dip angles of 30-45 degree are 2.5-4.0 m/s (e.g., Oglesby *et al.*, 2000; Ma and Hirakawa, 2013). On the other hand, according to the numerical calculation, the peak slip velocity of the back thrust which was the indirect earthquake surface fault from the 2008 Iwate-Miyagi Nairiku earthquake in Japan was 0.05 m/s (Ando and Yamazaki, 2013). Therefore, we may be able to distinguish between indirect earthquake surface faults and faults which directly connect to a earthquake source fault, from peak slip velocities. Thus I estimated the peak slip velocity of the Kushibiki fault which is considered as indirect back thrust of the Fukaya fault, from numerical experiments.

Relation between the Kushibiki fault and the Fukaya fault

Sugiyama *et al.* (2009) described that the Kanto-heiya-hokuseien fault zone is active fault zone which intervenes between the Kanto mountain terrain and the Kanto plain with NW-SE strike. The Kanto-heiya-hokuseien fault zone which is SW dipping thrust consists chiefly of fault groups along the Fukaya fault and the Fukaya fault.

The Hirai-Kushibiki fault zone which is considered as back thrust of Fukaya fault except the Hirai fault, consists of the Hirai fault, the Kushibiki fault and Kamikawa fault. In addition, the Kushibiki fault is bedding fault of Neogene sediments which have a dip angle of about 20 degree (Sugiyama *et al.*, 2009b; Shintani *et al.*,2009).

Methods

In this study, I performed numerical experiments about stratum deformation by faulting of the Kushibiki fault, and these experiments were executed by SDSSC (Strata Deformation Simulation System using CIP method) Ver 4.09. The model which feeds into SDSSC is modeled by the stratigraphy, the dip angle and the unit displacements from drilling surveys (Sugiyama *et al.*, 2009b) and trenching study (Shintani *et al.*, 2009).

Numerical experiments were performed with taking into account the erosional vacuity and the sedimentation for stratum by the faulting at the trenching area, and the peak slip velocity was estimated by comparison between experimental results and trenching results.

I adopted CWFS (cohesion weakening and frictional strengthening) model (Hajiabdolmajid *et al.* 2002) as the deformation characteristic about the stratum.

Result and Discussion

I estimated the peak slip velocity of the the Kushibiki fault at 1-1.5 m/s. Therefore, this conclusion leads to the suggestion that the peak slip velocity of the indirect back thrust is slower than the thrust faults.

Achnowlegement

For this study, I have used the computer systems of the Earthquake and Volcano Information Center of the Earthquake Research Institute,the University of Tokyo.

Spatial Variation on Recurrence-time Distribution of Paleoearthquakes and Its Influence for Long-term Forecast

NOMURA, Shunichi[1*] ; OGATA, Yosihiko[2]

[1]Graduate School of Information and Engineering, Tokyo Institute of Technology, [2]The Institute of Statistical Mathematics

The Earthquake Research Commitee (ERC) of Japan performs and publishes the long-term forecast of major paleoearthquakes in Japan. The ERC adopts renewal processes assuming that the recurrence intervals of paleoearthquakes are independently and identically distributed as the BPT (Brownian Passage Time) distribution. When applying this model, we need to estimate the mean and coefficient of variation (CV) on recurrence times. The estimation error in CV occationally affect so much on the long-term forecast. However, while the mean parameter can be estimated with a certain precision from only the number and approximate ages of historical activities,the estimates of CV parameter have quite large errors without plentiful and accurate data. So the ERC assumes a common estimate for all active faults in Japan to ensure a certain reliability for the estimate.But as the historical paleoseismic data are accumulated by investigations, some active faults show significantly large variation in recurrence times.

Renewal processes with the BPT distribution are based on an physical model that assumes a cyclic mechanism where stress on a fault surface is accumulated by tectonic forces until an earthquake occurs that releases the accumulated stress to a basal level. In this model, the mean recurrence time represents the rate of stress accumulation by tectonic motionand the CV implies the strength of stress perturbation caused by nearby seismicity. Therefore, these parameters are supposed to have regional trends as seen in the analysis of Nomura et al. (2011). In our study, we estimate the spatial variation of these parameters on the BPT distribution in Japanand apply it to the long-term forecast on the active faults with very few historical data. In addition, we compare our forecast with the forecast by the ERC to discuss the influence of parameter estimation on earthquake prediction.

Spatial distribution of faults and folds in the offshore extension of the western margin fault zone of the Takada plain

ABE, Shintaro[1*] ; ARAI, Ryoyu[2] ; OKAMURA, Yukinobu[1]

[1]AIST, [2]KGE.Co.,Ltd

We carried out a marine geological investigation on an offshore extension of the western margin fault zone of the Takada plain. The main purpose of this study is to clarify the total length of the fault zone and characterization of recent faulting. The western margin fault zone of the Takada plain is west dipping reverse fault, and the total length of this fault zone is 30 km from land to sea are based on the existing material.

We conducted 31 lines of high-resolution multichannel seismic reflection survey to recognize the detailed structure of the faults and folds. The reflection profiles depict the geological structure with extremely clear images.

The reflection profiles showed that the geological structure of the offshore area is characterized by the fold belt along the northern margin of the sedimentary basin that is formed in front of Takada plain. The shape of the fold is asymmetric weakly, and suggesting the fault related fold that has been deformed by west or north west dipping blind reverse fault as with land. This fault related fold zone is continuous to the Northern Kashiwazaki-oki Anticline from the Naoetsu-oki fault while changing asymmetry on the way. The North Kashiwazaki-oki Anticline is an active structure that has been pointed out the relevance of the source fault of the Chuetsu-oki earthquake.

Geologic structures and their activities around junction of main part and southern part of the active eastern boundary f

KOMATSUBARA, Taku[1*] ; SATO, Tomoyuki[1] ; KOU, Yoshihide[1] ; OZAKI, Masanori[1] ; KOMATSUBARA, Junko[1]

[1]Institute of Geology and Geoinformation, Advanced Industrial Science and Technology

A 130-km-long N-S trending active fold and thrust zone (eastern boundary fault zone of Ishikari lowland) occurs in the Ishikari lowland and off the Yufutsu plain. This fault system is one of the boundary faults between the Kuril arc and the Northeast Japan arc. This fault system consists of east-dipping thrusts accompanying with fault-related folds. This fault system is subdivided into two parts with gap and echelon arrangement around the Yufutsu plain. The main part is 72 km-long and its mean vertical displacement rate is larger than 0.4 m/ky since the late Pleistocene. The south part is 86-km-long and its mean vertical displacement rate is 0.2-0.3 m/ky since the late middle Pleistocene. The southern part of this fault zone includes discontinuous structures such as short-axis anticlines and short monocline in the terrestrial part. This discontinuity of geologic structure would be related to irregularity of basement rocks underlying the southern part of Ishikari Lowland.

Revisited most recent paleoearthquakes along the ISTL active fault system, central Japan

KONDO, Hisao[1*] ; TANIGUCHI, Kaoru[1] ; SUGITO, Nobuhiko[2]

[1]AIST AFERC, [2]Hosei University

The ISTL active fault system, central Japan, is well-known as one of the most hazardous fault systems based on the previously-reported paleoseismological works. Since the first paleoseismic trench survey was performed in 1980s, the number of paleoseismic sites becomes over 44 sites along the 150-km-long fault system, that is the highest density on active fault zone in Japan. In those studies, the timing of the most recent paleoearthquake had been reported around 1200 y.B.P., and the events had been longly estimated to be correlated with one muti-segment earthquake either 762 A.D. or 841 A.D. historical earthquakes. On the other hands, the recent result of geoslicer survey at the middle section of the ISTL indicate that the most recent event occurred around 2300 y.B.P., contradicting with the correlations with the historical earthquakes. Thus the most recent earthquakes on the ISTL is still ambiguous, therefore, we carried out systematic paleseismic surveys around the largest segment boundary, Lake Suwa segment boundary, at the middle of the ISTL active fault system. The Lake Suwa segment boundary is structural Quarternary basin formed by left fault step-over between left-lateral strike slip faults. At three paleoseismic sites inside of the Suwa basin, we revealed the most recent events occurred a few thousands years before ˜1200 y.B.P. and those are not correlatable with the historical earthquakes. These data indicate that the most recent earthquake along the ISTL did not rupture through the Lake Suwa segment boundary. In addition with this, the compiled timing of the most recent event along the entire the ISTL suggest that spatial clustering of the most recent earthquake. One large earthquake ruptured between the Kamishiro fault and the Gofukuji fault or possibly up to the Okaya fault, and another event ruptured between the Kamanashi-Yama faults and the Shimotsutaki fault. These two events will be correlated with either the 841 A.D. and the 762 A.D. earthquakes along with more reliable historical document surveys. Furthermore, this paleoseismic scenario during the most recent earthquake cycle do not deny the possibly that the larger multi-segment earthquake rupturing through the Lake Suwa segment boundary. In fact, paleoseismic event occurred between 2000 y.B.P. and 2300 y.B.P. was identified at the sites on the Gofukuji fault, the Okaya fault, and the Chino fault. Since those faults have left-lateral-strike slip component forming the pull-apart basin, the 2000-2300 y.B.P. event might have ruptured through the Lake Suwa segment boundary. To be testified this possibility, further investigation on the slip per event around the segment boundary is necessary.

[1]Earthquake Research Institute, University of Tokyo, [2]Department of Civil and Environmental Engineering, Faculty of Engineering, Iwate University, [3]Aichi Educational University, [4]Department of Geology, Faculty of Science, Niigata University

We collected and processed shallow high-resolution seismic reflection data in order to resolve shallow structures and to understand structural linkage between active faults and folds recognized at ground surface and deeper, complicated fold and thrust structures along the Kurehayama fault, Toyama Prefecture, central Japan. We deployed more than 800 seismic channels, 10-Hz geophones, and Enviro-Vib (IVI, Inc) as a seismic source along about 8-km-long seismic line. Common midpoint stacking by use of initial velocity analysis successfully illuminates subsurface geometries of active fault-related fold to 1.5 two-way time in time section and up to about 1.5 km in depth section. Detailed seismic reflection analyses including refraction and residual statics, migration, deconvolution, and time-space variant bandpass filters, and depth-conversion by use of stacking velocities enable to obtain subsurface depth section of these active structures.

Active faults in and around the Yoshinogari Heritage

KAGOHARA, Kyoko[1*] ; YOSHIDA, Haruka[2] ; SOEDA, Yoshio[3] ; OKADA, Shinsuke[4] ; MATSUTA, Nobuhisa[5] ; TODA, Shigeru[6] ; IMAIZUMI, Toshifumi[7] ; NAGAOKA, Shinji[8]

[1]Facultu of Education, Yamaguchi University, [2]non, [3]West Japan Engineering Consultants,Inc., [4]International Research Institute of Disaster Science, Tohoku University, [5]Disaster Mitigation Research Center, Nagoya University, [6]Aichi University of Education, [7]Graduate school of Science, Tohoku University, [8]formerly Nagasaki University

The normal faults are distributed around the boundary line of between Saga Plain and Sefuri Mountains (The Research group for Active tectonics in Kyushu, 1989, etc.). Shimoyama (2010) suggested that this normal fault zone relatively uplift the north side block, based on the displacement of boundary between Aso-4 and Mitagawa Formation. According to the Regional evaluation of the active fault (Kyushu), the Headquarter of Earthquake Research Promotion evaluated that the normal fault zone (Saga Heiya Hokuen Fault Zone) can be traced about 22 km from Ogi City to Yoshinonogari Town, based on the feature of gravity anomaly and tectonic geomorphology. However, the distribution and activities of active fault are not understood well. Yoshinogari Heritage, one of the Japan's important heritages, is on a terrace that is formed by Aso-4 pyroclastic flow deposits. Many relics during the Paleolithic era and Early-modern era have been excavated from here. Especially, it is famous for moat-surrounded settlements of the Yayoi period. The prospered moat-surrounded settlements were abandoned in the late third century. In the Nara period, Kando (ancient road) and government agencies which extend to Hizen Province (Saga and Nagasaki Prefecture) from Dazaifu,were established in the northern Saga Plain including the Yoshinogari Heritage. Yoshinogari Heritage and surrounding areas are regions where the civilizations of the many periods remain. Therefore, in this area that records man's activity for a long time, it is expected that influences of fault activities on civilizations can be known. To clarify the time and spatial relationships between active faults and ruins, we described the distribution map on active faults and ruins in and around the Yoshinogari Heritage, based on interpretation of topography using large-scale maps, aerial photograph, 5m DEM and results of field and archaeological surveys, and also conducted several very shallow seismic reflection profiles across clear tectonic scarps.

Keywords: Normal fault zone, Saga Plain, Yoshinogari Heritage, DEM, Very shallow seismic reflection profiling

Study on great palaeoearthquakes and the decline of the Sanxingdui and Jinsha civilizations, Sichuan basin, China

LIN, Aiming[1*] ; RAO, Gang[2] ; WANG, Maomao[1]

[1]Department of Geophysics, Graduate School of Science, Kyoto University, Kyoto 606-8502, Japan, [2]Department of Earth Sciences, Zhejiang University, Hangzhou 310027, China

The ruins of ancient civilizations damaged by large palaeoearthquakes, which have been reported worldwide, are often used as surface markers for Holocene tectonic and palaeoseismic events. Previous studies have demonstrated that recurring palaeoearthquakes have caused repeated soil liquefaction at the same site, leaving a record in both sediments and ancient ruins; such records can reveal a great deal about earthquakes that occurred prior to human-recorded observations or measurements5?10.

The Sanxingdui civilization, which developed on the Sichuan Plain, central China, during the Bronze Age (ca. 4800 years ago), flourished from ca. 4200 to ca. 3500 years ago until its sudden disappearance ca. 3200 years ago. Subsequently, the Jinsha civilization arose in the area around Chengdu city, ca. 40 km southwest of the Sanxingdui site, but it too suddenly disappeared ca. 2500?2200 years ago. It has been speculated that floods or regime changes might explain the collapse of both civilizations, but no solid evidence for such causes has so far been reported.

In this study, to search for a link between palaeoearthquakes and the abrupt unexplained falls of the Sanxingdui and Jinsha civilizations, we investigated the liquefaction induced by great palaeoearthquakes that occurred repeatedly in the past 5000 years on the Sichuan Plain, central China, in the region of the former Sanxingdui and Jiasha civilizations. Here, we present evidence that great palaeoearthquakes may have caused the collapse of both the Sanxingdui and Jinsha civilizations, as the cultures flourished in the periods during ca. 4200?3500 years and ca. 2800?2300 years ago, respectively, on an active fault zone of the Longmen Shan Thrust Belt (LSTB) that triggered the 2008 Mw 7.9 Wenchuan earthquake. Field observations, archaeological evidence, and radiocarbon dating reveal that at least four great palaeoearthquakes have induced liquefaction in wide areas around the Sanxingdui and Jinsha civilization sites during the past 5000 years, with an average recurrence interval of ca. 1000 years. We suggest that palaeoearthquakes occurring ca. 3300 and ca. 2200 years ago caused the fall and disappearance of the Sanxingdui and Jinsha civilizations, respectively, by causing extensive damage to infrastructure and manufacturing facilities, as well as numerous deaths.

Active thrusting beneath an alluvial terrace in the southern Longmen Shan range front, Sichuan basin, China

WANG, Maomao[1*] ; LIN, Aiming[1] ; JIA, Dong[2] ; SHAW, John[3]

[1]Department of Geophysics, Kyoto University, [2]Nanjing University, [3]Harvard University

The devastating 2008 Mw7.9 Wenchuan earthquake, China, demonstrates that the central and northern parts of the Longmen Shan are currently active. However, evidence for active faulting and folding in the southern Longmen Shan remains poorly documented. In this paper, we define the structural geometry, fault kinematics, and seismic hazard of the Qiongxi thrust fault system (QTF) along the southern Longmen Shan range front by integrating deep and shallow seismic reflection data and geomorphic observations. The QTF is a 50-km-long, N-S-trending set of faults and associated folds that exhibit geomorphic evidence of Quaternary surface deformation. Geomorphic observations and seismic reflection data reveal that these faults dip steeply to the east and merge at depth with a blind, west-dipping thrust ramp. The trend and reverse sense of slip along the QTF indicates that the structure accommodates east-west crustal shortening. Based on uplift of stratigraphic horizons across the fault zone, we define a late Pliocene to early Pleistocene fault slip rate of 0.2-0.3mm/yr, and a middle Pleistocene to present rate of 0.4-1.2 mm/yr on the west-dipping thrust ramp.. This ramp soles to a basal detachment in the Triassic section at a depth of 4.5-5.5 km. To the west, this detachment steps down onto a blind, northwest-dipping thrust termed the Range Front Thrust. A rupture of the QTF in combination with the Range Front Thrust could generate a Mw7.8 earthquake with averages displacement of 5.7m. This type of earthquake source poses significant hazards to the adjacent, highly populated Sichuan basin.

Identification of Fault Displacement and Stratigraphic Correlation of Black Soils based on Radiocarbon Ages

YASUE, Ken-ichi[1*] ; HIROUCHI, Daisuke[2] ; SAITO-KOKUBU, Yoko[1] ; MATSUBARA, Akihiro[1] ; FURUSAWA, Akira[3]

[1]Japan Atomic Energy Agency, [2]Shinshu University, [3]Furusawa Geological Survey

In order to clarify the stratigraphic correlation around the fault and the timing of faulting event, we carried out radiocarbon dating of the black soil sampled from the trench wall of the Atera Fault. Black soils were sampled at an interval of 3-6 cm along the vertical direction on both the hanging wall and footwall located approximately 50 cm away from the fault plane. Sample preparation and radiocarbon dating were carried out in the JAEA-AMS-TONO of Tono Geoscience Center, JAEA. Calendar years were obtained by calibrating ^{14}C age using OxCal 4.2.3 (Bronk Ramsey, 2013) with IntCal13 atmospheric curve (Reimer et al., 2013).

The dating results show that the soil ages vary from 4,000 to 2,000 years with depth of the sampling points. Black soil was deposited at approximately constant rate each at both sides of the fault in 4,000-2,000 years ago. This indicates that the fault didn't move during this period. In the upper part, there is no variation in ages of black soils including the gravel with depth. This suggests that sedimentation rate was faster. One of the causes that the sedimentation rate around the fault suddenly changes is fault displacement. It is thought that this fault move in about 2,000 years ago. About this timing, it is necessary to consider in behavioral segments of the Atera Fault zone in detail.

In addition, we are going to present results of the volcanic ashes analysis and radiocarbon ages of the lower part.

Keywords: radiocarbon dating, C-14 age, black soil, Atera fault, timing of faulting event

SEM observation on the active fault surface

TANAKA, Shiro[1*] ; KAMACHI, Takao[2] ; KANII, Takehiro[3] ; MIZOGUCHI, Kazuo[1] ; NAKATA, Eiji[1]

[1]CRIEPI, [2]KEPCO, [3]NEWJEC

SEM observation of the fault surface was attempted in order to clarify the feature of the fault plane of active fault. The sharp plane of cutting other structures in outcrop was judged to be the latest activity surface, and the block sampling of the latest surface was carried out. After identifying the continuity of the fault plane by observing the internal structure of the sample in detail using helical X-ray CT, the samples for SEM observation were prepared. As a result of observation on the latest activity surface with a stereomicroscope and a scanning electron microscope, the following features have been identified. (1) A slickenside and striations are observed on the latest fault surface. (2) The fault plane is formed of the crushed fine-grained particles, and the dumpling-like structure where fine-grained particle was covered with paste-like clay is observed as a feature. (3) Growth of euhedral minerals formed by diagenesis in deep such as illite and chlorite, were not observed on the latest fault surface.

The activity of a fault is normally evaluated by observing the displacement/deformation of strata which cover the fault. However, it is difficult to evaluate the activity of a fault which exists only in the basement rock without any overlying strata. In such a case, the fault activity needs to be judged carefully through a comprehensive approach to geomorphology, geology and present/past stress fields. Items in analyzing a fault zone include observation of the fault plane, width of fracture zone, color, hardness, magnetic susceptibility, form of fractured material, mineral and chemical composition analysis, dating, etc. Since some of these items have uncertainties in quantification and reproducibility, a method for evaluating fault activity by analyzing the fault zone in the basement rock is yet to be established. The authors have been carried out the observation and analysis of the fault zone to establish more scientific method of evaluation of fault activity.

In order to do the survey of certain active fault, we should study the outcrop of fault which give a displacement/deformation to the overlying certainly younger formations, and should observe the extension of fault from the overlying formations to the basement rocks. On the other hand, in order to do the survey of the fault zone of certain non-active fault, we should study the outcrop of fault which is covered by the old enough formations from the evaluation point of view.

We selected the outcrops which fulfilled the above-mentioned conditions through literature, then we decided the study outcrops through geological survey. The study area are limited in granite-bearing area, because granite show generally homogeneous and simple structure, is widely distributed in land, and well documented about fault rocks.

Examples of outcrops of active fault are one of the Gosukebashi Fault (Loc. 5 of Maruyama et al., 1997, Active Fault Res.) and one of the Rokko Fault (Loc.1 of Maruyama and Lin, 2002, Tectonophysics) in the Rokko Mountains, southern Hyogo Prefecture.

The fault zone of the Gosukebashi Fault appears in the Rokko Granite at the upperstream of the Gosuke-Dam site. Sand and gravel beds are bounded with granitic fault zone in the upper part of the outcrop. The fault zone consists of thick fault gouge in black and brown color, foliated cataclasite and granitic cataclasite.

At the western Funasaka, the Rokko Granite is in contact with rhyolitic volcaniclastic rocks of the Arima Group and overlying gravel beds through the Rokko Fault. The fault zone of the granite are remarkably altered and composed of brown fault gouge, foliated cataclasite and granitic cataclasite. The fault zone of the rhyolite is composed of black Fe-Mn-bearing layer, rhyolitic cataclasite and damaged rhyolite.

An example of non-active fault was selected from the fault which does not effect the strata of higher terrace deposits. Higher terrace deposits surrounded by badlands of weathered granite are well developed around the Rokko Horai-kyo in the northern Rokko Mountains. The fault including relatively thick gouge which is overlain by the deposits was selected for this survey, and is named the Rokko Horai-kyo Fault. For keeping the safety against the rock fall, the survey has done in the lower extension of granitic slope from the unconformity. The fault zone appears in the weathered granite, and composed of brown gouge, with black Fe-bearing layer and cataclasite.

The observation of fault zone (evaluation of fault plane, in-situ measurements of color and hardness), striation analysis, observation of fault structure by slabs, sections and SEM samples, mineral composition (XRF) and chemical composition (ICP-MS) analysis, mechanical and physical tests were done at the fault zones of these 3 faults. In this paper, the outline of this study and the results of geological survey are described. The details of the observation results of fault zones are explained in another paper (Okazaki et al., 2014, Abst. JpGU).

Examination of evaluation method for fault activity based on an observation of fault zone - 2. in-situ experiments -

OKAZAKI, Kazuhiko[1] ; KAMETAKA, Masao[1*] ; NAKAYAMA, Kazuhiko[2] ; SESHIMO, Kazuyoshi[2] ; AOKI, Kazuhiro[2] ; TANAKA, Yoshihiro[2] ; SHIMADA, Koji[2] ; SUZUKI, Kazushige[1] ; SHIMOGAMA, Kota[1] ; INADA, Noriyuki[1]

[1]Dia Consultants, [2]Japan Atomic Energy Agency

In order to establish a method for evaluating fault activity based on observation and analysis of fault zone in the basement rock, a comparative study has been carried out at outcrops of active and non-active fault. Of the three outcrops selected in the Rokko Mountains situated in southern Hyogo Prefecture, two were of an active fault and one of non-active fault. They are: the outcrop of Gosukebashi Fault at the upperstream of Gosuke-Dam site (GSB) and the outcrop of Rokko Fault at the western Funasaka (FSW) for active fault, and the outcrop of Rokko Horai-kyo Fault overlain by higher terrace deposits (HRK) for non-active fault (Kametaka et al., 2014). This paper focuses on an evaluation method which is relatively brief and easily enforceable at the outcrops, and describes the suitability of making a morphological observation of the fault plane and conducting in-situ experiments on hardness and color.

Fault plane of the active fault seems to be well continued, smooth surface and cut the older texture of the fault zone. To describe these features objectively and quantitatively, we measure 1) the relationships between the fault plane and the older texture, 2) the continuity of the fault plane, 3) planarity of the fault plane, 4) semi-quantitative observation using guideline of ISRM (Rock Net Japan, 1985, ISRM Guidelines), 5) arithmetic average toughness based on the authorized photograph. The results indicate that the fault plane of GSB and FSW show good continuities and well cut the older texture, while that of HRK show discontinuous part and poorly cut the older texture. The planarity, surface roughness and waviness, of the fault plane are well in GSB and poor in HRK, and partly poor in FSW possibly caused by the texture of alteration. The fault plane in the basement rock show relatively better planarity than that between basement rock and gravel beds. The arithmetic average toughness leads quantitative evaluation of fault plane, though there are some soluble problems about forming of outcrops and recognition of fault plane.

It qualitatively said that the fault gouge of an active fault is possibly soft and that of a non-active fault gouge is possibly hard and consolidated (Kimura, 1981, Jour. Japan Soc. Eng. Geol.). To quantify the hardness of intrafault materials, in-situ experiment of needle penetration test has been done. The result indicates that the fault gouge of GSB, FSW and HRK show 0 kN/m2. The altered cataclasite and weathered granite (damaged granite) of rock surface even show low value, while they show higher value at 20 cm below the surface. On the other hand, the fault gouge of the underground indicates still low value.

Fault gouge of an active fault possibly show reductive color and that of a non-active fault possibly show oxidative color (Research Core for Deep Geological Environments, AIST, 2012, GSJ Open File Rep.). To quantify the color of intra-fault materials, color measurements (Lab color) were done by using portable soil color meter. The results indicates that the fault gouge of GSB show low a∗value and low-middle b∗value, that of FSW show high a∗value and very high b∗value, and that of HRK show low-middle a∗value and low-high b∗value. The fault rocks around the fault gouge show intermediate value between fault gouge and non-deformed granite, indicating color change associated with weathering pass of granite.

In this paper, we show the specific contents of each measurement, and discuss about the validities of evaluation methods of the fault activity.

Thematic topographic maps have developed by the progress in analysis using digital elevation model (DEM) and have made clear representation possible.

We made digital stereoscopic topographic maps in scale 1:25,000, by using 5m mesh DEM data arranged by Geospatial Information Authority of Japan (GSI) . These 3D maps have same information, mode, scale and interval 10m contour, comparing to Quadrangle topographic sheet map.

We demonstrated the overlapping active fault line (Nakata and Imaizumi, edit 2002) on these 3D maps, in order to easily interpretation of the location of fault line, fault feature, evidence of faulting and displacement of faulting from professional and educational viewpoints.

Genetic algorithm-based displacement extraction technique for LiDAR dataset

SAOMOTO, Hidetaka[1*] ; MARUYAMA, Tadashi[1] ; KONDO, Hisao[1]

[1]Active Fault and Earthquake Research Center, AIST

Owing to recent progress of aerial survey with laser transmitting device, we can easily obtain detailed digital elevation model represented by point cloud data. This model is applicable to many purposes such as active fault detection, quantification of bluff lines, and extraction of ground displacement caused by an earthquake.

Although some methods for seismic displacement extraction from point cloud data have been proposed, we need more robust and powerful method in terms of noise immunity. In this study, we propose a new method based on the RBF (Radial Basis Function) interpolation and the GA (Genetic Algorithm) for the seismic dis-placement detection and then conduct a series of inquests including the parameter setting, the evaluation of noise resistance, and the comparison among four optimization techniques: GA, L-BFGS-B, Nelder-Mead, and COBYLA.

The results of considerations revealed that: (1) the size of unit for pattern matching should be set to 24 m square for the point cloud divided into 1 m grid; (2) the proposed method stably detect the correct dis-placement even under ill-posed condition; (3) the combination of the RBF and the GA is well suited for this problem because the objective function appearing in this study possesses extreme multimodality, suggesting that we should not use the optimization method based on gradient information.

Geologic structures around the coastal area of the southern part of the active eastern boundary fault zone of Ishikari l

SATO, Tomoyuki[1*] ; KOMATSUBARA, Taku[1] ; KOU, Yoshihide[1]

[1]Institute of Geology and Geoinformation, Geological Survey of Japan, AIST

A 130-km-long N-S trending active fold and thrust zone (eastern boundary fault zone of Ishikari lowland) occurs in the Ishikari lowland and off the Yufutsu plain. This fault system is one of the boundary faults between the Kuril arc and the Northeast Japan arc. We surveyed around the coastal area of the Yufutsu plain based on the marine high-resolution seismic-survey and the database of land borehole cores. As a result, two active anticlines (Yufutsu anticline and Hamaatsuma anticline) were recognized. These anticlines can be correlated to the anticlines described as a part of the active eastern boundary fault zone of Ishikari lowland (AIST, 2007). The trand of the Yufutsu anticline was N-S despite The Headquarters for Earthquake Research Promotion reported the trend was NW-SE. The Hamaatsuma anticline continued to the Mukawaoki anticline and the southern end of the fault zone extend to the southern end of the Mukawaoki fault which is concerned to the Mukawaoki anticline.

Seismic reflection survey across the northern part of the Western Boundary Fault Zone of the Yamagata Basin

OKADA, Shinsuke[1*] ; IMAIZUMI, Toshifumi[1] ; KAGOHARA, Kyoko[2] ; ECHIGO, Tomoo[3] ; YAGI, Hiroshi[4] ; MATSUBARA, Yoshikazu[5] ; MIWA, Atsushi[5] ; KOSAKA, Hideki[6]

[1]IRIDeS, Tohoku Univ., [2]Yamaguchi Univ., [3]Geo-Reaearch Institute, [4]Yamagata Univ., [5]OYO Corportion, [6]Kankyo Chishitsu Company Limited

The Western Boundary Fault Zone of the Yamagata Basin borders the western margin of the Yamagata basin and is traceable for about 60 km. In the northern part of this fault zone (from Sagae to Ooishida area), subpallarel traces of the active fault distribute in the western side of the basin. At the center of the basin, Kawashima-yama located as a tectonic bulge and its western side the Mogami river incise and meander in the fault zone. Along the eastern side of the Kawashima-yama, syncline is indicated as a frontal deformation by Ikeda (2002) and Imaizumi (2001).

To reveal the subsurface structure and tectonic evolution of this fault zone, we carried out two lines (Line A and Line B) of seismic reflection survey from September to October 2013. The Line A has a length of 4.11 km and started from Saigo area to Oomaki via. Kyouei bridge. The Line B has about 3.75 km length and started from Taruishi area to Goten along the Taruishi river. The source used in this survey was an Enviro Vib (IVI Inc.). Sweep length was 16 sec and sweep frequency range beginning at 10 Hz up to 120 Hz. The receiver was GS-20DX (natural frequency, 10 Hz; Geospace Inc.). The source and receiver spacing was 10m, with 192 ch geophones used for each recording. We selected the Geode (Geometrics) for the recording system and its sampling rate is 1 msec.

We thank to students of Tohoku University and Kanazawa University for their assistance in our survey. This work was supported by project research of the International Research Institute of Disaster Science (IRIDeS), Tohoku University.

Very shallow seismic surveys of the Shionohira earthquake fault appeared at the Fukushima-ken Hamadori earthquake

YAMAGUCHI, Kazuo[1*] ; ITO, Shinobu[1] ; KANO, Naomi[1] ; YAMANAKA, Yoshiaki[2] ; ITO, Shunichiro[2]

[1]AIST,GSJ, [2]Suncoh consultant

In the southern part of the Fukushima-ken Hamadori area, seismicity increased after 2011 Tohoku earthquake and an M7.0 earthquake occurred on April 11th, 2011. Remarkable surface raptures appeared along active faults by this earthquake. We conducted very shallow seismic surveys to reveal subsurface structure of the surface rapture down to 20 m in depth.

The survey line is located along a road in the Shionohira of Iwaki city. The displacement of the surface rapture is 2m east-side-up and 0.4m left lateral at the cross point of the survey line. The road was fixed and flat at the survey time.

The survey menus were S-wave survey and P-wave survey. Survey instruments and specifications are as following. Seismic source: S-wave/SWG-5(Suncoh), P-wave/10kg hammer, receiver: S-wave/GS20DM(Oyo Geospace, 28Hz), P-wave/GS11D(OyoGeospace, 4.5Hz), recorder: DSS-12(Suncoh), line length: 191m, source interval: 1m, receiver interval: 1m, stack number: 1-5, spread: S-wave/192ch fixed, P-wave/96ch landstreamer. The data quality was good because of low traffic noise.

The data were processed by S-wave refraction, S-wave reflection, P-wave refraction and surface wave methods. S-wave tomography and P-wave tomography analyses were applied and confidence of resolution and dependency to primary model were estimated. P-wave data were processed by inversion of phase velocity dispersion and S-wave velocity structure was obtained. S-wave data was processed by CMP stacking method and time section, migrated section and depth section were obtained.

According to S-wave velocities by S-wave refraction and surface wave methods, velocity layers below 0.7 km/s is thick to the west of the fault and thin to the east of the fault. Strong reflector between sediments and basement is deep and continuous to the west of the fault, shallow and uneven to the east of the fault and steps are recognized around the fault. The basement rises between this step and 135m of the survey line. This corresponds to the part of high Bouguer anomaly of 0.06 mgal.

Pit excavation along the Tachikawa fault at Sayama Shrine Site

ISHIYAMA, Tatsuya[1*] ; HIROUCHI, Daisuke[2] ; SATO, Hiroshi[1] ; SUZUKI, Takehiko[3] ; KOBAYASHI, Kenta[4] ; KORIYA, Yorihide[5] ; OMATA, Masashi[5] ; SHIBATA, Tsuyoshi[6]

[1]Earthquake Research Institute, University of Tokyo, [2]Department of Education, Shinshu University, [3]Faculty of Urban Environmental Sciences, Tokyo Metropolitan University, [4]Department of Geology, Faculty of Science, Niigata University, [5]Crearia, Inc., [6]Aero Photo Center

We excavated a 10-m-long, 2-m-deep pit across the hypothesized south-facing topographic scarp on along the Tachikawa fault. Preliminary results include clear evidence of accumulated, west-facing monoclonal folding of underlying conglomerates, predicted by the topographic scarp. Asymmetric ductile shear zone exposed on the bottom indicate nature of significant sinistral strike-slip component of faulting, rather than a simple reverse faulting. Future works include establishing stratigraphy based on radiocarbon dating and tephrostratigraphy.

Geological structure interpreted from two boring cores beside the Tachikawa Fault Zone, Tokyo, NE Japan

SUZUKI, Takehiko[1*]

[1]Tokyo Metropolitan University

In order to clarify the accurate position and activity of the Tachikawa Fault Zone, which possibly cause an earthquake under Tokyo in future, survey on the Quaternary sediments with tephrochronological method is effective. We conducted an all-core boring (TC-12-1) survey at Enoki in Musashi-Murayama City in 2012, where a relative subsidence will be occurred at its activity. By this result, we pointed out the evidence of deformation in altitudes of Middle Pleistocene gravel bed base, and also found a tephra layers estimated its age to be at 1.63 Ma. In this study, an additional all-core boring (TC-13-1) survey in relative uplifting side was carried out. The following are preliminary report of TC-13-1 core survey. Site of all-core boring (TC-13-1) with the length of 90 m is ca. 300 m northwest of Tachikawa Fault Zone of which the altitude is 109.50 m. Sediment with a depth 0 to 28.65 m is composed of coarse gravels with diameters 3 to 10 cm (max. 20 cm). Upper part of this gravel bed is equivalent to the fluvial terrace deposits of Tachikawa 2 Surface, and lower one is most likely to be the gravel bed identified as Middle Pleistocene sediment in the survey of TC-12-1 in 2012. Altitude of the base of this gravel bed (80.85 m) is higher than that of TC-12-1 (71.97 m), suggesting the evidence of fault activity with uplifting of east side. Sediment with a depth 28.65 to 90.00 m is composed of the alternation of silt (mudstone), sands, and gravels, and is correlative to the Kazusa Group of Lower Pleistocene. Five cycles of sedimentation composed of upper consolidated silt to mudstone and lower gravel bed were recognized. Also. shell in mudstone of 67.15-68.00m in depth and tuffaceous mudstone layers were found. We will examine theses sediments in detail. This survey was financially supported by Ministry of Education, Science, Sports, and Culture (Intensive Survey and Observation on the Tachikawa Fault Zone).

Examination of tectonics of the Shinano River basin, Niigata and Nagano prefectural border.

TAKAKUWA, Kensuke[1*]

[1]Department of Geology, Faculty of Science, Niigata University

In Niigata and Nagano, the trend of a general structure has a NNE-SSW strike called what is called the direction of Niigata. Moreover, it is thought that the trend of an active fault has the direction of Niigata similarly. However, the western Tokamachi fault belt continuous from Tokamachi city to Niigata and Nagano prefectural border contains in the south the Miyanohara fault which is an ENE-WSW strike(Headquarter of Earthquake Research Promotion 2010).

The Shinano River syncline which has in Tokamachi a NNE-SSW strike which exists in Shinano River and parallel being crooked in Tsunan-cho, and becoming an E-W trend.(Shimazu and Tateishi 1993. And Takeuchi et al 2000).

However, the exact position and a posture are not specified.

That is, it was not necessarily confirmed based on detailed investigation, the structure of the area is the direction.

The tectonics of the area has many questions as mentioned above. It inquired for the purpose of solving the tectonics of the area.

It was able to ask for the exact position of the Shinano Kawamuki slant continuous to a the area as a result of investigation. Moreover, Chikumagawa anticline and hokushin syncline was was newly authorized in the area.

Moreover, the sectional view over the Miyanohara fault in this research was compared with Sega (2012MS) in a Tokamachi basin west marginal fault belt. When done so, it turned out that the form of folding is alike. Therefore, it is thought that a Tokamachi basin west marginal fault belt and the Miyanohara fault are the same postures. Therefore, these connect and it is thought that the western Tokamachi fault belt is constituted. Moreover, the form of folding is alike also around hirataki. Therefore, the southernmost end of the western Tokamachi fault belt may be extended further west.

Furthermore, small fault method which used the Multiple Inverse Method was conducted. A result, it turned out that the small fault is recording two or more times of transcurrent fault type stress.

Horizontal gap stress is as conformable as the earthquake mechanism of aftershock of the northern Nagano earthquake in 2011,3,12.

Therefore, it is possible that Japan of those days was also placed by the same stress-ization as the present after the offing earthquake of the Tohoku earthquake.

Tectonic geomorphology around the eastern piedmont of the Myoko volcano and their tectonic implications

TAJIKARA, Masayoshi[1*] ; MIZUMOTO, Tadaki[1] ; MATSUDA, Tokihiko[1] ; TSUTSUMI, Hiroyuki[2] ; GOTO, Hideaki[3] ; NAKATA, Takashi[3]

[1]ERC, ADEP, [2]Kyoto Univ., [3]Hiroshima Univ.

The Myoko volcano group is located in the south of Takada plain, and its eastern piedmont is intermontane trough (hereafter, referred as the Myoko trough) between the Nishi-kubiki Mountains and the Higashi-kubiki Hills. The Myoko trough is located from the south of the Takada plain to the north of the Nagano Basin. The Takada-heiya-toen fault, Takada-heiya-seien fault, and the Nagano-bonchi-seien fault are located along the eastern margin of the Takada plain, the western margin of the Takada Plain, and the western margin of the Nagano Basin, respectively (Nakata and Imaizumi, 2002). Based on detailed analysis of areal photographs, we newly mapped active faults and tectonic landforms in the Myoko trough. we describe evidences of recent activity and discuss the property of these tectonic landforms and their tectonic implications. Newly mapped active faults and tectonic landforms are distributed almost continuously from the southern edge of the Takada-heiya-toen-fault to around Fujisato village in the Shinano town. Based on these distributions, we judged that newly mapped active faults constitute a part of the Takada-heiya-toen fault, and that the length of the Takada-heiya-toen fault may be elongated from 26 km to max. 55 km. However, active faults in the Myoko trough and the Nagano-bonchi-seien fault are distributed in parallel at distance of 13-14 km. Therefore, these two faults may be converged at depth of 6-7 km, and the southern part of the Takada-heiya-toen fault may be a backthrust of the Nagano-bonchi-seien fault.

Investigating the role of the Itoigawa-Shizuoka tectonic line in the evolution of the Northern Fossa Magna rift basin

PANAYOTOPOULOS, Yannis[1*] ; HIRATA, Naoshi[1] ; SATO, Hiroshi[1] ; KATO, Aitaro[1] ; IMANISHI, Kazutoshi[2] ; KUWAHARA, Yasuto[2] ; CHO, Ikuo[2] ; TAKEDA, Tetsuya[3] ; ASANO, Youichi[3]

[1]Earthquake Research Institute, the University of Tokyo, [2]Geological Survey of Japan, AIST, [3]National Research Institute for Earth Science and Disaster Prevention

The Itoigawa-Shizuoka tectonic line (ISTL) fault system is considered to have one of the highest probabilities for a major inland earthquake occurrence in the whole of Japan. It is a complex fault system with the dip directions of the local fault segments changing from north to south between an east-dipping low-angle thrust fault, a strike slip fault and a west-dipping thrust fault. The tectonic relations between the different parts of the fault system and the surrounding geological units are yet to be fully explained. This study aims to reveal the juncture of the northern and central parts of the ISTL and investigate its contribution towards the shaping of the Northern Fossa Magna rift basin. We conducted 3 deployments of 1 or 2 linear arrays of seismic stations across the central and northern ISTL regions and observed local micro-earthquakes for a period of 3 years. Each deployment recorded continuous waveform data for approximately 3 months. Using arrival times of 1193 local earthquakes, we jointly determined earthquake locations and a 3D velocity model, applying the tomography method. We were able to image the regional crustal structures from the surface to a depth of 20 km with a spatial resolution of 5 km. Subsequently, we used the obtained 3D velocity model to relocate the background local seismicity from 2003 to 2009. The juncture of the northern and central parts of the ISTL was well constrained by our results. The depth extension of the northern parts of the ISTL fault segments follows the bottom of the Miocene Northern Fossa Magna rift basin (NFM) and forms an east-dipping low-angle fault. In contrast, the central parts of the ISTL fault segments are estimated to lie along the eastern boundary of the Matsumoto basin forming an oblique strike slip fault.

Mapping of active faults in the area around the southern segment of the Itoigawa-Shizuoka Tectonic Line, central Japan

SANO, Mikako[1*] ; IIDA, Kenta[2] ; LIN, Aiming[1]

[1]Department of Geophysics,Graduate School of Science, Kyoto University, [2]Institute if Geosciences, Faculty of Science, Shizuoka University

It is well known that tectonic-related topographic features that develop around active faults record displacements during large-magnitude earthquakes, and that tectonic-related topographic studies are essential for developing a historic and/or paleoseismic perspective of the locations, magnitudes, recurrence intervals, and slip patterns of seismogenic faults. Therefore, it is important to recognize and identify active faults and tectonic-related topographic landform features for studying the present activity of active faults to assess the seismic hazard in a densely populated region.

This study focuses on the mapping of active faults in the area around the southern segment of the Itoigawa-Shizuoka Tectonic Line (ISTL), central Japan. Although previous studies have reported the presence of some active faults in this area, the detail distribution and geometric features of active faults are still unclear. In this study, we identified the active fault traces using perspective maps made from the digital elevation mode (DEM) data with 5-m-contours and stereo-examination of aerial photography and conducted field investigations. Interpretations of perspective topographic maps, field investigations, and structural analysis of fault zones reveal that i) many fault traces are newly found, which formed a deformation zone of up to ˜100-500 in width; ii) the active fault traces show more irregular shape than that previously reported, curved around boundary between the mountains and basin, indicating the lower dip-angle thrust fault structures; iii) the active faults developed along the southern sector of the ISTL are found to be extended to the south at least ˜25 km longer than that reported previously.

The findings of this study show that the detail mapping of the active faults can provide new insights to study the tectonic activity and fault nature of active faults and to reassess the seismic hazard for the densely populated area around the ISTL.

ESR dating of the Shimotsuburai and Hoozan faults in the Itoigawa-Shizuoka Tectonic Line Active Fault System

FUKUCHI, Tatsuro[1*] ; TANAKA, Mami[1] ; KITTA, Takuto[1] ; IMAI, Noboru[2]

[1]University of Yamanashi, [2]AIST

The Shimotsuburai fault, which is located in the south part of the Itoigawa-Shizuoka Tectonic Line (ISTL) Active Fault System, displaces the lower terrace deposits formed at about 20 kaBP. The trenching survey at the Tozawa outcrop revealed that the latest fault movement occurred at 1,550 +or- 70 yBP - 2,350 +or- 60 yBP (Toda et al., 2000). Along the fault plane of the Shimotsuburai fault, black injection veins are distributed forming complex networks and a part of the black veins is injected into the fault gouge or lower terrace deposits. Kano et al. (2004) proposed that this black intrusion veins are crushing-originated pseudotachylyte formed at 30-40m or less in depth at the time of the latest fault movement. On the other hand, the Hoozan fault is distributed about 6km west of the Simotsuburai fault. At the Dondokozawa outcrop, fault gouge is hardly recognized besides cataclasite and mylonite. This suggests that the Hoozan fault may not have moved since its formation in Neogene to early Quaternary, and that the main activity of the ISTL may have shifted to the Simotsuburai fault (Koyama, 1990). The Gofukuji fault located at the northwest extension of the Hoozan and Shimotsuburai faults may cause a Magnitude 8-class large earthquake, and besides its activity may have increased after the 2011 Tohoku-oki earthquake (M9.0). When the Gofukuji fault moves in the future, it is unclear whether or not its southeast extension would also move operating together. It is important to exactly assess the activity of the Hoozan fault as well as the Shimotsuburai fault. We thus carried out XRD (X-ray diffraction) and ESR (electron spin resonance) dating of fault rocks collected from the Shimotsuburai and Hoozan faults.

As a result of XRD analysis, smectite is detected from the Shimotsuburai fault gouge at the Tozawa outcrop, and smectite and a chlorite/smectite (C/S) mixed layer mineral from the black injection vein just on the fault plane, while besides illite chlorite and C/S are respectively detected from the black and gray gouges of the Hoozan fault at the Ishiutoro-gawa outcrop. In general, the formation depth of clay minerals tends to increase in order of smectite, C/S, chlorite and illite. Therefore, the result from the XRD analysis suggests that the Hoozan fault was much more active at deeper positions. As a result of ESR dating, strong signals of the Al and Ti centers are detected from quartz in the Shimotsuburai fault gouge and black injection vein however these centers show the tendency of saturation implying that the resetting by frictional heating did not work. Since the Al and Ti centers can be completely reset at about 300-350 degree C (Fukuchi, 2004), the result from the ESR dating shows that the frictional heat temperature did not rise so much at the time of the latest fault movement. On the other hand, the quartet signals intrinsic to montmorillonite are detected from the gray gouge of the Hoozan fault, and give the age of 2.8-3.2 +or- 0.4 Ma. The chlorite/smectite mixed layer is considered to be formed at about 130-200 degree C (Yoshimura, 2001), so that its formation age may be estimated as 2.2-3.3 Ma assuming the upheaval rate of 2 mm/y and the geothermal gradient of 30 degree C/km. This formation age is consistent with the ESR age obtained from the gray gouge.

The SEM observation on the latest active fault plane - the Atera Fault, Tase, Gifu prefecture-

NAKATA, Eiji[1*] ; UETA, Keiichi[1] ; AIYAMA, Kotaro[2] ; SIGEMATSU, Yasumune[3] ; OTSUKA, Yoshiharu[3]

[1]Central Research Institute of Electric Power Industry, [2]Dia Consultants Co.,Ltd, [3]Kansai Electric Power Co.,Inc.

To evaluate of seismic activity of fault, we performed mineralogical and morphological studies by SEM on the latest fault plane of the Atera fault. On the results of SEM observation, authigenic minerals do not crystallize on the whole shear planes including the latest active fault plane.

Study area is outcrop along the Tase path, Gifu prefecture (Toda et al., 1994). Granitic rock (hanging wall) is thrusted on the late Quaternary sandy formation including a lot of conglomerate and humus soil layer. The Atera fault consists on gouge: 3 - 20 cm thickness.

There are two light grayish green gouge zones: 3 - 10 cm width each, including dark brownish gouge: about 3mm width. The sharpest share zone, which is straightly brownish gouge, distributes in the gouge of hanging wall side. This gouge continues under the humus soil (440y B.P. Toda et al., 1994). This sharp zone was confirmed by X ray CT observation collected mass samples from the outcrop. Another dark brownish gouge zone runs parallel in the light grayish green gouge zone distributed the footwall side, converged into the sharpest shear zone at the central parts of the outcrop. At the footwall side, clayish sandy sediments were intruded into the light grayish green gouge with ductile deformation toward the left direction.

SEM observation was performed for the whole shear planes to be able to identify. For the dark brownish gouge zone, the observation was performed for the bottom, top, and sharp plane. On the results, authigenic minerals do not crystallize on the whole planes. Clay mineral (smectite) aggregates to form small clay ball (0.2 micron diameter), which covered the small particles as the paste (Kamachi et al., 2014).

Column shape? minerals (halloysite?) only coexist with Mn, Fe elements in the brackish lens zone including rhyolite and hexagonal biotite originating the foundation rock mass of the footwall side.

The results of this study show that authigenic minerals crystallized under the a few hundred degrees (clay and zeolite) do not confirm on the Atera fault plane to active after about 8400y B.P.

Sand boiling traces at the Netsuno ruin in Ishikawa Prefecture and the Morimto-Togashi fault zone

HIRAMATSU, Yoshihiro[1*] ; KOZAKA, Yutaka[2]

[1]Kanazawa Uiversity, [2]Hakusan Tedorigawa Geopark Promotion Council

Sand boiling traces detected at an archaeological site provides important information to reveal historical seismicity. In the Bunyudo ruins located at the central part of the Tedori-river fan, Hiramatsu and Kozaka (2013) detected sand boiling traces, which are the evidence of liquefaction, and discussed its relation to the activity of the Morimoto?Togashi fault zone. We report here sand boiling traces detected by an excavation survey of the Netsuno ruin, near the Bunyudo ruins, in 2013.

In the Netsuno ruin, we observe four sand boiling traces on the plane on which traces of vertical caves housing and Tsukikage wares of the late Yayoi period (1800-1900 years ago) were found. The sand boiling traces consist of ash gray sand with a diameter less than 1 mm. The largest trace has the maximum width of 20 cm and the length of about 2 m. This trace extends from a sand layer between a gravel layer and a silt layer located about 50 cm below the plane on which the traces are observed. Furthermore, this trace does not penetrate into a black soil layer above the plane that deposited from the late Yayoi period to the early Heian period. The observed traces are likely to have been covered by the black soil layer after the boiling on the ground surface at the time, implying that the formation age of the traces is from 1800-1900 to about 1100 years ago.

The Togashi fault is located near the Netsuno and the Bunyudo ruins, and, together with the Morimoto and the Nomachi faults, constitutes the Morimoto?Togashi fault zone of which a the total length is 26 km. No active fault has been reported around the Netsuno and the Bunyudo ruins. We, therefore, consider that the sand boil traces detected at these ruins are possibly formed by the activity of the Togashi fault or of the Morimoto?Togashi fault zone. An excavation survey at the Umeda area located at the northern part of the Morimoto fault revealed that a fault movement occurred about 1800-2000 years ago. A ruin where the surface displacement caused by the fault movement was observed is formed in the late Yayoi period. This period is the same as those of the Netsuno and the Bunyudo ruins. We, thus, conclude that the latest event of the Morimoto?Togashi fault zone is likely to be occurred 1800-1900 years ago.

Offshore active faults of the Mikata and Nosaka fault zones in Fukui Prefecture, revealed by high-resolution seismic pro

INOUE, Takahiko[1*] ; SUGIYAMA, Yuichi[1] ; SAKAMOTO, Izumi[2] ; TAKINO, Yoshiyuki[2] ; MURAKAMI, Fumitoshi[1] ; HOSOYA, Takashi[3] ; USAMI, Takuya[4]

[1]AIST, [2]Tokai University, [3]Corporation of Chuokaihatu, [4]Sogo Geophysical Exploration Co,Ltd

The Mikata and Nosaka fault zones are located in coastal and shallow sea area off Mihama, Fukui Prefecture. National Institute of Advanced Industrial Science and Technology (AIST) and Tokai University conducted, as part of MEXT 2013 nearshore active fault survey project, a high-resolution multi-channel seismic survey using Boomer and a 12-channel streamer cable, acoustic profiling survey using parametric sub-bottom profiler and shallow-sea drilling survey, in order to clarify distribution and activity of the Mikata and Nosaka fault zones. We present mainly about the results of the high-resolution multi-channel seismic survey.

The most remarkable reflection surface in the seismic profiles is the ravinement surface that truncated evenly the lower sediment. Holocene sediments cover this surface and the sediments become thinner toward offshore.

In seismic profiles across the fault zones, flexure-like deformation in the Holocene sediments continue in the N-S direction in the Mikata fault zone and in the NW-SE direction in the Nosaka fault zone along faults shown by Komatsubara et al. (2000). The deformation in the Holocene sediments has been growing by displacements of an underlying active fault. The vertical offset of the flexure on the ravinement surface is larger than those on other reflectors in the sediments covering the ravinement surface and these offsets decrease upward. This growing deformation indicates that faults are reactivated several times in the last 10000 years. At the Mikata fault zone, vertical displacement of ravinement surface is about 11 meters. Based on the formation age of the ravinement surface presumed by sea level change in the world, we estimate the mean vertical slip rate at about 0.9 m/ky. On the other hand, at the Nosaka fault zone, vertical displacement of the erosional surface is about 8 meters. We obtained core samples reaching to the erosional surface at the Nosaka fault zone. We will compare in detail the seismic profiles with sedimentation ages obtained from the cores, in order to estimate vertical slip rate of the Nosaka fault zone. Event history, latest event and slip rate of the Mikata and Nosaka fault zones are further examined, incorporated with advanced analysis of seismic survey data and core samples.

Offshore active fault survey ”Mikata fault and Nosaka fault zones”. Result of high-resolution stratigraphic survey.

YAGI, Masatoshi[1*] ; SAKAMOTO, Izumi[1] ; TAKINO, Yoshiyuki[1] ; FUJIMAKI, Mikio[2] ; TAJIMA, Tomoko[1] ; INOUE, Tomohito[1] ; SUGIYAMA, Yuichi[3] ; INOUE, Takuhiko[3]

[1]School of Marine Science and Technology, [2]COR, [3]Active Fault and Earthquake Research Center

The 26km long Mikata fault zone is extending from Kaminaka to Wakasa Bay. The fault zone consists of fault A, Hiruga fault, Mikata fault and Kuramitouge fault. The fault zone is estimated to cause M7.2 earthquakes (The Headquarters for Earthquake Research Promotion, 2002).

The 31km long Nosaka fault zone is extending from Nosaka Mountains to the Wakasa Bay. This fault zone consists of fault B, Nosaka fault and Nosaka southern fault. FaultB displaced the Holocene deposits and the vertical displacement rate is estimated to be about 0.8m/thousand years which are proposed by The Headquarters for Earthquake Research Promotion, 2002. Mikata fault and Nosaka fault zones show horizontal converges a single fault in the continental shelf.

Tokai University performed high-resolution stratigraphic survey to confirm a formation, distribution, and displacement of crust around the coastal area of the Mikata fault and Nosaka fault zones at Wakasa Bay in 2013. Transparent layer with poor internal reflection was observed as the surface layer in this survey area. This transparent layer is defined to as layer A. Layer A is ranges in thickness between 8 and 0 meter generally increase toward west. Displacement of the layer A is about 10m in most. Below layer A, sediments characterized by several reflections. First, we confirmed tilted reflection toward the Nosaka fault in the faults horizontal convergence section. Second, we confirmed progradation pattern reflection inclines to the offshore in the around Mikata fault.

Mikata fault and Nosaka fault are represented as a significant step in the seabed. The west side layer A is thicker than others. In the layer A, faults have not displaced surface sediments in this region. But several characteristic formations are which shows activities of fault has confirmed in sediments below layer A. The analysis still going on, the studies including the boring data will show more detail.

Drilling survey of the seaward extension of the Mikata and Nosaka fault zones off Mihama Town, Fukui Prefecture

SUGIYAMA, Yuichi[1*] ; INOUE, Takahiko[1] ; MURAKAMI, Fumitoshi[1] ; SAKAMOTO, Izumi[2] ; TAKINO, Yoshiyuki[2] ; NAGATA, Takahiro[3] ; HOSOYA, Takashi[4] ; USAMI, Takuya[5]

[1]AIST, [2]Tokai University, [3]Dia Consultants Co., Ltd., [4]Chuo Kaihatsu Corporation, [5]Sogo Geophysical Exploration Co., Ltd.

AIST and Tokai University conducted, as part of MEXT 2013 nearshore active fault survey project, high-resolution acoustic reflection surveys and shallow-sea drilling survey across the Mikata and Nosaka fault zones off Mihama Town, Fukui Prefecture. We present the major results of the drilling survey. For the N-S-trending Mikata reverse fault zone, a 4-m-deep core was extracted from the 51-m-deep sea bottom on the western (downthrown) side. For the NW-trending Nosaka strike-slip fault with a reverse component, 27m- and 12m-deep cores were obtained from the 12m-deep sea on the SW (downthrown) and NE (upthrown) sides, respectively. We compiled geologic columns at scale of 1: 10 and conducted magnetic susceptibility measurement, radiocarbon dating, volcanic ash analysis, and diatom and pollen analyses.

Regarding the Mikata fault zone, obtained radiocarbon ages are proportional to the depth, reaching 6,180 to 6,010 and 6,380 to 6,260 cal.yBP at a depth of 3.8m. The average sedimentation rate during the recent 6ky is calculated at 0.6 m/ky. Acoustic reflection surveys have revealed several continuous reflection surfaces displaced by the fault, including the probable base of the postglacial deposits. We are trying to identify faulting-event horizons, using height difference of each reflection surface across the fault. Because drilling survey was unable to determine the age of each reflection surface, we are making efforts to estimate them, extrapolating possible depth-age curves of the postglacial deposits.

The deposits extracted from the both sides of the Nosaka fault zone are divided into the following stratigraphic units based on lithofacies and radiocarbon ages: A1 (<ca.6ka), A2 (ca.6-7.3ka), A3 (ca.7.3-7.5ka), B1 and B2 (ca.7.5-8ka), C (ca.8-10ka) and D intercalating 30-ky-old AT tephra. A1 is subdivided into the upper part (<ca.4ka) and the lower part (ca.5.5-6ka). While the basal surface of B2 shows 5m height difference across the fault, that of the lower A1 represents 1.7m difference across the fault. The lower A1 also shows drastic change in thickness from 1.1 m on the downthrown side to 0.2 m on the upthrown side. These suggest that faulting occurred twice; in the periods post-C/pre-A (8-6ka) and post-lower A1/pre-upper A1(ca.5.5-4ka). Faulting history and slip per event are further examined, incorporated with analyses of acoustic reflection survey data.

The fault gouge along the Ikoma active fault zone

MITAMURA, Keisuke[1*] ; OKUDAIRA, Takamoto[1] ; MITAMURA, Muneki[1]

[1]Graduate School of Science, Osaka City University

The characteristic of the topography of Middle Kinki is reflected as an alternation arrangement of a mountainous district and the basin of north-south characteristics. Ikoma mountains share the Osaka plain and the Nara Basin. The NNE-SSW-N-S trending Ikoma active fault zone is recognized as a high-angle reverse fault under the E-W compressional stress field in the Quaternary Japan. However, from the rock mechanics point of view, high-angle fault is favorable as normal fault formed under extensional stress regime. The high-angle reverse faults may be resulted from the reactivation of the high-angle normal faults (inversion tectonics). In this study, we examined some fault gouge zones along the Ikoma fault zone (Katano and Ikoma faults).

We found three fresh outcrops of mesoscopic fault zones developed along the Ikoma fault zone at Kuraji of Katano City, Kiyotaki of Shijonawate City and Iimoriyama of Shijonawate City. In these fault zones, fault gouge wit the width of 5-20 cm can be observed. We collected some oriented samples and made thin sections parallel to the striation and normal to the fault plane. In the samples, many dark seams develop parallel to the main fault plane (striation) to form a distinct foliation within the fault gouges. Many fragments with various sizes are observed and their long axis aligned oblique to the fault plane. The parts where edges of the fragments meet the dark seam the edges tends to be rounded, suggesting that the formation of the dark seam was associated with material transportation due to pressure solution. The fragments with high aspect ratios tend to align oblique to the fault plane, suggesting the rigid-body rotation caused by non-coaxial shear deformation. The asymmetric structures, i.e., preferential orientation of the long axis of fragments, drag folds and shear lenses indicate the top-down-sense-of-shear. Furthermore, fractal dimensions of the fragments in samples near the main fault plane are higher than in samples at the margin of the fault gouge.

Consequently, we found the lines of evidence indicative of normal fault movement in the fault gouges associated with the Ikoma active fault zone, suggesting that the N-S striking Ikoma fault zone is recognized as a high-angle reverse fault under the E-W compressional stress regime are of reactivation of the preexisting high-angle normal faults that may be formed under extensional stress field.

Subsurface density structure in Southern Osaka Plain based on gravity and magnetic anomalies

INOUE, Naoto[1*] ; KITADA, Naoko[1] ; TAKEMURA, Keiji[2]

[1]Geo-Research Institute, [2]Beppu Geothermal Researh Laboratory, Institute for Geothermal Sciences, Graduate School of Science,

Geomorphological, geological and geophysical surveys have been carried out in the Osaka plain for the highly precise construction of a model to predict strong ground motion. In recent years, many seismic surveys were performed in the south of the plain. The outline of the basement configuration was estimated from the relationship between gravity anomaly and the depth of the basement. The depth of the basement inferred from the gravity anomaly was shallower than that from the seismic and micro tremor surveys at several points in the Osaka plain. The difference is considered the variation of density contrast due to some local distribution of the volcanic rocks. The magnetic anomaly indicates higher value at these points. The density structure was discussed from the gravity anomaly in consideration of the high magnetic anomaly area.

Keywords: gravity anomaly, magnetic anomaly, density structure, Osaka plain

Age and horizontal offset of the latest faulting event on the Okamura fault of the MTL fault zone in central Shikoku

IKEDA, Michiharu[1*] ; GOTO, Hideaki[2] ; TSUTSUMI, Hiroyuki[3] ; KONDO, Hisao[4] ; NISHIZAKA, Naoki[5] ; OHNO, Yuki[5] ; TSUYUGUCHI, Koji[6] ; KOBAYASHI, Shuji[1]

[1]Shikoku Research Institute Inc., [2]Hiroshima University, [3]Kyoto University, [4]AIST/AFERC, [5]Shikoku Electoric Power Co. Inc., [6]Yonden Consultantsu Co. Inc.

In general, information about fault offsets along active faults is one of the important factors to estimate faulting behavior in seismogenic zones. However, it is challenging to determine the information about fault offsets. So far, the average slip-rate and the amount of a single-event offset are obtained only 30 and 6 points on the Median Tectonic Line active fault zone (MTLAFZ) in the Shikoku area (200 km-length), respectively (Tsutsumi and Goto, 2006).

We conducted a trench survey for the Okamura fault which is a part of the MTLAFZ in order to determine the latest faulting event age and the fault offset. The Okamura fault is distributed in a rage of 30 km on the central Shikoku. The survey point, Hagioi point, locates on a central part of the Okamura fault. The amount of the fault offset at the latest faulting event is estimated to be below 5.7 m (Tsutsumi et al., 1991). However, this is just one data about fault offset on the Okamura fault. Moreover, the latest event age of the Okamura fault has not been sufficiently constrained by some previous research results; 4-7th century (Okada et al., 1998), 1090-960 yBP (Ehime Prefecture, 1999) and after 16th century (Goto et al., 2001).

The main two results of this trench survey are as fallowing. The latest faulting event age is estimated to be after AD 1490, consisting with after 16th reported in Goto et al. (2001). Moreover, the amount of fault displacement at the latest faulting event is estimated to be below 7.5 m. This value is consistent with the trend of the surface offset information that the surface slip associated with the latest event is greater than 5 m between the Zunden and Okamura faults, and decrease gradually to the east and west.

In taking hypothetical consideration, the fault offset 7.5 m is greater than 5.7 m (Tsutsumi et al., 1991) at 5 km away from this survey site. The recurrence interval (938-1500 years) calculated on the basis of average slip rate (5-8 mm/y) and the fault offset 7.5 m is consistent with the value (1245-1620 years) from the paleoseismological data (Morino and Okada, 2002; Okada et al., 1998). Therefore, the survey result might indicate variety of fault offsets along the Okamura fault, however this fault offset 7.5 m contains estimation errors. Since the fault offset becoming larger toward the fault end is unreasonable, this survey site might not locate on near the end of the Okamura fault and but near the asperity region.

Seafloor exploration at off Kochi Prefecture for coseismic subsidence during hysterical Nankai earthquakes

TANIKAWA, Wataru[1*] ; TOKUYAMA, Hidekazu[2] ; MURAYAMA, Masafumi[2] ; YAMAMOTO, Yuhji[2] ; EBIHARA, Shu[3]

[1]JAMSTEC/Kochi Kore Center, [2]Center for Advanced Marine Core Research , Kochi University, [3]Nippon Kaiyo ltd.

Paleoseismic trenching study and tsunami deposit analysis on land has been performed to understand the historical earthquakes and the scale of disasters caused by the earthquakes. Paleoseismic records are probably stored in seafloor sediments near the coast as well, though the seafloor researches were rarely performed.

In ancient documents, the great Hakuho Earthquake (684 A.D.), that had been classified a Nankai earthquake, had caused large subsidence near the coast and submerged a small village named "**Kuroda-gori**". In addition that, ancient artificial buildings and artifacts were found at off Kochi Prefecture from Aki city to Cape Ashizuri cape. However the relationship between the ancient foundation and the historical Nankai earthquake is not well understood.

Here, we investigate the seafloor foundation at off Kochi Prefecture based on marine seismic profiling and diving. We collect artifacts and sediment core samples from seafloors, and perform chemical and age analyses using them. We then evaluate the coseismic uplift and subsidence process and a magnitude scale of earthquake during paleo-Nankai earthquakes. We begin seafloor exploration at two sites, off-Tochi site and Nomi bay site in Kochi area. We introduce preliminary results of seafloor research on March 2014 and our future plan.

Acknowledgement
We appreciate the technical support by Nippon Kaiyo ltd..

Fault activity of the Kokura-higashi fault and the Fukuchiyama fault zone in northern Kyushu Island, Japan

YOSHIOKA, Toshikazu[1*] ; TANIGUCHI, Kaoru[1] ; HOSOYA, Takashi[2] ; YAGI, Tatuya[2]

[1]Active Fault and Earthquake Research Center, AIST, [2]Chuo Kaihatsu Corporation

The Kokura-higashi fault is an active fault extending in NNE-SSW direction with west-side-up vertical displacement. The Fukuchiyama fault zone consists of the Tonda and Fukuchiyama faults extending in NNW-SSE direction with also west-side-up vertical displacement. Both are located in the northern Kyushu Island. The Earthquake Research Committee evaluated that the probability of the earthquake occurrence in the future on the Kokura-higashi fault and the Fukuchiyama fault zone are unknown or ambiguous because of the luck of paleoseismological data. We carried out a trench excavation study and boring surveys in four sites with total 20 cores on these faults.

A trench is excavated across a reverse scarplet along the estimated fault trace of the Tonda fault in the Fukuchiyama fault zone. On the trench wall, steeply inclined sandstone and mudstone of the Paleogene Ashiya Group and overlaid gravel and silt layers are cropped out. However, no clear fault is observed in between bedrocks and sediments.

Based on arrayed boring surveys at the Shii and Shindoji site on the Kokura-higashi fault, a few meters differences in depth of the bedrocks are recognized.

Faults are observed in the cores from the arrayed boring surveys at the Ikeda and Horita sites on the Fukuchiyama fault zone.

Revised fault model of the 1771 Yaeyama tsunami, southwest Ryukyu

NAKAMURA, Mamoru[1*]

[1]Faculty of Science, Univ. Ryukyus

The 1771 Yaeyama tsunami (Meiwa tsunami) has been the largest and devastating tsunami in the Ryukyu Trench since about 300 years. The maximum runup height was about 30 m and 12000 people were dead by the tsunami. Although this tsunami is important for estimating the maximum tsunami in the Ryukyu Trench, the fault model has been unsolved. Then we estimated the source fault model of this tsunami.

(1) The maximum runup heights were 30 m near the southeast coast of Ishigaki Island, 15 m at Tarama Island, 15 m at Irabu Island, and 18 m at south coast of Miyako Island (Goto et al., 2011). The runup height at south coast of Miyako Island was estimated to 10.5 m from the old document ”Kyuyo”. However, folklore (Goto et al., 2011) and the inundation area estimated from the old document ”Otoegaki” (Kato, 1988) showed the runup height were about 20 m.

(2) Tarama Island is formed by the coral middle terrace at the height of 10-14 m. The tsunami reached at the villages (Nakasuji and Shiokawsa) which were located at the center-to-north of the Island. The estimated runup heights in these villages were about 15 m. Since the hill, whose height is 30 m, is located at the north of the villages, the tsunami will have inundated about 1.5-3.0 km from the south or east coast. Shimoji Island is also formed by the middle coral terrace at the height of 10-20 m. Although the Island was uninhabited at that time, the terrace was inundated by the tsunami, and the soil was stripped by the tsunami inundation, and cattle and domestic animals drown by the inundation (Shimajiri, 1988). These suggest that the wide area of the Tarama and Shimoji Island are inundated by the tsunami.

Using these data, we re-construct the fault model of this tsunami. We employed intraplate earthquake and landslide (Miyazawa et al., 2012), interplate earthquake (Nakamura, 2009), and splay fault (Hsu et al., 2013) models.

First, in the case of intraplate earthquake and landslide model, calculated runup heights were consistent with the observed ones. However, the calculated inundation area is limited within about 500 m from the shore at Tarama Island.

In the case of splay fault model, we set the western part of fault at the 125.5E based on Hsu et al. (2013). The calculated tsunami heights were smaller than the observed in the Ishigaki Island. The inundation area is limited within 500 m from the shore at Tarama Island.

Finally, we set the interplate earthquake model, which is revised the model of Nakamura (2009). We set the fault length, width, slip, and dip to 200 km, 70 km, 20 m, and 12 degrees, respectively (Mw8.6). In this case, the calculated runup heights were almost consistent with the observed ones except southeast coast of Ishigaki Island. The calculated inundation area is 1.5 km from the shore at Tarama Island. Then we added the local patch at the south of Ishigaki Island. The length, width, and slip of the patch is 40 km, 30 km, and 40 m (total Mw=8.7). Then we could reproduce the observed runup heights.

Systematical deflections and offsets of stream channels along the left-lateral strike-slip Kunlun Fault

YAN, Bing[1*] ; LIN, Aiming[2]

[1]Graduate School of Science and Technology, Shizuoka University, [2]Department of Geophysics, Graduate School of Science, Kyoto University

During the past two decades, the integration of geologic, geomorphic, seismic, and geophysical information has led to increased recognition and understanding of the tectonic significance of geomorphic features caused by strike-slip along active strike-slip faults. Tectonic landforms developed along active strike-slip faults are mainly characterized by systematic deflections and offsets of streams which are regarded as reliable displacement markers useful for reconstructing the long-term activity of active faults. It has been demonstrated that stream offsets have resulted from repeated large strike-slip earthquakes. The study of tectonic geomorphology will provide a new insight into the seismic activity, longevity and structural evolution of active strike-slip faults.

The Kunlun Fault is a typical active strike-slip fault zone extends for ˜1200 km in the northern Tibetan Plateau that has triggered the 2001 Mw 7.8 Kunlun great earthquake. In this study, we present evidence for the systematical sinistral deflection and/or offset of the stream channels and valleys of the upper Yellow River drainage along the eastern intramontane segment of ˜400 km of the fault zone. Topographic analysis of 3D perspective images constructed using Digital Elevation Model (DEM) data, high resolution Google Earth images and 15-m-resolution Landsat Enhanced Thematic Mapper (ETM+) images reveals the following: (i) various amounts of sinistral offset have accumulated on the tributary stream channels, valleys, and gullies of the upper Yellow River; (ii) the eastern intramontane segment of Kunlun fault accumulated sinistral offset amount for at least 12 km; (iii) the linear relationship between the between the accumulated offset amount and the upstream length from the deflected point to valley head of the stream involved can be reliable indicator of long-term slip rate.

The findings of this study support that the Kunlun Fault is a left-lateral strike-slip that partitions deformation into the eastward extrusion of the Tibetan Plateau to accommodate the continuing penetration of the Indian plate into the Eurasian plate.

On the generalization of the SPAC method and the development of a CCA method

CHO, Ikuo[1*]

[1]National Institute of Advanced Industrial Science and Technology

Introduction

Microtremor array methods refer to techniques for estimating subsurface velocity structures from the dispersion of Rayleigh-wave phase velocities obtained through array analysis of microtremors. Methods for analyzing Rayleigh-wave phase velocities include two major constituents: the spatial autocorrelation (SPAC) method [Aki, 1957] and the frequency-wave number spectral (FK) method [Capon, 1969]. SPAC method excels the FK method in the overall analysis efficiency, when account is taken of the requisite number of seismic sensors and the breadth of the wavelength ranges eligible for analysis [Okada, 2003]. The SPAC method, in addition, is intrinsically usable with a two-sensor seismic array [Aki, 1957], a potential that has received reappraisal during the past decade. Given this context, the SPAC method in recent years has not only come to be used more often, but has also seen progress in theoretical studies of its applicability.

Generalization of the SPAC method and the development of a CCA method

In our case, Cho et al. [2006] generalized the Aki's theory following Henstridge[1979], describing generic formulae to analyze a circular array of three-component microtermors on the basis of the theory of stationary random processes. The generic theory provided a basis for constructing various methods to efficiently analyze Rayleigh- and Love-wave phase velocities, Rayleigh-wave ellipticities, and power partition ratios of Rayleigh to Love waves. It also provided a theoretical foundation to examine applicability conditions and optimal observation durations for two-sensor SPAC methods.

The centerless circular array (CCA) method [Cho et al., 2004] represents one method on the basis of the generic theory to analyze phase velocity of Rayleigh waves. The CCA method is characterized, among other things, by its applicability to an array of three seismic sensors in irregular configuration. It is also characterized by superior analytic performance in long-wavelength ranges. Methods have been proposed to evaluate noise levels, which can negatively impact its analytic performance, in terms of signal-to-noise (SN) ratios and to compensate for the effects of noise.

In the first half of the presentation, the above history will be described after a simple explanation of the general features of microtremor array explorations.

Development of miniature array analyses for shallow surveys

In the second half, the situation on the miniature array analyses based on the CCA method will be reported. "Miniature array analyses" involves 15-min microtremor measurement sessions using very small seismic arrays, 1 m or less in radius, to obtain the dispersion of Rayleigh-wave phase velocities corresponding to depths of several tens of meters, and sometimes more than 100 m, beneath the surface. In addition to this feature, the analysis results are accompanied with quality control factors. In the last year, we dealt with the following problems so as to put the miniature array analysis into practical use: (i) What is an appropriate way to deal with analysis results of limited quality and dubious reliability in general? (ii) What is a better way to pursue the efficiency of surveys, including the step of estimating subsurface structures after the dispersion curve is obtained?

In the presentation, I will report the solution for this problem on the basis of the experience, the automatization of the analysis procedure (Cho et al., 2014; Senna et al., 2014), and a plan to release a new BIDO package (https://staff.aist.go.jp/ikuo-chou/bidodl.html) to draw 2D S-wave sections by miniature array analysis.

Acknowledgement The outcomes in the first half were obtained in the collaborative investigation with Dr. Taku Tada and Prof. Yuzo Shinozaki. Those in the second half were obtained in the collaborative investigation with Dr. Shigeki Senna and NIED, and through discussions with the members of the microtrmor working group.

Detection of Rayleigh wave and Love wave detection from microtremor array measurements

OHORI, Michihiro[1*] ; CITAK, Seckin[2] ; KUBO, Atsuki[3] ; OISHI, Yusuke[3] ; TAKAHASHI, Hirokazu[3] ; YAMASHINA, Tadashi[3]

[1]University of Fukui, [2]Japan Agency for Marine-Earth Science and Technology, [3]Kochi University

Microtremor array measurements are considered to be one of the most practical ways to explore the S-wave velocity structures for the seismic hazard evaluation. As seen in many articles (e.g. Horike, 1985), the Rayleigh-wave dispersive characteristics have been derived from vertical components to model the S-wave velocity structures. On the other hand, the detection of Love-waves from horizontal components seems to be limited in very few literatures (e.g. Yamamoto, 2000), because horizontal components of microtremors are composed of the Love-waves and the Rayleigh-waves and the separation of two different kinds of surface waves is usually considered to be difficult.

As representative methods to analyze the microtremoer array records, the FK spectral method proposed by Capon (1969) and the spatial autocorrelation (SPAC) method by Aki (1957) have been used. Both methods have been extended to treat three-component data and detect the Love-wave as well as the Rayleigh-wave: the FK spectral method by Saito (2007) and the SPAC method by Okada and Matsushima (1990) and Yamamoto (2000), respectively. It is considered to be significant to apply these extended methods to observed data in various test fields. In our previous study, we carried out microtremor array measurements at Takasu area in Kochi city, south-west Japan on November 2010. We used two circular arrays with radii of 50 m and 100 m simultaneously, and successfully detected dispersive characteristics of both Rayleigh-waves and Love-waves in a frequency range between 1.2 to 3.8 Hz (Ohori et al. 2013). In analyses of observed array records, we used two kinds of the FK spectral methods: Capon's technique (1969) applied to vertical component and Saito's one (2007) to horizontal components.

To make a better understanding about characteristics of microtremors for the targeted area and obtain surface wave dispersive characteristics in more higher frequency range (up to 6Hz), we additionally conducted a few smaller array measurements on March 2013, using 4 sets of three-component portable seismometers which compose a circular array with a radius varying step-by-step from 50 m to 25 m and 12.5 m. In our study, results from newly observed data are reported and discussed. Phase velocity results were obtained from FK spectral method for vertical and transverse components. We also applied the SPAC method (Yamamoto, 2000) and compared the estimated phase velocity results from the SPAC method with those from the FK spectral method. The SPAC method provided that the energy power ratio of Love-waves in horizontal components distributed within 40-70% in a frequency range between 1.4 to 6 Hz.

Estimating composition of ambient noise from three-component records at Tono array

TAKAGI, Ryota[1*] ; NAKAHARA, Hisashi[2] ; KONO, Toshio[1] ; OKADA, Tomomi[1]

[1]RCPEV, Graduate School of Sci., Tohoku Univ., [2]Geophysics, Graduate School of Sci., Tohoku Univ.

Ambient noise methods have become common tools to explore and monitor subsurface structure. However, effective uses of ambient noise should stand on the knowledge of a nature of ambient noise. In order to reveal the composition of ambient noise quantitatively, we extend the SPAC method to body wave incidence. Applying the extended SPAC method to the observation at Tono array, northeast Japan, we shows a good agreement between the theoretical cross spectra and the observed cross spectra. By fitting the theoretical cross spectra to the observed cross spectra, we estimated the composition ratio of Rayleigh, Love, and P waves. The characteristics of the composition ratio show a significant change at 1 Hz. While the P wave composition in total power is 5-15% and the lowest one below 1 Hz, the P wave composition suddenly increases above 1 Hz and reaches 50% and the highest one in those of the three wave modes. The change at 1 Hz is attributed to attenuation of high-frequency surface waves because the decay rate of the absolute value of power spectra of surface waves gets steeper around 1 Hz as compared with the constant decay of P wave. We also examine the temporal variation of the composition of ambient noise. Whereas power spectrum of each mode shows long-term and short-term temporal variations coincident with offshore significant wave height, the ratio between power spectra varies little with time. The constant composition ratio suggests that the mechanism and the source-receiver distance are stable in time. Accordingly, near coastal region is a possible region of the dominant source of the observed ambient noise. For applications of ambient noise, we should take account of the composition of ambient noise.

Toward Earthquake Ground Motion Prediction using the Onshore-Offshore Ambient Seismic Field in Subduction Zones

VIENS, Loic[1*] ; MIYAKE, Hiroe[1] ; KOKETSU, Kazuki[1]

[1]Earthquake Research Institute, University of Tokyo

Ground motion prediction is critical to evaluate the seismic hazard specially in high seismicity areas as Japan. A source of particular concern is the complex geological structures as sedimentary basins which can trap and amplify seismic waves. It has been proved by Prieto and Beroza (2008) that reliable phase and amplitude of the impulse response functions can be extracted by deconvolution of the ambient seismic field recorded by two on-land stations without any pre-processing. This approach has the great advantage to predict accurate ground motion of moderate earthquakes at periods longer than 4 s without the need of any external information about the velocity structure. However, this method allows only to recover relative, rather than absolute, amplitudes. To retrieve the corresponding Green's functions, impulse response amplitudes need to be calibrated using records of an earthquake which happened close to the "virtual" source. Moreover, as surface-to-surface Green's functions are extracted, some mismatches are observed between Green's functions and the earthquake records. This feature is due to the fact that depth and focal mechanism of the event are not taken into account. Despite of these disadvantages, accuracy of the predicted ground motion is high and such long-period ground motion investigation is critical to carried out seismic hazard assessment for high-rise buildings, bridges, or oil tank having long-period resonance. In this study, we use this technique in subduction zones to extract vertical-to-vertical component of the Green's functions between seismic stations located on the ocean bottom and on-land Hi-net stations. The target region is located in the Tokai/Tonankai areas where two submarine cable-based sea-bottom seismographic observation systems have been deployed by the Japan Meteorological Agency (JMA). We use one month of noisy data recorded in January 2013 to compute the Green's functions. The choice of these data is motivated by a strong signal-to-noise ratio of the causal part of the Green's functions during this period. We validate this approach by comparing computed Green's functions with offshore moderate earthquake (Mw ˜5) records in the Nobi sedimentary basin where the Nagoya city is located. As megathrust earthquakes are expected in this area, we extrapolate our results to predict magnitude Mw ˜6 or larger earthquake ground motions using the scaling law of seismic spectrum developed by Aki (1967). These results are finally compared to long-period ground motion prediction equations to evaluate their validity.

Review of study on microtremors and application for subsurface structure modeling

SUZUKI, Haruhiko[1*]

[1]OYO

The study on microtremors start by Kanai(1954). In his study, the relation between the subsurface structural model and the predominant period.

The method of the spectral ratio of two sites are devises. The influences source and path is removed.

From the 1980s, using spectral ratio between horizontal and updown component the subsurface structural model was estimated(Arai and Tokimatsu,2005). They assumed the microtremor consists by surface waves. On the other hand Nakamura(1988) assumed the microtremor consists by the SH waves.

H/V spectral ratio is using earthquake damage assumption investigations. Using H/V spectral ratio and phase velocity of Rayleigh wave, R/V spectral ratio of earthquake ground motion, the subsurface structural model from several meter to several kilometer depth are estimated in the Kanto area.

The Great East Japan Earthquake that occurred in 2011 off the Pacific coast of Tohoku caused the formation of two long cracks (crack 1 and crack 2) at Urayasu High School in Chiba Prefecture, Japan. Iwamoto et al. (2014) classified the survey area into different parts by examining the reclamation history and found the following three areas: A, 'Kaimenka-tochi'∗; B, reclaimed land from dredged seabed deposits; and C, the embankment and its surrounding zone. Crack 1 was situated between areas A and B, and crack 2 was between areas B and C.

Based on the investigation, the authors conducted micro-tremor observations at the three reclaimed land areas and Alluvial area. These measurements were conducted to reveal the area's geophysical aspects and to extrapolate three-dimensional data of the subsurface geology from two-dimensional data. At each measurement position, the results of micro-tremor observation were analyzed to give H/V spectra and the relationship between the site's geology and physical data. Field measurements of micro-tremors were performed with JU310, which was designed by the National Research Institute for Earth Science and Disaster Prevention. Measurements and analysis were performed using the i-Bido system (Senna et al., 2011), named after the Japanese word for micro-tremor, which was designed by the same institute.

Analysis revealed that the micro-tremors in areas A, B, and C had clear peaks at 1 Hz or slightly higher. This result corresponds to the impedance ratio at the boundary between the Holocene and Pleistocene deposits. Additionally, the micro-tremors observed at area B, which contains land reclaimed in 1965-1971, had peaks from approximately 4-5 Hz. These peaks were not observed or were unclear in areas A and C. For both crack 1 and crack 2, the peak was clear on one side but not on the other. The interval across a crack was only a few meters; therefore, these peaks depend on the impedance ratio between the silt bed, which was reclaimed by dredging from the seafloor, and the Holocene deposits. Additionally, the Nd-value∗∗of the silt bed was 0, as determined by a survey of the subsurface geology.

The analytical results determined using i-Bido supported the physical aspect put forth by Iwamoto et al. (2014) as the reason and mechanism by which the two cracks formed. Each frequency peak also showed the individual geological unit in the reclaimed bed, further supporting Iwamoto et al. (2014). The i-Bido system was very useful for analysis of the relationship between the site's geology and physical characteristics and for extrapolation of three-dimensional data from two-dimensional data. The authors hope that the methods discussed here will aid the progress of disaster prevention.

∗'Kaimenka-tochi' means land below sea level literally. Before reclamation, it was located in front of seashore, and it was in the possession of the private owner. and was used to reed cultivation etc.

∗∗Nd-value is brought by Dynamic Cone Penetration Test, which has the following conditions: a slide hammer with a weight of 5kg falling through a distance of 50cm, and diameter of 2.5cm cone. The number(i.e. Nd-value) of blows needed for the cone to penetrate each 10cm is recorded.

Acknowledgements

The authors are very gratful to Mr. Toshio NAKAYAMA of visiting researcher of NIED, who supported them for using i-Bido system.

H/V Spectral Ratios for Both Microtremors and Earthquake Motions and Interpretation based the Diffuse Field Theory

KAWASE, Hiroshi[1*] ; MATSUSHIMA, Shinichi[1]

[1]DPRI, Kyoto University

Horizontal-to-vertical spectral ratios (HVRs) of microtremors have been traditionally interpreted theoretically as representing the Rayleigh wave ellipticity or just utilized a convenient tool to extract predominant periods of ground. However, based on the diffuse field theory (Sanchez-Sesma et al., 2011) microtremor H/V spectral ratios (MHVRs) correspond to the square root of the ratio of the imaginary part of horizontal displacement for a horizontally applied unit harmonic load and the imaginary part of vertical displacement for a vertically applied unit load at the same position.

The same diffuse field concept leads us to derive a simple formula for earthquake HVRs (EHVRs), that is, the ratio of the horizontal motion on the surface for a vertical incidence of S wave divided by the vertical motion on the surface for a vertical incidence of P wave with a fixed coefficient depending on the bedrock wave velocity (Kawase et al., 2011). The difference of EHVRs from MHVRs comes from the fact that primary contribution of earthquake motions would be of plane body waves. Traditionally EHVRs are interpreted as the responses of inclined SV wave incidence only for their coherent S wave portions.

Before the advent of these compact theoretical solutions, EHVRs and MHVRs are either considered to be very similar/equivalent, or totally different in the previous studies. With these theoretical solutions we need to re-focus our attention on the difference of HVRs.

To that end we have compared HVRs at several dozens of strong motion stations in Japan. When we compared observed HVRs we found that EHVRs tend to be higher in general than the MHVRs, especially in higher frequencies than their fundamental peaks. As previously reported, their general shapes share the common features. Especially their fundamental peak and trough frequencies show quite a good match to each other. However, peaks in EHVRs in the higher frequency range would not always show up in MHVRs. When we calculated theoretical HVRs separately at these target sites, we found that the underground structures that are optimized for EHVRs would not explain perfectly MHVRs.

So we invert underground structures which can explain both EHVRs and MHVRs at the same time based on the different theoretical formula. Using the hybrid heuristic algorithm primarily based on the GA method with generation-dependent probability, we successfully obtain the detailed S-wave velocity structures for these investigated sites. The proposed method using HVRs is quite robust to obtain S-wave velocity structures that can be used quantitative simulation of strong motions at the target sites.

The Effect of the Basin Edge to the Directional Dependent Horizontal-to-Vertical Spectral Ratios of Microtremors

MATSUSHIMA, Shinichi[1*] ; DE MARTIN, Florent[2] ; KAWASE, Hiroshi[1] ; FUKUOKA, Yuri[3] ; SANCHEZ-SESMA, Francisco[4]

[1]DPRI, Kyoto University, [2]Risk and Prevention Division, BRGM, [3]School of Engineering, Kyoto University, [4]Institute of Engineering, UNAM

Based on the diffuse field theory (Perton et al., 2009), Horizontal-to-Vertical (H/V) spectral ratios of microtremors (or ambient noise) correspond to the square root of the ratio of the imaginary part of horizontal displacement for a horizontally applied unit harmonic load, Im[G_{11}] and/or Im[G_{22}], and the imaginary part of vertical displacement for a vertically applied unit load, Im[G_{33}], where both the loads and receivers are at the same point on the free surface (Sanchez-Sesma et al., 2011). This theory can be applied to a site where the subsurface structure cannot be considered as sufficiently flat, horizontally layered (i.e., Im[G_{11}] /= Im[G_{22}]), and lateral heterogeneity exists, and the H/V spectral ratio of microtremors can be derived by the square root of the Im[G_{11}] and/or Im[G_{22}] and Im[G_{33}] (Matsushima et al., 2014).

The authors have shown that by using a numerical method such as the 3-D Spectral Element Method (SEM) (e.g., De Martin, 2011) to calculate the Green's functions from 3-D wave propagation analysis using a 2-D basin structure, it is possible to qualitatively simulate the significant directional dependency that can be seen in H/V spectral ratios of microtremors observed at sites on Uji campus, Kyoto University. The NS/UD has higher peak amplitude and EW/UD has higher peak frequency. The H/V spectral ratios derived from numerical analysis using Green's functions calculated for a simple 2-D basin model with one layer over bedrock show that the observed H/V spectral ratios are qualitatively simulated (Matsushima et al., 2014). Also, Matsushima et al. (2014) has shown that the shape of the H/V spectral ratio is distorted at sites close to the basin edge. This is an indication that if we observe microtremors at several sites close to the assumed basin edge, there may be possibility to identify the shape of the basin edge in detail.

In this study, we focus on the effect of the basin edge to the H/V spectral ratios and study the relation between the basin edge shape and the difference between NS/UD and EW/UD by simulating the H/V spectral ratios at sites close to the basin edge by numerical calculation. We consider a simple 2-D basin model with one layer over bedrock and change the shape of the basin edge. Also, we made micorotremor observation for two line arrays orthogonal to the 2-D basin in Uji and found that the observed H/V spectral ratios show the characteristics assumed from the numerical analysis.

From these results, we can see that the condition of the basin edge changes the H/V spectral ratios drastically at sites close to the basin edge. If we accumulate the relation between the shape and condition of the basin edge to the shape of the H/V spectral ratios in two orthogonal horizontal directions, we will be able to use the information from the observed H/V spectral ratios of microtremors to determine the basin edge shape.

Sophistication of microtremor methods to survey shallow structures, PartI: Development of automatic reading algorithms

CHO, Ikuo[1*] ; SENNA, Shigeki[2] ; FUJIWARA, Hiroyuki[2]

[1]National Institute of Advanced Industrial Science and Technology, [2]National Research Institute for Earth Science and Disaster Prevention

We have been seeking an efficient way to maximize the potential of the microtremor methods for shallow surveys. It is considered that a practical approach has been gained in the observation by the development of portable seismometers (Senna, 2006, 2012) and by the finding of the full usability of the data obtained by a miniature array (radius $<$1 m), optionally together with a small irregular-shaped array (radius less than 10 m) consisting of three seismometers (Cho et al., 2013a).

As an efficient way to infer an S-wave velocity structure, we consider that a classical, simple profiling method (SPM), where a dispersion curve is directly converted into an S-wave velocity structure (e.g., Heukelom and Foster, 1960), is a good scheme from a view point of simplicity, thus, the balance between the efforts and the information to be extracted. It is true, however, that we frequently like to increase to resolution. Facing this dilemma, we suggested a simple tool ”H/V depth conversion” (Cho et al., 2013). We found that the use of an H/V depth conversion followed by a simplified inversion method (SIM) of Pelekis and Athanasopoulos (2011) can in fact increase the resolutions (e.g., Senna et al., 2013; Yoshida et al., 2013).

The current problem is to further promote the efficiency in the data processing procedure. A visual reading of analysis results, which we take at the current time, is time consuming to deal with a vast mount of microtremor data, now obtainable by a streamlined observational procedure. The reproducibility and biases constitute other kinds of problem of visual reading.

To address this problem, we invented the following automatic-reading algorithms. We applied them to observed data consisting of multiple arrays along a measurement line. As the results, natural images of two-dimensional S-wave velocity sections were obtained, not considerably different from the one obtained by visual readings (Senna et al., 2014).

Automatic readings of phase velocities

Let us suppose that multiple dispersion curves have been obtained by either multiple arrays or multiple analysis methods (i.e., nc-CCA, CCA, and SPAC methods) at a single observation point. In the first step, apply the following procedure to each dispersion curve. (i) Divide the frequency range used for analyses into equally-spaced intervals (bins) in a logarithmic scale. Take an average of phase-velocity data in each bin. (ii) Exclude the results from the analyses either when the wavelengths relative to an array radius lie out of the range defined a-priori for each method or when they exceeds the analysis limits having been evaluated by the use of an array with a sensor at the center point. Also, exclude the results when they seem to align in a line passing through the origin.

An automatic reading is obtained for each bin by averaging all values left after the procedure (ii). Readings are deleted, however, when they seem to align in a line passing through the origin.

Automatic readings of peak and troughs of an H/V spectrum

First, an H/V spectrum obtained at a single observation point, or an average spectrum if there are multiple spectra as a representative value, is smoothed using a spectral windows having a frequency-dependent window width. Peaks and troughs of the spectrum are searched from the lower side of the frequency range by using the derivatives. We search pairs of a peak and a trough to stabilize the analysis result: A pair is excluded from the reading results when the difference in either frequency or H/V ratio between a peak and trough is smaller than a threshold. Also, a pair is excluded when a peak (trough) value is smaller than that of an anterior peak (trough). The peak and trough of each pair, thus obtained, are used for the depth conversion, and the resulting depths are averaged to be the representative depth obtained by an automatic reading.

Sophistication of microtremor methods to survey shallow structures, Part2 : Application of automatic reading algorithms

SENNA, Shigeki[1*] ; CHO, Ikuo[2] ; FUJIWARA, Hiroyuki[1]

[1]NIED, [2]AIST

We have been seeking an efficient way to maximize the potential of the microtremor methods for shallow surveys. It is considered that a practical approach has been gained in the observation by the development of portable seismometers (Senna, 2006, 2012) and by the finding of the full usability of the data obtainable by a miniature array (radius less than 1m), optionally together with a small irregular-shaped array (radius less than 10 m) consisting of three seismometers (Cho et al., 2013a).

As an efficient way to infer an S-wave velocity structure, we consider that a classical, simple profiling method (SPM), where a dispersion curve is directly converted into an S-wave velocity structure (e.g., Heukelom and Foster, 1960), is a good scheme from a view point of simplicity, thus, the balance between the efforts and the information to be extracted. It is true, however, that we frequently like to increase to resolution. Facing this dilemma, we suggested a simple tool 'H/V depth conversion' (Cho et al., 2013). We found that the use of an H/V depth conversion followed by a simplified inversion method (SIM) of Pelekis and Athanasopoulos (2011) can in fact increase the resolutions (e.g., Senna et al., 2013; Yoshida et al., 2013).

The current challenge is to further promote the efficiency in the data processing procedure. A visual reading of analysis results, which we take at the current time, is time consuming to deal with a vast mount of microtremor data, now obtainable by a streamlined observational procedure. The reproducibility and biases depending on analyst constitute other kinds of problem of visual reading.

To address this problem, Cho et al. (2014, thismeeting) invented automatic-reading algorithms. In this study we test their algorithm by applying it to observed data to compare the results with those obtained with visual readings. Our method of observation and analysis is described in the following.

1. Observation

Observation duration is set to 15 minutes irrespective of the array shape, where either miniature arrays with a radius of 60 cm or irregular-shaped arrays with radii about 3 to 10 m are used.

2. Automatic analyses and readings of phase velocities and H/V spectra

The selectin of the data portions and the spectral analysis are automatically executed by using the software BIDO. Cho et al. (2014)'s algorithms are used for automatic readings of phase velocities and H/V spectra.

3. Inferring 1D S-wave velocity structures and constructing 2D sections

A dispersion diagram, represented by the relation between the wavelength, L, and phase velocity, Vr, is converted into a 1D S-wave structure having the relation between the depth, D, and S-wave velocity, Vs, where relations Vs= Vr/0.92 and D=0.375L are used (SPM). The resulting 1D structures are spatially interpolated to obtain a 2D section, where H/V depth conversions are overdrawn.

The above procedure from 1 to 3 is fully automatically executed. Incidentally, this study include no examination on SIM because no automatic algorithm has been developed yet because of the robustness problem.

We applied the above procedure to microtermor data obtained along survey lines in four different areas with variable geological environments (e.g., Itako City, Hadano City, Kashiwa City, Urayasu City). As the results, natural views of 2D S-wave velocity sections are obtained in all cases, similar to those obtained by visual readings. Furthermore, resulting velocity sections are consistent with other kinds of subsurface structural data (i.e., geological sections, N-value distributions, the 3D soil model of Senna et al. (2013)). We consider that, needing further improvement, Cho et al. (2014)'s algorithms can provide us with acceptable results at the first stage of automating the analysis procedure.

Future Initiatives of development of microtremor survey observation system

SENNA, Shigeki[1*] ; FUJIWARA, Hiroyuki[1]

[1]NIED

The microtremor observation has treated till today as physical investigation information, including the structure model creation for strong motion prediction of the researcher and engineer , etc.

If microtremor observation can observe easily and the observed data can be easily transmitted to a database with information on that observation point, it can expect that the number of collection of observational data will increase explosively in the future because an amateur can also observe, and the advancement of structural model and prediction of seismic strong motions will be attained by leaps and bounds.

It will become an unprecedented thing which leads to grasp of detailed damage distribution, and the improvement in accuracy of real-time earthquake information from the above.

Estimation of phase velocity of Rayleigh wave using linear array

ZHANG, Xinrui[1*] ; MORIKAWA, Hitoshi[1]

[1]Tokyo Institute of Technology

Since the spatial autocorrelation (SPAC) method has been proposed by Aki (1957), the observation using a circular array of evenly spaced sensors and a central sensor becomes a commonly used measurement technique in the microtremor survey method (Okada, 2003). However, in practice, the strict arrangement of sensors required by the method is difficult to conduct because of the limit of real environment. In order to slacken the requirement of the arrangement, Chavez-Garcia et al. (2005) discussed the validity of performing the SPAC method with a linear array. However, the conclusion of this research is result-based and is not backed by theoretical demonstration. Aki's autocorrelation coefficient could be alternatively seen as the azimuthal average of CCFs (Okada, 2003; Shiraishi 2006). A CCF consists of the Bessel function and an error term which varies with the azimuth of sources. By taking the azimuthal average, the error term vanishes and direct J_0(kr) can be obtained. The discrete formula of the CCF offers the possibility of extending the original SPAC method. In this research, we develop the solution by controling the error term in CCF which can obtain directly the phase velocity instead of using records of sensors in a line instead of azimuthally arranged ones.

Under the assumption: 1) Only the fundamental mode is dominated. 2) Different sources are not correlated, the real part of discrete formula of CCF could be expressed as (Shiraishi, 2006). If we neglect the terms of order larger than 6, we can obtain:

$\mathrm{Re}(\gamma_{pq})=J_0(kr)-2J_2(kr)\sum\lambda_l\cos2\theta_l+2J_4(kr)\sum\lambda_l\cos4\theta_l$. It can be seen that there are only three unknown variables kr, $\sum\lambda_l\cos2\theta_l$ and $\sum\lambda_l\cos4\theta_l$. It is required of at least three sensors (3 different intervals) to solve the 3 unknown variables theoretically. The three sites need to be in a line to make the three CCFs share the same unknowns. Because of the coupling variables and non linear functions, we use the genetic algorithm and particle filter to solve out the optimum solution.

In order to comfirm the validity of this new theory preliminarily, the simple wavefield composed of unidirectional plane wave is used to examine the accuracy of estimating phase velocity obtained from a linear array with 3 sensors. The distances between adjacent sensors (r and 0.5r, r=30m) are set to be different so that we can have totally 3 different CCFs to solve out the optimum solution. Except for the analytical simulation, we also applied a field test to examine the availability of the new method. We have applied field test to comfirm the availability of the method. Observation was conducted on 23 October 2013 at the parking lot of Zoorasia Yokohama Zoological Gardens (ZRS) in Yokohama city of Japan. We deployed 7 seismometers (KVS-300, moving speedometer) constituting two linear arrays. The two linear arrays forms an angle of 60 degree so that the SPAC method could be applied for confirmation.

In the analytical simulation, we confirmed the availability of the new method. The sensitivity of CCF with respect to phase velocity depends on the direction of linear array. When the sensitivity is low, the estimation will be bad. Hence, it is better to use at least two linear arrays forming an angle (90 degree is the best). In the field test in Yokohama, we applied both the SPAC method and the new method using 7 speedometers. Both SPAC method and the new method show good match with the theoretical dispersion curve. The new method shows narrower effective scope and shows some unstablity in both low and high frequency range. Through both simulation and field test, the availability of the new method has been confirmed. This new method makes the arrangement of sensors easier which needs only two linear arrays with a non-strict angle. In the future, we will study more about improving the inversion technique and the application of linear array.

Estimation of Subsurface Structure using Microtremor Observation in Ogasawara Iwo-To Island

MURAKOSHI, Takumi[1*] ; KOMORI, Etsuro[1] ; SHIMADA, Masaki[1]

[1]National Defense Academy

Ogasawara Iwo-To island is an active volcanic island which is located on the southernmost part of Izu-Ogasawara arc. The microtermor obserbation was carried out during the period from December 18 to 21, 2013 in Ogasawara Iwo-To island. The microtremor measurements were performed at 54 sites as 3-component seismometers for horizontal-to-vertical spectral ratio (HVSR) analysis. The obtained HVSRs of microtremor are used to determine the dominant frequencies of vibration of the subsurface structures beneath several recording sites in Ogasawara Iwo-To island. The H/V peak period varies from 1.1 to 3.5 sec.

For using the SPAC method of microtremor, the circular-array microtremor data were recorded by 6 seismometers distributed along the circumferences of two circles as well as a seismometer deployed in the center at two sites in the center of the island. The phase velocities and the S-wave velocities of the subsurface structures down to a depth of several km were estimated at each site from the microtremor data by using the SPAC method.

Determination of Subsurface Structure of the Mt. Daisen area in Tottori Prefecture by Microtremor and Gravity Survey

NOGUCHI, Tatsuya[1*] ; KAGAWA, Takao[1] ; YASUNAGA, Harunobu[1] ; ISHIGO, Masaharu[1] ; KOASAKA, Shuhei[1]

[1]Tottori Univ.

Earthquake damages occurred by the earthquake that occurred at the Middle West of Tottori in 1983 , 2002 and the 2000 Western Tottori earthquake in Mt.Daisen area of Tottori Prefecture. It is supposed that the damage influenced the subsurface structure. It is important that the information of subsurface structures is obtained for prediction of ground motion in the area. Microtremor and gravity surveys were carried out in the plains of the shore part and Mt.Daisen area. S-wave velocity models are obtained at the array observation 3 sites and predominant period distribution at 3-components observation newly. The gravity anomalies were obtained by gravity survey data newly.

Estimation of inter-station Green's functions using microtremor array data

HAYASHIDA, Takumi[1*] ; YOSHIMI, Masayuki[2]

[1]International Institute of Seismology and Earthquake Engineering, BRI, [2]Geological Survey of Japan, AIST

The seismic interferometry technique is used to evaluate seismic velocity structure beneath two observation sites [e.g., Ma et al. (2008); Yamanaka et al. (2010); Asano et al. (2012); Hayashida et al. (2014)]. The technique can be applied under the assumptions of non-stationary and uniform distribution of microtremor (ambient noise) sources and it is important to investigate whether the data satisfy the conditions. The array observations of microtremor [Yoshimi et al. (2012)] were conducted at 13 sites in Niigata prefecture, Japan. The surveys were carried out for more than 10 days per site and each array consists of three equilateral triangular arrays whose radii range from several hundred meters to several kilometers. Here we used the data to estimate inter-station Green's functions with the seismic interferometry technique. The stacked cross-correlation functions (CCFs) of microtremor showed coherent and dispersive wave trains in frequency ranges between 0.4 and 1.0 Hz for the small array, 0.2 and 0.7 Hz for the middle array and 0.1 and 0.6 Hz for the large array. The wave trains derived for each array correspond well to each other regardless of azimuth angles, showing the effect from the abnormal microtremor source can be negligible in this study. We also calculated theoretical Green's functions from the estimated S wave velocity structures with the spatial autocorrelation (SPAC) method for each site, assuming 1D velocity structure. The agreements between the calculated Green's functions and the derived CCFs from the seismic interferometry are generally good, especially at lower frequencies. Our results suggest that a combination of velocity structure estimation with surface-wave phase velocity (conventional array methods) and velocity structure validation with Green's function (seismic interferometry technique) provides better estimations for S wave velocity structures.

Seismic basement structure estimated from seismic interferometry and microtremor analysis

KOIZUMI, Ryo[1] ; SAWADA, Akihiro[1] ; HIRAMATSU, Yoshihiro[1*] ; THE GROUP, Aftershock observation[2]

[1]Kanazawa Uiversity, [2]the group for the joint aftershock observations

Recently, seismic interferometry has been considered to be a powerful tool for subsurface structure survey. Seismic interferometry is a method that produces pseudo reflected waveform data by computing the autocorrelation function (ACF) of seismic waveform record. In this study, we estimate the seismic basement structure beneath the northwestern Noto Peninsula from seismic interferometry and microtremor analysis. We examine the reliability of seismic interferometry and microtremor analysis by comparing those results with the results from gravity anomalies and a reflection seismic survey (Sato et al., 2007) in this area.

For seismic interferometry, we use waveform data of the aftershocks of the 2007 Noto Hanto earthquake at 44 seismic stations which are located in the northwestern Noto Peninsula. We apply high-pass filter of 2 Hz to SH component of displacement waveform and set a time window of 10 s after the arrival of S wave to calculate ACF. We make the average ACF by stacking all ACFs at each station. For microtremor analysis, we performed microtremors observation at 44 points where the stations for the aftershock observation were located and calculate H/V spectrum at each station. We estimate the basement structure in the analyzed area by assuming two-layer structure from ACF and H/V spectrum.

For the ACF analysis, it is difficult to identify the dominant peak of ACF for most stations. Especially, we cannot estimate the basement depths where the basement depths estimated from the reflection seismic survey (Sato et al., 2007) are shallower than 100 m. Finally, we obtain the basement depths at 14 of 44 stations. On the other hand, for the microtremor analysis, we can estimate the basement depths at 35 of 44 points. This indicates that the seismic interferometry with ACF is not an effective approach to estimate the basement depths in the northwestern Noto Peninsula.

We compare the basement depths estimated from ACF, H/V spectrum and gravity anomaly each other. These estimates are approximately coincident each other and shows that the basement depth of the Kuwatsuka block is shallower than that of the Saruyama block. Coseismic uplift was observed in the Kuwatsuka block at the 2007 Noto Hanto earthquake. Therefore, the results of this study is coincident with the hypothesis that the activity of active faults on seafloor near the coast causes the uplift of the Kuwatsuka block and makes its basement depth shallower (Hiramatsu et al., 2008).

Acknowledgements: We are grateful to the group for the joint aftershock observations of the 2007 Noto Hanto Earthquake for the use of waveform data and to NIED for the use of the instrument of microtremor observation. We thank Dr. Shigeki Senna for helpful advice.

Retrieval of Green's function in a 3D inhomogeneous medium with nonisotropic source distribution using interferometry

CHIMOTO, Kosuke[1*] ; YAMANAKA, Hiroaki[1]

[1]Tokyo Tech.

Seismic interferometry is known to retrieve Green's functions in an elastic homogeneous medium with isotropic source distribution (e.g., Wapenaar and Fokkema, 2006), and is applied to estimate velocity structures using long time series of ambient noises (e.g., Shapiro and Campillo, 2004). However, the realistic noise field might be an inelastic inhomogeneous medium with nonisotropic source distribution, and thus the reliability of retrieval of Green's functions using seismic interferometry should be examined.

We study on the reliability of seismic interferometry in a 3D inhomogeneous structure model of Kanto basin with nonisotropic source distribution. The numerical study on seismic interferometry was conducted by using 3D FDM. We cross correlated the surface responses at two sites with multiple surface sources. We used Yamanaka and Yamana (2006) for the 3D inhomogeneous model of Kanto basin. Nonisotropic source distribution was made by using sources located only on the sea area. We investigated the influence for the cross correlation functions by comparing with that in a homogeneous medium or isotropic source distribution.

In a case of homogeneous medium with isotropic source distribution, we see slight difference between the cross correlation function and Green's functions, but the surface wave component was well retrieved and surface wave velocity compares well with the Green's function. The slight difference might have been caused by the approximations in seismic interferometry (e.g., Kimman and Trampert, 2010). The cross correlation function showed symmetry for positive and negative lagtimes. In a case of homogeneous with nonisotropic source distribution, the cross correlation function shows asymmetry whose surface wave cannot be seen in positive lagtimes. However, the cross correlation functions in negative lagtime compares well with that retrieved with isotropic source distribution, and it showed good agreement in terms of group velocity. These indicate the influence of source distribution on seismic interferometry would be large as indicated in numerous studies (e.g., Tsai, 2010).

In a case of a 3D inhomogeneous model of Kanto basin, the cross correlation function showed asymmetry even with isotropic source distribution. That is, an inhomogeneity complicates wave propagations and then make apparent source distribution non-isotropic even with the isotropic case. Specifically, larger amplitudes in negative lagtimes than that in positive lagtimes indicate that eastern sources became large apparently. Considering the Kanto basin model, Kanto mountains located in western part and Pacific Ocean located in eastern part, where have thick sediment layers, the eastern sources would have excited surface wave significantly, which caused apparent nonisotropic source distribution. Due to asymmetry in the cross correlation function, it does not match with the Green's function. Group velocities also show asymmetry, however, they agrees to that of Green's function. In a case of a 3D inhomogeneous model with nonisotropic source distribution, the cross correlation function shows asymmetry and show less agreement with the Green's function. However, the group velocity shows agreement.

As a result, the retrieval of Green's function using seismic interferometry is strongly influenced by source distributions. Moreover, an inhomogeneity affect to source distribution, it would also be the problem. In a realistic case, therefore, to understand how much isotropy is satisfied is important. Because understanding the source isotropy is tough, it is important to examine the influence considering with realistic applications. However, on group velocity estimations as many applications, the reliability showed good in this study, suggesting the high possibility for reliable applications in seismic interferometry.

Estimation of subsurface structure by high density microtremor observations in Kochi Plain

OISHI, Yusuke[1*] ; KUBO, Atsuki[2] ; TAKAHASHI, Hirokazu[3] ; YAMASHINA, Tadashi[2]

[1]Studies in Science, Graduate School of Integrated Arts and Sciences, Kochi University, [2]Kochi Earthquake Observatory, Faculty of Science, Kochi University, [3]Faculty of Science, Kochi University

Kochi Plain is located around source region of the great Nankai Earthquake. Strong ground motion is expected in this area, because soft subsoil is widely deposited in Kochi Plain. In this study, we investigate H/V spectra of microtremor in the Kochi Plain. Microtremor study with single station is cheaper, quick and easier way than sampling boring core. It is convenient to reveal horizontal variation of soil/basement structure. We append 213 measurements in addition to previous reported 1041 measurements (Oishi et al., JpGU 2013, SSS35-P02). In total 1254 measurements are used to H/V spectral analysis. Figure shows distribution map of dominant periods by H/V spectral analysis based on microtremor observations in Kochi Plain. In perspective, dominant periods of H/V spectra around northern Urado-Bay region are longer than other regions. According to soil/basement model using boring data, the bedrock depth at this region is especially deep but boring which reaches the bedrock is limited. In contrast, H/V spectral analysis is useful to grasp the extent of region with deep soil/basement boundary. Dominant periods of H/V spectra around western part of Kochi Plain are relatively shorter than Urado region. The damaged areas of the past 2 (1854 and 1946) Nankai Earthquakes match with areas where the dominant period is long and/or the amplification factor is large. High density observations in this region show clear local variations. These are not reflected on current hazard maps or seismic intensity estimation maps. Using H/V spectral analysis based on high density microtremor observation, we are detecting patterns of soil/basement structure which has not be grasped using only boring core data.

Recent Geological Interpretation of A Liquefied Area: A Case Study in Urayasu City, Japan (1)

IWAMOTO, Hiroshi[1*] ; HIGASHI, Masashi[2] ; HIGUCHI, Shigeo[3] ; INADA, Akira[3] ; ITO, Akihide[4] ; KAMIKASEDA, Satoshi[5] ; KAWASAKI, Kenichi[6] ; KUSUNOKI, Keiko[7] ; SATO, Shinji[8] ; SHINADA, Shoichi[2] ; SUENAGA, Kazuyuki[9] ; WATANABE, Takumi[3]

[1]Kanto Natural Gas Development Co., Ltd, [2]JAPEX, [3]No affiliation, [4]Chiba-kita High School, [5]NTC Consaltants Co., Ltd., [6]Chiba-nishi High School, [7]Urayasu High School, [8]Chishirodai High School, [9]Earth System Science Co., Ltd.

At Urayasu High School (Urayasu City, Chiba Prefecture), where one of authors worked, the 2011 Great East Japan Earthquake caused the formation of two large open cracks from which large amounts of sand and water erupted as a result of soil liquefaction (Kusunoki et al., 2011). The objectives of this study were to investigate both the cause and the mechanism of this phenomenon. The site is located on reclaimed land, and a survey of the site's subsurface geology was carried out by hand auger boring and simple dynamic cone penetration testing to observe the stratigraphy of the reclaimed bed. Aerial photographs of the different stages of the reclamation were also used for analysis.

The survey area was the school grounds, which are located several hundred meters from the former seashore. Holocene deposits were situated at a depth of approximately 3-4 m. Two large open cracks formed in the ground: crack '1' in the NNE-SSW direction and crack '2' in the WNW-ESE direction. Beneath the cracks, we found row of piles from the original ground reclamation work. These rows of piles had been laid underground, and the reclaimed bed consisted of sand and silt. The cracks appeared to be due to the difference in vibrational characteristics between the opposite sides of each crack. Also, the facies of the reclaimed bed were notably different on the opposite sides of each crack. In the cross section of crack '2', the Nd-value∗was very large on the northeast side (Nekozane River side) but relatively smaller on the southwest side. In the cross section of crack '1', the facies of the reclaimed bed from approximately 2 m above to the top of the Holocene deposits were sandy on the western side relatively large Nd-value, but on eastern side mainly formed of silty material recorded almost 0.

Analysis was conducted using aerial photographs and revealed that both cracks '1' and crack '2' were located on the same discontinuity in the reclamation work history, both spatially and temporally. Therefore, the survey area contained three sections of reclaimed land demarcated by the two cracks. Moreover, a fourth section consisted of Holocene deposits. Chronologically, the survey area contained (a) 'Kaimenka-tochi' ∗∗(Urayasu City, 1985), (b) reclaimed land composed of sand and silt dredged from the seabed, and (c) the surrounding embankment. The reclamation process differed between areas (a) and (b). Area (b) was the widest and was typical of reclaimed land. Area (c), in contrast, was not constructed by dredging sand and silt from the seabed. Crack '1' was located between areas (b) and (c), and crack '2' was located between areas (a) and (b).

Therefore, the occurrence of these cracks seems attributable to discontinuities in the reclamation history. This case shows that recognizing the geological and historical processes of both the Holocene deposits and the reclaimed land is an important aspect of disaster prevention.

∗Nd-value is brought by Dynamic Cone Penetration Test, which has the following conditions: a slide hammer with a weight of 5kg falling through a distance of 50cm, and diameter of 2.5cm cone. The number(i.e. Nd-value) of blows needed for the cone to penetrate each 10cm is recorded.

∗∗'Kaimenka-tochi' means land below sea level literally. Before reclamation, it was located in front of seashore, and it was in the possession of the private owner. and was used to reed cultivation etc.

Development of analysis strategy for continuous total geomagnetic field data around Mt. Fuji

ABE, Satoshi[1*] ; MIYAHARA, Basara[1] ; MORISHITA, Hitoshi[1] ; KOBAYASHI, Katsuhiro[1] ; TOYOFUKU, Takashi[1] ; KOYAMA, Takao[2] ; OGAWA, Tsutomu[2]

[1]GSI of Japan, [2]Earthquake Research Institute, The University of Tokyo

Geospatial Information Authority of Japan (GSI) has conducted continuous total geomagnetic field observation at Fuji Yoshida observation station (FUJ), which is located the northeast mountainside of Mt. Fuji, and Fuji-City observation station (FJI), which is located at the southern bottom of Mt. Fuji, since 2000. These stations were established in order to enhance observation infrastructure to monitor low-frequency earthquakes underneath Mt. Fuji which had rapidly increased since October 2000. Additional continuous observation in the northwest mountainside of Mt. Fuji had also been started by utilizing electrical power and communication line of Remote GNSS Monitoring System (REGMOS) at Fuji Oniwa. Furthermore, Earthquake Research Institute, the University of Tokyo has conducted continuous total geomagnetic field observation at Fuji Yoshida (FJ1) and continuous geomagnetic observation at Yatsugatake (YAT). These data are also available and useful to monitor and understand geomagnetic variation around the Mt. Fuji.

Although GSI has been monitoring total geomagnetic field difference between the station at the bottom, FJI, and the stations at the mountainside, FUJ and REGMOS, it is almost impossible to identify variation truly caused by volcanic activities because total geomagnetic field around volcanoes can be fluctuated by both volcanic activities and locally unique geomagnetic variation as well as earth's main magnetic field and external magnetic field variation. Therefore, GSI tries to extract volcano-induced total geomagnetic field variation from the observation data around Mt. Fuji by principal component analysis, and develop monitoring strategy by principal component analysis of total geomagnetic fields around Mt. Fuji.

Classification of tsunami dynamo phenomena in terms of ocean depths

MINAMI, Takuto[1*] ; TOH, Hiroaki[1]

[1]Graduate School of Science, Kyoto University

Conductive seawater moving in the geomagnetic main field drives an electromotive force and induces secondary electromagnetic (EM) fields. This effect is well known as ”oceanic dynamo effect” and has been investigated for many years, especially for low-frequency phenomena such as tides and steady oceanic flows. However, it was recently found that tsunamis are also significant sources of the oceanic dynamo effect. Toh et al. (2011) reported tsunami-induced EM field data observed at the northwest Pacific seafloor EM station (NWP) at the time of the 2006/2007 Krill tsunamigenic earthquakes. Ever since, many events associated with the oceanic dynamo effect by tsunamis, hereafter called ”tsunami dynamo effect”, have been reported (e.g., Manoj et al. 2011; Suetsugu et al., 2012; Ichihara et al., 2013). To explain the tsunami dynamo effect, most of the preceding studies adopted analytical approaches in the frequency domain (e.g., Tyler, 2005). However, it is difficult to understand how EM fields are generated by tsunami propagations, although analytical solutions are very useful and handy.

In order to understand the tsunami dynamo effect more physically, we compared analytical solutions and results of numerical simulations using solitary waves, and revealed that tsunami dynamo phenomena can be classified according to the influence of the diffusion term in the induction equation for the magnetic field. In tsunami dynamo phenomena, the ocean depth has a dominant influence on the diffusion term. When the ocean depth is shallow enough, the diffusion term is large and comparable with the source term, while the self-induction term is small. In this case, the self-induction effect cannot attenuate the magnetic field induced by the coupling of the oceanic flows (v) and the geomagnetic main field (F), namely $\mathbf{v}\times\mathbf{F}$. We can understand this case mostly by the Ampere’s Law. On the other hand, when the ocean depth becomes deeper, the self-induction effect gets larger and reduces the amplitude and causes delay in phase of the magnetic field induced by $\mathbf{v}\times\mathbf{F}$. Especially for the ocean depth deeper than 5000 m, the amplitude is attenuated to approximately 70 percent and the phase is delayed by more than 70 degrees compared with the magnetic field due to $\mathbf{v}\times\mathbf{F}$, which can be understood by analogy with ”Frozen Flux”. As for the case of the tsunami dynamo phenomena reported by Toh et al. (2011) as well as Minami and Toh (2013), we can regard the phenomena as the self-induction dominant case because the ocean depth at the observation site, NWP, is approximately 5600m. This is consistent with the fact that sea level changes observed at the two DART sites in the vicinity of NWP are in phase with that of the vertical component of the magnetic field observed at NWP. In addition, our analysis using analytical solutions revealed that magnitudes of the tsunami-induced magnetic field have maximum peaks around the ocean depth of 2000m, when the tsunami height is fixed to 1m. This is because the self-induction and the diffusion effect, which vary differently according to the ocean depth, balances around that specific depth. These results are important because they enable us to predict how EM fields are induced by tsunamis in a variety of ocean depths, even though the number of observed examples of tsunami dynamo phenomena is limited at present. It is possible that our results are applied to tsunami early warning or mitigation of tsunami hazards in the future.

In the presentation, we will report the methodology of our classification of tsunami dynamo phenomena and discuss how tsunami-induced EM fields vary according to the ocean depth. We will also discuss how the ocean depth influences on the recently found initial rise (Minami and Toh, 2013) in the horizontal magnetic component observed prior to tsunami arrivals.

Electric conductivity of earth's medium derived from earthquake-excited electromagneic siganals

TSUTSUI, Minoru[1*]

[1]Kyoto Sangyo University

We have been observing electromagnetic (EM) pluses excited by earthquakes, using tri-axial electromagnetic sensors installed in a deep borehole of 100 m in depth. We simultaneously captured waveforms of EM pulses in the borehole and of seismic waves installed near the borehole. We have confirmed that the detected EM waves were co-seismic ones readily generated by piezo-electric effect in earth's crusts [1].

We detected an EM pulse in the borehole when an earthquake of M3.0 occurred at 10 km depth and at 5.4 km north of the EM observation site at 03:57 on Dec. 25, 2013. Figure 1 shows waveforms of (a) east-west component (S_{ew}) of the seismic wave, and of (b) east- west component (H_{ew}) of magnetic field of the EM pulse. The waveform of the S_{ew} wave shows an impulsive amplitude at the arrival of its S-wave, which is because the earthquake hypocenter was close to the EM observation site. On the other hand, the waveform of H_{ew} shows that its amplitude was increasing from about 1 sec prior to the S-wave arrival, and after that it was decreasing.

The amplitude change of H_{ew} can be explained as follows: Since the electronic conductivity of the earth's medium is large, the amplitude of an EM wave shows an exponential decrease as a function of the distance, in which the decay rate is so-called Skin depth. Since the source of EM pulse was propagating with the S-wave velocity, the amplitude of the EM wave measured at the EM observation site is exponentially increasing as time goes on, and after the S-wave arrival it is exponentially decreasing. Therefore we obtained the Skin depth ?for the frequency of 20 Hz and the electronic conductivity as 850 m and 0.0175 S/m, respectively.

Electrical conductivity structures of volcanic areas: a proxy for volcanic gas fluxes

KOMORI, Shogo[1*] ; KAGIYAMA, Tsuneomi[2] ; FAIRELY, Jerry[3]

[1]Institute for Earth Sciences, Academia Sinica (Taiwan), [2]Aso Volcanological Laboratory, Kyoto University, [3]University of Idaho

The efficiency of degassing of volcanic gases in magma is one of the key parameters controlling the explosive potentiality of the eruption and the diversity of the volcanic activity. Therefore, to evaluate the mass flux of volcanic gases is important in considering the constraint conditions of the activity. When volcanic gases are dissolved into the pore water of an aquifer, the aquifer has a high electrical conductivity (E.C.); this is because that the pore water conductivity is increased due to the high-salinity and temperature, and that the surface conductivity of rock matrices is also increased due to hydrothermal alteration. Therefore, the spatial extent of the high E.C. region could be related to the abundance of the mass flux of volcanic gases. We have developed the method to estimate the mass flux of volcanic gases using the E.C. structure of volcanic areas as follows.

[Effect of exposure temperatures on the surface conductivity of rock matrices]

There has already been some quantitative formula about the effect of temperature and salinity on the E.C. of the pore water. On the other hand, it has been known that temperatures are closely related to the generation/stability of smectite, which makes a great contribution to the increase of E.C. However, their effect on the surface conductivity has not been understood quantitatively. We performed the E.C. measurements using drillcore samples obtained from drilling projects, to estimate the surface conductivity. Results showed that the relation between surface conductivities and the temperatures to which the rock matrices have been exposed well corresponds to generation/stable condition of smectite. Thus, the surface conductivity could be represented as relatively simple function of exposure temperatures, and the formula could be incorporated into the modeling of dissipation of volcanic gases (Komori et al., 2010, 2013).

[Simplified model for the dissipation of volcanic gases and its application to Unzen volcanic area]

In Unzen volcanic area, there are various geophysical and geochemical studies to understand the formation process of hot springs associated with magma degassing and the magmatic activity. Ohba et al. (2008) proposed three-stage magma degassing; the first magma degassing occurs at the depths of 4-6 km. Correspondingly, the pressure sources are estimated at the similar depths (Kohno et al., 2008). In addition, the high temperature region greater than 200 ℃ are present above the sources (NEDO, 1988), which corresponds to the high E.C. region inferred from TDEM surveys (Srigutomo et al., 2008).

Based on the above background, we developed the simple model of volcanic gases dissipation into the aquifer at the area, to estimate the mass flux of volcanic gases. The model assumes the isotopic physical properties and the simple geometry of the aquifer. The temperatures and salinity of the pore water are distributed by the simulated flow regime, which is the consequent of the injection of the thermal waters formed by the mixing between volcanic gases and groundwater. Their distributions are converted to the pore water and surface conductivities; which are then converted to the bulk E.C. Results showed that the spatial extent of the high E.C. region is essentially controlled by the volcanic gases flux and rainfall recharge (Komori et al., under review).

[Possibility of effective magma degassing]

The above model was applied to the E.C. structure of the area. The estimated volcanic gas flux was 10^4.8±0.5 t/yr, yielding the CO_2 flux (10^3.1±0.5 t/yr) and the magma input rate (10^0.1±0.5 million t/yr). These values are consistent with other petrology, geochemical and geophysical evidences. Our result suggests that the magma is steadily releasing the volcanic fluids into the aquifer. This effective degassing might lead to the decrease of water content of magma, and be one of the reason of the recent effusive volcanism like dome-forming eruptions (Komori et al., under review).

Audio frequency magnetotelluric imaging and tectonic activity evaluation of the Cimandiri Faullt, West Java, Indonesia

FEBRIANI, Febty[1*] ; YAMAYA, Yusuke[2] ; HATTORI, Katsumi[1] ; WIDARTO, Djedi S.[3] ; HAN, Peng[1] ; YOSHINO, Chie[1] ; NURDIYANTO, Boko[4] ; EFFENDI, Noor[4] ; MAULANA, Iwan[4] ; GAFFAR, Eddy[5]

[1]Chiba University, [2]National Institute of Advanced Industrial Science and Technology, [3]Upstream Technology Center, [4]Indonesian Geophysical, Meteorological, Climatological Agency (BMKG), [5]Research Center for Geotechnology, Indonesian Institute of Sciences (LIPI)

The tectonic activity around the Cimandiri fault zone, Pelabuhan Ratu, West Java, Indonesia, has been analyzed for 30 years (1973-2013). The subsurface electrical resistivity structure close to the Cimandiri fault has been also investigated by twenty five audio-magnetotelluric (AMT) sites. The AMT exploration was carried out during two weeks, from July 27, 2009 to August 8, 2009. The sites were distributed on two lines along about 13 km x 6.5 km profile. There are two profiles of the AMT: (1) the A-A' line of the AMT which is perpendicular to the fault (2) the B-B' line of the AMT which is parallel to the fault. Two-dimensional modelling using the code developed by Ogawa and Uchida 2-D inversion has been applied in the AMT data. The result of tectonic activity analysis shows that the Cimandiri fault is the active fault. The subsurface electrical resistivity structure of the Cimandiri fault zone is characterized by (1) the A-A' and B-B' lines present a conductive zone (1-100 Ωm) from the surface up to the depth of 1 km, which is possibly associated with quarternary volcanics. At the surface, there are also some very conductive spots (1-5 Ωm) which are indicating the existence of the marine sediments in the study area. (2) The gradual conductive-resistive (500-1,000 Ωm) zone at the depth of 1-3.5 km overlays above a low resistivity zone (10-100 Ωm). This low resistivity zone may reflect the combined influences of a fluid network and the presence of the young and less compact sediments with the 500-1,000 Ωm zone as a cap rock that defines the upper boundary of the low resistivity zone (10-100 Ωm). Finally, the result of both methods presents that the Cimandiri fault is the strike-slip fault.

Robust magnetotelluric inversion

MATSUNO, Tetsuo[1*] ; CHAVE, Alan[2] ; JONES, Alan[3] ; MULLER, Mark[3] ; EVANS, Rob[2]

[1]National Institute of Polar Research, [2]Woods Hole Oceanographic Institution, [3]Dublin Institute for Advanced Studies

A robust magnetotelluric (MT) inversion algorithm has been developed on the basis of quantile-quantile (q-q) plotting with confidence band and statistical modelling of inversion residuals for the MT response function (apparent resistivity and phase). Once outliers in the inversion residuals are detected in the q-q plot with the confidence band and the statistical modelling with the Akaike information criterion, they are excluded from the inversion data set and a subsequent inversion is implemented with the culled data set. The exclusion of outliers and the subsequent inversion is repeated until the q-q plot is substantially linear within the confidence band, outliers predicted by the statistical modelling are unchanged from the prior inversion, and the misfit statistic is unchanged at a target level. The robust inversion algorithm was applied to synthetic data generated from a simple 2-D model and observational data from a 2-D transect in southern Africa. Outliers in the synthetic data, which come from extreme values added to the synthetic responses, produced spurious features in inversion models, but were detected by the robust algorithm and excluded to retrieve the true model. An application of the robust inversion algorithm to the field data demonstrates that the method is useful for data clean-up of outliers, which could include model as well as data inconsistency (for example, inability to fit a 2-D model to a 3-D data set), during inversion and for objectively obtaining a robust and optimal model. The present statistical method is available irrespective of the dimensionality of target structures (hence 2-D and 3-D structures) and of isotropy or anisotropy, and can operate as an external process to any inversion algorithm without modifications to the inversion program.

Preliminary report of self-potential observation during a water injection experiment at 1800 m depth in Nojima fault

MURAKAMI, Hideki[1*] ; HIGA, Tetsuya[2] ; SUZUKI, Takeshi[2] ; YOSHIMURA, Ryokei[2] ; GOTO, Tada-nori[3] ; KAWASAKI, Shingo[4] ; OUCHI, Yuhei[5] ; YAMAGUCHI, Satoru[6]

[1]Natural Sciences Cluster-Science Unit,Research and Education Faculty,Kochi University, [2]Graduate School of Science,Kyoto University, [3]Graduate School of Engineering,Kyoto University, [4]Disaster Prevention Research,Kyoto University, [5]Faculty of Science, Osaka City University, [6]Graduate School of Science,Osaka City University

We report self-potential variations during 2013 water injection experiment at 1800 depth in Nojima fault, which is a surface earthquake fault of the 1995 Hyougoken-nanbu earthquake (Mw6.9). The 2013 water injection test started in 15 September and ended in 29 September. Fresh water was injected into the fault system through the open hole part of the borehole (1800m depth). Average injection rate was 20 litter/min and pressure was 5 MPa. Self-potential variations around the 1800m borehole were very smaller than those in the previous water injection experiments (1997, 2000, 2003, 2004, 2006, and 2008) at 540m depth and self-potential variations did not appear clearly to correspond to the operation of the water injection. The previous water injection experiments have been repeated in the same conditions. The observed variations during the experiments have the following features: 1) self-potential variations appeared to correspond to the operation of water injections; 2) the negative voltage appeared around the water injection borehole, and 3) the magnitude of self-potential variations decreased with increasing distance from the borehole. And the self-potential variations in the previous experiments have become larger every experiment. These features suggest that the observed variations were caused by the streaming potential and the permeability around the open hole part of the borehole (540m depth) has decreased. If the line source model to explain the self-potential variations associated with the water injection is correct, the small self-potential variations observed this experiment may suggest that the permeability of the fault fracture zone at 1800m depth is larger than that around the fault at 540m depth.

Long-term variation of geomagnetic transfer function in Japan

TAKEDA, Masahiko[1*]

[1]Data Analysis Center for Geomagnetism and Space Magnetism, Kyoto Univ.

Time variation of geomagnetic transfer function in Japan was studied for long period of since 1985. Most of the long-term variation is common at most observatories, and some of then are due to the solar activity. However, different behavior of the variation was found at some observatories, which may be caused by time variation of the local conductivity structure in the earth.

Numerical simulations for the electrical prospecting of the rock samples

SUZUKI, Takeshi[1*] ; YOSHIMURA, Ryokei[2] ; OSHIMAN, Naoto[2]

[1]Graduate School of Science, Kyoto University, [2]Earthquake Hazards Division, Disaster Prevention Research Institute, Kyoto University

For the purposes of oil explorations and surveys of active faults, electrical and electromagnetic methods are powerful tools to reveal the underground properties, since the resistivity images have high sensitivity to the existences of the fluid. Obtained resistivity images are interpreted in relation to the porosity of rock and its connectivity with several mixing lows. In order to verify the applicability of such interpretations, we plan to carry out high-density electrical soundings for hand size rock samples whose other geological characteristics are well known.

As the first step of laboratory experiments, we made numerical simulations to estimate the optimal electrode arrangement and the scale of detectable anomalies. In this presentation, we will report the results of numerical simulations and the future plans of laboratory experiments.

Volcano-Loop observation at Kusatsu-Shirane volcano

HINO, Yuta[1] ; OGAWA, Yasuo[2*] ; KANDA, Wataru[2] ; HASE, Hideaki[2] ; SEKI, Kaori[1]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [2]Volcanic Fluid Research Center, Tokyo Institute of Technology

We have made successful measurement of time domain electromagnetic signals using transmitting and receiving loops at the same location. This system is being planned to work for monitoring the volcano vent.

The test measurement was conducted in the Kusatsu-Shirane volcano where detailed resistivity structure is known by audio-magnetotelluric method. The stepwise waveform was used and off-time response was measured using a transmitting and receiving loop both with 33m radius. The induced voltage was measured from the 0.1ms to 30ms. The observed voltages as a function of time in logarithm were inverted using Occam's algorithm and the model resistivity and resolution of the model were investigated. We also compared the result with those obtained by magnetotelluric method and found that the upper surface layers which have 1d structure are consistent with volcano loop results. We plant to use the system for repeated measurements or continuous monitoring the volcano in the future.

Fault zone architecture and related permeability structures form primary controls on fluid flow in upper-crustal, brittle fault zone. As the electrical resistivity of rocks is sensitive to distributions of fluids, the magnetotelluric (MT) method can be a powerful tool in investigating the fault zone architecture.

The Yamada Fault is located in Kyoto, Japan. The Yamada Fault zone consists of the main part of the Yamada Fault zone and the Gomura Fault zone. The Gomura Fault zone extends over 34 km and can be grouped into the Gomura Fault, the Chuzenji Fault and so on. The Gomura Fault appeared as a result of 1927 Tango earthquake.

In oreder to delineate subsurface structure of the fault, we made an audio-frequency magnetotelluric survey at 12 stations along the transect (4 km) across the surface trace of the Gomura Fault. The MT response function was obtained at each station, using remote reference processing. After dimensionality analysis by Phase Tensor method (Caldwell et al., 2004; Bibby et al., 2005), two-dimensional inversions for TE and TM modes were carried out, using the code of Ogawa and Uchida (1996).

The model is characterized by two resistive zones and four conductive zones. The most significant conductive zone is recognized beneath the surface trace of Gomura Fault with a width of more than 650 m and located in a depth range of 0.45-1 km. It is noteworthy that the conductive zone beneath the Gomura Fault is comparable in width to the damage zone determined by geological survey.

A Summary report on the investigations of an electrical resitivity structure beneath Chugoku and Shikoku regions, south

SHIOZAKI, Ichiro[1*] ; UTO, Tomofumi[1] ; YOSHIMURA, Ryokei[2] ; OSHIMAN, Naoto[2] ; KUBO, Atsuki[3] ; MURAKAMI, Hideki[4]

The purpose of this study is to estimate crossing and longitudinal electrical resistivity structure sections in the southwest Japan arc in order to clarify the relation between the deep crustal low resistivity region and seismic activities. Therefore, based on the investigation research of the electrical resistivity structures in Japan arc and the southwest Japan arc, in Sanin region, it is important to clarify the relation between earthquake occurrences out of the strain concentration zone, volcanoes not having eruption records for a long time and crustal fluid, and to find the structural heterogeneity in the inland earthquake occurrence area, the inland seismic gap (beneath the third class and quaternary volcano) and deep low frequency earthquakes. In Shikoku region, it is also important to find the relation between the occurrence pattern and structural locality of crustal earthquakes and deep low frequency earthquakes and the fluid supposed to be supplied from ocean plate subduction.

Our research group has shown that there is a clear relationship between resistivity and seismicity in the Sanin and Shikoku regions. We investigated deep crustal resistivity structures in the measurement lines that traverse a linear seismic activity area along with the coastal part of Japan Sea. As the result, in the eastern part of San-in region, it was found that a conductive area exists in the deep crust part under the seismic region, which is a resistive area, along with the seismic activity area stretching nearly in the east and west direction

However, Ozaki et al.(2011) showed that the crust has generally a high resistivity in the earthquake occurrence region in the middle-west part of Tottori pref. (2002, Mj5.3). This observation fact conflicts with the model advocated by the group including the author that has studied electrical resistivity in Sanin region. That is, there is a possibility that the deep low resistivity area beneath the Sanin region does not exist in series. Assuming that inland earthquakes occur because of local stress concentration caused by heterogeneity beneath a seismic activity band (Iio, 2009), the heterogeneity should be clarified by a spatial and structure analysis, and a more detailed surfacial structure data should be completed hereafter.

On the other hand, in the Shikoku region, the same investigation was carried out mainly in the outer zone, the south side of MTL and the result suggested that a remarkable conductive area should exist in the upper crust of the outer zone, and that the conductive area in the central and western part should have a clear relation with the non-seismic area.

These studies suggest that high conductivity(low resitivity) is possibly caused by the existence of deep crustal fluids, which probably play an important role in the inland earthquake occurrence mechanism of these regions. As one of the possible interpretations of water supply system, it is thought that the fluids in the deep crust are supplied from the subducting Philippine Sea plate by means of the dehydration processes. However, the existence of the plate is not thoroughly identified in the geological inner zone of the southwestern Japan Arc. Therefore, in order to grasp a whole tectonic setting, from the fore to the back arc side in the southwestern Arc, quantitative discussions based on the wideband MT survey covering whole these regions should be required. Consequently, for making the island arc crossing structure section in the southwest Japan arc, an additional structure investigation in the unmeasured area, the area of Setouchi as the main area is required to clear the northern edge of Philippine Sea plate.

In this presentation, the summary report on joint structure analysis result in Chugoku and Shikoku regions and key features of spatial resistivity distributions in these regions, using the recent data acquired in the Seouchi area incorporated in the existing data, will be shown.

Electrical resistivity in the crust and upper mantle depends on the pore-fluid distribution, salinity, and connectivity of fluid-filled rock pores. Thus imaging of resistivity distribution based on magnetotelluric surveys gives us fundamental information about fluid distribution of subduction zones. Marine magnetotelluric survey is important to understand dynamics of the NE Japan subduction zone because dehydration of subducting Pacific plate occurs under the Japan Sea. In this study, we discuss resistivity distribution around back-arc areas in the NE Japan subduction zone based on the marine MT data.

We collected natural EM signals with ocean bottom electro-magnetometers (OBEMs) in the eastern Japan sea area between April and August 2013 by MR13-02A and NT13-18 JAMSTEC scientific cruises. In addition, 3 land MT stations were settled in islands in the Japan Sea (Tobishima, Awashima and Sado islands) between April and October 2013. These recorded time-series data were converted to a frequency-domain impedance tensor based on the BIRRP program [1]. The remote reference technique [2] was applied in the data processing using horizontal magnetic field data from Kakioka Station in the period range between 10 and 20000 seconds. As results, high-quality MT responses and geomagnetic tippers in both the trench and back-arc areas.

We calculated phase tensors [3] based on MT impedances by this and previous studies [4] to discuss re-sistivity distribution beneath the back-arc area. The phase tensor ellipse indicates high Φ_{max} ($>$65 degrees) and Φ_{min} ($>$50 degrees) in the long periods ($>$8000 seconds). Large β of phase tensor and large amplitude of geomagnetic transfer function are also shown. These features cannot be explained with bathymetry and sediment effects based on the 3-D forward modeling [5]. Thus strong three-dimensionality and deep conductor possibly distributed beneath the Japan sea. In order to discuss detailed resistivity structure, 3-D inversion approaches are required by using a newly developed 3-D MT inversion code for marine data to treat complicated ocean bottom and land topography [6].

Abstract

The Yamasaki fault zone (YFZ) of southwest Japan is a typical strike-slip fault system consisting of the Nagisen fault, the main strand of YFZ, and the Kusadani fault. The main strand of YFZ extends for over 79km and is divided into northwestern (NW) and southeastern (SE) groups based on their latest seismic activity. The NW group consists of the Ohara, Hijima, Yasutomi and Kuresaka-touge faults, and the SE group consists of the Biwako and Miki faults. The maximum magnitudes of the earthquakes generated by the NW and SE groups are estimated to be 7.7 and 7.3, respectively. Simultaneous activation of both fault groups is also pointed out to be as large as M = ˜8.0 (The Headquarters for Earthquake Research Promotion, 2013).

The subsurface structure beneath the fault segment gap between both groups will be the key information for assessing the possibility of such large earthquake.

To infer the structure, we carried out Audio-frequency Magnetotelluric (AMT) survey at 11 sites along a transect between the NW group and the SE group and showed the two-dimensional resistivity model along the transect based on MT impedances. This model is characterized by three conductive zones. They locate beneath the points where the transect crosses the extension lines of the surface trace of the Yasutomi, Kuresaka-touge, and Biwako fault. We thus concluded that the Yasutomi and Kuresaka-touge faults are extended to southeast and the Biwako fault is extended to northwest further than the recognized terminals of their surface trace.

In this presentation, we show the improved resistivity model which is determined by not only MT impedance but tipper vectors.

The westward migration of large magnitude earthquakes along the North Anatolian Fault Zone indicates that a major event may take place at and around the Marmara region, following the Izmit (Mw7.4) and Duzce (Mw7.2) earthquakes that took place in 1999 in northwest Turkey. For this reason many studies were conducted around Marmara sea, west of these events. These studies focused mostly on the northern part of this area because of the high damage risk near Istanbul, but the similar potential is also present for the southern Marmara. In order to investigate the upper crustal electrical resistivity structure at this location, wide-band magnetotelluric data were collected at sixteen sites forming two parallel profiles. These profiles were constructed to cross the southern branches the North Anatolian Fault. Following the application of Groom and Bailey decomposition that has been applied to remove the surplus features and to deduce the appropriate geo-electric strike direction which is an important requirement for two-dimensional interpretation, an inversion algorithm developed by Ogawa and Uchida (1996) was utilized to develop electrical resistivity models. These models pointed out a relatively complicated shallow (surface-to-5 km) structure which may be associated with the presence of crustal fluids, but below these depths the electrical resistivity is more uniform with only a deep conductor appearing beneath the northern ends of the two profiles. The known faults in the survey area correlate well with the features characterized in the final geo-electric models. A resistive-conductive boundary between Manyas - Karacabey basin and Bandirma-Karadag uplift on the western and Uluabat uplift and Mudanya uplift on the eastern profiles may be associated with the South Marmara Fault.

Installation of a Vector Magnetometer for a Ground-based Tsunami Early Warning

KAWASHIMA, Issei[1*] ; TOH, Hiroaki[2] ; YOSHIMURA, Ryokei[3] ; FUJII, Ikuko[4] ; OOGI, Junpei[4] ; ABE, Satoshi[5]

[1]Graduate School of Science, Kyoto University, [2]Data Analysis Center for Geomagnetism and Space Magnetism, Graduate School of Science, Kyoto Univers, [3]Earthquake Hazards Division, Disaster Prevention Research Institute, Kyoto University, [4]Kakioka Magnetic Observatory, Japan Meteorological Agency, [5]GeoSpatial Information Authority of Japan

Conductive sea water moving in the geomagnetic main field generates electromagnetic variations by a physical process called the oceanic dynamo effect. This effect at the time of tsunami passages was recently detected on the seafloor in the northwest Pacific (Toh et al., 2011) and on Easter Island (Manoj et al., 2011). The tsunami-induced electromagnetic field is expected to contribute to existing global tsunami warning systems.

We are carrying out a project that aims to observe geomagnetic variations associated with tsunami passages by ground-based real-time observations. This project requires a pair of geomagnetic observation sites for clear detection of tsunami events. The geomagnetic coast effect and the external field due to ionospheric and/or magnetospheric disturbances can be removed by taking real-time differences between a coastal and an inland geomagnetic sites. We installed a vector magnetometer at Umaji located in the middle of Muroto Peninsula, where artificial electromagnetic noises are very small. This location is selected as a counterpart of the existing observation site at Muroto located at the tip of the peninsula, which is operated by Geospatial Information Authority of Japan (GSI).

In this presentation, we will make a progress report on our ground-based tsunami warning system consisting of a pair of vector magnetometers. This system is intended to detect the geomagnetic field variations induced by tsunamis at the time of Nankai/Tonankai earthquakes.

The several Records of tsunami induced magnetic field obtained by the JMA Chichijima observation station(CBI).

TATEHATA, Hidee[1*] ; HAMANO, Yozo[2]

[1]JMA, [2]JAMSTEC

Through the geomagnetic field, electrically conducting seawater movement generates electric fields and currents in generally. Furthermore, the current induces secondary magnetic fields. Our Chichijima geomagnetic observation station (CBI) is located on the solitary island in the Pacific Ocean. Addition this, located the tsunami observation station (Futami tide gauge) that is subject to the JMA. We are able to obtain concurrent tsunami and magnetic data because the distance between these observation points is only 1 km. So, this Chichijima Island is suitable in order to research tsunami induced magnetic fields research. We have investigated in CBI data (samples taken every 1 second) and Chichijima Futami tide gauge data (every 15 seconds) from 1995 to 2013, finally obtained 9events tsunami induced phenomena. The many of the signal of these events is small, but three of them has clear record, the 2011 off the Pacific coast of Tohoku Earthquake Tsunami (2001/3/11 M9.0), The 2010 Chile earthquake (2010/2/27 M8.8) and 1996 the Irian Jaya Earthquake Tsunami (1996/2/17 M8.1). The other events are week, but their magnetic signals are detectable enough. it may be worth worldwide renown that so many induced magnetic phenomena have been fund in one observation station Chichijima (CBI). In the low solar activity periods, the induced magnetic signal may be detectable, if the half tsunami amplitude is 20cm or over. Some of these events might have been disturbed and dismissed due to magnetosphere substorm, even though the induced magnetic field was enough to detect. Each of above-mentioned three examples has over 1 m tsunami height, and clear induced magnetic record. Especially, in spite of weak magnetosphere substorm, the record of the 2011 off the Pacific coast of Tohoku Earthquake Tsunami is very clear. So, on 1 m or more-high tsunamis, it is safely said that the induced magnetic fields is detectable definitely. These induced magnetic field records will be one of mediation between the geomagnetic science and the tsunami disaster prevention science.

Geomagnetic total intensity variations associated with vertical crustal movement in the eastern part of Izu Peninsula

SASAOKA, Masahiro[1*] ; OGAWA, Tsutomu[2]

[1]Kakioka Magnetic Observatory, Japan Meteorological Agency, [2]Earthquake Research Institute, University of Tokyo

In order to detect geomagnetic changes associated with the earthquake swarm and anomalous crustal activities, continuous observations of the geomagnetic total intensity have been conducted in the eastern part of Izu Peninsula. The continuous data of the geomagnetic total intensity were utilized after an analysis of removing the effect of external magnetic field from those data during 2010 - 2012. An association between the geomagnetic field variation and the vertical crustal movement was examined comparing the day-to-day variation of the geomagnetic total intensity with that of the geodetic height measured by GPS (Global Positioning System). It is found that the day-to-day variation in the geomagnetic total intensity shows each seasonal change on the quiet seismic period during 2010 and on the relatively active seismic period during 2011 and shows no significant change on the quiet seismic period during 2012, though the day-to-day variation in the vertical crustal movement shows seasonal changes during 2010 - 2012. It is inferred that the hydrothermal activity related to the Dec. 2009 earthquake swarm caused by magma injection had been lasting up to less than two years and the hydrothermal movement associated with the vertical crustal movement had caused the seasonal changes in the geomagnetic total intensity during 2010 - 2011. This suggests the observed variations of the geomagnetic total intensity were not directly associated with seismic faulting. The continuous observation of the geomagnetic total intensity is expected to have a monitoring advantage in predicting the course of the earthquake swarm activity in the eastern part of Izu Peninsula.

Validity of using space approximation in calculating EM variations generated by the piezomagnetic effect

YAMAZAKI, Ken'ichi[1*]

[1]Kyoto University

Variations in the magnetic field generated by the piezomagnetic effect, which is referred to as the piezomagnetic field, has been discussed in a framework of magneto-statics, in which temporal variations are totally ignored. This treatment is valid for quasi-static processes, but possibly invalid for dynamic processes including fault ruptures. The earlier works by the author has demonstrated that, when the temporal variations in the EM field is considered, finite conductivity of the Earth's crust alters the feature of the piezomagnetic field. However, consideration of the temporal variations in the EM field makes estimation of the piezomagnetic field complicated, even in a simple two-layered model which consists of the Earth's ground with finite conductivity and the air as a perfect resister.

The problem will be largely simplified if the situation is approximated by a finite space model with a uniform electrical conductivity.

In the present work, variations in the EM field generated by the piezomagnetic effect are compared for two situations: finite space and semi-finite space models with finite conductivity, assuming the source of the piezomagnetic field is two-dimensional. It is demonstrated that, for some situations, the simpler model provides a good approximation of the expected piezomagnetic field.

Testing paleointensity determination using Wilson method

FUKUMA, Koji[1*] ; SHCHERBAKOV, V. P.[2] ; SHCHERBAKOVA, V. V.[2]

[1]Dept. Env. Sys. Sci., Doshisha Univ., [2]Borok Geophysical Observatory, Russian Academy of Sciences

The classical Thellier method still remains most reliable for paleointensity determination, but requires a quite demanding and rarely satisfied condition; a natural remanent magnetization (NRM) must be completely replaced by a laboratory thermoremanence (TRM) at every temperature interval. If a significant amount of multidomain grains is present, this condition is not satisfied and resulting in erroneous paleointensities as obtained from curvatures seen on the Arai diagrams.

A single-step heating method, which sounds quite primitive as adopted in early times (e.g., Folgheraiter [1899]) but is essentially still alive as in the Shaw method, escapes from the strict condition posed on the Thellier method. The Wilson method, being a sort of single-step heating methods, was developed a half century ago (Wilson, 1961 & 1962); comparison of high-temperature continuous thermal demagnetization curves, measured for a natural remanent magnetization (NRM) and then a thermal remanent magnetization (TRM) acquired in a known laboratory field, yield a paleointensity. The reason why the Wilson method was rarely used for paleointensity studies is that magnetization needs to be measured at elevated temperature. Yet this method has a great advantage of being extremely quicker than the other paleointensity methods. If using a modern automated high-temperature magnetometer, we can complete a Wilson measurement within one hour for a 1-cc cube.

We performed testing paleointensity measurements based on the Wilson method for 27 1-cc cubes of basalts and scorias of the 1983 eruption in Miyakejima (the expected field of 45.1 microT). A 1-cc cube was heated in air at the rate of ˜40 deg.C per minute along with measuring three-component NRM at elevated temperature using a Orion three-component vibrating sample magnetometer at the Borok Geophysical Observatory. When the magnetization is decreased less than 1 percent of the initial value, heating was stopped and then total TRM was imparted during cooling down in the magnetic field of 45 microT. The total TRM was also continuously demagnetized in the same way as NRM.

We did find nicely straight lines on the NRM-TRM diagrams for 85% of measured samples, indicating that the shapes of unblocking temperature spectrum are essentially unchanged for NRM and TRM. We obtained the expected field intensity of 45.1 microT for the about half of the samples. The Thellier method for the sister samples also gave the expected field, but some of the samples did not. For the another half, the gradients of NRM-TRM lines significantly deviated from unity to higher or lower values. This means that thermal alteration (NOT including domain alteration) increased or decreased TRM capacity but did not appreciably changed unblocking temperature spectrum. Such a kind of alteration is not detected on NRM-TRM diagrams, therefore it is possible to give erroneous paleointensities.

Although the Wilson method is quick and robust even for samples containing multidomain grains, we need to take caution that thermal alteration is not necessarily detected from the linearity on NRM-TRM diagrams. This caution should be exercised for other kinds of single-step heating methods.

Microscopic observation of titanomagnetite grains during paleointensity experiments of volcanic rocks

TANAKA, Hidefumi[1] ; YAMAMOTO, Yuhji[2*]

[1]Faculty of Education, Kochi University, [2]Center for Advanced Marine Core Research, Kochi University

Titanomagnetite (Tmt) grains, some partially maghemitized, of various oxidation levels were microscopically observed under reflected light as a function of temperature step in a Kǒnigsberger Thellier Thellier experiment in air. The reflected light microscopy indicated that the brownish colour of homogeneous Tmt turned blue at ∼300 ℃. This false blue colour was caused by submicron scale rugged stripes on the surface, according to scanning electron microscope observations, which was made after the final heating step. The typical grey-to-bluish colour of maghemitized parts of Tmt grains turned to a brownish colour at ∼300 ℃, indicating inversion of titanomaghemite to a mixture of magnetite and ilmenite (Ilm) or haematite (Hem). Although these observations were from Tmt grains on the sample surface, oxidation must have proceeded similarly within samples because the surface changes in the Tmt grains were highly correlated with behaviour of data points on Arai plots. Alterations in Tmt after heating at 610 ℃ in air for increasing times from 10 to 500 min were evaluated by reflected light microscopy and scanning electron microscopy at the end of the experiment. Mottled patches gradually emerged in the Tmt grains during subsequent heatings. However, the formation of new Ilm lamellae was not observed, even after the final 500 min heating. In conclusion, the alteration of Tmt during laboratory heating in air at ∼600 ℃ is likely not due to the typical high-temperature oxidation that forms trellis-type Ilm lamellae. Below ∼400 ℃, the process should be closer to low-temperature oxidation. On the other hand, maghemitized parts of Tmt grains invert instantaneously at 300 ℃, and a trellis-type structure with Hem lamellae soon emerges when heated at 610 ℃.

Archeointensity trend between 8th and 11th century in Okayama

KITAHARA, Yu[1*] ; YAMAMOTO, Yuhji[2] ; HATAKEYAMA, Tadahiro[3] ; TORII, Masayuki[4] ; KAMEDA, Shuichi[5]

[1]Graduate School of Integrated Arts and Sciences, Kochi University, [2]Center for Advanced Marine Core Research, Kochi University, [3]Information Processing Center, Okayama University of Science, [4]Faculty of Informatics, Okayama University of Science, [5]Faculty of Biosphere-Geosphere Science, Okayama University of Science

This study presents three new archeointensity estimated from Sayama-area (Bizen city, Okayama prefecture), for the period of 8th to 11th century. The baked-earth samples (archaeological artifacts) we used in this study were collected from old kilns (part of floor and wall) of Sue wares. These kilns were found during the course of five excavations which were conducted under an archaeological project (see Archaeological lab, Okayama University of Science, 2012; 2013) aiming to trace development-history of ceramics production activity in Sayama-area between Nara and Heian-era. If we adopt the archeological chronology based on the Sue-mura type (e.g. Nakamura, 2006), the Sayama-Shin-ike kiln and the Sayama-Higashiyama kiln were estimated to be under operation during last half of 8th century (? 775±25 year), and the Sayama-Higashiyama-Oku kiln to be at around 10 century (? 900±50 year) (See Archaeological lab, Okayama University of Science, 2012; 2013).

Various rock magnetic and stepwise thermal demagnetization experiments revealed that (1) the samples are generally resistant to laboratory heating, (2) shape anisotropy is small, and (3) main magnetic carriers are Ti-poor titanomagnetite with high blocking temperature. Archeointensity measurements were done by using the IZZI Thellier method (double heating method; Yu & Tauxe, 2005). We applied this method to 19 specimens from 15 samples of the Shin-ike kiln, 10 specimens from 10 samples of the Higashiyama kiln, and 19 specimens from 9 samples of the Higashiyama-Oku kiln. After applying a set of very strict criteria, averaged archeointensity (with one standard deviation) is obtained as follows: 61.6±4.4 μT for the Shin-ike kiln (N=4), 51.8±6.5 μT for the Higashiyama kiln (N=8), and 49.8±9.8 μT for the Higashiyama-Oku kiln (N=9). These values are not contradicted from the ones obtained by the Tsunakawa-Shaw method (Tsunakawa and Shaw, 1994; Yamamoto et al., 2003) though they are preliminary. Our new data show general agreement with the most recent archeointensity compilation in Japan (Yoshihara et al., 2003) and confirm the rapid intensity decrease at ˜600 AD on average.

Absolute paleointensity determinations of welded tuffs: Correlations between relative and absolute paleointensity data

FUJII, Satomu[1] ; MOCHIZUKI, Nobutatsu[2*] ; HASEGAWA, Takeshi[3] ; OKADA, Makoto[3] ; SHIBUYA, Hidetoshi[1]

[1]Department of Earth and Environmental Science, Kumamoto University, [2]Priority Organization for Innovation and Excellence, Kumamoto University, [3]Department of Earth Science, Faculty of Science, Ibaraki University

Absolute geomagnetic paleointensities (APIs) have been estimated from igneous rocks, while relative paleomagnetic intensities (RPIs) have been reported from sediment cores. These two datasets have been treated separately, as correlations between APIs and RPIs are difficult on account of age uncertainties. We present a procedure for directly correlating APIs with RPIs of a RPI stack. Correlations between APIs and RPIs were conducted with virtually no associated age errors using both tephrochronologic correlations and RPI minima. Using the stratigraphic positions of tephra layers in oxygen isotope stratigraphic records, we directly compared the RPIs and APIs reported from welded tuffs contemporaneously extruded with the tephra layers. In addition, RPI minima during geomagnetic reversals and excursions were compared with APIs corresponding to the reversals and excursions. The comparison of APIs and RPIs at these exact points allowed a reliable calibration of the RPI values. In this study, we applied the Tsunakawa-Shaw method to 21 welded tuffs to increase API dataset. We obtained mean paleointensities for 16 of the 21 welded tuffs. Since eight of the 16 welded tuff units were correlated with the oxygen isotope stratigraphy, they can be added to the API data used in the correlation procedure. Combining these API data with the reported data, we correlated API data with RPIs from the PISO-1500 stack and SINT-800 stack. For 13 correlation points, RPIs of the PISO-1500 stack showed a linear relationship with virtual axial dipole moments (VADMs) calculated from the APIs, indicating that the PISO-1500 stack has a linear relation to the axial dipole moment. On the other hand, PRIs from the SINT-800 stack has a tread with VADMs and the correlation coefficient is lower than that of the PISO-1500 stack. The correlation procedure with increased API data can contribute to constraining the relation between RPI of a RPI stack and API and calibrating a RPI stack to absolute values.

Rock magnetic study of the North Atlantic sediment during late Pliocene and early Pleistocene

SATO, Masahiko[1*] ; OHNO, Masao[1] ; HAYASHI, Tatsuya[2] ; KUWAHARA, Yoshihiro[1] ; MIYAGAWA, Chizuru[1] ; FUJITA, Shu[1] ; KITA, Itsuro[1]

[1]Kyushu University, [2]Mifune Dinosaur Museum

As the ocean is a major component in the climatic system, it is crucial for palaeoclimatic study to understand the past evolution of the thermohaline circulation. The North Atlantic Ocean is one of the most important sea areas because newly formed deep water mass is redistributed to the global ocean from there (Broecker et al., 1991). In order to recover the past change in deep ocean circulation at the North Atlantic Ocean, a variety of proxies have been studied. However, the change during Pleistocene and Pliocene is still poorly understood.

In this study we conducted rock magnetic measurement of deep-sea sediments recovered from IODP Site U1314 on the Gardar Drift, to investigate the past change in bottom current flows at the North Atlantic Ocean. Since a coercivity of magnetic mineral varies sensitively with its state such as chemical composition, grain size, grain shape, stress, and so on, coercivity spectra can be used as a proxy for the constituent spectra of the sediment.

The samples were collected at 16 - 50 cm resolution from 199.3 to 262.5 mcd of the core, which corresponds to the age between 2.22 and 2.75 Ma according to the age model by Hayashi et al. (2010). Rock magnetic properties were measured for these samples using a MicroMag 2900 Alternating Gradient Magnetometer. The isothermal remanent magnetization (IRM) acquisition curve was obtained by the application of stepwise-increasing uniaxial fields to the sample at 30 steps from 1 mT to 1 T. The ratio of IRM acquired in a back-field of 0.1 T to that in a forward-field of 1 T (S-ratio) was also measured for all samples.

In order to reveal constituents of the sediment, decomposition of coercivity spectra were conducted. The IRM acquisition curve was normalized by the IRM intensity at 1 T and then the first derivative of the curve was calculated with respect to log10 field (hereafter referred to as IRM gradient curve). The least square fit was performed so as to decompose the IRM gradient curve into linear combination of two end-members. Two end-member components were calculated by averaging the IRM gradient curves of selected samples. Samples with low S-ratio ($<$0.57) and younger than 2.4 Ma were chosen for component 1. Samples with high S-ratio ($>$0.88) and during MIS100, which were associated with the ice rafted debris, were chosen for component 2. These components were distinctly different from each other; coercivity distribution of component 1 was magnetically harder than that of component 2.

In consequence of the decomposition, the fitting error was significantly small for all samples, indicating that North Atlantic sediments in the Garder Drift during late Pliocene and early Pleistocene are explained by mixing of two end-member components. The fraction of two components periodically changes with time and agrees well with the LR04 $\delta^{18}O_{benthic}$ stack (Lisiecki and Raymo, 2005): the high-coercivity component dominated during interglacial periods, and the low-coercivity component dominated during glacial periods.

On the basis of the elemental ratio of potassium to titanium (K/Ti), Grutzner and Higgins (2010) reported change in proportion of sources of sediment at Site U1314 during the last 1.1 Ma. They demonstrated that Ti-rich basaltic material transported by the Iceland-Scotland Overflow Water and K-rich particle (continental rock like) derived from the other source dominated during interglacial periods and glacial periods, respectively. Our result is consistent with their result because high-coercivity and low-coercivity components are interpreted as the fine-grain titanomagnetite of Icelandic sources and the coarse-grain magnetic mineral of continental sources, respectively. Therefore the change in fraction of two end-member components represents change in fraction of bottom currents, and the bottom current flow patterns similar to those during the last 1.1 Ma might prevail at the North Atlantic Ocean during late Pliocene and early Pleistocene.

Magnetic properties of REY rich red clay near Minami-Torishima in the Pacific Ocea

YAMAZAKI, Toshitsugu[1*] ; USUI, Yoichi[2] ; SHIMONO, Takaya[3]

[1]AORI, University of Tokyo, [2]JAMSTEC, [3]University of Tsukuba

Red clay accumulates slowly on the seafloor deeper than CCD in mid-latitudes. Paleoceanographic and paleomagnetic studies were limited so far because red clay does not yield microfossils that can be used for precise age estimation and sedimentation rates were extremely low, less than a few meters per million years. However, red clay has attracted interest since Kato et al. (2011) reported that red clay rich in REY (rare-earth elements and yttrium) distributes widely in the Pacific Ocean. In this paper, we present magnetic properties of red clay cores obtained from the seafloor near Minami-Torishima during the R/V Kairei KR13-02 cruise. From these cores, extremely high REY contents were reported (Fujimoto et al., 2013, JpGU; Suzuki et al., 2013, JpGU). We will discuss a possible relationship between REY content and magnetic properties.

It is known in red clay that magnetostratigraphy can be established back to only ˜3 Ma, and this also holds for the KR13-02 cores. However, noisy but rather coherent inclinations were obtained throughout the cores even where polarity reversal patterns were obscure. Although a possibility that these directions are of magnetic overprint cannot be excluded, the observed inclinations are not much lower than that expected from the GAD model at the present latitude. This may suggest that the sediments including the intervals of high REY content are not very old, possibly Eocene to Oligocene or younger in age, and that they deposited in the northern latitudes not very far from the present sites. This result is not consistent with the idea that the high REY content is influence of hydrothermal activity along the East Pacific Rise. The cores showed a common magnetic susceptibility variation pattern, and a peak of REY content occurs just below an interval of high magnetic susceptibility. The REY peak coincides with a sharp upward decrease in the ratio of ARM to SIRM, which indicates an increase of the mean magnetic grain size and/or an increase in the proportion of detrital to biogenic magnetic mineral component. These results suggest that the increased REY concentration may have occurred in association with a paleoceanographic event.

A method for measuring rapid magnetization change in high field using a pulse magnetizer: A new rock magnetic approach

KODAMA, Kazuto[1*]

[1]Center for Advanced Marine Core Research, Kochi University

Pulse magnetizers have frequently been used in rock magnetic studies for the convenience of the production of high magnetic field without the need for a large electromagnet, enabling the rapid acquisition of isothermal remanent magnetization (IRM) for short (*c*. 10^{-2} sec) period of time. Because the demand for high field is limited as much as 10 T for rock magnetism, the pulse magnetizer can be compact and low-cost, and several commercial systems are available for the purpose of imparting IRM. We propose in this study a new method for measuring the dynamical behavior of magnetization in pulsed high-field, a new cost-effective system comprised of a fast broad-bandwidth digital oscilloscope and a newly designed coil system. We show examples of such dynamical behaviors from a set of natural samples, and discuss these results in comparison with conventional rock magnetic analyses.

Paleomagnetic study of the Holocene volcanic rocks and tephras from post-caldera central cones of Aso Volcano

ABIRU, Takuya[1] ; SHIBUYA, Hidetoshi[2*] ; MOCHIZUKI, Nobutatsu[3] ; YATO, Takanori[2] ; MIYABUCHI, Yasuo[4]

[1]Faculty of Science, Kumamoto University, [2]Department of Earth and Environmental Sciences, Kumamoto University, [3]Priority Organization for Innovation and Excellence, Kumamoto University, [4]Faculty of Education, Kumamoto University

We have conducted a paleomagnetic study on Holocene volcanic rocks and tephras from post-caldera central cones of Aso Volcano. Paleomagnetic sampling was made at 25 sites of seven units. Nineteen out of 25 sites gave reliable mean paleomagnetic directions that had a 95% confidence circle of lower than 5 degree. Different sites from a few lavas, which had been treated as a single unit in the geological map of Aso Volcano (Ono and Watanabe, 1985), gave distinct mean directions at 95% confidence level. For Kishimadake lava, Ojodake lava, Nakadake young volcanic edifice, two different mean directions were obtained from multiples sites. These differences in mean directions indicate that multiple flows were extruded with a temporal gap of more than 10 or 100 years. We also found that Kamikomezuka scoria, two sites of Kishimadake lava, two sites of Ojodake lava gave identical mean directions at 95% confidence level. The concordance of the mean directions suggests that the multiple vents erupted simultaneously, in a time interval of the order of 10 years, and these lavas were extruded over a wide area of the post-caldera central cones. In this study, we also made paleomagnetic measurements on tephra layers in a section. Oriented samples were collected from 22 layers of a tephra section, 4km NNE of Nakadake vocano (Miyabuchi and Watanabe, 1997). Seventeen of the 22 layers gave mean paleomagnetic directions that had a 95% confidence circle of lower than 5 degree. Most of the N6 layer, and N5 and N4 layers give an identical direction, which suggests these layers were formed in a short period of several tens of years. A tephra layer record a same direction of a lava flow, which suggests a simultaneous formation of the tephra layer and lava flow.

Paleomagnetic secular variation record for the last 7000 years observed in piston cores from the Ichinomegata Maar

ANRAKU, Kazuhiro[1*] ; HAYASHIDA, Akira[2] ; HARAGUCHI, Tsuyoshi[3] ; YAMADA, Kazuyoshi[4] ; SHINOZUKA, Yoshitsugu[5] ; GOTANDA, Katsuya[6] ; YONENOBU, Hitoshi[7]

[1]Graduate School of Science and Engineering, Doshisha University, [2]Department of Environmental Systems Science, Doshisha University, [3]Department of Geosciences,Graduate School of Science,Osaka City University, [4]School of Human Sciences, Waseda University, [5]Faculty of Environmental Earth Science, Hokkaido University, [6]Faculty of Polycy Informatics, Chiba University of Commerce, [7]Graduate School of Education, Naruto University of Education

The Ichinomegata is a maar lake located in Oga peninsula, Akita Prefecture. Thin-wall core samples (IMG06) obtained in 2006 provided a Holocene paleomagnetic secular variation (PSV) record through measurements of natural remanent magnetization (NRM) of u-channel samples. In this study, we collected the piston-core samples (IMG13P-1 and IMG13P-2) from the center of the lake, and measured magnetic susceptibility, anisotropy of magnetic susceptibility (AMS) and natural remanent magnetization (NRM) of 7cc cubic samples. According to correlation between IMG06 and the piston cores based on lithological and magnetic susceptibility data, both IMG13P-1 and IMG13P-2 cover the last 7000 years. Stepwise AF demagnetization of the NRM showed that high intensity NRM decayed toward the origin linearly in most samples, so we determined the directions by applying the principal component analysis. We excluded some by evaluating inclinations of minimum axis and shape parameters q of AMS ellipsoids. Excepting some intervals that probably disturbed in coring, inclination and relative declination are showed consistent variations between IMG13P-1, IMG13P-2 and IMG06 cores. Therefore, we argue that the sediments of the Ichinomegata Maar are suitable for PSV studies. The paleomagnetic record from the Ichinomegata Maar shows a good similarity with the archeomagnetic secular variation from southwest Japan (Shibuya, 1980) and the PSV record from Lake Biwa (Ali et al., 1999), implying a great importance in regional reconstruction of the PSV record in Japan.

Thermomagnetic characteristics in the Hikageyama lava: searching a paleomagnetic record of the Laschamp excursion

NISHIYAMA, Hiroto[1*] ; HAYASHIDA, Akira[2] ; SAWADA, Yoshihiro[3] ; DANHARA, Tohru[4] ; KAWANO, Shigenori[5]

[1]Sci. Environ. Math. Model., Grad. Sci.&Engi., [2]Dept. Environ. Sys. Sci., Doshisha Univ., [3]Shimane University, [4]Kyoto Fission-Track Co., Ltd., [5]Tochigi Prefectural Museum

In the JpGU 2013 Meeting, we reported a paleomagnetic record from the Hikageyama lave. Among the 9 sites, 4 sites in the eastern part of the Hikageyama yielded consistent site mean directions characterized by shallow inclinations and easterly deflection. These site mean directions provide virtual geomagnetic poles (VGP) at around 50 N and 100 W. It can be assumed therefore that the Hikageyama dacite recorded anomalous geomagnetic field at the time of the Laschamp excursion. In addition to the above record, stepwise thermal (TH) demagnetization revealed that the above 4 sites yielded consistent site mean directions.

Thermomagnetic analysis revealed that most samples are composed of a single phase Curie temperature, suggesting magnetite as a remanence carrying mineral. And, the above 4 sites are classified into two groups. One (HKG-9, 10) shows a single phase, similar to the above. The other (HKG-11, 12) shows two phases, suggesting titanohematite and hematite. According to TH demagnetization results, one has two or three NRM components remanence. The other has a single component, which showed highly stable remanence which cannot be demagnetized at peak alternating field of 100 mT as previously reported. We will report these components discussion together with the thermomagnetic results.

Electromagnetic core-mantle coupling and length-of-day variation in numerical dynamo models

TAKAHASHI, Futoshi[1*]

[1]Tokyo Institute of Technology

Exchange of angular momentum between the core and the mantle is likely to be responsible for the decadal variations in the length-of-day (LOD). If the changes in the angular momentum of the mantle are balanced by the opposite changes of the core, some coupling mechanisms between the core and the mantle should be invoked. Here we examine the electromagnetic (EM) coupling as a possible mechanism of angular momentum exchange. We use numerical dynamo simulations to investigate the mechanism to explain the LOD variations with respect to time including the decadal time scale. In numerical dynamo models, we impose a uniformly electrically conducting layer of about 200 km-thick on the mantle side of the core-mantle boundary corresponding to the D" layer. The electric current associated with the dynamo-generated magnetic field can flow in the conducting layer and the Lorentz force can yield a net EM torque with respect to the rotation axis. The electrical conductivity of the layer is varied from 200 - 500 S/m in dynamo models. The LOD variations can put some feedback effects on flows in the core through the changes in the angular velocity, which emerge as a change in the effective Ekman number and the Poincare force. Influences of such a feedback are also included in numerical models. The Ekman number adopted as a nominal value is 10^{-4}. We have obtained the EM torque resulting in typical angular velocity variation of the order of 10^{-6} relative to the nominal angular velocity in a time scale of the magnetic diffusion time. Much smaller changes in shorter time scale are also observed. Based on the findings in the present study, it is suggested that the EM core-mantle coupling in a likely range of the conductance within the D" layer is a promising mechanism to yield LOD variations in decadal to longer time scale.

Infulence of surface displacement on fluid motions induced by Joule heating in the inner core of the Earth

TAKEHIRO, Shin-ichi[1*]

[1]Research Institute for Mathematical Sciences, Kyoto University

The elastic anisotropy of the earth's inner core as revealed by recent seismic observations is considered to originate from the alignment of texture formed along the solidification of the core or alignment of the preferred orientation of crystals by plastic deformation of fluid motions. The depth dependency of the anisotropy is difficult to explain by the solidification mechanism, whereas the various factors driving fluid flows in the inner core considered thus far do not appear to yield sufficiently strong stresses for generation of the elastic anisotropy. Takehiro (2011) proposed Joule heating of the magnetic field penetrating diffusively from the inner core boundary (ICB) as a possible source of inner core flows. His specific calculation in the case of toroidal magnetic field with the horizontal structure of spherical harmonics $Y_2{}^0$ showed that downward flow in the equatorial region and upward flows in the polar region are induced by the Joule heating. This flow field has non-zero radial velocity component at the ICB, causing mass exchange between the inner and the outer core. This feature is a result of the constant normal stress boundary condition at the ICB, and it is implicitly assumed that the phase change occurs instantaneously at the ICB. However, the actual speed of the phase change is finite. If the speed of the phase change is slow enough, the ICB would be deformed and the surface displacement is induced by the non-zero radial velocity at the ICB. This surface displacement may prevent inner core flows due to the buoyancy force originated from the density contrast between the inner and the outer cores. Therefore, in this study, we investigate influence of surface displacement on fluid motions induced by horizontally heterogeneous Joule heating in the inner core. We examine the extent of development of the surface displacement and modification of flow field of the inner core.

The difference of the governing equations from those of Takehiro (2011) is the boundary conditions at the ICB. Temperature disturbance at the ICB coincides with the melting temperature which varies depending on the surface displacement. The normal component of stress equates with buoyancy induced by the surface displacement. The toroidal magnetic field and surface displacement with the horizontal structure of $Y_2{}^0$ is given. The flow fields are calculated numerically for various amplitudes of the surface displacement with the expected values of the parameters of the cores.

The results show that, when the surface displacement is the order of 0.01–0.001m or less, the flow and stress fields are similar to those of Takehiro (2011), where the surface displacement vanishes. As the amplitude of the surface displacement is increased, counter flows from the polar to the equatorial regions come to emerge around the ICB, while the flow in the inner regions is directed from the equatorial to the polar regions in the inner region and non-zero radial component of velocity at the ICB still exists. When the surface displacement is about 0.14–14m, radial component of velocity at the ICB vanishes, the surface counter flows becomes stronger than the flow in the inner region, and the amplitude of the stress field near the ICB dominates that of the inner region, which might be inconsistent for the elastic anisotropy in the inner core.

Paleomagnetism of the Znp-Ohta tephra in eastern Honshu: relative tectonic rotations at local and regional scales?

HOSHI, Hiroyuki[1*] ; FUTAMURA, Sho[2]

[1]Aichi University of Education, [2]Futagawa Minami Elementary School

We present paleomagnetic data suggesting relative tectonic rotations in eastern Honshu since 3.9 Ma. Samples were collected from a widespread ash bed, called the Znp-Ohta tephra, at three localities. One is the Tomioka locality located to the east of the Abukuma Mountains, where the ash bed (local name = SF4.5 tephra) was samples at three sites. The other two are the Miyobara and Kohsaka localities on the Boso Peninsula, where the ash bed (local name = An85 tephra) was sampled at three sites at each locality. Stepwise demagnetization was performed on all specimens, and the principal component analysis was applied to the demagnetization data to extract characteristic remanent magnetization (ChRM) components. At Tomioka, site-mean ChRM directions were determined at all sites. They are tightly clustered after tilt correction and have a southerly direction of reverse polarity. Interestingly, the direction is deflected significantly counterclockwise with respect to the direction of the correlative tephra at Chita in central Honshu (Hoshi & Deguchi, 2013). At Miyobara and Kohsaka, the locality-mean ChRM directions are significantly different to each other. The paleodeclination of Miyobara is similar to that of Tomioka, and the paleodeclination of Kohsaka is almost identical to that of Chita. The difference in paleodeclination between Miyobara and Kohsaka seems to be related to the difference in the general geological trend of Neogene strata on the Boso Peninsula, suggesting relative rotation on the peninsula. Our results imply that in eastern Honshu, relative rotations have taken place at local and regional scales since the Pliocene.

Past continental shape inferred from GPS data

KAWAI, Keigo[2] ; KATO, Tadayoshi[2] ; HARADA, Yasushi[1*]

[1]Department of Marine and Earth Science, Tokai University, [2]Department of Marine Mineral Resouces, Tokai University

Kono et al.,1985 analyzed paleomagnetic data around Andes and showed past shape of the south American continent about 50Ma and figured the Andes mountain range were more linear shape than at present. We tried to reconstruct the 50Ma shape of the south American continent from the current crustal motion of GPS data. Plate motion vectors observed from space geodesy including GPS, can comparable with plate motions of geological time scale. Gordon, 1993 showed VLBI plate motion (time scale of years) and NUVEL-1 plate motion (3 million years mean motion) are in great harmony with each other.

We applied a method of Harada and Kato(AGU Fall Meeting 2012), and calculated about 50Ma shape of the south American continent (figure below). The shape of the Andes mountain range were linear and in good harmony with the result of Kono et al.,1985. We conclude, thus, decades scale GPS data can compare with plate deformation of ten thousands years.

Problems related to the past motion of the Philippine Sea Plate

TAKAHASHI, Masaki[1*]

[1]Geological Survey of Japan, AIST

Plate motion through geological time is reconstructed based on the correlation of marine magnetic anomaly patterns and/or hot-spot track analysis. But the past motion of the Philippine Sea Plate cannot be clarified because the plate is surrounded by convergent plate boundary (trench) and it has no hot-spot track. Therefore the paleomagnetic approach is the only method to reconstruct the past location and motion of the plate. However this method contains unacceptable problems that the paleomagnetic declination does not indicates the total rotation of the plate around its Euler pole in most cases. The paleomagnetism has been thought as an effective tool to reconstruct the Philippine Sea Plate motion, but actually it is impossible to clarify the past motion of the plate by paleomagnetic method.

Environmental rock-magnetism of red clay in the South Pacific Gyre during the Cenozoic: relation with rare-earth content

SHIMONO, Takaya[1*] ; YAMAZAKI, Toshitsugu[2] ; SUZUKI, Katsuhiko[3]

[1]Graduate School of Life and Environmental Sciences, University of Tsukuba, [2]Atmosphere and Ocean Research Institute, The University of Tokyo, [3]Institute for Research on Earth Evolution, Japan Agency for Marine-Earth Science and Technology

Red clay occupies ˜40% of the global ocean floor. Paleoceanographic and paleomagnetic studies of red clay were limited so far because red clay does not yield microfossils that can be used for precise age estimation and sedimentation rates were extremely low, less than a few meters per million years. However, red clay has attracted interest since Kato et al. (2011) reported that red clay rich in REY (rare-earth elements and yttrium) distributes widely in the Pacific Ocean. Among the cores studied by Kato et al. (2011), especially REY-rich mud (2110 ppm at the maximum) of ˜40 m thick occurs below 13.5 m below seafloor (mbsf) at the Deep Sea Drilling Project (DSDP) Site 596 at the western edge of the South Pacific Gyre. However, the core sections have large gaps, and rock- and paleomagnetic studies were not conducted. In 2010, Integrated Ocean Drilling Program (IODP) Expedition 329 Site U1365 occupied at almost the same position as Site 596. Continuous pelagic red clay cores of ˜76 m thick was recovered above the basaltic basement of ˜100 Ma in age.

We conducted an environmental magnetic study using the Site U1365 cores to investigate long-range climatic and paleoceanographic changes during the Cenozoic. We also investigate a relation between magnetic properties and REY of the red clay. On the basis of rock magnetic analyses and transmission electron microscopy, magnetic mineral assemblages are dominated by bacterial magnetites (magnetofossils) throughout the cores (Yamazaki and Shimono, 2013). In the uppermost several meters, terrigenous maghemite probably transported as eolian dust increases. High REY mud (2470 ppm at the maximum) of ˜40 m thick occurs below 8 mbsf. The variation pattern of REY constant is similar to that at Site 596. The ages of the Site U1365 cores were transferred from those of Site 596, which is based mainly on a constant Co-flux model at Site 596 (Zhou et al., 1992), by inter-core correlation using magnetic susceptibility and REY variation patterns. Paleomagnetic stratigraphy is available for the uppermost several meters at Site U1365.

We discuss a possible relationship between REY content and magnetic properties. The REY peak coincides with a sharp upward decrease in the ratio of κ_{ARM} to SIRM, which indicates an increase of the mean magnetic grain size and/or an increase in the proportion of detrital to biogenic magnetic mineral component. A peak of REY content occurs just below an interval of high magnetic susceptibility. These characteristics are similar to those of red clay cores near Minami-Torishima (Yamazaki et al., 2014, JpGU). This suggests that the increased REY concentration may have occurred in association with a common paleoceanographic event. Eolian dust supply may have increased since ˜30 Ma. The Eocene/Oligocene (E/O) transition (˜34 Ma) is known as the time when major ocean gateways (the Drake passage and Tasmanian gateway) opened and the Antarctic Circumpolar Current was formed (Scher and Marting, 2004, 2006; Stickley et al., 2004). The onset and increase of dust supply in the South Pacific may have occurred after this time. Northward movement of Australia continent to an arid region (middle-latitude) may have also contributed an increase of dust supply. Hyeong et al. (2013) suggested that phosphatization on the Mid-Pacific mountains took place between 36 and 12 Ma, and it peaked at the E/O transition. They connected the results to paleo-deepwater circulation. A REY peak occur near the E/O transition at Site U1365, which may be related with the phosphorus budget.

Regional differences in magnetic properties of topmost sediments of the Northern Lake Biwa

ISHIKAWA, Naoto[1*] ; ISHIKAWA, Kanako[2]

[1]Graduate School of Human and Environmental Studies, Kyoto Univ., [2]Lake Biwa Environmental Research Institute

Rock-magnetic investigations have been performed on topmost sediments above about 30 cm below sediment surface (bss) cored in summer (June to July) and winter (November to December) at eight sites with different water depth, where dissolved oxygen (DO) content in bottom water and its seasonal variation are different, in the first depression at the North Basin of Lake Biwa in order to reveal early diagenetic effect on magnetic properties of the sediments.

Low-temperature magnetometric results indicate that a partially-maghemitized magnetite is a principal magnetic mineral in the sediments. Warning curves from 6 to 300K of isothermal remanence (IRM) imparted at 6K in 1T after zero-field cooling show a remarkable decrease of IRM between 90 and 120K, which is regarded as a suppressed Verway transition of magnetite. The amount of IRM decrease between 90 and 120K increase downcore at all site, implying the dissolution of maghemite skin covering magnetite. The IRM decrease is more slightly remarkable in the sites with shallower water depth. The degree of maghemitization may be lower in the site. Samples from sites with deeper water depth below about 70m show another IRM decrease between 20 and 30K with the inflection point at about 29K. The IRM drop disappears in samples with hydrochloric acid treatments. These low-temperature IRM behaviors may imply the presence of ferro-rhodochrosite. The IRM drop is detected in samples above about 18 cmbss, and the samples in two zones of 0-3 cm-bss and 6-15 cm-bss show the IRM drop more clearly. The IRM drop is more remarkable in samples with deeper water depth. The occurrence of the magnetic mineral with the characteristic low-temperature magnetic behavior seems to be influenced by the DO values and its seasonal change.

As common characteristics in downcore changes of magnetic properties, the downcore decrease of magnetic coercivity is observed in the uppermost sediments above about 10 cm-bss, and the amount and grain size of magnetic minerals subsequently decreases and increases downcore below 10cm-bss, respectively. These changes are considered to be associated with the dissolution of maghemitized magnetite by the early diagenetic effect. The presence of magnetic minerals with finer grain size and higher magnetic coercivity in the sediments above 10 cm-bss is more remarkable in sites with deeper water depth.

Magnetic properties of the sediments and suspended solids in the sea surface water at the Hiroshima bay station.

KAWAMURA, Noriko[1*]

[1]Japan Coast Guard Academy

Suspended solids (SS) in sea water are consisted of planktons and insoluble particles, and are an indicator of transparency. SS particles adsorb and incorporate metallic ions. Iron is a metallic ion, and an essential element for phytoplankton. It is supplied from river to sea as bivalent or trivalent ions, and exists as iron compounds as organic complexes in sea water. Aeolian dusts are consisted of SS, and also consists of iron compounds. They will deposit on seafloor, and be sediments as the climatic record. It is important to investigate the distribution and mode of iron compound in SS for the present and past environmental studies. This study aims to diagnose magnetic minerals in SS. Enough amount of SS sample for magnetic measurements are collected by magnetic separation from seawater at the Hiroshima bay station. 4 L of seawater is filtrated, and the particles above 0.45 um in diameter are recovered for XRF analysis. The amount of magnetic particles in sea surface water shows relatively high values from April to July in the bay. The maximum value is found at the station, which is located near an iron works (the supply source). The particle is opaque minerals and looks like needle. The values of IRM imparted at 0.3 T and 2.5 T are not stable. It suggests that SS has strong anisotropy. Results of thermo-magnetometry indicate that magnetic carriers of SS samples are mainly magnetite, and goethite and hematite is also recognized. Magnetic minerals in the sediments at the station are magnetite, hematite, and greigite. It is implied that goethite present in the sea surface water and it may be dissolved on sea floor.

Emplacement mechanism of marine volcaniclastic sediments (IODP Site U1397, 1398) based on rock magnetic properties

SAITO, Takeshi[1*] ; KATAOKA, Kyoko S.[2]

[1]Faculty of Science, Shinshu University, [2]Research Institute for Natural Hazards and Disaster Recovery, Niigata University

Large numbers of marine volcaniclastic sediments with various origins were recovered from the sites U1397 and U1398 during IODP Expedition 340. They were most likely derived from volcanoes on Martinique and possibly from Dominica, Lesser Antilles volcanic arc. Some volcaniclastic units were transported and deposited as turbidites, some were as thin tephra fall deposits and others show both characteristics. They contain various amounts of bioclastic component, pumice and lithic fragments and hemipelagic mud clasts. Therefore, these volcaniclastic sediments are suitable for investigating transport and emplacement mechanisms of volcanic materials and the resultant sedimentary and petro-facies in marine settings. This study focuses on magnetic minerals in the marine volcaniclastic sediments and carried out rock magnetic measurements.

Thermomagnetic measurements showed almost reversible curves and induced magnetization decayed to almost zero below 580 ℃, suggesting little contribution of maghemite or hematite. Two Curie temperatures (Tc) with 350-400 ℃ and 500-550 ℃ indicate that the main magnetic carriers are Ti-rich titanomagnetite and Ti-poor titanomagnetite. The proportion of low-Tc titanomagnetite in central and bottom part of thick turbidite units was larger than that in hemipelagic sediments and in the topmost part of turbidite units, suggesting Ti-rich titanomagnetite is derived from volcanic events. Tephra fall deposits also showed large contributions of Ti-poor titanomagnetite, resulted from large amount of volcanic materials. On the other hand, thin turbidite units showed small contributions of Ti-poor titanomagnetite. This suggests that thin turbidite units are derived from diluted flows which contain few heavy Fe-bearing magnetic minerals.

Magnetic susceptibility and hysteresis measurements showed that heavy and large magnetic minerals in most thick turbidite units were concentrated at the lower part of the unit. Samples from the topmost and bottom part of turbidites showed higher degrees of anisotropy than those from the central part, indicating strong influence of suspension settling at the topmost part and shearing at the bottom part. Bottom parts of fall units contain heavy and large magnetic minerals, whereas upper parts of fall units contain fine magnetic minerals. On the other hand, in thin turbidite units such features cannot be observed and hysteresis parameters and susceptibility values were almost concentrated. Probably thin turbidite units did not experience segregation of specific particles during transportation and settling under the relatively calm condition.

These preliminary results suggest that magnetic minerals are useful indicators of volcanic events and rock magnetic approaches can identify various types of depositional processes about marine volcaniclastic sediments.

Paleomagnetic direction of the Tomikusa Group in southern Nagano Prefecture and its tectonic significance

SAKO, Kazuki[1*] ; HOSHI, Hiroyuki[1]

[1]Aichi University of Education

We report here a new paleomagnetic direction from Early Miocene (18-17 Ma) sediments of the Tomikusa Group in southern Nagano Prefecture, and discuss the formation of curvature of the Median Tectonic Line (MTL) in central Honshu. Sedimentary rock samples collected from 24 sites were demagnetized stepwise, and site-mean directions were determined for 23. Rock magnetic experiments suggest that the main magnetic minerals are magnetite and maghemite. The site-mean directions pass a reversal test, indicating primary remanent magnetization. The overall mean direction with a northerly declination is indistinguishable from the Early Miocene reference direction derived from the Asian continent. This comparison suggests no significant rotation in the study area with respect to the continent since 17 Ma. The mean declination is deflected about 15 deg counterclockwise with respect to the strike of the nearby MTL. The same angular relationship is also found in other sedimentary basins in central Honshu (Ichishi in Mie Pref., Chita Peninsula in Aichi Pref., Shitara in Aichi Pref., and Chichibu in Saitama Pref.). Thus we conclude that the MTL was straight in the late Early Miocene (18-17 Ma).

Rock magnetism and its petrological charactization of fossil Porites coral frameworks in Ishigaki island, Japan

KUMAGAI, Yuho[1*] ; NAKAMURA, Norihiro[1] ; SATO, Tetsuro[1]

[1]Graduate school of Earth Science, Tohoku University.

Radiocarbon (^{14}C) is produced by the cosmic rays in the atmosphere and is utilized for analysis of the past sun activity. But the Earth's geomagnetic field also controls radiocarbon variability, suggesting that a strong field would shield the planet from high energy charged particles. This mimics lower sun activity. Also, the short-term (in decadal or centennial scale) movement of the geomagnetic pole to the low latitude, such as geomagnetic jerk, could lead to an increased cosmic ray flux impinging on the terrestrial atmosphere and thus to a higher ^{14}C production rate. Therefore, in order to study the past sun activity from the ^{14}C production rate, we need to know the movement of geomagnetic pole position, its field strength and the variability of radiocarbon production during decadal to centennial periods. Many researches, which aim to reveal the paleomagnetic secular variation (PSV), have been performed using datasets obtained from volcanic rocks, sediment, and fired kilns. The some reconstruction models of geomagnetic dipole moment are also established from these data sets. But there are few recorders that can be used for the reconstruction of PSV in a decadal or centennial scale. Here we propose an alternative candidate of fossil coral frameworks as a possible paleomagnetic recorder for PSV research. The coral framework has an advantage in reconstructing both the radiocarbon variability and the geomagnetic field, although usual corals show extremely weak intensity of remanence and its low stability. However, it is shown that our recently-ceased coral framework samples from Ishigaki island possess a remanence intensity of 10^{-5} -10^{-4} A/m and a single-domain like stability from Lowrie-Fuller test. We prepared the standard 1-inch core samples cut parallel to the growth direction of coral *Porites*, including coral's growth bands for a ten to several tens of years. Our thermal and AF demagnetization experiments of oriented coral samples show that a characteristic remanence direction is parallel to the present Earth's magnetic field with some fluctuations. On the other hand, some samples exhibit different remanence directions from the present geomagnetic field with a calcite peak of X-ray diffraction analysis. The presence of calcite indicates that the meteoric diagenesis which changes aragonite coral frameworks into calcite affect the direction of initial magnetization. To constrain the remanence carriers, we are conducting a first order reversal curves (FORC) measurement and petrologic observations by a Schottky field-emission scanning electron microscope (FE-SEM) of acid-treated residuals of our corals. Our results suggest that Porites coral framework samples provide a role as a potential use for paleomagnetic recorder for annual to decadal scales with careful examination of calcite content.

Effect of thermal expansion on Neel's relaxation nomograph of magnetite and its agreement with the radiocarbon age

SATO, Tetsuro[1*] ; NAKAMURA, Norihiro[1] ; GOTO, Kazuhisa[2]

[1]Earth Science, Tohoku University, [2]International Research Institute of Disaster Science (IRIDeS),Tohoku University

Age gap between the paleomagnetic viscous dating and the radiocarbon age of tsunamigenic boulders in Ishigaki Island is focused. Recent researchers have conducted radiocarbon dating to label tsunami age, being able to calibrate the paleomagnetic viscous dating. These ages should be the same for the initial tsunami event. In the paleomagnetic viscous dating, time-temperature relation assuming Neel's single domain (SD) theory of magnetite is used. This monograph shows the older remagnetized component in nature can be erased by the higher temperature in the laboratory, and younger is its reverse. Thus, we can predict the age acquired the secondary magnetization by calculating demagnetization temperature and heating time. Our viscous dating results sometimes represented that the unblocking temperature of viscous components for tsunamigenic boulders is higher than the temperature predicted from Neel's relaxation theory of single domain magnetite, suggesting the older age than the one determined from the calibrated radiocarbon age. Previous numerous studies confirmed that the departure from Neel's theory is attributed to the presence of multi-domain magnetite. However, Lowrie-Fuller test, FORC (first order reversal curves) experiments and Low-temperature demagnetization of tsunamigenic boulders confirmed the presence of single domain magnetite. To solve this problem, we consider the thermal expansion of magnetite during stepwise thermal demagnetization process and propose a modified time-temperature relation to be able to fill the age gap. Currently, thermal expansion coefficient of magnetite is reported by some researcehrs (e.g. Nikolaev and Shipilin, 2000; Levy et al, 2004). If magnetite volume is bigger than initial volume during thermal demagnetization, unblocking temperature should indicate higher value under the assumption of constant coercive force. To confirm this hypothesis, we conducted stepwise thermal demagnetization to a boulder emplaced by 1771 Meiwa tsunami (242 years ago) and compare them to our new modified time-temperature relation.

Rock magnetic study of single zircon crystals sampled from river sands

SATO, Masahiko[1*] ; YAMAMOTO, Shinji[2] ; YAMAMOTO, Yuhji[3] ; OKADA, Yoshihiro[4] ; OHNO, Masao[1] ; TSUNAKAWA, Hideo[4]

[1]Kyushu University, [2]The University of Tokyo, [3]Center for Advanced Marine Core Research, Kochi University, [4]Tokyo Institute of Technology

Geomagnetic field paleointensity data provide critical information such as thermal evolution of the Earth (Stevenson et al., 1983). Also a state of geomagnetic field closely relates to a surface environment (Kulikov et al., 2007). It is pivotal to know the variation of geomagnetic field intensity throughout the history of the Earth. Until now we have not yet obtained, however, enough data to resolve billion-year-scale geomagnetic field variation (Tauxe and Yamazaki, 2007) and need to obtain more paleointensity data.

In this study we focus on a paleointensity experiment using single zircon crystal. Since river sand originates in rocks widely distributed in river basin, detrital zircons in the sand have various ages (Rino et al., 2004). Therefore if the geomagnetic paleointensity can be measured using the single zircon crystal, we will probably obtain paleomagnetic data enough to resolve the long-term geomagnetic field variation.

Zircon crystals used in the present study were sampled from sands of the Nakagawa River, Tanzawa Mountain. The Nakagawa River flows along bodies of tonalite, which is a representative rock of the continental crust. Using coarse-grain single zircon crystals with weight of about 0.1 mg, a suite of rock magnetic measurements were conducted: low-temperature demagnetization (LTD) and stepwise alternating field demagnetization (AFD) of saturation isothermal remanent magnetization (SIRM), and low-temperature cycle using an Magnetic Property Measurement System (MPMS).

SIRM intensities of the single zircon crystals vary four orders of magnitude ranging from $1x10^{-12}$ - $2x10^{-9}$ Am^2, and especially a few percent of the grains have strong SIRM larger than $1x10^{-10}$ Am^2. The zircon crystals contain nearly pure magnetite (Fe_3O_4), and they are in both single-domain (SD) and multidomain (MD) states. The SD magnetite contained in the zircon crystals has the potential to record the paleomagnetic information. The existence of MD magnetite suggests that stepwise-demagnetization after LTD treatment is an efficient approach for paleomagnetic measurement. Taking into account the relation between SIRM intensity and thermoremanent magnetization (TRM) intensity for magnetite (e.g., Yu, 2010), TRM of single zircon crystal may be measured with a high-sensitivity magnetometer such as a SQUID magnetometer.

Now we plan to sample river sand at the Mississippi River and to conduct rock magnetic measurements of the zircon crystal collected from the sand. On the basis of the rock magnetic studies for the zircon crystals from the Nakagawa River and the Mississippi River, we will discuss the feasibility of the paleointensity experiment using single zircon crystal.

Development of the Japan Archeomagnetism Database

HATAKEYAMA, Tadahiro[1*]

[1]Information Processing Center, Okayama University of Science

Here we will report the online service of Japan Archeomagneitsm Database which is developed since 2012. Now the database includes about 700 site archeodirection dataset, and we are working to add new data from the backyard stocks which has uncertainty about the independent archeological chronology. Therefore we have to confirm that with searching the dating in the original excavation reports.

Moreover we have added new archeomagnetic data from the archeological archives. More than 100 archeomagnetic data have been manually discovered in the reports.

Now we are also providing a paleomagnetic direction at the Far-East region calculated from the Japanese geomagnetic secular variation models.

Medium soscale crustal structure based on magnetic and gravity anomalies in the eastern part of Hokkaido, Japan. -part 2

MORIJIRI, Rie[1*] ; NAKAGAWA, Mitsuru[1]

[1]Geological Survey of Japan, AIST

The Pacific coast of the eastern Hokkaido (from Kushiro to Nemuro Peninsula) is characterized by high gravity and high magnetic anomalies. However, it was difficult to get a suitable model due to gravity anomalies on land and aeromagnetic anomalies. We sampled basalts in this area and measured densities, natural remanent magnetization, susceptibilities and other magnetic properties. These results were presented in Japan Geoscience Union Meeting 2007. Moreover, new gravity and magnetic anomaly maps of offshore of cape Ochiishi were published by GSJ, AIST (2012). We picked up profiles and modified previous models. Data including new profiles suggested similar models to previous studies.

Seismogenic shear-induced thermal turbulence in Nojima fault gouges: micro-textural and rock magnetic considerations

NAKAMURA, Norihiro[1*] ; FUKUZAWA, Tomohiko[1]

[1]Dep. Earth Science, Tohoku University

Nojima fault gouges exhibit a characteristic flow microtexture of laminated slip zones, billow-like wavy folds and turbulent disordered structures. Power spectral analysis of the wavy folds indicates that the geometry roughly obeys a power-law of -1.9, agreeing well with the previously measured value of Kelvin-Helmholtz (KH) turbulence in natural environments. The well-known example of KH instability is a cloud that the cloud-atmosphere interface becomes an unstable vortex sheet that rolls up into a spiral. The instability occurs at the interface between two fluids of different densities shearing at different velocities (Thorpe 2005). The KH wave in Nojima fault gouges was found along a slip plane in a blackish cohesive gouge (pseudotachylyte-like gouge), resulting in the presence of instability at the slip interface during ancient earthquake or creep. Thin section observations showed the blackish cohesive gouge consisted of granular materials for both sides of the interface and the KH wave occurs in a denser granular material along an earthquake-originated sharp slip plane. Our scanning Magneto-Impedance magnetic microscope observation shows the KH wave dense layer is only magnetized in isothermally-magnetized thin section, revealing the production of magnetic mineral in KH wave. Because the Nojima fault gouge contains iron-carbonate (siderite), the thermal decomposition of siderite produces magnetite more than 400 ℃. Therefore, we suggest that the KH wave is generated through KH instability in a high-temperature (>400 ℃) granular dense layer with different densities and different slip velocities. This result suggests that shear-induced thermal turbulence in the fault gouge plays an important role to weaken a frictional strength during earthquake slip dynamics.

Analyzing the early 19 century's geomagnetic declination in Japan from Tadataka Inoh's Santou-Houi-Ki.

TSUJIMOTO, Motohiro[1*] ; OMOTANI, Akitoshi[2] ; INUI, Takaaki[3] ; MIYAUTI, Satoshi[4]

[1]Japan Cartographers Association, [2]San-in System Consultant, [3]Matsue Municipal comitee of property, [4]Studyies of Inoh's map and writing Assoc

Santou-Houi-Ki national treasure of Japan recorded by cartographer Tadataka Inoh in 1800-1816, is 67 volumes ledger consist of approximately 200,000 magnetic compass land survey azimuth data accuracy of 0 degree 05 min, from eastern coast of Hokkaido to Yakushima Isl in western Japan. We continue the work of analysis that stopped after only analysis in 1917, which done about the survey data at known position of the retirement home of Inoh at Fukagawa in Edo (Tokyo) in 1802-1803.

(1)It is able to change Japan as one of the most concentrated area of accurate geomagnetic declination data in the world, in early 19th century, from insufficient area of data, and supply new data to northeast Asia by analysis of Santou-Houi-Ki.

The total number of analyzed points exceeded 178, and the outline isogonic line in Japan archipelago and the distribution of the declination in every15 minutes in western Japan coast in those days, begun to appear.

(2)Compare the isogonic Atlas by Gauss and Weber (hereinafter Gauss Atlas) consisted of observed data in 1828-1830, with the analysis from Santou-Houi-Ki, the foundational structure of isogonic lines in Japan archipelago is roughly similar. But we recognize the contradiction to reverse with secular variation in Northern Kyushuu area and Tsushima Island. There are no observed data in Japan in the table supplemented with Gauss isogonic Atlas. The recorded observational data in Gauss Atlas in East Asia were inland area from Pekin to Eastern Siberia, Ohotsk, Kamchatka etc. From the analysis of Santou-Houi-Ki, we recognize the magnetic declination supposed as the local geomagnetic anomaly in southern coast of eastern Hokkaido. The isogonic line of declination in surrounding area of Japan in Gauss Weber's Atlas had drawn by calculated estimates, on a matrix of 5 degree in latitude and 10 degree in longitude, one cell of this matrix is 500km long. Therefore the analysis of Santou-Houi-Ki becomes very important. Today it is very important to verify with the isogonic map of Andrew Jackson et al Gufm1 by NOAA (1800-1815).

(3)Procedure and advantage of interdisciplinary and simultaneous analysis of Santou-Houi-Ki across geomagnetism, cartography, and local history. 1.It increase precise evidence to verify the azimuth and the name or short description of the reference point or the target points recorded in Santou-Houi-Ki, with not only the survey diary by Inoh or Inoh map or the survey map of today, add historical local map, historical local source material, the old survey map by former Japan imperial army. 2. Use the recreation software of scenery or digital map of GSI Japan to grasp the outline of particular latitude and longitude of the reference point and target points and real azimuth. 3. Calculate the average of remainder as the declination, to deduct the magnetic azimuth recorded in Santou-houi-Ki from the real azimuth. 4. The important point is to calculate backward the precise position of the reference point should be adjusted to the position, where all of the declination values from the magnetic survey azimuth to different targets at the reference point are approximately equal to each other, to use the consecutive formula of Excel for speed up and keep accuracy. 5. Use GPS transmitter at the reference point to investigate longitude and latitude, and recalculate the position under 0 second in latitude and longitude, minute accuracy declination, more detail and accurate than traditional study. 6.It is able to find areas or points of local geomagnetic anomaly, or to restore the precise position of survey reference point by Tadataka Ino, accuracy of less than second in latitude and longitude, or the objective point of survey in accuracy second where the valuable in local history, including disappeared constructions or big tree etc.

Slab dehydration, intermediate-depth earthquakes, and arc magmatism: A review of seismological observations

NAKAJIMA, Junichi[1*]

[1]RCPEV, Graduate School of Sci., Tohoku Univ.

We review recent seismological observations beneath the Japanese Islands and show important roles of geofluids on seismogenesis at intermediate depths and arc magmatism.

Seismicity in the subducting crust of cold slabs is most active at depths of 70-90 km, where seismic velocity in the crust abruptly increases, suggesting that high pore pressures generated as a result of dehydration reactions in the crust facilitate intermediate-depth seismicity. In contrast, seismicity is almost absent in the subducting crust of warm slabs like Cascadia and Nankai. The aseismic crust may be explained by slow dehydration rates in warm slabs, which cannot increase pore pressures effectively.

Magmatism beneath the arc has been discussed in terms of the heterogeneities in seismic velocities together with geochemical and petrological constraints. We recently developed simple but useful method to estimate seismic attenuation structures and applied it to waveform data in NE Japan. Seismic attenuation provides additional insights into ongoing magmatic processes in subduction zones, because higher-temperature environments or the existence of fluids may have different effects on seismic attenuation from on seismic velocity. The obtained results show that a depth profile of Qp?1 in the back-arc mantle is explained by attenuation expected for a two-dimensional (2-D) thermal model. However, an inclined high-attenuation zone observed in the back-arc mantle wedge, which is interpreted as an upwelling flow, shows higher attenuation than that calculated from the 2-D thermal model. The higher seismic attenuation is probably caused by the concentration of partial melt in the upwelling flow. Our results further imply the breakdown of hydrous minerals in a hydrous layer above the Pacific plate at a depth of ˜120 km.

Imaging mantle melting processes and the effect of water beneath island arcs and backarc spreading centers

WIENS, Douglas[1*] ; WEI, S. shawn[1]

[1]Washington University, St Louis, MO, USA

We use arrays of land and ocean bottom seismographs to image melting processes in the Mariana and Tonga-Lau mantle wedges. Both regions show arc volcanism, active backarc spreading, and a gradient in mantle water content going from slab to backarc spreading center. The Lau backarc in particular shows a gradient in inferred mantle water content as the spreading centers approach the arc and slab in the south. Water contents range from near-MORB conditions in the Central Lau Spreading Center (CLSC) to high water content for the Eastern Lau Spreading Center (ELSC) and nearly arc-like for the Valu Fa Ridge (VFR).

For both Mariana and Lau we find significant slow velocity and high attenuation anomalies in the upper 100 km of the mantle beneath the volcanic arc and the spreading center. In the Mariana region, the anomalies are separated by a high velocity, low attenuation region at shallow depths (<80 km), implying distinct arc and backarc melting regions, with the anomalies coalescing and possibly allowing material interchange at greater depths. The maximum anomaly in the backarc is shallower (˜30 km) than in the arc (˜65 km), consistent with geochemical indications on the depth of melt production in these regions. The strongest anomaly beneath the backarc spreading center is narrow (˜70 km) and extends from close to the moho to 80 km depth. Data analyses for the Tonga-Lau project are preliminary, but show similarities to the Mariana images. Extremely low seismic velocity and high attenuation are found in a 100 km wide region beneath the spreading center in the upper 80 km. At deeper depths the anomaly is displaced westward in both velocity and attenuation images, suggesting that partial melting occurs along an upwelling limb of mantle flow originating west of the backarc. 3-D images from Rayleigh wave tomography show a much stronger anomaly along the CLSC when compared to the southern ELSC and VFR. The backarc velocity and attenuation anomalies are stronger in the Lau basin than in the Mariana backarc, perhaps due to higher mantle temperatures inferred from petrology.

Both Q and velocity anomalies are larger than expected for temperature effects based on laboratory-derived relationships, and their configuration is inconsistent with the expected temperature field. In addition, the observed anomalies are roughly inversely proportional to inferred mantle water content, suggesting that water content does not cause the observed large seismic anomalies. However, experimental results suggest that seismic attenuation and velocity are highly sensitive to the presence of even very small amounts of partial melt. Therefore we suggest the high attenuation and low velocity anomalies delineate the melt production regions beneath the ridge axis and volcanic arc, but that only small melt fractions (<1 %) are required to explain the seismic data. Smaller amplitude anomalies beneath the VFR, where large amounts of subduction-derived water are incorporated into the melt, may indicate lower mantle melt porosity due to low melt viscosity and more efficient transport of the water-rich melt, or a different topology of melt in the matrix. A lower melt porosity for aqueous melts is also consistent with the smaller seismic anomaly seen for the water-rich volcanic arc melting regions compared to the backarc melt production zone for both regions.

Slab Melting in Subduction Zones

SCHMIDT, Max[1*] ; MANN, Ute[1]

[1]ETH Zurich, Switzerland

Depending on temperature, slab-to-mantle element transfer in the subarc region may either occur through fluids or melts. In this contribution we present pelite melting experiments systematically varying H_2O and CO_2 contents and review the presently available information on slab melting. Synthetic pelite model compositions containing variable proportions of H_2O (0.7-4.4 wt%) and CO_2 (0-4 wt%) was melted at 3-4.5 GPa and 750-1200 ^oC. The fluid-saturation concentration at 3-8 GPa (i.e. the H2O stored in phengite as the only hydrous phase) is 0.8-0.9 wt% H_2O. We locate the fluid-absent solidus of the H_2O-pelite system at 3 to 4.5 GPa at 880 ^oC to 1050 ^oC about 150-200 ^oC higher than the wet solidus (3 to 4.5 GPa, 730 to 860 ^oC). CO_2 increases the fluid-saturated solidus temperature by ˜30 ^oC but leaves the fluid-absent solidus temperature unchanged. For all systems considered, the onset of melting is controlled by phengite and only in the fluid-absent experiments K-feldspar becomes a product of melting (at 3 GPa).

Compiling all available information, we parameterize the amount of melt to be formed as a function of temperature for fluid-saturated and fluid-undersaturated conditions. Melt compositions themselves are meta- to peraluminous high Si-granites (71-77 wt% SiO_2 on a volatile free basis) with low Fe,Mg, and Ca contents and are uniform to ˜50% melting when plotted as a function of melt fraction (but not temperature), almost independent of starting compositions. At $>$2 wt% bulk H_2O melts are sodic (K/Na =0.2-0.4), while at $<$1.5 wt% melts are mostly potassic (K/Na=0.9-1.7). Only the fluid-poor H2O-CO2 and the CO2-only experiments of Thomsen and Schmidt (2008, EPSL) and Tsuno and Dasgupta (2011, CMP) produce significantly different melts i.e. rather potassic phonolites (Na being increasingly retained in jadeitic cpx with pressure). Near 5 GPa a fundamental change occurs: the H_2O-silicate solidus comes to an endpoint while in CO_2-rich systems a carbonatite replaces the silicate melt lowering the solidus temperature by more than 100 ^oC to 9 GPa.

Regarding the likelihood of sediment melting in the subarc region, only the wet solidus is within reach of the hottest geotherms of the thermal models that predict the highest slab-surface temperatures, i.e. none of the Arcay et al (2007, EPSL) slab surface P-T paths cross the solidus while for Syracuse et al. (2010, G3) about 7 out of 56 modeled slab segments have P-T-paths that may lead to significant melting for H_2O-saturated pelites at 3-4 GPa. As retention of significant amounts of fluids within a subducting lithology is not an option, flushing with fluids from dehydrating serpentinites would be the only option for achieving significant melting in the hottest subduction zones (at the required P-T conditions, there are no suitable reactions in the mafic crust or the sediments themselves). An alternative option to reach widespread pelite melting would be to dismiss the rigid slab surface concept and allow for sediment diapirs to rise into the hot mantle (Gerya and Yuen, 2003, EPSL; Behn et al, 2011, Nature Geosci.) in which case the pelites could bleed out their incompatible elements completely. Nevertheless, these diapirs are propelled by a density contrast resulting from partial melting and it remains unclear whether they could start rising without melting in the first place.

In conclusion, combining P-T paths, phase diagrams and degrees of melting suggests that significant pelite melting at a rigid slab-mantle interface appears to be a rather rare on present day Earth (and hence much more so for mafic materials), the only option for widespread pelite melting appears to be entrainment of the sediments into the mantle wedge. Removal of CO_2 through melting is utterly inefficient and as subsolidus metamorphic reactions lead to low X_{CO2} fluids, most of the subducted CO_2 will be fed into the deep beyond-arc C-cycle.

Diverse magmatic effects of subducting a hot slab in SW Japan: results from forward modeling

KIMURA, Jun-ichi[1*] ; GILL, James[2]

[1]JAMSTEC, [2]University of California Santa Cruz

In response to the subduction of the young Shikoku Basin of the Philippine Sea Plate, arc magmas erupted in SW Japan throughout the late Cenozoic. Many magma types are present including ocean island basalt (OIB), shoshonite (SHO), arc-type alkali basalt (AB), typical sub-alkalic arc basalt (SAB), high-Mg andesite (HMA), and adakite (ADK). OIB erupted since the Japan Sea back-arc basin opened, whereas subsequent arc magmas accompanied subduction of the Shikoku Basin. However, there the origin of the magmas in relation to hot subduction is debated. Using new major and trace element and Sr-Nd-Pb-Hf isotope analyses of 324 lava samples from seven Quaternary volcanoes, we investigated the genetic conditions of the magma suites using a geochemical mass balance model, Arc Basalt Simulator version 4 (ABS4), that uses these data to solve for the parameters such as pressure/temperature of slab dehydration/melting and slab flux fraction, pressure, and temperature of mantle melting. The calculations suggest that those magmas originated from slab melts that induced flux-melting of mantle peridotite. The suites differ mostly in the mass fraction of slab melt flux, increasing from SHO through AB, SAB, HMA, to ADK. The pressure and temperature of mantle melting decreases in the same order. The suites differ secondarily in the ratio of altered oceanic crust to sediment in the source of the slab melt. The atypical suites associated with hot subduction result from unusually large mass fractions of slab melt and unusually cool mantle temperatures.

Fluids and earthquakes in the Japan subduction zone

ZHAO, Dapeng[1*]

[1]Tohoku University, Department of Geophysics

Detailed tomographic images are determined for the source areas of large crustal and megathrust earthquakes that occurred in the Japan subduction zone during 1995-2013, thanks to the availability of the dense Japanese seismic network that could locate accurately the mainshocks and aftershocks of those large earthquakes and provide high-quality arrival-time data for tomographic imaging. Suboceanic events are relocated precisely using sP depth phase. Large crustal earthquakes in the forearc region such as the 1995 Kobe earthquake (M 7.2) and the 2011 Iwaki earthquake (M 7.0) might be triggered by fluids that are released from the dehydration of the subducting slab and directly ascend to the crust and enter an active fault zone. In contrast, along the volcanic front and in back-arc areas, the seismogenic layer in the upper crust is thinned and its mechanical strength is weakened because of ascending hot magmas and fluids which are produced by a combination of slab dehydration and corner flow in the mantle wedge. Large crustal earthquakes are apt to take place at the edge portion of the thinned seismogenic layer which exhibits low velocity, high Poisson's ratio, and high electrical conductivity. To clarify the generating mechanism of the 2011 Tohoku-oki earthquake (Mw 9.0) and the induced tsunami, we determined high-resolution tomographic images of the Northeast Japan forearc. Significant lateral variations of seismic velocity are visible in the megathrust zone, and most large interplate thrust earthquakes are found to occur in high-velocity (high-V) areas. These high-V zones may represent high-strength asperities at the plate interface where the subducting Pacific plate and the overriding Okhotsk plate are coupled strongly. A shallow high-V zone with large coseismic slip near the Japan Trench may account for the mainshock asperity of the 2011 Tohoku-oki earthquake. Because it is an isolated asperity surrounded by low-velocity patches, most stress on it was released in a short time and the plate interface became decoupled after the Mw 9.0 earthquake. Thus the overriding Okhotsk plate there was shot out toward the Japan Trench and caused the huge tsunami. Further details of the role of arc magma and fluids in the nucleation process of a large earthquake can be clarified by high-resolution geophysical imaging and multidisciplinary studies of the earthquake fault zones.

Silicate solute in aqueous fluids governs trace element and stable isotope behavior in subduction zones

MYSEN, Bjorn[1*]

[1]Geophysical Laboratory, CIW, USA

Physical and chemical properties of fluids equilibrated with subducting deep crust and overlying upper mantle are saturated in silicate components [1]. These components govern physical and chemical properties of the fluids. For example, the solution behavior of volatile components such as hydrogen, carbon, and nitrogen, which form bonding with silicate components in fluids, will differ from the behavior in pure H_2O fluids [2]. This can also affect isotope fractionation between fluids and condensed silicate materials.

In pure H_2O, hydrogen bonding plays a role to temperatures $<$600 ℃ at pressures in the 1 GPa-range with a $\triangle$H for hydrogen bond formation near 20 kJ/mol. At temperatures less than 600 ℃, physical properties of fluids, including density, compressibility, and viscosity, are non-linear functions of temperature, whereas at higher temperature and in the absence of hydrogen bonding, these properties tend to become linear functions of temperature. Solution of silicate components in aqueous fluids changes these relationship. The silica solubility in equilibrium with quartz/coesite reaches $>$5 mol/kg near 5 GPa and 900 ℃ with polymerized silicate species, SiO_4, Si_2O_7, and SiO_3 in the fluid. In equilibrium with enstatite and forsterite, the silicate solubility is ~50% less and only SiO_4 and Si_2O_7 species exist in the fluids. Those variables affect D/H isotope ratios. For example, the fluid/melt partition coefficients for hydrogen, KH, varies by ~40% as a function of variable silicate speciation in fluids in the 500 ℃-800 ℃/0.5-1 GPa temperature and pressure range. The hydrogen fluid/melt partition coefficient exceeds that of deuterium. Their temperature-dependence also differs so that for the exchange equilibrium of D and H between coexisting water-saturated melt and silicate-saturated aqueous fluid, the $\triangle$H is between -4 and -6 kJ/mol. This difference is because in the more silicate-rich fluids (higher proportion of polymerized silicate species), the abundance ratio, OD/OH, is higher in the more polymerized silicate species in the fluid. As a result, increasing pressure, which leads to increasingly polymerization of silicate, will cause the D/H ratio of the fluid will increase. This also means that D/H fractionation between aqueous fluid and condensed silicate increases with increasing pressure.

Interaction between dissolved silicate components and other elements can also affect their solubility and, therefore, their roles as geochemical tracers. For example, in the system rutile+H_2O, the Ti solubility in the few-GPa-range at ~1000 ℃ is on the order of 1-100 ppm as compared with thousands of ppm in silicate-saturated aqueous solution [3]. This difference between pure H_2O and silicate-saturated fluid is related to interaction with the silicate species dissolved in the fluid, $2M_6Si_2O_7 + 4H_2O + TiO_2 = 4(MH)_2SiO_4 + M_4TiO_4$, where M is a metal cation. Similar situation likely exist for other nominally insoluble, highly charged elements (e.g., Al^{3+}, Zr^{4+}, Hf^{4+}, P^{5+}).

When modeling isotope fractionation and partitioning of nominally insoluble elements between fluid and condensed phases (melts and minerals) in the deep crust and upper mantle of the Earth, the silicate solute concentration and structure in the fluid and the water concentration and structure of silicate melts both can have major effects on the fractionation factors. These factors depend on the element or isotope ratio in question. They also vary with pressure (and likely temperature) because the structure if dissolved silicate in aqueous fluids varies with pressure and temperature.

D/H intramolecular partitioning in alkali silicate melts: with implications for tracing subduction processes

LE LOSQ, Charles[1*] ; CODY, George[1] ; MYSEN, Bjorn[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington

The D/H ratio is an important probe for studying the cycle of water in the Earth interior in general, and in subduction zones in particular. Indeed, D/H ratios in melt inclusions (MIs) of arc magmas for instance indicate that the δD of subduction fluids is high, near -30 ‰, compared to the δD of the mantle that is near -80 ‰. A possible explanation for these different values is that D/H fractionation during dehydration of the slab in subduction zones enriches the subduction fluids in D, leading to high δD values in subduction magmas. This might be accomplished with hydrogen exchange between the melt and another source enriched in D before entrapment of MIs or a diffusive loss of H from within the inclusion leading to D/H fractionation. However, chemical effects affecting the δD ratio have not been considered because it is usually assumed that D and H have the same chemical and structural properties in silicate melts and glasses.

However, recent results from ^{2}H and ^{1}H MAS NMR of $Na_2Si_4O_9$ glasses quenched from melt (equilibrated with fluid at 1400?C and 1.5 GPa) with various amounts of $(D_xH_{(1-x)})_2O$ (x = D/[D+H]) lead to the conclusion that D and H isotopes occupy different structural positions in the network. From the ^{1}H MAS NMR spectra OH^- groups are distributed in two environments with mean O ⋯ O distances close to 0.26 and 0.29 nm in the $Na_2Si_4O_9$ glass. These environments give rise to two strong NMR lines at 16 and 5 ppm respectively. By contrary, ^{2}H MAS NMR spectra of the same glasses display a strong line at 16 ppm accompanied by a small band near 5 ppm regardless of D/H ratio and total water concentration. This observation leads to the suggestion that OD^- groups are mainly present in an environment with small O ⋯ O distances. In other words, the structural behavior of OH^- and OD^- groups in the quenched silicate melts (glasses) differs.

In $M_2Si_4O_9$ glasses, (M = Li, Na or K) with different concentrations of pure H_2O or D_2O (from 3.3 up to 17.6 mol%), ^{2}H and ^{1}H MAS NMR spectra confirm that by exchanging H with D the intensity of the 16 ppm NMR line increases greatly, whereas the intensity of the 5 ppm line decreases drastically. Interestingly, such a spectral evolution is also observed when increasing the size of the alkali element in the network of hydrous alkali silicate glass. These effects are attributed to steric and electronic effects in the environment of alkali elements, which cause shifts in the equilibrium between H_2O the O^{2-} of the silicate network:

$H_2O_{mol} + O^{2-} \Leftrightarrow 2OH^-$, (1)

The specific preference of OD^- groups for small O ⋯ O sites is in this mind intriguing, but is not in conflict with previous observations. Indeed, increasing the ionic size of alkali elements lead to promote OH^- in the small O ⋯ O environment. Similarly, it appears that increasing the size of the proton (by substituting H by D) promotes their existence in this small O ⋯ O environment. On this basis, we propose that those two observations have a common origin, maybe related to the probability of interaction between H/D and alkali elements depending of their ionic size and/or to molar volume effects related to those ionic sizes.

This large structural-controlled partitioning of D and H in melts, which depends on the melt composition, might be another fractionation process affecting the δD of subduction melts. Consequently, δD values recorded in MIs might be the result of such a structural process and might not reflect the δD of released fluids in the mantle wedge during slab subduction.

Speciation and solubility of F and Cl in coexisting fluids ad silicate melts: implications for F and Cl signature in arc

DALOU, Celia[1*] ; MYSEN, Bjorn[2] ; FOUSTOUKOS, Dionysis[2]

[1]Jackson School of Geosciences, The University of Texas at Austin, [2]Geophysical Laboratory, Carnegie Institution of Washington

The effect of pressure and temperature on the structure of silicate melts coexisting with silica-saturated aqueous electrolyte solutions enriched in fluorine or chlorine in the Na_2O-Al_2O_3-SiO_2-H_2O system has been determined. In-situ measurements were conducted with the samples at desired temperatures and pressures in a hydrothermal diamond anvil cell (HDAC) by using microRaman and FTIR spectroscopy techniques. The data were acquired at high temperature and pressure (up to 800oC and 1264 MPa, respectively), and during cooling/decompression to ambient conditions.

The intensity of the Raman bands assigned to stretch vibration of the OH-groups relative to those of coexisting molecular H_2O in silicate melts is lower in the presence of F and Cl. This difference reflects the interaction of F or Cl with H_2O in the melts. With decreasing pressure and temperature (P-T) conditions, SiF complexes are favored in the melt rather than in the fluid, perhaps because of decreasing silicate concentration in fluids with decreasing temperature and pressure. In melts, the solubility of Cl, likely in the form of $NaCl_{(aq)}$, increases with decreasing P-T conditions, whereas the abundance of such complexes in coexisting fluids decreases.

Our experiments data were employed to help model the ascent of a magma-fluid system from the upper mantle to the shallow crust. The information offers particular insights into F and Cl partitioning between and the speciation of F and Cl in melts and magmatic fluids. We suggest that the formation of stable SiF and NaCl complexes and their increasing solubilities during magma ascent explain the late volcanic degassing of F and Cl, compared to other volatile species.

It explains why F and Cl are often undersaturated in arc basaltic magmas (Carroll and Webster, 1994), indicating that they often do not a significant experience a degassing event. In contrast to H_2O, CO_2 and S, F and Cl signature in primary arc magmas (arc melt inclusions) can be consider as primary and likely retain information on arc magma sources.

Those results also imply that, while Cl is enriched in aqueous fluids from slab dehydration, F preferentially dissolves in slab melts or supercritical fluids, during flows from the subducted slab into the zone of melting in the mantle wedge. It is therefore expected that at given pressure and temperature, the Cl/F ratio is significantly lower in slab melt and supercritical fluids, than in aqueous fluids. This difference in Cl/F signatures decrease when slab components are dragged down to the deep mantle.

The Structure of Water-Saturated Carbonate Melts

FOUSTOUKOS, Dionysis[1*] ; MYSEN, Bjorn O.[1]

[1]Geophysical Laboratory, Carnegie Institution of Washington, USA

The structure of water-saturated Ca- and Mg-bearing carbonate melts under reducing and oxidizing conditions was investigated in a series of hydrothermal anvil cell experiments conducted at 400 - 1100 ^{o}C and 442 - 2839 MPa. Equilibria were investigated in the calcite-H_2O, calcite-CaO-H_2O, magnesite-H_2O and magnesite-MgO-H_2O systems, with redox conditions controlled by Re/ReO_2 and Ti/TiO_2assemblages. Melting relationships and the C-O-H speciation of the coexisting aqueous fluid and melt were assessed in-situ by Raman vibrational spectroscopy. Hydrous melting of $MgCO_3$-MgO occurred at ˜850 ^{o}C, 1.5 - 2 GPa. In the $CaCO_3$-CaO-H_2O system, melt was formed at 600 - 900 ^{o}C and pressures of 0.5 - 1.5 GPa because of melting-point depression imposed by the presence of CaO. The C-O-H speciation of the carbonate melts and coexisting supercritical aqueous solutions was mainly H_2O and ${CO_3}^{2-}$, with traces of $CO_{2(aq)}$ and $CH_{4(aq)}$ in the fluid phase. The melt-fluid H_2O partition coefficients attained in the Mg-bearing melt (median 0.5) were higher than in the Ca-bearing melt (median 0.3). Under oxidizing redox conditions, dissolved ReO^{4-} was present in all phases, underscoring the enhanced solubility of trace elements and metals in carbonate-bearing melts and carbonatites. In effect, the enhanced solubility of H_2O along with the ionic nature of the carbonate melts may promote the solvation of ionic species in the melt structure.

From in-situ vibrational spectroscopy, the v_1-${CO_3}^{2-}$ vibration recorded in the melt spectra suggests the presence of intermolecular interactions between the oxygen of the carbonate ion with water dissolved in the melt. The thermodynamic properties of this water appear to be similar to the supercritical aqueous phase. For example, the estimated enthalpy for the breakage of the hydrogen bonding between water molecules attained values of 6.8 $\pm$ 1.5 kcal/mol and 8.4 $\pm$ 1.3 kcal/mol in the melt and fluid phase, respectively. The calculated partial molar volume of H_2O in the melt (˜48 $\pm$ 6 cm^3/mol) is also comparable to the partial molar volume of supercritical water at similar conditions. Interestingly, this value is considerably greater than published partial molar volume values for H_2O in silicate melts (10-12 cm^3/mol).

The pressure-temperature melting relationships of the CaO-CO_2-H_2O and MgO-CO_2-H_2O systems highlight the important role of water and alkali earth oxides on the hydrous melting of the carbonate-bearing subducting oceanic crust. Carbonates present in marine sediments or serpentinized peridotites may melt before complete dehydration at the slap-mantle wedge transition zone, and thus, never reach sub-arc depths. To this end, melting of carbonate minerals at crustal temperatures and pressure can contribute to the volcanic CO_2 flux at the arc through melt/fluid interactions.

Later phase observations and seismic velocity structure in the subducting crust of the Pacific slab beneath Hokkaido

SHIINA, Takahiro[1*] ; NAKAJIMA, Junichi[1] ; TOYOKUNI, Genti[1] ; MATSUZAWA, Toru[1] ; KITA, Saeko[2]

[1]RCPEV, Grad. Sch. of Sci., Tohoku Univ., [2]NIED

The subducting crust at the uppermost part of the oceanic lithosphere is considered to play important roles for generation of intraslab earthquakes (e.g., Kirby et al., 1996) and arc-magmatism in the mantle wedge (e.g., Nakajima et al., 2013), because the crust involves a large amount of water in form of hydrous minerals and these hydrous minerals affect seismic velocities in the crust (e.g., Hacker et al., 2003). Therefore, to understand water circulation in the subduction zones and genesis of intermediate-depth earthquakes, it is important to reveal where dehydration reaction of hydrous minerals occurs in the crust. However, it is generally difficult to obtain the detailed velocity variation in the crust because the thickness of the crust is ˜7 km.

Later phases, such as mode-converted wave and guided wave, are sensitive to heterogeneous structure in the crust because of their longer propagation paths in the crust, and hence they are very useful to resolve small-scale seismic velocity structure in the crust (e.g., Matsuzawa et al., 1986; Abers, 2005).

At the Hidaka mountain range, middle of Hokkaido, northern Japan, some later phases are reported from earthquakes that occurred in the Pacific slab (e.g., Shimizu and Maeda, 1980). A later phase (Xp phase) recorded in this region has some characteristics: 1) amplitudes of Xp phase are similar to or larger than those of the P wave, 2) Xp-P time lies in a range of 2-10 s and increases with epicentral distances. Shiina et al. (2013, SSJ) discussed the origin of the Xp phase with numerical modeling and interpreted the Xp phase as guided P-wave that propagated in the crust. Moreover, we identified a later phase (Xs phase) that arrives several second after the theoretical initial S waves, and such a phase usually appears in seismograms with guided P-wave. We interpreted the Xs phase as guided S-wave by comparison characteristics of guided P-wave and results of numerical modeling.

In this study, based on these interpretations for later phases that observed in the western part of Hidaka mountain range, we estimated P- and S-wave velocity distributions in the subducting crust beneath the eastern part of Hokkaido. The number of arrival times of guided P- and S-waves picked in this study is 117 records and 56 records, respectively. Then, we obtained Vp of 6.8-7.7 km/s and Vs of 3.5-4.0 km/s at depths of 50-100 km in the crust. The obtained Vp in the crust is similar to that observed beneath Tohoku (Shiina et al., 2013) and lower than that expected for fully-hydrated MORB materials (e.g., Hacker et a., 2003). This result suggests that aqueous fluids may co-exist with hydrous minerals in the crust beneath the eastern part of Hokkaido.

Pore fluid geochemistry and carbonates in cores and cuttings from the Nankai accretionary prism

EVEN, Emilie[1*] ; SAMPLE, James C.[2] ; FUCHIDA, Shigeshi[1] ; IODP EXPEDITION 348, Shipboard scientists[3]

[1]Graduate School of Science, Osaka City University, [2]School of Earth Sciences and Environmental Sustainability, Northern Arizona University, [3]IODP Expedition 348

The recent IODP Exp 348 at Site C0002 has successfully deepened Hole C0002F (Exp 338) down to 3058.5 mbsf, deep into the accretionary prism of the Nankai Trough. During Exp 348, cuttings were collected and analysed from drilled interval of Holes C0002N (875 mbsf- 2325 mbsf) and C0002P (1965 mbsf- 3059 bsf) and limited coring was performed from 2163 to 2218 mbsf in Hole C0002P. The major-element composition of the solid cuttings and the geochemistry of interstitial water in cores was determined. Results provide insights into exchange of elements between minerals and pore water phases, and into geochemical signatures related to lithological changes within the prism. This study reports the main geochemical results from IODP Exp 348.

Interstitial waters were collected using the GRIND method (Wheat et al., 1994), in which core sediments were ground in an agate mill with ultra-pure water. The interstitial water percentage was determined by drying sediments at 60 ℃ and 105 ℃, the former to minimize loss of clay-bound water, and the latter to follow the GRIND procedure used in previous expeditions. Concentrations were interpreted with data corrected for dilution at 60 ℃, 105 ℃ and normalised to chlorinity values. Profiles of carbonates (as $CaCO_3$), organic carbon and total nitrogen were determined from cuttings of 1-4 mm and $>$4 mm sizes and are compared with the observed lithological boundaries. Carbonate veins were observed in a core sample exhibiting a fault zone at ?2205 mbsf, but no increase was observed at the same depth in the carbonates profile.

The GRIND method has limitations in recovering absolute values of dissolved ions in interstitial waters, and yielded very high dissolved-ion concentrations in some samples. But comparison of ions normalized to chlorinity yielded results comparable to what was observed in pore waters at shallower depths of Site C0002. Some of the trend variations in the cuttings profiles of carbonates, organic carbon and nitrogen match the unit boundaries determined by observation of lithological changes in the cuttings. Therefore, it can be suggested to integrate these data when defining geological units.

Solution mechanism of water in depolymerized silicate melts

CHERTKOVA, Nadezda[1*] ; YAMASHITA, Shigeru[1]

[1]Okayama University, ISEI

It is known that the effect of dissolved water on the viscosity of silicate melts is larger for polymerized melts than for depolymerized melts [*e.g.*, 1, 2]. Direct spectroscopic measurements of melt structure and water speciation at high temperature provide information about the mechanism of water dissolution and its influence on the physical properties of the melts. While *in situ* measurements of water speciation were widely conducted for rhyolitic melts and their analogues [*e.g.*, 3, 4, 5], only limited data are available for depolymerized silicate melts.

We performed high-temperature near-infrared and Raman spectroscopic measurements of hydrous $Na_2Si_2O_5$ melts (2.3-8.1wt% H_2O) using externally heated diamond anvil cell (HDAC). $Na_2Si_2O_5$ composition was chosen as a structural analogue of basaltic melt (anhydrous NBO/T = 1). Experimental pressure was monitored with the pressure- and temperature-dependent Raman shift of ^{13}C diamond [6]. Near-infrared spectra of the homogeneous liquid phase, observed above 820 degree C, 1.7GPa in the $Na_2Si_2O_5$+2.3wt%H_2O system and above 700 degree C, 1.6GPa in the $Na_2Si_2O_5$+8.1wt%H_2O system, contain absorption peaks corresponding to molecular H_2O (at ~5200 cm^{-1}) and structurally bound OH groups (at ~4500 cm^{-1}). At 900 degree C and 1.6-1.9GPa the ratio of these peaks height remains approximately constant (2.6-2.2), implying a constant (structurally bound OH)/(molecular H_2O) ratio for this range of water contents. This observation differs from the regularities reported for more polymerized melts (rapid decrease of OH/H_2O with total water content) [*e.g.*, 4, 7]. At the same time no pressure effect on the ratio of 4500 cm^{-1} peak height to 5200 cm^{-1} peak was observed below 2.4 GPa.

Effect of the upper mantle structure on the Moho geometry

TENZER, Robert[1*] ; CHEN, Wenjin[1]

[1]School of Geodesy and Geomatics, Wuhan University

We investigate the effect of the lateral density structure within the upper (most) mantle on the Moho geometry. The gravimetric forward and inverse modeling methods are applied to determine the Moho depths using the gravity data corrected for major known anomalous density structures within the Earth crust. In our numerical experiment we compute and compare the Moho geometry determined using uniform and laterally varying models of the Moho density contrast. The laterally varying model of the Moho density contrast incorporates the information on the upper mantle lateral density structure taken from the CRUST1.0 global crustal model. For the uniform density contrast model, the constant value of the Moho density contrast is determined based on minimizing the spatial correlation between the gravity data and the Moho geometry. Except for the upper (most) mantle, the deeper heterogeneous mantle density structures including the core-mantle boundary zone are not taken into consideration due to the absence of a reliable 3-D density model of the whole mantle. The numerical results revealed that the consideration of the upper mantle density structure improves the fit of the gravimetric solution with the seismic Moho model.

Conductivity anisotropy of partial molten peridotite under shear deformation

ZHANG, Baohua[1] ; YOSHINO, Takashi[1*] ; YAMAZAKI, Daisuke[1]

[1]Institute for Study of the Earth's Interior, Okayama Univ.

Recent ocean bottom magnetotelluric investigations have revealed a high-conductivity layer (HCL) with high anisotropy characterized by higher conductivity values in the direction parallel to the plate motion beneath the southern East Pacific Rise (Evans et al., 2005) and beneath the edge of the Cocos plate at the Middle America trench offshore of Nicaragua (Naif et al., 2013). These geophysical observations have been attributed to either hydration (water) of mantle minerals or the presence of partial melt. Currently, aligned partial melt has been regarded as the most preferable candidate for explaining the conductivity anisotropy because of the implausibility of proton conduction (Yoshino et al., 2006).

In this study, we report development of the conductivity anisotropy of partial molten peridotite in three directions parallel and normal to shear on the shear plane, and perpendicular to the shear plane as a function of time and shear strain. Starting samples were pre-synthesized partial molten peridotite (Fe-free and Fe-bearing systems), showing homogeneous melt distribution. The Fe-free and Fe-bearing partially molten peridotite samples were deformed in simple shear geometry at 1 GPa and 1523 and 1723 K, respectively, in a DIA-type apparatus with uniaxial deformation facility. Conductivity of the partially molten peridotite parallel to the shear direction was initially identical to that normal to shear. However, shear-parallel conductivity increased by more than one order of magnitude after the initiation of shear by piston advancement. Shear-parallel conductivity then stayed constant for the duration of the experimental run. On the other hand, conductivity normal to the shear direction on the shear plane remained constant, whereas conductivity perpendicular to the shear plane decreased gradually after initiation of shear and finally close to that of olivine. Conductivity difference between parallel and normal to shear direction reached one order, which is equivalent to that observed beneath asthenosphere. In contrast, such anisotropic behavior was not found in the melt-free samples, suggesting that development of the conductivity anisotropy was generated under shear stress.

Microstructure of the deformed partial molten peridotite shows partial melt tends to preferentially locate grain boundaries parallel to shear direction, and forms continuously thin melt layer sub-parallel to the shear direction, whereas apparently isolated distribution was observed on the section perpendicular to the shear direction. The resultant melt morphology can be approximated by tube like geometry parallel to the shear direction. This observation suggests that the development of conductivity anisotropy is caused by the realignment of partial melt (forming tube-like melt) parallel to shear direction in the silicate matrix.

In conclusion, the high anisotropy of conductivity in the direction of plate motion can be well explained by anisotropic interconnection of melt in partially molten rocks at the top of asthenosphere, but not hydration of nominally anhydrous minerals. Therefore, our results provide the direct experimental evidence for supporting these geophysically observed high-conductivity anisotropy at the LAB and verify the validity of partial melting hypothesis (Yoshino et al., 2006; Naif et al., 2013).

Surface-wave phase velocity maps of North America with inter-station waveform analysis

HAMADA, Kouta[1*] ; YOSHIZAWA, Kazunori[2]

[1]Graduate School of Science, Hokkaido University, [2]Faculty of Science, Hokkaido University

The western United States encompasses a variety of tectonic features, including regions with east-west extension, volcanic areas and relatively stable cratonic regions.

In the last decade, the Transportable Array (USArray) has been installed throughout the U.S, and these waveform data have facilitated a variety of tomographic studies in this region using body and surface waves, and ambient noise analysis making the most of the high-density seismic network.

In this study, we have developed a new method of fully non-linear waveform fitting to measure inter-station phase velocities, using the Neighborhood Algorithm (NA) as a global optimizer. This algorithm searches for model parameters to fit two observed waveforms on a common great-circle path by perturbing the phase term of the fundamental-mode Love and Rayleigh waves. We have employed the reliability parameter, which represents how well the waveforms at two stations can be fitted in a time-frequency domain. This parameter is used as a data selection criterion for the subsequent step of phase velocity mapping.

The method has been applied to observed waveform data of the USArray from 2007 to 2010, and we could collect a large-number of phase speed data (over 45000 for Rayleigh and 15000 for Love) in a period range from 30 and 200 seconds, at short distances less than 1000 km. The phase velocity models for Rayleigh and Love waves indicate good correlation on large scales with the recent tomographic maps derived from different approaches for inter-station phase velocity measurements (Foster et al., 2013); e.g., significant slow velocity anomaly in volcanic regions in western Unites States and extremely fast anomaly in the cratonic region in the longer period range, which implies the robustness of such tectonic features as well as the validity of our new measurement technique. The current method can be expanded for the measurements of inter-station higher-mode phase velocities, which will be of great help in enhancing the vertical resolution of the 3-D shear wave models.

Diffusion to dislocation creep transition in the upper mantle inferred from silicon grain boundary diffusion rates

FEI, Hongzhan[1*] ; KATSURA, Tomoo[2] ; KOIZUMI, Sanae[3] ; SAKAMOTO, Naoya[4] ; HASHIGUCHI, Minako[5] ; YURIMOTO, Hisayoshi[5] ; YAMAZAKI, Daisuke[1]

The majority of the dynamical processes in the upper mantle are controlled by creep of minerals. Dislocation creep causes non-Newtonian viscosity and seismic anisotropy whereas diffusion creep causes Newtonian viscosity and no seismic anisotropy. Determination of deformation mechanism in the upper interior is thus essential to understand mantle dynamics. Previous deformation studies on olivine suggested that the shallow regions of the upper mantle should be dominated by dislocation creep and the deeper regions dominated by diffusion creep [Karato, 1992; Karato and Wu, 1993; Hirth and Kohlstedt, 2003]. However, recent study [Fei et al., 2013] demonstrated that those deformation experiments largely misunderstood the creep rate due to the experimental difficulties. Since the creep of olivine is controlled by silicon diffusion, we measured silicon grain-boundary diffusion coefficient in Mg-olivine aggregates as a function of pressure, temperature, and water content. The activation energy, activation volume, and water content exponent are found to be 240-260 kJ/mol, 1.8 ± 0.2 cm^3/mol, and 0.22 ± 0.05, respectively. Together with the silicon lattice diffusion data [Fei et al., 2012; 2013], our results predict the diffusion to dislocation creep transition in the upper mantle, which is in contrast with the previously considered model. In the asthenosphere, dislocation creep should dominate because of the high temperature. In the lithosphere, diffusion creep dominates in shallow regions and dislocation creep dominates in deeper parts. The seismic anisotropy jumps at mid-lithosphere discontinuity beneath continents and at Gutenberg discontinuity beneath oceans are caused by the transition from diffusion to dislocation creep. The weak anisotropy in cold lithospheres could be attributed to the fossil anisotropy formed at the spreading ridges. Dominance of diffusion creep in upper lithosphere accounts for the Newtonian rheology suggested by postglacial rebound.

Aluminum incorporation into phase A - a new hydrous silicate in the deep upper mantle

CAI, Nao[1*] ; INOUE, Toru[1] ; FUJINO, Kiyoshi[1] ; OHFUJI, Hiroaki[1] ; KURIBAYASHI, Takahiro[2] ; YURIMOTO, Hisayoshi[3]

[1]Geodynamics Research Center, Ehime University, [2]Institute of Mineralogy, Petrology and Economic Geology, Graduate School of Science, Tohoku Universi, [3]Division of Earth and Planetary Sciences, Hokaido University

A new aluminum bearing hydrous silicate was found in the experiments under the deep upper mantle conditions, using phase A ($Mg_7Si_2O_8(OH)_6$) and $Al(OH)_3$ as the starting materials. Using electron probe micro analysis (EPMA) and secondary ion mass spectrometry (SIMS), the composition was determined to be very close to $Mg_{5.5}AlSi_2O_8(OH)_6$, which contained about 12 wt % of water. Almost pure phase was obtained in the subsequent experiments. The powder x-ray diffraction pattern and transmission electron diffraction patterns showed a hexagonal structure, with an abnormal large c axis. This new phase has similar stability region with phase A. At lower pressure and higher temperature, it breaks down into Chondrodite + Garnet + Brucite + Fluid, while at higher pressure and higher temperature, it breaks down into Al-superhydrous phase B + Garnet + Brucite + Fluid.

Besides, present study shows that phase A coexists with this aluminum bearing hydrous phase, with a small amount of aluminum ($<$1 wt%) incorporated into phase A structure, which predicts that phase A can preserve only trace of aluminum.

According to Inoue's unpublished data, aluminum can easily incorporate into some dense hydrous magnesium silicates and form aluminum bearing hydrous phases such as phase B, superhydrous phase B, and even perovskite. However, rather than aluminum bearing phase A, the present study shows a small amount of aluminum incorporation into phase A structure, and an appearance of a new aluminum bearing hydrous phase, with the composition very similar to phase A but structure very different from it. Further investigations are needed to clarify these two phases.

Changbai intraplate volcanism and deep earthquakes in Northeast Asia

ZHAO, Dapeng[1*] ; TIAN, You[1]

[1]Tohoku University, Department of Geophysics

The origin of the intraplate volcanoes in Northeast Asia is considered to be associated with upwelling of hot and wet asthenospheric materials in the big mantle wedge above the stagnant Pacific slab in the mantle transition zone. Among these intraplate volcanoes, Changbai is the largest and most active one, and very deep earthquakes (500-600 km depths) in the Pacific slab under East Asia occur ~300 km to the east of the Changbai volcano. Integrating the findings of geophysical, geochemical and petrologic studies so far, we suggest a link between the Changbai volcanism and the deep earthquakes in the Pacific slab. Many large shallow earthquakes occurred in the Pacific plate in the outer-rise areas close to the oceanic trench, and seawater may enter down to the deep portion of the oceanic lithosphere through the active normal faults which generated the large outer-rise earthquakes. The seawater or fluids may be preserved in the active faults even after the Pacific plate subducts into the mantle. Many large deep earthquakes are observed that took place in the subducting Pacific slab under the Japan Sea and the East Asian margin. At least some of the large deep earthquakes are caused by the reactivation of the faults preserved in the subducting slab, and the fluids preserved in the faults within the slab may cause the observed non-double-couple components in the deep earthquake faulting. The fluids preserved in the slab may be released to the overlying mantle wedge through the large deep earthquakes. Because large deep earthquakes occur frequently in the vicinity of the Changbai volcano, much more fluids could be supplied to this volcano than other areas in Northeast Asia, making Changbai the largest and most active intraplate volcano in the region.

Semiconductor diamond heater (SCD): An innovation for ultrahigh temperature experiments in the Kawai cell

XIE, Longjian[1*] ; ITO, Eiji[1] ; YONENDA, Akira[1]

[1]Institute for Study of the Earth Interior , Okayama University

We developed the semi-conductor diamond heater in the Kawai high pressure cell. The starting material of the semi-conductor diamond heater is born(B)-doped burned-graphite. We succeeded to improve the machinability of the B-doped burned-graphite by decreasing porosity. Following is the motivation and the background of the semi-conductor diamond heater project.

It is important to generate extremely high temperature (~3000 ℃) in a large sample volume (~0.1mm^3) in the Kawai apparatus.X-ray transparency is also desirable for in-situ synchrotron analysis. However, any traditional heater used in the Kawai apparatus so far does not satisfy the both requirements simultaneously.

Semiconductor diamond is a candidate material to generate temperatures higher than 3000 ℃ with low x-ray absorption. Anton Shatskiy (2009) have generated a temperature of 3500 ℃ by using the semiconductor diamond heater in a large-volume Kawai-type high-pressure apparatus, although their temperature measurement is questionable from a viewpoint of the power-temperature relation. Furthermore, their semi-conducted diamond heater, made of boron and graphite powders, was not machinable and difficult to control the temperatures. It often became unstable at around 1000~1300 ℃ and impossible to generate higher temperature.

Systematic experiments have done to improve the performance of the semiconductor heater. We used a machinable block of graphite contain 3 wt.% boron as the starting material for the semi-conductor diamond heater. The graphite-diamond transformation started at ~1000-1200 ℃ at 15 GPa in the Kawai apparatus. After the transformation, we stably generated temperature to 2000 ℃. Activation energy of B-doped diamond is about 0.1 eV, which is much lower than that of pure diamond (5.45eV).

Recent Global Tomography Models: Where are We Heading for?

TAKEUCHI, Nozomu[1*]

[1]Earthquake Research Institute, University of Tokyo

Many high-resolution global tomography models have been obtained and we now have consensus about overall features of 3-D heterogeneous structure in the Earth. Majority of models have been obtained by using conventional ray theory which assumes that scale length of lateral heterogeneities is sufficiently large compared with wavelength of seismic waves analyzed.

Primary efforts in recent studies appear to introduce better theories to overcome resolution limits caused by the above-mentioned assumption. The efforts include delay time tomography with finite frequency kernels (e.g., Montelli et al. 2004, Science; Obayashi et al. 2013, GRL) and waveform tomography with 2-D (e.g, Li and Romanowicz 1996, GJI, Panning and Romanowicz 2004, Science) or 3-D (e.g, Takeuchi 2007, GJI; Takeuchi 2012, EPSL) finite frequency kernels. Waveform tomography with further better theories is also becoming feasible (e.g., Lekic and Romanowicz 2011, GJI; French et al. 2013, Science).

In this presentation, I want to propose another direction to improve resolution: use of a new type of dataset. I will propose to use incoherent part of seismic signals (i.e., scattering waves or coda waves). Scattering waves are sensitive to heterogeneities whose scale length is comparable with wavelength of seismic waves analyzed. Use of such waves therefore should provide new information beyond resolution limit of ray theory. At the time of the presentation, I plan to show feasibility and examples of such analyses to reveal distribution of smaller scale heterogeneities in the subduction zone around Japan.

Lattice preferred orientation of stishovite in deformation experiment

XU, Fang[1*] ; YAMAZAKI, Daisuke[1] ; TSUJINO, Noriyoshi[1]

[1]ISEI, Okayama University

Seismic observations reveal strong negative anisotropy ($V_{SV}>V_{SH}$) at around 550 km depth in the lower part of mantle transition zone (Visser et al., 2008). The mantle tomography indicates the obvious association of this negative anisotropy with the subduction zones (Panning and Romanowicz., 2006). The observed anisotropy can be caused by lattice preferred orientation (LPO) of constituting material when the material is elastically anisotropic. Majorite and ringwoodite, which are the dominant minerals in this region, are nearly isotropic (Chai et al., 1997; Weidner et al., 1984). On the other hand, stishovite, which may occur in significant amounts in this region derived from the delaminated subducting basaltic layer (Karato et al., 1997) and continental crust (Kawai et al., 2012), shows strong elastic anisotropy (V_{SV}/V_{SH} is as large as 150%) indicated by the acoustic velocities study (Yoneda et al., 2012) on single crystal of stishovite. Therefore, the LPO of stishovite has a high potential to interpret the seismic anisotropy in the lower part of the transition zone and indicate the geometry of mantle flow.

To investigate the LPO of stishovite, deformation experiments on stishovite were conducted in both simple shear and uni-axial geometry. We prepared starting material of polycrystalline stishovite with grain size of ~10 μm at 12 GPa and 1450 ℃ in a Kawai-type high-pressure apparatus. Then deformation experiments were carried out at 12 GPa and 1600 ℃ by Kawai-type apparatus for tri-axial deformation (KATD installed at Tokyo Institute of Technology) and deformation-DIA apparatus (SPEED-Mk. II installed at SPring-8). Sintered diamond piston was used in the uni-axial deformation experiment. Shear strain was ~1.0 estimated from the rotation of platinum strain maker after deformation. From the change of sample length, uni-axial tension and compression strain were 0.4 and 0.1 respectively. The microstructure and crystallographic orientation of the deformed samples were investigated by SEM with EBSD.

The EBSD results reveal that the [001] direction of stishovite tends to be parallel to the shear direction. (100) plane, though not so obvious, tends to parallel to the shear plane. The slip system is consistent with rutile TiO_2 (Blanchin and Faisant., 1979), which has the same structure with stishovite. The calculated seismic anisotropy indicates a fast shear wave along shear direction. Polarization anisotropy reported by Visser et al. (2008) can be attributed by a vertical flow and LPO of stishovite in the transition zone. The negative anisotropy along subduction zones in Panning and Romanowicz. (2006) indicates the type A slabs (slabs which penetrate directly into the lower mantle without much deflection in the transition zone) (Karato et al., 2001).

Phase transitions and mineral chemistry in pyrolite at 1600-2200C across 660-km seismic discontinuity

ISHII, Takayuki[1*] ; KOJITANI, Hiroshi[1] ; AKAOGI, Masaki[1]

[1]Depertment of chemistry, Gakushuin University

It is widely accepted that pyrolite is a model rock which represents the chemical composition of the Earth's upper mantle. Because the post-spinel transition in pyrolite occurs at about 23 GPa along mantle geotherm (e.g. Litasov et al. 2005), it has been accepted that the transition is responsible for the seismic 660-km discontinuity. Slow velocity anomalies by global seismic tomography which may indicate mantle upwelling have been found in the transition zone and the lower mantle, and these regions are higher in temperature than average mantle. To elucidate the origin and dynamics of the mantle plume, informations on phase relations in pyrolite are essential. However, few investigations on phase relations in pyrolite have been made at hot-plume temperatures (1800-2200C) (Hirose, 2002; Nishiyama and Yagi, 2003). In this study, we demonstrated detailed phase equilibrium experiments in pyrolite composition at hot plume conditions.

The starting material was prepared as the oxide mixture in pyrolite composition after McDonugh and Sun (1995) excluding minor components (MnO, K_2O and P_2O_5). Quench experiments were made at about 20-28 GPa and 1600-2200C for 2-10 hours using a Kawai-type 6-8 multianvil high-pressure apparatus at Gakushuin University. The starting material was packed with pressure calibrants ($MgSiO_3$ and pyrope) in a Re multi-sample capsule. A $LaCrO_3$ heater and a W5%Re-W26%Re thermocouple were inserted in a Cr_2O_3-doped MgO pressure medium. Phases of recovered samples were identified with microfocus-Xray diffractometer and SEM-EDS.

The mineral assemblages of $MgSiO_3$-rich perovskite (Mpv) + magnesiowustite (Mw) + garnet (Gt) + $CaSiO_3$-perovskite (Cpv) and Mpv + Mw + Cpv at 1600-2200C are stable at pressure range of 22-24 GPa and above 24 GPa, respectively. The mineral assemblage of ringwoodite (Rw) + Gt + Cpv at 1600C changes to that of Rw + Mw + Gt + Cpv at 1800-2000C, and Rw disappears perfectly above 2200C. From mass balance calculation of analyzed compositions of the phases, we found that Gt content increases with increasing temperature before and after formation of Mpv. We also calculated the densities in pyrolite at each temperature. The density of average pyrolite mantle (1600C) is higher than pyrolite plume (1800-2200C) across 660-km discontinuity due to increase in Gt content with increasing temperature. Therefore, we conclude that hot-plume ascending nearby 660-km discontinuity has positive buoyancy by the phase transitions.

Elastic properties of delta-AlOOH under high-pressure: Implications for high Vs anomaly in the mantle transition zone

MASHINO, Izumi[1*] ; MURAKAMI, Motohiko[1] ; OHTANI, Eiji[1]

[1]Faculty of Science, Tohoku University

delta-AlOOH is a high-pressure polymorph of diaspore (alpha-AlOOH) and boehmite (gamma-AlOOH) (Suzuki *et al*., 2000). Since delta-AlOOH is identified to be stable from 20 to 120 GPa, and temperatures up to 2300 K, this phase is considered to be a possible carrier and reservoir of water in subducting cold slab into the deep mantle (Ohtani *et al*., 2001; Sano *et al*., 2004; 2008). In order to investigate the effect of composition on seismic velocities in subducting slab, it is important to measure the elastic properties of delta-AlOOH at high pressure.

We have conducted high-pressure acoustic-wave velocity measurements of delta-AlOOH using Brillouin spectroscopy and also explored the chemical bonding of delta-AlOOH by Raman spectroscopy at high pressure in a diamond anvil cell. We obtained sharp peaks from transverse acoustic mode (V_S) of delta-AlOOH over the entire pressure range explored up to a pressure of 89 GPa. The peaks from longitudinal acoustic mode (V_P) of delta-AlOOH were masked by the diamond shear acoustic modes from 35 GPa. The pressure dependence of the aggregate velocities for the delta-AlOOH at 300 K suggests that the hydrogen-bonding symmetrization with the space group changes from $P2_1nm$ to $Pnnm$ occurs during compression above 7 GPa. The shear and adiabatic bulk moduli and their pressure derivatives at zero pressure were determined to be K_0 = 192.2(8) (GPa), G_0 = 158.8(3) (GPa), $(dK/dP)_0$ = 3.63(6), and $(dG/dP)_0$ = 1.35(6) for the pressures above 15 GPa. Raman spectroscopic measurements have shown that the B_1 mode frequencies of $P2_1nm$ disappeared around 6 GPa and A_g mode frequencies of $Pnnm$ appeared above 5.6 GPa, which also indicates the hydrogen-bonding symmetrization around 6 GPa. These results indicate that delta-AlOOH becomes harder by the hydrogen-bonding symmetrization and probably exists as a phase ($Pnnm$) with the symmetric hydrogen bonding in the mantle transition zone and lower mantle.

Shear wave velocities for delta-AlOOH are larger than those of hydrous wadsleyite (by 30 %), hydrous ringwoodite (by 29 %), and majorite (by 29 %). Those of delta-AlOOH are approximately 7 % below those of stishovite. The delta-AlOOH phase thus found to be one of the hardest phases compared to the minerals of mantle transition zone. The existence of delta-AlOOH may contribute to the cause of high V_S and V_P anomalies. Shear velocities for sediment containing delta-AlOOH phase are larger than those of pyrolite (by 10 %) and MORB (by 5 %). The subducting slabs often stagnate at the transition zone before reaching the lower mantle. Particularly beneath Korean peninsula, there is a high V_S anomaly (~2 %) in the lower part of the transition zone (Zhang *et al*., 2012). The seismic data under the eastern part of northeast China (NEC) also indicates a slight positive anomaly of V_S (~1 %), but the V_S value observed around 600 km depth under NEC is ~1 % lower than that beneath Korea. We explain the difference in the V_S anomalies beneath the NEC and Korea by the amount of sediment containing the delta-AlOOH phase and the stagnating duration. If sediments stagnate at the transition zone before reaching the lower mantle in this region, we can estimate that the higher V_S anomaly (~1 %) than NEC would correspond to sediments with 13.4 vol% in stagnant slab. The average oceanic crust subduction rate is estimated to be about 8 cm/yr around Japan. Assuming this estimated rate of subduction, the slab stagnetion has lasted for at least 30 million years.

Mechanisms of ultra-deep earthquakes (h>660km) in a slab penetrating the 660-km discontinuity

FUKAO, Yoshio[1*] ; OBAYASHI, Masayuki[1] ; YOSHIMITSU, Junko[1]

[1]IFREE/JAMSTEC

Recent mantle tomography has begun to reveal the characteristic differences between the deep hypocentral distributions associated with stagnant slabs and those associated with penetrating slabs (e.g., Fukao and Obayashi, 2014). We here show that there are differences in focal mechanism as well. Mechanisms of deep shocks within tomographically imaged stagnant slabs (typically in Bonin and Tonga) are characterized by horizontal compression (e.g., Bonnardot et al., 2009). Those within tomographically imaged penetrating slabs (typically in Java and Tonga) are characterized by very steeply dipping compressional axes (e.g., Alpert et al., 2010).

The deepest seismicity is especially active in Tonga, where many shocks occur at depths greater than 660km. Such ultra-deep shocks show in general very unusual mechanisms, typified by nearly vertical tensional axes with a large amount of CLVD component, as demonstrated in Figure 1 (Mechanisms viewed from the side). This figure also shows a remarkble contrast of mechanisms of deepest shocks just above and below the 660km depth. The source region of the ultra-deep shocks (h>660km) is underlain by the greatly deepened post-spinel phase boundary (Niu and Kawakatsu, 1995) so that the source region is at the pre-spinel state while the underlying portion is at the post-spinel state. This situation along with contortion of the slab associated with its interaction with the post-spinel phase boundary (e.g., Cizkova and Bina, 2013) may explain the mechanism change across the 660km depth as observed in Figure 1. We explore the finer velocity structure and hypocentral distribution in the source region by a technique of differential travel time tomography.

A pyrolitic lower mantle with $(Mg,Fe^{3+})(Si,Al^{3+})O_3$ perovskite

WANG, Xianlong[1*] ; TSUCHIYA, Taku[1]

[1]GRC, Ehime University and ELSI, Tokyo Institute of Technology

To better understand the Earth's lower mantle (LM), thermodynamic properties (TDPs) of LM minerals with Fe and Al dopant should be illustrated more clearly. We have so far reported the TDPs of Fe-bearing MgO, $MgSiO_3$ perovskite (Pv) and post perovskite. [1-4] We furthermore study the TDPs of Fe- and Al-bearing Pv, where the internally consistent LSDA+*U* method and the lattice dynamics method are applied. Two spin states, high (HS) and low spin state, two substitution sites, Mg and Si site, and several possible distribution configurations are considered. In the LM pressure range, HS Fe^{3+} substituted at the Mg site with Al^{3+} at the adjacent Si site (Fe-Al pair) is the most stable configuration and tends to distribute homogeneously in LM. Furthermore, negative frequency cannot be observed in the Fe-Al pair-bearing Pv, and Al contributes to middle frequency while Fe mainly to low part due to its heavy mass. This indicates that the Fe-Al pair is vibrationally stable. Incorporation of the pair for geophysically relevant concentrations can increase volume of Pv a little and has marginal effects on the TDPs of Pv except for thermal expansivity and Gruneisen parameter. Simulated densities, adiabatic bulk moduli ,and bulk sound velocities show that a composition close to pyrolite is accountable for the reference Earth model.

Linear analysis on the onset of thermal convection of highly compressible fluids

KAMEYAMA, Masanori[1*]

[1]GRC, Ehime University

A series of linear stability analysis was performed on the onset of thermal convection in a highly compressible fluid, in order to study the fundamental nature of mantle convection of massive super-Earths in the presence of strong adiabatic compression. We consider the temporal evolution (growth or decay) of an infinitesimal perturbation superimposed to a highly compressible fluid which is in a hydrostatic (motionless) and conductive state in a basally-heated horizontal layer. As a model of pressure-dependence in material properties, we employed an exponential decrease in thermal expansivity and exponential increase in (reference) density with depth. The linearized equations for conservation of mass, momentum and internal (thermal) energy are numerically solved for the critical Rayleigh number as well as the vertical profiles of eigenfunctions for infinitesimal perturbations. The above calculations are repeatedly carried out by systematically varying (i) the dissipation number which measures the effect of adiabatic compression, (ii) the temperature at the top surface and (iii) the magnitude of pressure-dependence in thermal expansivity and reference density.

Our analysis demonstrated that the onset of thermal convection is strongly affected by the adiabatic compression, through modulating the static stability of thermal stratification in the fluid layer. For sufficiently strong adiabatic compression where a sufficiently thick “stratosphere” of stable stratification develops in the layer, for example, the critical Rayleigh number explosively increases with the dissipation number. The explosive changes in the critical Rayleigh number are associated with drastic decreases in the length scales of perturbations both in vertical and horizontal directions. In particular, for very strong adiabatic compression, the vertical motion of fluid is significantly suppressed in a thick “stratosphere”, which narrows the incipient convection in a thin sublayer of unstable thermal stratification. In addition, when the effect of adiabatic compression is extremely strong so that the thermal stratification becomes stable in the entire layer, no perturbation is allowed to grow with time regardless of the Rayleigh number and/or the horizontal wavelength. We also found that the effect of adiabatic compression becomes prominent for higher temperature at the top surface of the fluid layer. These findings may imply the crucial importance of adiabatic compression in understanding the dynamics and evolution of the mantles of massive super-Earths, particularly for those orbiting their parent stars very closely.

In Situ observation of the Segregation Process of Molten Iron from Partially Molten Silicate using X-ray Radiography

YAGI, Takehiko[1*] ; GOTOU, Hirotada[2] ; IIZUKA, Riko[1] ; SUZUKI, Akio[3]

[1]Geodynamics Research Center, Ehime University, [2]Institute for Solid State Physics, University of Tokyo, [3]Department of Earth Science, Tohoku University

We have made in situ observation of the segregation process of molten iron from partially molten silicate at 5 GPa and 1800 K using X-ray radiography. Earth ' s core is believed to have formed by the similar process in the early stage of Earth formation. Although two measure mechanisms, " rain fall " and " percolation ", have been proposed for this process, experimental results are still quite controversial. Most of the previous works were made either by the texture analysis of the quenched and recovered sample or by the electrical conductivity measurement. In the present study, an uniform mixture of the powders of $Mg(OH)_2$, SiO_2, and Fe was compressed to 5 GPa at room temperature and then X-ray tomography observation was made with increasing temperature up to 1800 K. Addition of H_2O component into silicate-iron system reduces the melting temperature of both silicate and iron considerably. The dynamical process of the formation of iron ball at the bottom of the sample chamber was clearly observed. It was proved that this technique is quite useful to study such process in detail.

Influence of majorite on mantle convection

ICHIKAWA, Hiroki[1*] ; KAMEYAMA, Masanori[2] ; SENSHU, Hiroki[3] ; KAWAI, Kenji[4] ; MARUYAMA, Shigenori[5]

[1]GRC, Ehime University and ELSI, Tokyo Institute of Technology, [2]Geodynamics Research Center, Ehime University, [3]Planetary Exploration Research Center, Chiba Institute of Technology, [4]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [5]Earth-Life Science Institute, Tokyo Institute of Technology

Influence of $MgSiO_3$ majorite on the mantle convection has been investigated by using numerical simulations. According to a first principles study (Yu et al., 2011), wadsleyite decomposes to an assemblage of majorite plus periclase with a large negative Clapeyron slope. Since stability field of majorite is limited at high temperature, downwellings are considered to be unaffected by this phase boundary. On the contrary, the upwelling plumes may be significantly modified by this phase boundary. The asymmetry on upwelling and downwelling caused by the phase transitions may induce strong effects on the thermal evolution and the thermal structure of the mantle.

In this study, we performed 2-D numerical simulations on thermal convection of the mantle incorporating majorite stability field. According to our numerical results, very hot upwelling plumes are strongly influenced by the phase transitions related to majorite. The dynamics of these upwellings are controlled by the release and the absorption of latent heat induced by the transitions as well as interruption of currents due to the large negative Clapayron slope of the transition between wadsleyite and majorite plus periclase.

Rapid lateral variation of P-wave velocity at the base of the mantle beneath the Western Pacific

TANAKA, Satoru[1*] ; KAWAKATSU, Hotoshi[2] ; OBAYASHI, Masayuki[1] ; NECESSARRAY, Project team[2]

[1]JAMSTEC, [2]ERI, Univ. Tokyo

We examine P-wave velocity structure at the base of the mantle beneath the Western Pacific, where is the western edge of the Pacific Large-Low Velocity Province (LLVP), by using high-quality seismograms that are provided by the NECESSArray project. Forward modeling with the reflectivity method is conducted to explain the variation of P-wave travel times as function of epicentral distance near the core shadow zone after station and ellipticity corrections are applied. Additionally PcP-P travel times are also examined to enlarge the survey area. As a result, a rapid variation of P-wave velocity structure at the base of the mantle is detected. Thin (10 to 60 km thickness) and very low velocity (-2 to -6 %) layers at the base of the mantle are intersected with a 100 km thickness and high velocity (+3%) layer, and a slightly fast layer exists at the north of the region with the thin and low velocity layers. Their spatial separations are typically several hundred kilometers and it would be difficult to explain by only a thermal effect. These observations suggest that very complicated thermo-chemical reactions occur near the edge of Pacific LLVP.

Methods for inversion of body-wave waveforms for localized three-dimensional seismic structure and an application to D”

KAWAI, Kenji[1*] ; KONISHI, Kensuke[2] ; GELLER, Robert J.[3] ; FUJI, Nobuaki[4]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [2]School of Earth and Environmental Sciences, Seoul National University, [3]Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo, [4]Institut de Physique du Globe de Paris

We formulate the inverse problem of waveform inversion for localized 3-D seismic structure, computing partial derivatives of waveforms with respect to the elastic moduli at arbitrary points in space for anisotropic and anelastic media. In this study we minimize computational requirements by using the Born approximation with respect to a laterally homogeneous model, but this is not an inherent limitation of our approach. We solve the inverse problem using the conjugate gradient (CG) method, using Akaike’s Information Criterion (AIC) to truncate the CG expansion. We apply our method to invert for three-dimensional shear wave structure in the lowermost mantle beneath Central America using a total of 2154 waveforms at periods from 12.5 to 200 s recorded at stations near the Pacific coast of North America for 29 deep and intermediate-depth events beneath South America. The resulting model shows lateral heterogeneity in the E-W direction which may be associated with a subducted cold slab surrounded by hotter materials with slower velocities. Various tests show that our model is robust.

A magnetic probe into Earth's core and deep-mantle dynamics

SAKURABA, Ataru[1*]

[1]Department of Earth and Planetary Science, University of Tokyo

It is widely recognized that Earth's core dynamics is an important research subject in understanding the past, present and future states of our planet, firstly because the metallic core is a vast domain accounting for one thirds of Earth's mass and plays a significant role in thermal history, and secondly because it dynamically generates the main geomagnetic field that has historically been observed for several hundred years and geologically recorded in rocks since more than a billion years ago. This review attempts to cover this subject with an attention to general questions: how geomagnetic-field data can be used to advance the deep-Earth science, and what theoretical progresses have been made and could be made. I will deal with some of the following particular topics: (1) various driving sources of convection, such as thermal and compositional buoyancy and inertial forcing (e.g., luni-solar precession); (2) a dynamo without a solid inner core; (3) a dynamo that operates in a part (e.g., an inner part) of the outer core; (4) sensitivity of the geomagnetic field structure (e.g., dipolarity), intensity, and time variations (e.g., reversal frequency) to the above mentioned various parameters.

[1]Osaka Univ., [2]Univ. Tokyo, [3]Okayama Univ., [4]JASRI, [5]HPCAT

It is important to understand the relationship between sound velocity and density of liquid Fe-alloys under high pressure for obtaining a constraint of the composition of the molten outer core from observed seismic data. We have studied a relationship between sound velocity and density of liquid alloy based on simultaneous measurement of these properties under high pressure and high temperature. Sound velocity was measured using ultrasonic pulse-echo overlapping method and density was measured employing X-ray absorption method combined with X-ray tomography technique. The measured P-wave velocity and density of liquid Ni?S both increase with pressure. From these data, adiabatic bulk modulus (K_{S0}) of the liquid sample can be well constrained to 29 GPa. It is note that the measured P-wave velocity is found to increase linearly with increasing density. This result provides an important issue in terms of Birch's law for liquid material.

Magnetic-Coriolis waves in convection-driven dynamos: Implications for geomagnetic westward drift

HORI, Kumiko[1*] ; JONES, Chris[2] ; WICHT, Johannes[3] ; SHIMIZU, Hisayoshi[1]

[1]Earthquake Research Institute, University of Tokyo, [2]University of Leeds, UK, [3]Max-Planck Institute for Solar System Research, Germany

A prominent feature of the geomagnetic secular variation is the westward motion of the non-dipole part of the field, which is significant in the Atlantic hemisphere with timescales of a few hundred years. Potential mechanisms to account for longitudinal geomagnetic drifts are advection due to large-scale zonal flows in the Earth's core as well as propagation of rotating magnetohydrodynamic (MHD) waves, particularly of slow Magnetic-Coriolis (MC) Rossby waves. More commonly the westward motion is thought to reflect zonal flow advection, an assumption that is used when inverting the secular variation signal for the flow at the top of the core. However, recent geodynamo simulations have successfully reproduced longitudinal magnetic drifts and some authors reported that the drift is at least partly a wave propagation.

To assess to what extent waves could play a role in geomagnetic drift, we explore nonlinear simulations of convection-driven MHD dynamos in rotating spherical shells. By performing a tempo-spatial spectral analysis of simulation data, we identify a slow MC-Rossby mode, that follows the dispersion curve predicted by a quasi-geostrophic linear theory. The result indicates that such waves can be excited in the planetary fluid core and that wave propagation may indeed play a role in the magnetic drifts. This gives a framework for further exploration of different wave types, which can provide valuable information about the physical properties in the deep interior fluid core.

A generating process of the geomagnetic drifting field

YUKUTAKE, Takesi[1*] ; SHIMIZU, Hisayoshi[2]

[1]None, [2]Earthquake Research Institute, University of Tokyo

The geomagnetic field is comprised of drifting and standing field. The drifting field is the field that drifts westwards nearly steadily over the past several hundred years and the standing field is that stays at the same place. The drifting field has two major characteristic features. When the field is expressed in a spherical harmonic series, the drifting field mainly consists of sectorial harmonics. Secondly the rate of drift is uniform irrespective of the harmonics. This means the drift velocity is non-dispersive.

We here propose a model of the generating process of the drifting field. Because of the non-dispersive nature of the drift velocity, we assume the westward drift is a phenomenon closely tied with material flow rather than a magnetohydrodynamic wave. Furthermore we take it a phenomenon near the surface of the core where the dipole field is dominant.

If the mantle is approximated by an electrical insulator, the electric current in the core normal to the core-mantle boundary must be zero. This provides a strong constraint on the liquid flow near the surface. If we assume infinite conductivity of the core for simplicity, only the sectorial flow is allowed for the toroidal flow, and the meridional flow for the poloidal flow. The sectorial toroidal flow, interacting with the dipole field, induces sectorial poloidal field, whereas the meridional poloidal flow produces the meridional poloidal field. The surface layer, which is rotating westwards as a whole, carries these fields westwards together. Since the rotation of the meridional field is unrecognizable, only the sectorial field is observed as the drifting field.

We present a simplified model that describes the above process.

Electrical resistivitiy of hcp-Fe under Earth's core conditions

OHTA, Kenji[1*] ; KUWAYAMA, Yasuhiro[2] ; HIROSE, Kei[3] ; OHISHI, Yasuo[4]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [2]Geodynamics Research Center, Ehime University, [3]Earth-Life Research Institute, Tokyo Institute of Technology, [4]Japan Synchrotron Radiation Insititute

Iron is the primary component of the Earth's core. Convection of the conductive liquid outer core generates the geomagnetic field, and secular cooling of the core induces growth of the solid inner core and dynamics in the Earth's inside. Synchrotron x-ray diffraction study suggests that iron crystallizes in the hexagonal close-packed structure at the inner core conditions (Tateno et al., 2010). Thus, the electrical resistivity of hexagonal close-packed iron (hcp-Fe) is a key piece of information for estimating the transport properties of the core. We report high temperature electrical resistivity for hcp-Fe to 185 GPa measured in a laser-heated diamond anvil cell. We observed resistivity saturation in hcp-Fe under high pressure and high temperature conditions as predicted in a recent laboratory-based model for the conductivity of the Earth's core (Gomi et al., 2013). The saturation effect is significant in estimating electrical and thermal conductivity of the core, which strongly affect the dynamics and thermal evolution of the Earth.

Spatial dependence of anisotropic thermal diffusivity and its influence on dynamics in the Earth's core

MATSUSHIMA, Masaki[1*]

[1]Tokyo Institute of Technology

Small-scale fluid motions in the Earth's core are likely to be highly anisotropic because of rapid rotation of the Earth and a strong magnetic field in the core. We have carried out direct numerical simulations of rotating magnetoconvection to investigate the effect of anisotropic diffusivity on dynamics in the Earth's core, as one of pilot studies. When a computational region is expressed in terms of a rectangular box with periodic boundaries in the three-directions, the prescribed anisotropic thermal diffusivities were found not to influence the character of rotating magnetoconvection, such as kinetic and magnetic energies averaged over the computational region. When a computational region is expressed in terms of a rectangular box with rigid boundary surfaces perpendicular to the gravitational direction, the prescribed anisotropic thermal diffusivities have a significant effect on the character of rotating magnetoconvection; that is, kinetic and magnetic energies can be increased even by a small anisotropy. The degree of increase depends on the direction of anisotropy and the direction of gravity corresponding to location of the computational region. These results suggest that anisotropic thermal diffusivity insignificantly influences dynamics in the bulk of the core, but that it should be effective near rigid boundary surfaces. Therefore, it is likely that anisotropic diffusivity has a more significant effect on MHD dynamos in rotating thin spherical shells. Such an implication can be examined through global numerical simulations of MHD dynamo models with anisotropic diffusivity being variable in the core.

Instead of such a study, we perform further direct numerical simulations of rotating magnetoconvection by prescribing anisotropic thermal diffusivities with spatial dependence; for example, in one case, anisotropic thermal diffusivities are presumed to be effective only near rigid boundary surfaces; in another case, anisotropic thermal diffusivities are presumed to be effective only far from rigid boundary surfaces. Hence this is another pilot study. Kinetic and magnetic energies in the former case seem to be larger than those in the latter case. The result is consistent with that obtained in our previous studies.

Can a stably stratified layer interrupt the top-down dynamics of Earth's core?

NAKAGAWA, Takashi[1*]

[1]IFREE, JAMSTEC

Takashi Nakagawa

In some of previous studies of numerical dynamo simulation with a stably stratified region below the outer boundary, the long-wavelength feature of radial magnetic field can be only found on the outer boundary because a stratified layer can filter small-scale features of radial magnetic field generated in the convective region below the stratified boundary [Christensen, 2006; Nakagawa, 2011]. The existence of the stably stratified region below the core-mantle boundary (CMB) is recently exposed from high pressure mineral physics [e.g. Pozzo et al., 2012] and seismological data analysis [e.g. Helffrich and Kaneshima, 2013].

Regarding the modeling on geomagnetic secular variation from numerical dynamo simulations, the heterogeneous thermal/chemical anomalies at the core-mantle boundary is important for understanding the time-scale of secular variation such as polarity reversals and excursions suggested from paleomagnetic observations [e.g. Olson et al., 2011; Olson et al., 2013] and current observational magnetic field [Aubert et al., 2013]. However, their investigation was not included in the effects of the stably stratified region below the CMB in their dynamo simulations.

Here we introduce several examples of numerical dynamo simulations with both heterogeneous outer boundary prescribed by the CMB heat flux calculated from numerical mantle convection simulations and a stably stratified layer. Preliminary results are found that the large-scale and ?amplitude of thermal/chemical anomalies induced by the heterogeneous boundary condition, that is, thermal wind type flow, may be trapped at the imposed stratified boundary. This may imply that the geomagnetic secular variations related to the core-mantle coupling may be suggested that the core surface flow would be a key physics.

Sound velocity measurements of liquid Fe-Ni-S alloy at high pressure and temperature via inelastic X-ray scattering

IMADA, Saori[1*] ; NAKAJIMA, Yoichi[2] ; KOMABAYASHI, Tetsuya[3] ; HIROSE, Kei[4] ; TSUTSUI, Satoshi[5] ; UCHIYAMA, Hiroshi[5] ; ISHIKAWA, Daisuke[5] ; ALFRED, Baron[2]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [2]Material Dynamics Laboratory, RIKEN SPring-8 Center, RIKEN, [3]School of Geosciences, The University of Edinburgh, [4]Earth-Life Science Institute, Tokyo Institute of Technology, [5]Japan Synchrotron Radiation Research Institute

The liquid Earth's outer core is mainly composed of Fe-Ni alloy with some amounts (5˜10%) of light element(s), such as hydrogen, carbon, oxygen, silicon, and sulfur. Moreover, it has been known that the Mars and Mercury have also liquid (outer) core, although there are less observational data (Dehant, 2003, Margot et al., 2007).

In order to identify the kind and amount of the light elements dissolved in these planetary cores, sound velocity data of iron alloys at high pressure and temperature are important because the seismic wave speeds are the primary observed information in the deep Earth's interior. While sound velocity measurements of solid core materials up to core pressures have been extensively conducted via ultrasonic method, inelastic X-ray scattering (IXS), nuclear resonance IXS, due to its experimental difficulty, there exist few reports on sound velocity measurements of liquid Fe alloys at high pressure (Nishida et al. 2012).

We measured sound velocity of liquid of $(Fe,Ni)_3S$ up to 30 GPa. Sulfur has been considered to be a major candidate for the light element in the Earth's outer core as well as in the Martian and Mercury's cores (e.g. Lodders and Fegley 1997). We conducted high-pressure and -temperature experiments with an externally-heated diamond-anvil cell (EHDAC). The starting materials were a synthesized or a powder mixture of Fe, Ni, and FeS, with compositions of $(Fe_{0.83}Ni_{0.17})_3S$, or $(Fe_{0.64}Ni_{0.36})_3S$. Sound velocity was measured using high resolution IXS at BL35XU, or BL43XU of SPring-8. IXS spectra were collected in the range of the momentum transfer, Q=3.2?6.59 $nm^{?1}$ with a resolution of 0.45 nm^{-1}. EHDAC was put in a vacuum chamber to reduce the background of the spectra.We will present the sound velocity data of liquid and solid of $(Fe,Ni)_3S$ and discuss the composition of the terrestrial, Martian, and Mercury's liquid outer core.

Experimental approach to the core-mantle boundary region of Mercury

OKAMOTO, Miho[1] ; URAKAWA, Satoru[1*]

[1]Dept Earth Sci, Okayama Univ

MESSENGER mission revealed precise moment of inertia parameters of Mercury and its surface chemistry [1, 2]. These data allow to model the internal structure of Mercury, which has a large liquid core with ∼2000 km radius and a solid outer shell with ∼400 km thickness [3, 4]. As density of solid outer portion is apparently higher than that of the expected mantle silicate, the solid outer layer must include dense materials. Recent models [3, 4] showed that the Mercury's core contains sulfur and silicon as light elements due to high S fugacity and low oxygen fugacity of its interior. Those models presented a solid FeS layer at bottom of solid outer shell of Mercury as a dense layer, which separated from liquid outer core as a FeS-rich liquid due to liquid immiscibility of the Fe-S-Si ternary system. To investigate the FeS-rich layer at the top of Mercury's core, we performed the high-pressure experiments on the Fe-S-Si system using a KAWAI-type multi-anvil apparatus.

Pressure is fixed at 5 GPa corresponding to the CMB of Mercury and temperature is 1800 K, which is 200 K above the liquidus of Fe-S-Si system reported by Sanloup and Fei [5]. Fe-S-Si sample was kept for 30 min at this condition, and then it was quenched into room temperature. Oxygen fugacity of run charges was maintained around 3 log unit below IW buffer. Texture and chemistry of recovered samples were examined by electron microprobe.

We found two immiscible liquids in one run charge, which consist of Fe,Si-rich metallic liquid and FeS-rich sulfide liquid. Sulfur content of metallic liquid ranges 6 to 9 at%, which is higher by ∼5 at% than those reported by Morard and Katsura [6]. Differences in texture of recovered samples and run duration between this study and Morard and Katsura [6] suggest that the latter experiments were in disequilibrium state. Our data shows the liquid immiscible region has a narrower extent than the previous estimation and the Mercury immiscible Fe-S-Si core must contain at least 6-9 at% sulfur. The quenched FeS-rich liquid phase consists mainly of crystalline FeS (∼90 vol%) and Fe-Si alloy. In the case that FeS-rich liquid contacted with MgO sample container, $(Mg_{0.8}Fe_{0.2})S$ crystalline phase coexisted with FeS-rich liquid. Mg-sulfide phase could be made by Fe-Mg exchange reaction between MgO and FeS-rich liquid. In the Mercury core, when FeS-rich liquid ascends to add the bottom of the CMB due to its buoyancy, it makes a stable low density layer. Mg-sulfide phase is produced under low oxygen fugacity and high sulfur fugacity at CMB, and then it incorporates into mantle. This is consistent with the results of X-ray fluorescence spectrometry on the Mercury's surface, which indicates the presence of Mg and Ca sulfides [2].

Single-crystal elastic property of silicate perovskites

FUKUI, Hiroshi[1*] ; YONEDA, Akira[3] ; SHATSKIY, Anton[4] ; TSUTSUI, Satoshi[5] ; BARON, Alfred[2]

[1]Graduate School of Material Science, University of Hyogo, [2]Materials Dynamics Laboratory, RIKEN SPring-8 Center, RIKEN, [3]Institute for the Earth's Interior, Okayama University, [4]V.S. Sobolev Institute of Geology and Mineralogy, Russian Academy of Science, Siberian Branch, [5]Research and Utilization Division, SPring-8/JASRI

Information of single-crystal elasticity of silicate perovskite is essential for comprehensive understanding of the lower mantle. We have measured single-crystal elastic property of $Mg_{1-x}Fe_xSiO_3$ perovskite (x = 0 or 0.035) by means of inelastic x-ray scattering at the ambient condition. The present results show relatively low values compared to previous reports for the iron free sample. The effect of iron increases both adiabatic bulk modulus and shear modulus. Combining the present results with pressure and temperature derivatives reported in literature, the chemical composition of the lower mantle will be discussed.

Measurement of thermal conduction of high-pressure minerals at pressures of the transition zone and to the lower mantle

OSAKO, Masahiro[1*] ; YONEDA, Akira[2] ; YOSHINO, Takashi[2]

[1]National Museum of Nature and Science, [2]Institute for study of the Earth's interior

Knowledge of thermal diffusivity or thermal conductivity of the mantle is vital for study of the dynamics of the Earth. So far thermal diffusivity and thermal conductivity of mantle minerals were measured under high pressure using a pulse-heating method of one-dimensional heat flow. This method is a predominant one for study in deep Earth's materials under pressure because it requires comparatively small amount of samples. It is also applicable to materials with anisotropy in thermal conduction. In addition its measurement yields heat capacity data under pressure.

Thermal conductivity or thermal diffusivity of olivine and garnet increases 3-4 % per 1 GPa, and olivine still reveals anisotropy in thermal conduction under the conditions of the upper mantle. Antigorite, a high-temperature form of serpentine, has low thermal diffusivity and low thermal conductivity which are much lower than those of olivine, whereas talc has high thermal diffusivity and thermal conductivity comparable to those of olivine. All those data were obtained from the measurements at pressures up to 10 GPa and temperatures to 1100 K. An advanced cell assembly was needed to expand the pressure range of measurement.

A new pressure-cell assembly similar to our previous one is designed for a sample of 3 mm in diameter and 0.7 mm in thickness. This smaller cell was applied to pyroxene samples of which sizes were necessarily limited. The measurements were conducted using the Kawai-type apparatus at the Institute for study of the Earth's interior, Misasa. This cell enabled to make measurements of thermal properties at pressures exceeding 15 GPa, which will covers the condition in the mantle transition zone.

We made preliminary measurements by this cell for the garnet sample as a test material. The thermal diffusivity showed slightly lower value (5˜10 %) and the thermal conductivity was slightly high (0˜10 %) value compared with the previous results by the large cell. The precision of measurements should be improved by well-controlled machining of the cell assembly and by refining the data acquisition system. After that this cell will be used for measurements of wadsleyite, ringwoodite and majorite. A cell assembly of more reduced in size is planned. This cell will be used for measurements of MgSiO3 perovskite.

Elemental partitioning in the Fe-S-Si system at high pressure and temperature: Implications for the Earth's core

SAKAIRI, Takanori[1*] ; OHTANI, Eiji[1] ; SAKAI, Takeshi[2] ; KAMADA, Seiji[1] ; MIYAHARA, Masaaki[3] ; HIRAO, Naohisa[4]

[1]Department of Earth science, Tohku University, [2]Geodynamics Reserch Center, Ehime University, [3]Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University, [4]JASRI

It is widely accepted that the Earth's core is mainly composed of iron and contains light elements to account for the core's density deficit. Alloying with light elements significantly affects the physical properties of iron and the arguments on the chemical structure of the Earth's core. Therefore, the melting relation of the Fe-light elements system is the key to clarifying the chemical structure of the core because the inner core has formed by crystallization of the molten outer core. Although there are many candidates for light elements in the core, based on geochemical modeling and high-pressure partitioning experiments, sulfur and silicon are considered to be the major light elements. Despite the importance of the effect of sulfur and silicon on the physical properties of iron, previous studies, including high-pressure melting experiments in the Fe-S-Si system, did not cover the pressure conditions of the core. To better understand the properties of the core, we investigated the melting relations of the Fe-S-Si system under high-pressure conditions corresponding to the Earth's core.

We report on the melting relations in the Fe-S-Si system up to 135 GPa. Melting experiments were performed in the pressure range of 37-135 GPa and the temperature range of 1800?4100 K using a double-sided laser-heated diamond anvil cell. The composition of the starting material was $Fe_{80.1}S_{12.7}Si_{7.2}$ (Fe-8 wt.% S-4 wt.% Si). Melting relations were examined on the basis of quenched textures of the recovered samples and chemical analysis of observed phases. The chemical composition of the coexisting phases in the samples was obtained with an energy-dispersive X-ray spectroscopy (EDS) system attached to the FEG-SEM. We determined the compositions of the coexisting phases and investigated the partitioning behavior of sulfur and silicon between the metallic melt and the coexisting iron alloy.

We consistently found that a quenched melt with a dendritic texture coexists with a solid Fe alloy in the recovered samples, implying that the samples were partially melted under the experimental pressure and temperature conditions. Based on the present results, the partition coefficients of sulfur and silicon between the liquid and solid Fe alloy were determined in the pressure range from 37 to 135 GPa. The value obtained for D_{sulfur} at 37 GPa was 0.032(28), whereas $D_{silicon}$ was 4.53(73), which is significantly higher than D_{sulfur}. The obtained values of Dsulfur were between 0.032(28) and 0.135(35) and those of $D_{silicon}$ were between 2.63(12) and 5.58(56) in this study. The present results indicate that the solid Fe alloy is silicon rich whereas the metallic melt is enriched in sulfur. We can find that this trend continues up to the core-mantle boundary (CMB) pressure.

The information on partitioning of light elements between the metallic melt and hcp-Fe is the key for clarifying the chemical structure of the Earth's core because the inner core is considered to have crystallized from the liquid outer core during cooling of the Earth. Moreover, previous studies strongly implied that both sulfur and silicon were the plausible candidates for the light elements in the core. Therefore, our experimental results in the Fe-S-Si system offer important clues for understanding the composition of the Earth's core. Based on the present results, if the Earth's core cools down below the melting temperature of the core material, silicon could be preferentially partitioned into hcp-Fe from the Fe-S-Si liquid during crystallization of the inner core. The present data demonstrated that if the Earth's core contains both sulfur and silicon as light elements, the present-day Earth has a sulfur-rich outer core and a silicon-rich inner core.

Influence of the electrical conductivity heterogeneity at the CMB on the flow and magnetic field in the core

SHIMIZU, Hisayoshi[1*]

[1]Earthquake Research Institute, University of Tokyo

The effects of electromagnetic induction in the heterogeneous mantle on the observed electromagnetic fields have been studied numerically to investigate possible causes of short time-scale variation known as the geomagnetic jerk. We found previously that the jerk-like magnetic and electric field variations observed at the surface of Earth can be explained by an input of a sudden variation of the toroidal field at the top of the core and large-scale conductivity heterogeneity of which conductivity is about 100 times higher than the background electrical conductivity. In this study, the effect of the heterogeneity on the flow in the core and magnetic field is evaluated by using a simple plane model of a heterogeneous mantle. Preliminary results suggest that the signature of the magnetic field may be detected as a stationary field at the Earth's surface if the heterogeneity is planetary scale, but the penetration length of its effect in the core is much shorter than the length scale of the heterogeneity.

Potassium solubility into the Earth's core at the base of the magma ocean -Implication for the heat source of the core

WATANABE, Kosui[1*] ; OHTANI, Eiji[1] ; KAMADA, Seiji[1] ; SAKAMAKI, Tatsuya[1] ; MIYAHARA, Masaaki[2]

[1]Department of Earth Science, Graduate School of Science, Tohoku University, [2]Department of Earth and Planetary Science, Graduate school of Science, Hiroshima University

Since the densities of the Earth's inner/outer cores are smaller than pure iron at the core conditions, the core has been thought to include light elements, such as H, C, S, O, Si (e.g., Poirier, 1994). Although the light element(s) in the core has not been decided yet, high-pressure experiments and cosmochemical estimations suggested that Si and O are plausible light elements. The energy causing the geodynamo is derived from the accretion energy at the early stage of the Earth, the latent heat of crystallization of the inner core, the gravitation energy associated with the exclusion of light materials from the inner core, and the radioactive decay of radioactive elements which are potentially present in the core. The Earth's core might contain long-lived radioactive elements such as U, Th, and K. In particular, potassium (K) is more depleted in the mantle than other volatile elements. Thus, potassium may be included in the core. In order to verify the amount of potassium in the core, we have performed potassium partitioning experiments under high pressure and temperature.

We studied partitioning of potassium between aluminosilicate (adularia, $KAlSi_3O_8$) and metal containing oxygen and silicon, and partitioning of potassium without light elements (Fe-O, Fe-Si, pure Fe) at pressures up to 50 GPa and 3500 K using a double-sided laser-heated diamond anvil cell. Our results for the pressure, temperature, and compositional effects on the partitioning coefficient of potassium, D_K (i.e., the content of potassium in metal [wt%] divided by the content of potassium in silicate [wt%]), reveal that the temperature effect is slightly positive but weaker than that reported previously, whereas the pressure effect is negative and oxygen in metal increases the potassium content in metal, although silicon in metal has the opposite effect. According to the effects on potassium partitioning, we estimated that the amount of potassium in the core is less than 32 ppm and that it generates less than 0.14 TW heat in the core. This amount of heat is small compared with the heat flux at the core-mantle boundary (5-15 TW).

Thermal structure of the NE Japan-Hokkaido subduction system: The effects of 3-D slab geometry and oblique subduction

WADA, Ikuko[1*] ; JIANGHENG, He[2] ; HASEGAWA, Akira[3] ; TAMURA, Yoshihiko[4] ; NAKAJIMA, Junichi[3]

[1]IRIDeS, Tohoku University, [2]Pacific Geoscience Centre, Canada, [3]Graduate School of Science, Tohoku University, [4]Japan Agency for marine-Earth Science and Technology

In this study, we first examine the effects of along-strike variation in slab geometry and oblique subduction on subduction zone thermal structures by comparing 3-D numerical thermal models with a range of generic subduction geometries and parameters with a 2-D reference model. We found that changes in slab dip along a straight margin have modest effects on the mantle flow pattern and thus the thermal field. However, concave and convex ocean-ward margins result in cooler and warmer mantle wedges, respectively, and oblique subduction results in a warmer mantle wedge, compared to the 2-D reference model. We developed a 3-D thermal model for the NE Japan-Hokkaido margin, using a well-constrained 3-D slab geometry model. In general, there is little 3-D effect on the thermal structure of the shallow part (<70 km depth) of the subduction system, where the mantle does not participate in the slab-driven wedge flow. We also found that the 3-D effect is small in the deeper part of the southern half of the system, where the margin is relatively straight and the slab dip does not vary significantly along the margin. These results indicate that 2-D models provide excellent approximations for the thermal structures of the shallow part and the southern part of the subduction system. However, from the northern part of NE Japan to Hokkaido, the mantle flow pattern is affected by the concave ocean-ward margin and oblique subduction, and the wedge is cooler near the NE Japan-Hokkaido junction and warmer in Hokkaido than the 2-D thermal models for the respective regions. We compare the 3-D thermal modeling results with along-strike variations in surface heat flow, arc magma geochemistry, and earthquake distribution in NE Japan and Hokkaido.

Effects of a local deepening of slab-mantle decoupling depth on slab surface temperature

MORISHIGE, Manabu[1*] ; VAN KEKEN, Peter E.[2]

[1]JAMSTEC, [2]University of Michigan

In the subduction zone, we generally observe low seismic attenuation in the forearc mantle. In addition, surface heat flow shows low value in the forearc and a sudden transition to high value in the arc. These observations suggest that the forearc mantle is cold and is not involved in the corner flow in the mantle wedge. We can understand it in terms of slab-mantle decoupling depth (D_{dec}). Above D_{dec}, the mantle does not move with the slab just beneath it. Therefore, it becomes cold quickly due to the cooling from the overriding plate and the slab. Below D_{dec}, on the other hand, the mantle moves with the slab. It keeps this part of mantle warm by advection of hot material due to the corner flow. Thus, D_{dec} is a key parameter which strongly affects thermal structure in the subduction zone. Comparison of the observed surface heat flow and the one predicted with 2D numerical model suggests that D_{dec} does not vary much for each subduction zone and is 70-80km, but in each subduction zone D_{dec} may show some degree of along-arc variation. One such example is the junction between Japan and Kurile arcs, where the down-dip limit of thrust type earthquake is locally deepened by around 15km. In this presentation, we investigate the effects of a local deepening of D_{dec} on slab surface temperature.

Toward the goal, we use time-dependent 3D finite element models to compute mantle flow and temperature. Only mantle wedge is treated as a dynamic entity. We use a simple slab geometry and assume a local deepening of D_{dec} to see its effects. We find that the increase in slab surface temperature at D_{dec} is larger where we assume a deepening of D_{dec}, which produces a warmer region there. It is caused by 3D flow in the mantle wedge due to along-arc variation of D_{dec}. We also calculate surface heat flow from obtained thermal structure, but it does not show significant along-arc variation. These results do not change even when we use a realistic slab geometry which is similar to that of the junction between Japan and Kurile arcs. While the surface heat flow anomaly and deepening of the seismic belt in S. Hokkaido cannot be easily explained by these models, the temperature excursions at the slab surface are significant. These models predict potentially strong variations in the conditions that the fluids leave the slab, which may be visible by various new geothermometers, such as those based on the H_2O/Ce ratio.

Thermal modeling associated with subduction of the Philippine Sea plate in southwest Japan

YOSHIOKA, Shoichi[1*] ; JI, Yingfeng[1] ; MATSUMOTO, Takumi[2]

[1]RCUSS, Kobe University, [2]NIED

By constructing a parallelepiped three-dimensional thermal convection model, we investigated temperature, mantle flow and heat flow distributions associated with subduction of the Philippine Sea (PHS) plate in southwest Japan. We proposed new, realistic, and high-resolution temperature field on the plate interface, and attempted to clarify its relationships with the occurrences of megathrust earthquakes, long-term slow slip events (SSE), and low frequency tremors (LFEs). For this purpose, we newly developed a numerical model to deal with subduction of an oceanic plate with 3D arbitrary geometry. We modeled subduction of the PHS plate by using the up-to-date three-dimensional slab geometry, referring to high resolution P-wave seismic tomography and seismic reflection studies. We also used large number of heat flow data such as BSRs, borehole, heat probe, and Hi-net to constrain calculated temperature field, and took account of complicated subduction history in southwest Japan. The results showed that the interplate temperature was lower by approximately 100^{o}C in western Shikoku where a larger true subduction angle exists than eastern Shikoku. Temperature change due to erosion and sedimentation affected surface heat flow with short wavelength. We also found that the obtained interplate temperature in the Nankai seismogenic zone was wider than that in the Tonankai seismogenic zone. The LFEs occurred near the plate interface with temperatures ranging from 350^{o}C to 450^{o}C at depths of 30 to 40 km. The existence of large temperature gradients from the surface to the inside of the PHS plate was considered to be related to the occurrence of long-term slow slip events beneath the Bungo Channel.

Slab-wedge mantle boundary preserved in the Sanbagawa belt, SW Japan

WALLIS, Simon[1*] ; MORI, Hiroshi[1] ; NAGAYA, Takayoshi[1] ; KAWAHARA, Hirokazu[1]

[1]Dept. Earth & Planetary Sci., Nagoya Uni.

The Sanbagawa belt of SW Japan is a high-pressure low-temperature subduction type metamorphic belt. The rock types consists of mafic, siliceous and pelitic schists derived from the subducted slab. There are also a series of ultramafic bodies whose origin is disputed: both a slab and wedge mantle origin have been proposed. However, the clear relationship between the distribution of the mantle rocks and metamorphic grade provides strong evidence that they were derived from the wedge mantle. We carried out a detailed study of the Shiragayama body as an example of serpentinized mantle from close to the corner of the wedge. Studies of this region can contribute to our understanding of non-volcanic tremor and fluid flow that occurs in these otherwise inaccessible parts of subduction zones.

Phenomenology of Episodic Tremor and Slip

OBARA, Kazushige[1*]

[1]Earthquake Research Institute, UTokyo

Episodic Tremor and Slip (ETS) is a coupling phenomenon composed of continuous weak seismic events and geodetic short-term slow slip event (SSE) in the transition zone between the brittle seismogenic zone and stable sliding regime recognized in southwest Japan and Cascadia. This paper reviews characteristics of ETS and related phenomena to contribute to discussion for subduction process.

ETS is interpreted as a stick slip on the plate interface accompanied by seismic swarm at small patches surrounded by the SSE plane because of coincidence of their sources and linear relationship between the duration of tremor episode and the moment of SSE estimated geodetically for each episode. ETS is distributed in a narrow belt-like zone along the strike of the subducting plate. ETS zone is divided into several segments in which episodes recur at each regular recurrence interval. However ETS is not ”characteristic earthquake” because the rupture area and recurrence interval are fluctuated. Sometimes we observe rupture propagation through a couple of segments. The segment is usually bounded by gap which is considered as not a barrier but an easily sliding portion because of the existence of multi-segment migration.

ETS activity has depth dependent property. At the deeper part of the ETS zone minor episode frequently occurs, on the other hand major episode occurs infrequently at the shallower part. Large ETS usually initiates from the deeper part and migrates upward then activates at the shallower part. This might be caused by gradual change in frictional property with increasing the depth. At the downdip edge of the ETS zone tremor episode easily occur due to weak strength and stress concentration from stable sliding zone. Each small episode transfers the stress to the updip side. Finally a small episode can propagate to the updip edge then develop as a large ETS episode.

The activity style of ETS in southwest Japan and Cascadia is very similar; however there are some differences. One is the existence of deep very low frequency earthquake (VLF). In Japan the VLF earthquake is usually associated with ETS but has not been detected in Cascadia. It might depend on the detection capability or difference in inhomogeneity of the plate interface because the distribution of VLF earthquake in southwest Japan is more localized compared to that of tremor.

The other difference is the existence of long-term SSE. It is detected at the updip side of ETS zone in the Bungo Channel and Tokai in southwest Japan but not detected in Cascadia. The long-term SSE with duration from several months to years activates tremor at the adjacent limited region in the ETS zone. On the other hand, the tremor activity at the downdip part is not affected. Similar long-term SSE has been detected in Alaska and Mexico, where tremor activity was recently detected at the downdip side of the source fault of the long-term SSE. The tremor is seems to be activated during the SSE period like as in southwest Japan. The long-term SSE in Tokai is located above the anomalously high Vp/Vs region in the slab. In Mexico, a ultra slow speed layer was found in the long-term SSE source region. Therefore, the anomalous structure might be a cause of the long-term SSE. ETS and long-term SSE are quite different in the slip velocity. It might reflect the difference in the frictional property. In Tokai, the source region of the long-term SSE and ETS is bounded by the inland Moho discontinuity. Therefore, ETS occurs at the interface between the subducting plate and overlying mantle wedge.

ETS has not been recognized besides in southwest Japan and Cascadia; however ambient tremor has been detected in some regions. We expect that the ambient tremor is triggered by small SSE which is not detected by the current observation. Understanding detail relationship between tremor and SSE based on improvement detection capability is important to reveal the mechanism of ETS.

Enhancement of slow earthquakes by geometrical irregularity of subducting oceanic crust

KATO, Aitaro[1*] ; OBARA, Kazushige[1] ; TAKEDA, Tetsuya[2]

[1]ERI University of Tokyo, [2]NIED

Along the worldwide subduction zones, slow earthquakes commonly occur on the deep extension of major tectonic boundary which hosts megathrust earthquake rupture. Slow earthquakes silently release stress to the adjacent seismogenic zone, raising the likelihood of promoting unstable fast slip. However, what controls the transitional variations in fault-slip behaviors from fast to slow modes on the deep extension of megathrust fault remains controversial. Here we use a high-resolution receiver function and seismic tomography illustrated by dense seismic arrays to analyze the structural elements in the subduction complex and fore-arc mantle wedge beneath the Shikoku Island, Japan, where episodic tremor and slow-slip events (ETS) have been most intensive for over a decade.

We find out that deformed oceanic crust with irregularity of surface geometry horizontally lies in the ETS zone, where low seismic velocity zone with high Poisson's ratio that we interpret as high pore-fluid pressure. Step-like discontinuous alignments of intra-slab seismicity support the flat-subduction of the oceanic crust with faulting structure. In contrast, at depths shallower than the ETS zone, the low velocity anomaly within the oceanic crust is weak and dipping towards the NW, implying less amount of high-pressured fluid in the tilting oceanic crust. In addition, lithology of the overlying plate changes to partially serpentinized mantle wedge in the ETS zone. Locally flat-geometry of the subducting oceanic crust combined with the contact of serpentine enhances accumulation of high-pressurized fluids along the plate interface, leading to segregation between slow and fast slip modes at the deep transition zone of mega-thrust fault.

Deformation experiments on serpentinite at high PT conditions with implications for the mechanisms of slow earthquakes

OKAZAKI, Keishi[1*] ; HIRTH, Greg[1] ; PROCTOR, Brooks[1] ; KATAYAMA, Ikuo[2] ; TAKAHASHI, Miki[3]

[1]Department of Geological Sciences, Brown University, [2]Department of Earth and Planetary Systems Science, Hiroshima University, [3]Geological Survey of Japan, AIST

To understand the spatial and temporal distribution of earthquakes and deformation in subduction zones, it is important to constrain the rheological properties of metamorphic rocks (i.e., altered mantle, oceanic crust and sediments), and how they evolve during metamorphic reactions following hydration, carbonation and dehydration of the down-going slab. Especially, antigorite (the high-temperature serpentine polytype) serpentinite, the dominant metamorphic phase in hydrated mantle material at the condition of mantle wedge, is the key metamorphic rock to understand the generation mechanism of slow earthquakes and slab-mantle coupling at the plate interface in subduction zones.

Deformation experiments on antigorite serpentinite were conducted within and above the thermal stability field of antigorite using a gas pressure-medium apparatus and a solid pressure-medium apparatus to understand how dehydration reactions influence the mechanical behavior of antigorite serpentinite. At 400 ℃, within the stability field of antigorite, antigorite serpentinite shows stable sliding and a positive velocity dependence of shear stress (i.e., friction coefficient). Shear stress increased with increasing confining pressure, while the friction coefficient decreases from 0.55 to 0.37 with increasing confining pressure from 200 MPa to 1500 MPa. These results indicate that antigorite serpentinite deforms by brittle and semi-brittle processes in subduction zones.

During the experiments using a gas pressure-medium apparatus at a confining pressure of 200 MPa and temperatures close to the dehydration temperature of antigorite (450-550 ℃), antigorite serpentinite shows a slow stick-slip behaviour, which is characterised by relatively long durations and small stress drops during slip, while this type of behaviour was not observed at higher temperatures when the antigorite becomes completely dehydrated. Stick-slip in this temperature range is consistent with the temperature range where slow earthquakes occur at the corner of the mantle wedge in southwest Japan and Cascadia. The scaling law of slow stick-slip in the antigorite serpentinite gouge is distinct from that of regular earthquakes and a theoretical duration estimated from the apparatus stiffness, but similar to that of slow earthquakes.

We also conducted deformation experiments in which temperature was increased above the thermal stability of antigorite to simulate a prograde metamorphism in subduction zones, similar to the experiments by Chernak and Hirth (2011) but with a general-shear geometry. With increasing temperature from 400 ℃ to 700 ℃ during deformation, differential stress decreased and reached 120 MPa. Recovered sample suggest that the strain localizes within shear fractures and limited dehydration occurred during the experiments.

These results suggest that the dehydration of antigorite can form weak zones within the mantle wedge along the plate interface in subduction zones, even if the extent of the dehydration reaction is limited. In addition, slow instabilities of the slip interface can be caused by the dehydration of antigorite within the weak zone in the antigorite serpentinite layer, which can result slow earthquakes.

Metasomatic fault-zone weakening of subduction plate boundary faults

HIRAUCHI, Ken-ichi[1*] ; SPIERS, Christopher[2]

[1]Shizuoka University, [2]Utrecht University

Fluid influx along faults triggers stress-induced dissolution and precipitation processes, leading to syntectonic growth of weak phyllosilicates. In subduction zones, slab-derived Si-rich fluids may infiltrate into the forearc wedge and transform primary mantle minerals into hydrous phases such as serpentines and talc, changing the mechanical and seismogenic properties of subduction plate boundary faults. However, it remains unclear how frictional strength and sliding stability of the plate boundary faults evolve via Si-metasomatism.

Hirauchi et al. (2013, *Geology*) performed frictional sliding experiments on antigorite (70%) plus quartz (30%) gouges at a pore fluid pressure (P_f) of 200 MPa, an effective normal stress (σ_{eff}) of 200 MPa, temperatures (T) of 20, 300, 400, and 500 ℃, and sliding velocities (V) of 0.1-30 μm/s, using a hydrothermal ring shear machine. At temperatures of 300-500C, the gouges exhibited a peak friction coefficient (μ) of 0.40-0.62, followed by strain weakening towards a quasi-steady-state μ of 0.25-0.47. The weakening was mainly due to the development of through-going, talc-rich boundary shears. The steady-state μ of the gouges decreased systematically as the talc-rich layer widened.

At central California, there are several boundary faults that separate serpentinite bodies from shale-matrix melanges of the Franciscan accretionary complex. The serpentinite body is overprinted by anastomosing development of crack-seal veins of talc, serpentine, and calcite, suggesting that intense water-rock interaction took place in connection with faulting. The serpentinite along the faults represents a cataclastic shear zone that records brittle deformation, consisting of angular fragments that are suspended in fine-grained, randomly-oriented talc matrix. Frictional sliding experiments conducted at P_f = 40, 80, and 120 MPa, σ_{eff} = 60, 120, and 180 MPa, T = 20, 150, and 300 ℃, and V = 0.3-100 μm/s showed that the serpentinite has friction coefficients that agree with Byerlee's law (μ 0.6), while the cataclasite is much weaker with friction coefficients as low as 0.2. Examination of the velocity dependence of friction revealed that the serpentinite exhibits both velocity-weakening and velocity-strengthening behavior, whereas the cataclasite is velocity strengthening under all conditions investigated.

Our results demonstrate that in the lowermost part of the forearc wedge, where silica-saturated fluids infiltrate from the dehydrating slab, metasomatically produced talc will form in the intensely sheared serpentinite, causing a much larger weakening effect than expected for serpentines, even if the total amount of talc formed is minor (<10 vol%). The continued reaction with Si-rich fluid will also result in a transition from seismic to aseismic behavior of the plate boundary faults.

Coupled mass transport and serpentinization at crust/mantle boundary: Insights from hydrothermal experiments

OKAMOTO, Atsushi[1*] ; OYANAGI, Ryosuke[1] ; TSUCHIYA, Noriyoshi[1]

[1]Graduate School of environmental Studies, Tohoku University

Serpentinization commonly proceeds by a supply of water passing through crust, and thus a large mass transport could occur during serpentinization reactions. Especially, silica activity is known as a control of the reaction paths and rate during the hydrothermal alternation of peridotites [1, 2]. However, it is still unclear the role of mass transport on reaction paths, overall hydration rate and volume change during serpentinization. In this study, we conducted two types of hydrothermal experiments on serpentinization. First one is the metasomatic-reaction experiments between olivine (Ol) ? quartz (Qtz) zones as analogue of boundary of mantle and crustal rocks. Second one is the hydrothermal experiments with sintered olivine (analogue of low porosity rock). Both types of experiments were carried out at 250 ?C and vapor-saturated pressure (= 3.98 MPa) in alkaline aqueous solution.

In the Ol-Qtz metasomatic experiments (up to 46 days.), composite powders, which was composed of Qtz zone and Ol zone was set in inner tubes and then loaded into autoclave. After the experiments, the mineralogy and H2O content of the products were evaluated as a function of the distance from Ol/Qtz boundary. The reaction products after olivine are serpentine (Srp), brucite (Brc), magnetite (Mgt) and smectite (Smc) (instead of talc). The products systematically change from the Smc+Srp to Srp+Brc+Mgt with increasing the distance from the Ol/Qtz boundary. The H2O content of the products is low at the Ol/Qtz boundary (i.e., 3.9 wt.% after 46 days), and increases toward the margin of the tube (12 wt.% at ˜30 mm from the Ol/Qtz boundary).

The detailed mass balance calculation between 25 to 46 days reveals the characteristic nature of the metasomatic reactions and porosity change as follows. Near Ol/Qtz boundary (Smc+Srp zone), smectite was formed by supply of silica in two ways; hydration of olivine and dehydration of serpentine. In contrast, at the zone far from the boundary (Srp+Brc zone; $>$20 mm from O/Qtz), the production rate of serpentine and brucite are constant without any silica supply. At the transition zone between Smc+Srp and Srp+Brc zones, a large amount of serpentine is formed by consumption of both brucite and olivine, which results in a largest porosity reduction (˜30 %). In the Smc+Srp zone, dehydration and porosity reduction occurs simultaneously, implying a possible raise of fluid pressure. Silica metasomatic reactions causes a significant variation not only in mineral assemblage but also in porosity and fluid pressure, which will characterize the dynamic change of mechanical properties at crust/mantle boundary.

In the hydrothermal experiments of the sintered olivine, the starting olivine aggregate (initial porosity $<$˜10 %, covered by Pt jacket), which was made by hot press at 1200 degreeC, 1 GPa and 4 days, was emplaced in the alkaline water. After 3 days, we recognized the progress of serpentinization reaction to produce serpentine and brucite. An interesting finding of this experiment is that brucite did not formed in pores of the core sample, but it was formed only at the top of the cylindrcial core of the sample. This result is quite different from with our previous experiments with using olivine powder (initial porosity is ˜50 %) [3], in which brucite and serpentine was formed uniformly. The result of our present study of the sintered olivine suggests that, when the rock porosity is low and volume expansion is difficult, brucite is segregated into open space (c.a. open fracture) during serpentinization; which may also affects on the formation of the local weak zone within the mantle peridotite.

Saline fluids recorded in jadeitites in subduction-zone melanges of southwest Japan

MORI, Yasushi[1*] ; SHIGENO, Miki[1] ; KAWAMOTO, Tatsuhiko[2] ; NISHIYAMA, Tadao[3]

[1]Kitakyushu Mus. Nat. Hist. Hum. Hist., [2]Inst. Geotherm. Sci., Kyoto Univ., [3]Grad. Sch. Sci. Tech., Kumamoto Univ.

Slab-derived fluids play essential roles in mass transfer along subduction-zone channels between the subducting slab and mantle wedge (e.g., Bebout 2013 Metasomatism and the chemical transformation of rocks; Spandler and Pirard 2013 Lithos). Salinity of such slab-fluids probably affects solubility and fluid-rock partitioning of elements; therefore, it remains to be investigated in various rocks. Jadeitite is a rock composed mainly of jadeite (sodium pyroxene, $NaAlSi_2O_6$) and occurs typically in serpentinite mélanges intercalated to high-pressure and low-temperature metamorphic belts. This curious rock is thought to be the product of direct precipitation from aqueous fluids and/or of fluid-induced metasomatism of a protolith (Harlow *et al*. 2007 Geology of gem deposits, Tsujimori and Harlow 2012 Eur J Mineral, and references therein). Fluid inclusions are commonly observed in jadeitites, and they may provide information about the fluid composition in subduction-zone mélanges. We determined major components and salinity of fluid inclusions in the jadeitites collected from eight localities in Japan: Omi-Itoigawa (Omi-Renge belt), Oya and Osa (Suo belt), Kochi (Kurosegawa belt), Mie and Tone (Nishisonogi metamorphic rocks), and Shimonita and Yorii (the origin unclear). In all of the studied rocks, primary fluid inclusions consist of a liquid phase and a gas bubble. Raman spectra show the presence of H_2O liquid and vapor with or without minor CH_4 gas. The freezing point of the liquid phase indicates high-salinity (up to 8 wt% NaCl equivalent) of the primary fluid inclusions. The salinity varies among the localities of the jadeitite. For example, the salinity of the primary fluid inclusions is about 7.1 $\pm$ 0.1 wt% NaCl equivalent in the albite jadeitite from Oya and about 4.6 $\pm$ 1.2 wt% NaCl equivalent in quartz inclusions bearing jadeitite from Tone. Some jadeitite samples contain secondary CH_4-rich fluid inclusions along healed microcracks. The presence of minor CH_4 is also reported in the saline fluids inclusions with 5.1 $\pm$ 1.9 wt% NaCl equivalent from the Myanmar jadeitite (Shi *et al*., 2005 Geochem J). The present findings suggest that saline fluids with or without CH_4 are common in subduction-zone mélanges in Japan as well as in Myanmar. The reduced conditions can be caused by serpentinization processes. This is contrast to the CO_2-bearing saline fluids in the peridotite xenoliths from fore-arc mantle wedge (Kawamoto *et al*., 2013 PNAS). The high-salinity of the slab-fluids probably enhances the mobility of elements such as Pb in subduction-zone channels (Keppler, 1996 Nature, Shigeno *et al*., 2012 Eur J Mineral).

Serpentinite structure above subduction surface: Analysis of a natural example in Sanbagawa metamorphic belt

MIZUKAMI, Tomoyuki[1*] ; SODA, Yusuke[1] ; YOKOYAMA, Hironori[1] ; HIRAMATSU, Yoshihiro[1]

[1]Kanazawa University

Serpentinization is a key reaction in forearc mantle. Formation of strong schistosities and shear zones under high differential stresses provides anastomosing networks of fluid pathways as well as seismically anisotropic nature in the mantle. Understanding of such structural development is important for both interpretation of seismic analyses and forward modelling of subduction system including thermal structure, material circulation, magma process and slip behaviours of subduction boundaries.

We report results of petrological and structural analyses of layered antigorite (Atg) serpentinite in the marginal part of the Higashi-akaishi ultramafic unit in the Sanbagawa belt. This is a product of hydration of dunite (a rock consisting of almost 100% olivine (Ol)) due to metamorphic fluid from the underlying meta-sediments and meta-basites. Strong shape preferred orientation of Atg and existence of boudinaged layers indicate fluid-rock reaction under extensional deformation.

The layered structure is defined by a centimeter to meter-scale interlayering between Ol-rich and Atg-rich units. The modal amounts of Atg in these units form peaks at 15 vol% and 50 vol%, respectively, showing a bi-modal distribution as a whole. Effects of initial microstructures on the extent of serpentinization are limited: Porphyroclastic and fine-grained dunite, that occupy a large part of the outcrop, are transformed to both Ol-rich and Atg-rich layers although dunite with more than 50 % of coarse Ol grains has been poorly serpentinized. Each Atg layer shows millimeter-scale spaced foliations defined by amounts of Ol and Atg and locally shows a diffusive variation in millimeter to centimeter-scales. Thickness and proportion of Atg-rich layers increase near the contact with crustal rocks.

Reaction for the Atg formation is constrained based on re-distribution of elements among Ol, Atg and opaque minerals. As serpentinization proceeds, Ol is enriched in Fe and Ni owing to their incompatibility in Atg. Taking concomitant formations of minor amounts of magnetite and sulfides into account, the variation of the Ol composition and modal amounts of serpentinization products are quantitatively explained by the following reaction: Ol + $SiO_{2,aq}$ + H_2O $\Rightarrow$ Atg. This indicates that the development of Atg has been controlled by a supply of silica in aqueous fluids.

We measured thickness of 70 layers for each and, taking the layers with the thickness lower than 200 centimeters, we found exponential relationships in cumulative frequency distributions both for Ol-rich and Atg-rich layers. Relative thickness between neighbouring units [d(Ol)/d(Atg)] also shows an exponential distribution. We could not find any regular relationships among width and spacing like Liesegang patterns.

It is known that pattern structures appear in reaction-diffusion systems. The above observations strongly suggest that the development of layered structures in Atg serpentinite is controlled by interaction between reaction and material transfer. In this case, potential causes of heterogeneous serpentinization may be diffusional contrast between H_2O and SiO_2 or permeability contrast between Ol-rich and Atg-rich layers. Scaling analyses of deep low frequency tremors showed that duration-amplitude and size-frequency distributions of tremors in SW Japan can be fit with exponential models rather than power-law models. The seismological observations imply structural heterogeneity with unique scale length. Further examination on the exponential relationships developed in serpentinite may contribute to understand the slip phenomena on plate interfaces.

Awaruite in serpentinites from Oshima Peninsula, Fukui Prefecture, Japan

YAMAGUCHI, Kai[1*] ; UEHARA, Seiichiro[2]

[1]Department of Earth and Planetary Sciences, Faculty of Science, Kyushu University, [2]Department of Earth and Planetary Sciences, Faculty of Science, Kyushu University

Awaruite is one of native Ni-Fe alloys, and the compositional range is Ni_2Fe to Ni_3Fe. The space group is *Fm3m* or *Pm3m* (e.g., Williams, 1960; Ahmed et al., 1981). Typical grain sizes are 10-300 μm, and grain shapes are typically irregular, anhedral or skeletal. It is found only in the serpentinized peridotites and chondritic meteorites (e.g., Ramdohr, 1967; Clarke et al., 1970). In general, awaruite is observed in serpentine vein (Sakai and Kuroda, 1983), and coexist with other metal minerals (Kanehira et al., 1975). This study deals with the characteristic occurrence of awaruite in pseudomorph texture in the Oshima serpentinites from Oshima peninsula, Fukui prefecture, Japan.

All samples were examined with polarizing microscope observation, X-ray diffraction analysis and SEM-EDS analyses. Preparation of TEM specimen and microtexture observation were conducted with an ion milling machine (JEOL EM-09100IS) and TEM (JEOL JEM-2000FX, JEM-3200FSK) in the Research Laboratory for High Voltage Electron Microscopy (HVEM), Kyushu University, Japan. Chemical analyses of microtexture were also examined using JEM-3200FSK equipped with EDS.

Peridotites in this area are partially or perfectly serpentinized. Texture of the serpentinite is mesh texture after forsterite and vein texture. Scarcely serpentinized enstatite is also observed. Each mesh texture is composed of mesh rim shows optical anisotropy and mesh core shows optical isotropy. The serpentinization of mesh texture is strong in close to vein textures. Most mesh rims near vein texture consist of some layers; outer rim, outer-inner rim boundary and inner rim. These rims consist of chrysotile, about 50 nm in width and 2 μm in length, and lizardite, about 300 nm in width and 1 μm in length, and outer-inner rim boundary about 2 μm in width are filled with serpentine fine grains, up to 100 nm in diameter.

A number of awaruite fine grains, 200-300 nm diameter, array along cell boundary, outer-inner rim boundary and rim-core boundary. These awaruite coexist with no other metal minerals; pentlandite, magnetite and etc. In contrast, metal minerals in vein texture are magnetite and minor pentlandite. These results indicate that mesh texture in serpentinite is extremely reductive environment compared with vein texture. The chemical composition of awaruite (average of four analysis) is Ni 73.13% and Fe 26.87%. The cross-section of these awaruite grains is square or rhombic, indicating that these grains are cube or octahedral crystals (fig. 1a). These grains seem to be euhedral from grain shapes, and this is characteristic compared with previous studies (e.g., Rubin, 1991). The SAED pattern recorded along the [001] zone axis shows strong 200, 220 reflections and weak 100, 110 reflections (fig. 1b). This indicates space group of the Oshima awaruite is *Pm3m*, which is ordering phase of *Fm3m* awaruite. Lower symmetry of the Oshima awaruite will be formed lower temperature.

Keywords: Awaruite, Mesh texture, Serpentinite, Microtexture, Serpentine minerals, TEM

Antigorite CPO measured by U-stage, EBSD and synchrotron X-rays

SODA, Yusuke[1*] ; ANDO, Jun-ichi[2] ; URATA, Yoshito[2] ; WENK, Hans-rudolf[3]

[1]Kanazawa University, [2]Hiroshima University, [3]University of California, Berkeley

Foliated antigorite serpentinite with crystallographic preferred orientation (CPO) probably causes shear wave splitting observed at subduction zones (e.g., Katayama et al., 2009). Therefore, the study of type and intensity of antigorite CPO is an important to understand the detail of this phenomenon.

Soda and Wenk (2014) measured CPOs of antigorite serpentinite from the Sashu Fault at the Saganoseki Peninsula, Oita Prefecture, by three independent methods, U-stage (with optic microscope), EBSD and synchrotron X-rays. The obtained antigorite CPOs by three methods are almost same without the fabric strength, maxima of pole figures in multiples of random distribution. The fabric strength decreases in the following order, U-stage >EBSD >synchrotron X-rays, which is probably caused by the characteristics of three methods. Through U-stage measurement, we can obtain the fabric pattern of antigorite CPO mainly from coarser antigorite grains (>30 μm). In the case of EBSD measurement, we measure antigorite CPO within an area of ca. 0.8 mm $\times$ 0.8 mm. Measurement points of only ca. 30% can be used to make fabric patterns. Residual ca. 70% points are neglect, because the quality of Kikuchi lines from them is too low to identify the orientation. In the synchrotron X-rays method, the result represents the bulk fabric from a volume of ca. 0.5 mm $\times$ 0.5 mm $\times$ 1.0mm.

The serpentinite measured antigorite CPO develops mylonitic structures with a penetrative foliation and lineation (Soda and Takagi, 2010). The antigorite grains show undulose extinction. And their grain boundary is unclear under the microscopy. Mg# (Mg/(Mg+Fe)) of antigorite grains is wide range 0.98-0.88. The BSE images indicate Fe-rich antigorite infilling the grain boundaries and fractures of Mg-rich antigorite.

The same serpentinite has already observed by TEM (Urata et al., 2009). The results indicate that the m-vales of antigorite grains, the number of octahedral along the [100] modulation wave, make two groups, high m-vale (16-18) and low m-vale (13-14). This result suggests that the antigorite are crystallized mainly two stages, which is supported by the variation of Fe contents of antigorite (Fe-rich and Mg-rich). The Mg-rich antigorite grains are main minerals composed of the serpentinite, Fe-rich antigorite grains occupy at the periphery of the others and within the vein. The TEM observation indicates that the Mg-rich antigorite grains are subdivided into sub-grain with 50-100 nm in size, which can be recognized as an undulose extinction under optic microscope.

These microstructures of antigorite grains potentially influence the outcome of CPO measurements. The weaker fabric patterns from the synchrotron X-rays are probably attributed to the fine-grained antigorite crystallized at the deferent stages and to sub-grain. And the U-stage and EBSD measurements focus only the selected grains, which may result in overestimation of elastic wave anisotropy of serpentinite.

Olivine CPO in non-deformed peridotite due to topotactic replacement of antigorite

NAGAYA, Takayoshi[1] ; WALLIS, Simon[1*] ; KOBAYASHI, Hiroaki[1] ; MICHIBAYASHI, Katsuyoshi[2] ; MIZUKAMI, Tomoyuki[3] ; SETO, Yusuke[4] ; MIYAKE, Akira[5] ; MATSUMOTO, Megumi[6]

[1]Department of Earth and Planetary Sciences, Nagoya Nagoya University, [2]Institute of Geosciences, Shizuoka University, [3]Department of Earth Science, Kanazawa University, [4]Department of Earth and Planetary Science, Kobe University, [5]Department of Earth and Planetary Science, Kyoto University, [6]Center for Supports to Research and Education Activities, Kobe University

Olivine crystallographic preferred orientation (CPO) is thought to be the main cause of seismic anisotropy in the mantle, and its formation is generally considered to be the result of plastic deformation of mantle by dislocation creep. Olivine CPO has been reproduced in laboratory deformation experiments and considerable success has been achieved in understanding the deformation conditions (e.g. stress, temperature and water content) under which different olivine CPO patterns develop. This opens the possibility of mapping conditions in the mantle using seismic anisotropy and has been the subject of considerable study. Here we report an alternative mechanism for olivine CPO without the need for deformation. This process may be important in understanding the seismic properties of mantle in convergent margins.

Metamorphic studies show peridotite in the Happo area, central Japan, formed by the dehydration of antigorite- schist related to contact metamorphism around a granite intrusion. Both field and microstructural observations suggest the olivine has not undergone strong plastic deformation. This was confirmed by TEM work that shows the olivine has very low dislocation densities and lacks low angle tilt boundaries. Such tilt boundaries are general stable even after annealing. These features show that peridotite in the Happo area formed in the absence of solid-state deformation.

The olivine of the Happo peridotite formed dominantly by the dehydration breakdown of antigorite schist. We propose that the olivine CPO formed as a result of topotactic replacement of antigorite by the newly formed olivine. EBSD measurements in samples where both antigorite and new olivine are present and in contact show a very close crystallographic relationship between the two minerals: the *a*-axes are parallel, and the *b*- and *c*-axes are perpendicular. We conclude the strong olivine CPO in the Happo area was inherited from the original CPO of the antigorite. Such a process is likely to also occur in subduction zones where serpentinite is dragged down by plate movement. Topotactic growth of olivine may be an important cause of mantle anisotropy in convergent margins.

Cr-rich olivine in deserpentinized peridotite and its implication

ENDO, Shunsuke[1*]

[1]Institute of Geology and Geoinformation, AIST

Formation of Cr-rich olivine (Cr_2O_3 >0.1 wt %) in the presence of Cr-spinel ± pyroxene has been thought to require extremely reducing and/or high-temperature conditions. Indeed, terrestrial olivine is Cr-free except for some high-T occurrences from Archaean komatiites, inclusions in diamonds, and ultrabasic pseudotachylytes. Deserpentinization is an important fluid release process in subduction zones. One of the best studied examples of this process occurs in Cerro del Almirez (SE Spain), where the antigorite-out reaction front (Atg = Ol + Opx + Chl + H_2O) at eclogite facies conditions is well preserved. Large elongate olivine crystals (similar to spinifex textures in komatiites) at the reaction front contain abundant exsolution lamellae of Cr-magnetite, and estimated primary compositions of the elongate olivine show high Cr content (0.1-0.4 wt% Cr_2O_3), leading to a proposal of the spinifex-like textured peridotite being pseudotachylyte (>1600 ℃, Evans & Cowan, 2012), in contrast to the generally held view that the elongate olivine crystalized under ambient subduction-zone T (~680 ℃ at 1.9 GPa) but high supersaturation conditions.

To better understand the dehydration process of serpentinite in subduction zones, this study focuses on a deserpentinized peridotite from the Eclogite unit of the Sanbagawa belt (SW Japan). It consists of porphyroblastic olivine (~70 vol %, Mg#=0.952±0.004, NiO=0.37±0.04 wt%), antigorite (Al_2O_3=0.3-0.5 wt%), brucite, zoned Cr-spinel and Ni sulfides. Olivine porphyroblasts contain inclusions of antigorite, brucite, magnetite and Ni sulfides, suggesting that the olivine-forming reaction Atg + Brc = Ol + H_2O took place after serpentinization of a dunitic protolith. Sporadic occurrences of Ni-rich olivine (up to 8.1 wt% NiO) within the olivine porphyroblasts suggest prograde breakdown of Ni-rich sulfides. Zoned Cr-spinel grains are composed of a chromite core, a ferritchromite mantle, and an irregular-shaped overgrowth of Cr-magnetite. The chromite core, being the only primary mineral preserved, shows Cr-rich/Ti-poor compositions [Cr/(Cr+Al)=0.74-0.76, TiO_2 <0.14 wt%] indicative of a forearc wedge mantle origin. The Cr-magnetite rim contains inclusions of Cr-rich olivine (Cr_2O_3 = 0.12-0.70 wt %, Mg#=0.950±0.004, NiO=0.37±0.04 wt%), in addition to Cr-rich antigorite (Al_2O_3=0.5-3.1 wt%, Cr_2O_3=0.3-3.9 wt%), diopside and brucite.

Formation of the Cr-rich olivine inclusions can be explained by dehydration of Cr-rich antigorite that developed around Cr-spinel grains. Slow diffusivity of Cr^{3+} compared to the olivine growth rate may have caused disequilibrium Cr incorporation into olivine under low-T conditions just above the Atg + Brc breakdown equilibrium (~460-500 ℃). Alternatively, a distinct Cr substitution mechanism (Cr^{3+} + Fe^{3+} = Mg + Si) than that proposed for high-T olivine (Cr^{2+} = Mg or 2Cr^{3+} + vacancy = 3Mg) could explain the low-T formation of Cr-rich olivine. In any case, the local uptake of Cr in olivine from the Sanbagawa metaserpentinite does not imply very high-T conditions, and this weakens the main basis of the pseudotachylyte hypothesis for the spinifex-like textured peridotite in Cerro del Almirez. The geological record on the causal link between deserpentinization and deep earthquake nucleation remains elusive.

Spatial variation in scale length of deep low-frequency tremor inferred from duration-amplitude scaling in western Shiko

HORINO, Kazuki[1*] ; HIRAMATSU, Yoshihiro[2] ; MIZUKAMI, Tomoyuki[2] ; OBARA, Kazushige[3] ; MATSUZAWA, Takanori[4]

[1]Division of Natural System, Graduate School of Natural Science and Technology, Kanazawa University, [2]School of Natural System, College of Science and Engineering, Kanazawa University, [3]Earthquake Research Institute, University of Tokyo, [4]National Research Institute for Earth Sciences and Disaster Prevention

Slip properties on plate interface vary largely along dip direction from seismic to aseismic slip. At the transition zone at depths of 25-35 km, non-volcanic deep low-frequency (DLF) tremor and short-term slow slip event occur in the Nankai subduction zone. Recent detailed studies (e.g. Obara, 2010) reveal along dip and along strike variations in the occurrence and the migration of DLF tremor in the transition zone. We report here an along dip variation in scale length of DLF tremor inferred from duration-amplitude scaling in the western Shikoku.

A physical process of natural phenomena is reflected by scaling law, for example, frequency of occurrence versus size distribution. Watanabe et al. (2007) reported that a duration-amplitude distribution of DLF tremor shows a better fit to the exponential model rather than the power-law model, which is different from regular earthquakes. We investigate the duration-amplitude distribution of DLF tremor using Hi-net data in the western Shikoku. The procedure of analysis is the same as that of Watanabe et al. (2007).

We focus on the slope of the exponential distribution for the duration-amplitude distribution of DLF tremor. The value of the slope is small in the western area and large in the eastern area. Noting along dip direction, we can recognize a weak variation of the value of the slope. Deeper DLF tremor tends to show a larger value of the slope than shallower DLF. A large value of the slope means a small scale length and vice versa.

Beneath the western Shikoku, the configuration and the age distribution of the subducting Philippine Sea plate changes significantly along the strike, generating a large variation in a thermal structure. Such a variation causes various modes of serpentinization in the hanging wall mantle. The resultant structures due to the different modes are the most likely cause of the detected transition of the scale length.

Lithospheric Rheology and Stress and the Dynamics of Plate Tectonics

ZHONG, Shijie[1*]

[1]Department of Physics, University of Colorado

Plate tectonics is a kinematic theory that describes relative motions of Earth ′ s surface tectonic plates. However, with the subduction of cold lithosphere into mantle interiors, plate tectonics has profound implications on the thermal and dynamic evolution of planets. Earth appears to be the only planetary body in the solar system that has active plate tectonics. The cause of plate tectonics remains one of the most important unresolved questions in Earth and planetary sciences. The recent discovery of a large population of exoplanets further raises the question on how common plate tectonics is to planetary bodies and what causes plate tectonics. In this presentation, I will discuss two issues that are important to understanding the origin of plate tectonics: lithospheric rheology and stress. Lithospheric rheology is important for understanding crustal and lithospheric dynamics, and the conditions for plate tectonics. For example, numerical modeling studies suggest that plate tectonics emerge from the dynamics of mantle convection when a small coefficient of friction μ ($<$0.1) or small yield stress for lithosphere is used [Moresi and Solomatov, 1998]. However, both in-situ borehole stress measurement (to ˜10 km depth) and laboratory studies suggest that μ˜0.6 [Kohlstedt et al., 1995; Zoback and Townend, 2001]. A recent study that models the seismically observed elastic flexure and seismicity at Hawaiian islands in response to volcanic loading indicates $\mu>$0.25 [Zhong and Watts, 2013]. The loading study [Zhong and Watts, 2013] also suggests that lithospheric rheology related to low-temperature plasticity is significantly weaker than laboratory studies [Mei et al., 2010] and that lithospheric stress at Hawaiian islands is 100-200 MPa, possibly largest lithospheric stress on the Earth, given that Hawaiian islands represent the largest uncompensated surface loads on the Earth. These studies highlight the importance to understand the evolution of lithospheric stress and rheology from plate interiors to plate boundaries, in order to understand the cause of plate tectonics. I will also discuss the convection-driven stress in the top thermal boundary (lithosphere). Convection-driven stress scales with Rayleigh number and hence mantle viscosity. A larger mantle viscosity or smaller Rayleigh number leads to a larger viscous stress in the lithosphere in mantle convection models. Some recent mantle convection studies for plate tectonics generation reported $>$500 MPa stress in lithosphere. It is important to develop independent observable measures to examine the relevance of modeled lithospheric stress. I will discuss possible measures that may be developed and used in this context.

3D numerical modeling of thermal regime and mantle flow associated with subduction of the two oceanic plates

JI, Yingfeng[1*] ; YOSHIOKA, Shoichi[1]

[1]RCUSS, Kobe University, [2]Graduate School of Science, Kobe University

Based on a thermal convection model for an arbitrarily curved oceanic plate, we newly constructed a 3D model for subduction of two oceanic plates, and investigated its thermal regime and mantle flow. The 3D parallelepiped modeled domain for numerical simulations is a length of 840 km, a width of 840 km, and a depth of 300 km, with 72∗72∗72 grids, and the total calculation time up to 15 Myr. Geometry of one continental plate and two oceanic plates are prescribed in the simulation. The two oceanic plates subduct with prescribed velocities beneath the continental plate along neighboring two trenches, adjoining with a right angle. The upper oceanic plate and the lower oceanic plate contact each other at their intersection zone. Both of the oceanic plates are assumed to be 30 km in thickness. Giving boundary conditions of adiabatic and permeable walls, half-space cooling and rigid upper surface, and stratified initial temperature condition, we solved equations of mass conservation, momentum, and energy, using the finite difference method (FDM) and Finite Volume Method (FVM). In this study, the dynamical properties of the thermal regime associated with double subduction are investigated in detail. In our numerical simulation for the subducting two oceanic plates, the convergent rate of the upper oceanic plate should be paralleled to the intersection line of the two plates so as to reach a stable and sustainable subduction. Dip angles of the two oceanic plates, obliquity of the lower oceanic plate, and subduction velocity are assumed to be 10 deg, 0 deg ˜75 deg, and 5 cm/yr, respectively. As a result of numerical simulation, we found that there are remarkable low temperatures in the inter-slab zone due to subduction of the two cold oceanic plates. We also found that obliquity and relative directions of plate subduction velocities contribute to the obliquity of subduction-induced mantle flow convection adjacent to the two oceanic plates, and spiral mantle convection may be produced by the difference of the obliquity of two oceanic plates.

Mantle flow and overriding plate stress state in 3-D models of thermo-mechanical subduction

HOLT, Adam[1] ; BECKER, Thorsten[1*]

[1]University of Southern California

The formation of back-arc basins is a fundamental component of plate tectonics, yet the dominant mechanism for their formation, and whether an individual mechanism is dominant over different tectonic settings, is not entirely clear. On top of the classic mechanism of extension being driven by basal tractions due to poloidal return flow, recent numerical and experimental modeling studies have indicated that, for slabs with finite widths, toroidal return flow around slab edges plays an important role. We investigate the relative contribution of poloidal and toroidal flow field components to back-arc extension by examining the overriding plate stress regime in conjuction with the flow field for various model setups. We characterize the velocity field by decomposing it into toroidal and poloidal components at various stages of subduction, and calculating the ratio of the toroidal to polodial RMS velocities (TPR).

Models are carried out using a thermo-mechanical setup of the finite element code, CitcomCU. We find that the presence of an overriding plate reduces the development of trench curvature, and so 3-D modeling studies that neglect the presence of the overriding plate may be significantly overestimating the rate of development of trench curvature. Within the overriding plate, we observe long wavelength back-arc extensional stresses at a large distance from the trench and more localized forearc compressive stresses. Fixing the position of either the subducting or overriding plate causes the amplitude of back-arc extension to be greater than that for the case when both plates are free. This occurs because, for the fixed overriding plate models, all of the slab rollback is forced to occur at the expense of overriding plate thinning/extension, and for the fixed subducting plate models, increased rollback causes heightened toroidal flow. For all models with significant slab rollback, the poloidal RMS velocity is maximum in the very upper and lower portions of the model whereas toroidal flow is maximum at mid-domain depths due to return flow around slab edges, indicating that slab rollback-induced toroidal flow is focussed at sub-lithospheric depths, where it has the potential to contribute to back-arc extension. Reducing the width of the plate vastly reduces the rate of slab rollback, yet increases the degree of back-arc extension and focuses it closer to the trench. In such models, toroidal flow magnitude is approximately constant throughout the domain resulting in only minor TPR variation with depth, and yet the magnitude of overriding plate extensional stress is large, possibly suggesting an alternate control on back-arc extension.

Finally, we investigate the effect that Byerlee plasticity and a laterally confining side plate has on both overriding plate stress state and the flow field. Including a side plate does not modify the slab dynamics and overriding plate stress state, yet significantly reduces the toroidal RMS velocity component throughout the model, while retaining the systematic variation, which results in uniformly reduced TPR throughout the domain. The inclusion of plasticity, intended to approximate brittle failure, gives rise to elevated forearc compression, due to increased plate convergence, and reduced backarc extension.

Magnetic spectral analysis over the Atlantic Ocean off Portugal

MATSUSHIMA, Jun[1] ; OKUBO, Yasukuni[2] ; ANTONIO, Correia[3] ; UCHIDA, Youhei[2*]

[1]Graduate School of Engineering, [2]Geological Survey of Japan, [3]University of Evora

Magnetic spectral analysis, which has often been applied to estimate Curie point depths, was used to delineate thermal and crustal structure of the Atlantic Ocean off Portugal. The Atlantic oceanic plate covers the study area deepening eastward and volcanic islands rise in the eastern margin. We used EMAG2, the resolution and the altitude of which are 2 arc minute and 4 km above geoid, respectively. Linear magnetic anomalies are dominant over the study area. They are attributed to the seafloor spreading of the oceanic plate. The magnetic lineation forms a strong directional feature not only in the space domain but also in the spectral domain. Taking the directional feature, we developed a pseudo-one dimensional spectral analysis using two dimensional data sets. The gradient of the power spectrum across the lineation depends on the centroid depth of magnetic layer. The bottom depth is easily calculated by the centroid and the seafloor depth, assuming that the top of magnetic layer corresponds to the seafloor. The bottom of magnetic layer over young oceanic plate deepens with time, because the Curie point depth deepens with time. Taking the relationship, we assume that the bottom of magnetic layer over the Atlantic oceanic plate corresponds to the Curie point depth and delineates a thermal structure. The results of spectral analysis show that the bottom depths over the oceanic plate are deepening gradually from the ridge to Europe. The results correlate well with magnetic isochrons and thermal history of the oceanic plate. The bottom depths over the volcanic islands are anomalously shallow indicating a rise of high thermal structure.

Subduction Processes and a New Hypothesis for "Top-down Hemispherical Dynamics" of the Earth

IWAMORI, Hikaru[1*] ; NAKAMURA, Hitomi[2] ; HANYU, Takeshi[1] ; KIMURA, Jun-ichi[1] ; NAKAKUKI, Tomoeki[3] ; NAKAGAWA, Takashi[1] ; YOSHIDA, Masaki[1] ; TANAKA, Satoru[1] ; SUETSUGU, Daisuke[1] ; OBAYASHI, Masayuki[1]

[1]JAMSTEC, [2]TITEC, [3]Hiroshima University

Water-rock interactions reduce the rock strength, and possibly produce weak plate boundaries, inducing active plate tectonics. Water-rock interactions may also have geochemical impacts, causing the unique differentiation of the Earth (e.g., formation of granitic continental crust and hydrothermal ore deposits). However, how water actually interacts with the rocks and circulates within the solid Earth to contribute to material differentiation and dynamics has been poorly constrained. In this paper, we present numerical models of water and element transport in subduction zones, as well as global geochemical evidences for water and the associated element cycling in the mantle. Then we compare these geochemical evidences with the geophysical observations and modeling to propose "top-down hemispherical dynamics" for the whole Earth's interior.

Water-rock interaction may significantly reduce the viscosity of rocks [1], and affects the subduction zone dynamics. Hydrated subducting slabs release water as the slabs are heated up, which hydrates the bottom of mantle wedge just above the subducting slab, to form a serpentinite layer. In this case, the slab-wedge mechanical coupling is reduced, and weakens the wedge corner flow, decreasing the slab surface temperature. The serpentinite layer is stabilized to extend deeper, enhancing mechanical decoupling between the slab and the wedge. This positive feedback has a large impact on the overall thermal-flow structure and magmatism in subduction zones [2]. We compare the model results and the observations such as position of arc magmatism, heat flow and seismic structures to constrain the actual structure and dynamics.

Water may enhance elemental transport once a fluid phase is formed and
migrates, which potentially causes specific elemental fractionation. We have constructed two-dimensional models of trace element transport in subduction zones, incorporating (i) slab subduction-dehydration, (ii) fluid migration and its reaction with the convecting mantle, (iii) melt generation and (iv) associated elemental partitioning among the solid, aqueous fluid and melt [3]. This model predicts various trace element abundances in solid, fluid and melt, and shows that significant variability in terms of trace element ratios is produced in subduction zones and can be brought down to the deep mantle. The trace element variability must affect long-term radiogenic isotopic evolution of the mantle (e.g., Sr, Nd and Pb isotopic compositions). Recently, a global isotopic structure has been found based on a statistical analysis of a large geochemical data set including MORB, OIB and arc basalts [4]: the eastern mantle hemisphere is enriched in subducted aqueous fluid components compared to the western hemisphere. Magnitude of the radiogenic ingrowth for the hemispherical structure suggests that it has been mostly developed within the last several hundred million years. These observations can be explained by focused subduction towards the supercontinent (Rodinia, Gondwana and Pangea), which has created the large-scale mantle heterogeneity. A strikingly similar pattern is found for the seismic velocity structure of the inner core [5,6]. Such hemispherical structures may be key to understanding the global dynamics of the Earth. We propose that the focused plate subduction governs the flow and thermal structure of the deep interior, in a "top-down" manner.

Effects of plate-like behavior and material recycling on lateral variation of CMB heat flux

NAKAGAWA, Takashi[1*]

[1]IFREE, JAMSTEC

We studied the relationship between heat flux across the core-mantle boundary (CMB) and seismic anomalies in the CMB region in numerical mantle convection simulations in a 3-D spherical shell with a simple temperature- and depth-dependent viscosity [Nakagawa and Tackley, 2008]. That study suggested that the relationship between CMB heat flux and seismic anomalies was not simple linear function because of the post-perovskite phase transition and/or compositional heterogeneous structure in the deep mantle. However, in that study, we did not include the complicated rheology that occurred to the plate tectonics-like behavior and the segregation of oceanic crust in the deep mantle because they would be important for regulating the heat flux across the CMB [e.g. Nakagawa and Tackley, 2010].

Here we revisit to investigate the relationship between heat flux across the CMB and seismic anomalies in the deep mantle including plate tectonics-like behavior and material recycling. Preliminary result suggests that the heat flux tends to be more linear relationship with seismic anomalies in the deep mantle including plate tectonics-like behavior and material recycling but the uncertainty of this relationship between two quantities is very strong. The peak-to-peak of lateral variation of CMB heat flux is much larger than that obtained from our previous study. This is still problematic for magnetic field generation caused by geodynamo.

Petrology and Geochemical Evolution of Lavas from the Ongoing and Voluminous Puu Oo Eruption of Kilauea Volcano, Hawaii

GARCIA, Michael[1*] ; PIETRUSZKA, Aaron[2] ; GREENE, Andrew[3] ; MARSKE, Jared[4] ; RHODES, Michael[5]

[1]Dept. Geology-Geophysics, Univ. of Hawaii, [2]USGS, Denver, [3]Depart. Natural Sciences, Hawaii Pacific University, [4]Dept. Terrestrial Magnetism, Carnegie Institution of Washington, [5]Dept. Geoscience, Univ. Massachusetts

The Puu Oo eruption of Kilauea Volcano is one of the longest-lived (31 years and continuing) Hawaiian eruptions. Volumetrically, it is the most significant historical eruption. It has produced over 4 km3 of lava from several vents along its east rift zone. We have continually monitored the compositional and isotopic signatures of its lavas, which have shown remarkable variations. These variations resulted from diverse crustal and mantle processes including crystal fractionation, magma mixing and storage, assimilation of crust and melting of a heterogeneous plume source. Crystal fractionation is an important process in these lavas based on their wide range of MgO contents (5-10 wt.%) and normally zoned minerals (mostly only olivine). During the first two years, the effects of crystal fractionation were superimposed on hybrid magmas created by mixing two evolved, rift zone-stored magmas with a new, mantle-derived magma. Later lava erupted show no signs of mixing except for one-day, uprift events in 1997 and 2011. Small, systematic variations in Pb and Sr isotopes, incompatible trace element ratios and MgO-normalized (10 wt.%) major element abundances of post-mixing lavas document rapid changes in the parental magma composition unrelated to crustal processes. Lavas erupted between 1985-1998 continued the post-1924 composition trend of Kilauea lavas towards more depleted composition. This trend was initiated by the collapse of summit crater during a period of very low magma supply. Puu Oo lavas showed a systematic temporal evolution towards historical Mauna Loa lava composition from 1998-2003. This trend reversed in 2003 and again in 2008 creating a cyclic pattern of geochemical variations. These reversals in composition are contrary to previous models for geochemical trends during sustained basaltic eruptions. The cyclic variations of Pb isotopic and some trace element ratios during the Puu Oo eruption suggest melt extraction from a mantle source with thin strands of vertically-oriented source heterogeneities. These strands may be 1-3 km in diameter in order to explain the scale of isotopic variations for the Puu Oo eruption. This continuing eruption provides a dynamic laboratory for evaluating models of the generation and evolution of basaltic magmas.

When did the plate tectonics start on the Earth?

MARUYAMA, Shigenori[1*]

[1]ELSI Tokyo Institute of Technology

Initiation of plate tectonics on the Earth is a key to make life-sustaining rocky planet Earth, because primordial ocean was highly toxic and primordial atmosphere had high XCO2. Transportation of huge amounts of CO2 into mantle by plate subduction depends on pH of seawater and composition of oceanic slab.

Plate tectonics has been proposed from the data set of the ocean-floor, firstly by ocean-floor spreading theory followed by rigid lithosphere. Yet, the oldest lithosphere goes back to only 200Ma, hence demonstration of plate tectonics on the Earth is restricted to the Earth after 200Ma.

Hence, we need to make logical framework of pre-200Ma plate tectonics of the Earth. The principle of Accretionary Complex Geology (ACG) is an only key issue which is centered by Ocean Plate Stratigraphy (OPS). ACG is a technology which separates the subducted oceanic slab from trench turbidites, and offers the MORB, OIB, pelagic sediments, and subduction zone magmatic rocks from the mixture of rock units formed at trench.

Application of this technology to 3.8Ga Isua ACs clarified Early Archean plate tectonics which had different aspects of plate tectonics from the modern plate tectonics, e.g., thickness and composition of lithosphere (Komiya et al., 1999). Specifically, thickness of MORB was 20km which seems to be buoyant to prohibit subduction (e.g., Davies, 1992). But if slab-melting is common, the buoyancy turns to be negative to cause more rigorous slab-pull force at subduction zone (Komiya et al., 2002).

For the Hadean Earth, there are no geologic units remained on the modern Earth, except for zircons with back to 4.4 Ga. Mineral inclusions within the Hadean zircons suggest the host melt with granitic magma. Formation of granitic melts could be most probable for the operation of plate tectonics. But this is logically imperfect, because small amounts of granitic melts can be formed and actually present on the Moon. Conversely, the forward modelling of planetary tectonics could be more important than zirconology. Formation of primordial ocean causes the formation of rigid lithosphere, and hydrous minerals on the slab surface would act as liberated lubricants along Benioff plane. This is plate tectonics and plays even in the state of magma pods remains in the asthenospheric mantle (Sleep et al., 2011). If so, initiation of plate tectonics on the Earth could be back to Hadean Earth, presumably back to 4.4Ga.

Difference of tectonics and rheological structure between Earth and Venus

AZUMA, Shintaro[1*] ; KATAYAMA, Ikuo[1] ; NAKAKUKI, Tomoeki[1]

[1]Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University

Venus has been regarded as a twin planet to the Earth, because of density, mass, size and distance from the Sun. However, the Magellan mission revealed that plate tectonics is unlikely to work on the Venus. The plate tectonics is one of the most important mechanism of heat transport and material circulation of the Earth, consequently, its absence might cause the different tectonic evolution between Earth and Venus. Rheological structure is a key to inferring mantle structure and convection style of planet interiors because the rock rheology controls strength and deformation mechanism. In previous study, the behavior of Venusian lithosphere has been inferred from the power-law type flow law of dry diabase. They indicated that lower crust can be weaker than upper mantle, which might result decoupling at the crust-mantle boundary (Moho depth) and mantle convection without crustal entrainment. However, the power-law creep cannot be applicable to infer the rheological structure at Moho depths, because the dislocation-glide control creep (Peierls mechanism) is known to become dominant at relatively low temperatures in materials with a relatively strong chemical bonding such as silicates. In this study, we conduct two-phase deformation experiments to directly investigate rheological contrast between plagioclase (crust) and olivine (mantle) and discuss the difference between these planets in terms of rheological behaviors. Moreover, one-dimensional and two-dimensional numerical calculation is performed to evaluate the influence of the strength contrast on the Venusian tectonics. Our experiments using solid-medium deformation apparatus directly determine the relative strength between plagioclase (crust) and olivine (mantle) without any extrapolating of flow law. The experimental conditions were ranging 2GPa and 600-1000 degrees under dry conditions. The experimental results show that olivine is expected to always be stronger than plagioclase. This result contradicts to that inferred from power-law creep of olivine and plagioclase, suggesting that Peierls mechanism could be dominant deformation mechanism in both olivine and plagioclase at relatively low temperatures. In the case of the Earth, rheological structure of oceanic lithosphere is constrained well by Byerlee's law and power-law type flow law. The oceanic crust and mantle lithosphere are strongly coupled mechanically because the Moho has no strength contrast, so that they could move and subduct together into the deep. In contrast, our experimental results imply that large strength contrast exists at Moho in Venus, resulting decouple of the motion between the crust and mantle lithospheres because the weak lower crust acts as a lubricant. Also one-dimensional numerical calculations show us that the surface velocity becomes more sluggish in the model with larger strength contrast (from two-digit to four-digit difference in viscosity) at Moho. Therefore the crustal part is less likely to be involved to mantle convection when strength contrast gets larger and larger. In fact, two-dimensional simulations suggest that the crustal portion cannot subduct with the mantle lithosphere if the strength contrast exists at Moho

On the origin of plate tectonics: Thinking outside of the convective box

SOLOMATOV, Viatcheslav[1*]

[1]Washington University in St. Louis

From the observational point of view, there is no evidence of plate tectonics on other planets in the Solar System. Remote sensing methods for detecting plate tectonics on exoplanets are yet to be developed and are unlikely to be as robust as the surface observations that were conducted for Venus, Mars, and Mercury. The observational constraints on the tectonics of the early Earth are probably the most important clues to the plate tectonics origin and yet, their interpretations remain ambiguous. Some researchers see a very early start of plate tectonics in the data while others do not exclude a relatively late start. From the theoretical point of view, the absence of plate tectonics is easy to explain and can be considered as a normal state of any rocky or icy body. Two decades ago, both the observational data and theoretical studies led to the reversal of the question “why do other planets not have plate tectonics” to “why does the Earth have plate tectonics”. Since then various theories and numerical models focused on the latter question and investigated how plate tectonics began and what conditions are required for plate tectonics to occur on a planet. In most models the starting state of a planet is a non-plate tectonics regime (e.g. stagnant lid convection) which then transitions to plate tectonics. The forces responsible for the transition can be caused by convective motions below the lithosphere and with thermal (e.g. lithospheric relief) and compositional density variations (e.g. continents) near the surface. The role of the factors involved can be complicated. For example, the crust can both hinder and help plate tectonics. The transition to plate tectonics can also be caused by external factors, such as impacts and tidal forces. Similar to the previous, internal factors, these external factors can also either help or hinder plate tectonics initiation. For example, even though impacts are sometimes considered as a possible cause of plate tectonics, they can create conditions that would hinder plate tectonics initiation later on or stop it in case if plate tectonics was previously initiated by other mechanisms. Plate tectonics could also have emerged from a magma ocean, bypassing the stagnant lid regime. In this scenario plate tectonics is a continuation of convection in the magma ocean. As the magma ocean crystallizes, the surface boundary layer, which has little difficulty to recycle in the liquid magma, eventually transforms into tectonic plates as the crystallizing magma ocean undergoes a transition from turbulent convection controlled by melt viscosity to laminar convection predominantly controlled by solid-state creep. Regardless of the origin of the first episode of plate tectonics, the question of how plate tectonics survived and evolved into a relatively stable regime is a challenge for any of these models and may require a combination of many factors such as asthenosphere, surface oceans and volatile cycling.

Estimation of the lithosphere-asthenosphere transition from multi-mode surface waves

YOSHIZAWA, Kazunori[1*]

[1]Earth and Planetary Dynamics, Faculty of Science, Hokkaido University

The lithosphere-asthenosphere transition (LAT) is a key to the understanding of the present-day plate motion, but its seismological determination is not straightforward unlike material boundaries such as the Moho and core-mantle boundary. Some recent works on the LAT using body-wave receiver functions have revealed evidences for clear converted signals at the bottom of lithosphere, particularly in oceanic region. To the contrary, receiver functions normally do not show clear converted signals from the expected bottom of cratonic lithosphere at about 200 km depth, where surface wave studies indicate fast wave speed anomalies of the thick continental lithosphere.

In this study, we investigate a quantitative way to estimate the depth and thickness of the LAT from S-wave speed models derived from surface waves. Although surface waves are inherently not very sensitive to the sharpness of boundaries due to their long-wavelength features, the depth of LAT can be roughly estimated from the depth of either the negative peak of velocity gradient or the slowest shear velocity beneath the lithosphere. In this study, we consider that the former represents an upper bound of LAT and the latter a lower bound. The thickness (or sharpness) of LAT can be deduced from the differences between the upper and lower bounds.

We have performed synthetic experiments using several types of S-wave models including different smoothness (or sharpness) of LAT. Synthetic experiments using multi-mode surface waves (including up to fourth higher modes) result in a successful recovery of the smooth LAT (with a depth range over 50 km), which is expected at the base of the cratonic lithosphere. However, if we use the fundamental mode only, the recovery is unsatisfactory even for the smooth boundary, and the effects of the sharpness of boundary are almost indistinguishable in the recovered models. Surface waves have less sensitivity to a sharp boundary (with a transition thickness less than 25 km), but our experiments indicate that the estimated depth from the velocity gradient (upper bound of LAT) are found to be coincide well with the depth of sharp boundary, which may indicate the distribution of oceanic LAT can be well represented by the negative peak of vertical gradient in S-wave speed profiles derived from surface waves.

Advances in laboratory acoustic emission study

LEI, Xinglin[1*]

[1]Geological Survey of Japan, AIST, Japan

Acoustic emission (AE) is an elastic wave radiated by rapid cracking in solids. As a technology of nondestructive inspection, AE has a long history of development and has been applied in numerous areas including material sciences, medical sciences and engineering fields. In stressed rocks, macroscopic fracturing is preceded by a very complex pervasive evolution of some pre-failure damage. Thus, studies focusing on both fracture dynamics and pre-failure damage are a subject of interest and can be inferred from AE statistics as the number of AE events is proportional to the number of growing cracks, and the AE amplitudes are proportional to the length of crack growth increments in the rock. In Earth science, since the similarity in size distribution of earthquakes and acoustic emissions (AE) was found in the 1960s, many laboratory studies have been motivated by the need to provide tools for the prediction of mining failures and natural earthquakes. This report aims to draw an outline of laboratory AE studies in the last 50 years, which have addressed seismological problems, with special focuses on some key issues associated with fault nucleation and growth in brittle rocks.

The AE technique, which monitors the spatiotemporal distribution of AE events, is applied to the analysis of the micro-cracking activity inside the sample space, and it can be performed under an artificially controlled pressure, which is very important for the simulation of underground conditions. During the last five decades, a great number of studies were done following developments in experimental technology, AE monitoring technology, and data processing methodology. Fifty years ago, only the hitting time of an AE could be recorded with a single sensor or a small number of sensors. The rock fracture test was performed under simple loading conditions. Later, the number of sensors that could be used in a study increased and thus allowed the determination of the hypocentre of an AE. Developments in transient memory technique in the 1970s through to the 1980s lead to the ability to make a digital multichannel recording of the full waveform of an AE. Hypocentre location was improved greatly by the use of more precise arrival times obtained through waveform analysis. In addition, it became possible to determine the mode of fracture, i.e., the focal mechanism solution of an AE source. In the present day, AE are usually monitored by 16-32 sensors with digital waveform recording at up to a 200 MHz sampling rate and up to a 16 bit A/D resolution. The dead time of a recording is sufficiently short and continuous recording is possible by use of very large amounts of memory. The waveform of most events can be captured with multiple channels, even for the period of dynamic failure in which the AE rate may reach several thousand a second. Rock fracture experiments can be performed under triaxial compression conditions with controlled fluid injection and pore pressure. AE hypocentres are determined with a location error of a few mms. A focal mechanism solution can be determined for individual events or a group of events. As demonstrated by very recent studies progress in laboratory AE study, particularly studies focusing faulting nucleation, is shedding more and more light on earthquake seismology.

By summarising recent results, it can be concluded that the fault nucleation behaviour, including critical size, duration time, and AE productivity, depend on the heterogeneity of the area of weakness of the fault compared with that of the host rock. If the fault is as strong as the host rock then the fracture makes no difference and the rock remains intact. Furthermore, a homogeneous fault or rock mass appears to fracture in unpredictable ways without a consistent trend in precursory statistics, while inhomogeneous faults fracture with clear precursors related to the nature of the heterogeneity.

Microfracture distributions indicating formation of large-scale cracks in the rock mass ahead of the mining front

NAOI, Makoto[1*] ; MORIYA, Hirokazu[2] ; NAKATANI, Masao[1] ; MURAKAMI, Osamu[3] ; THABANG, Kgarume[4] ; THABANG, Masakale[5] ; LUIZ, Ribeiro[6] ; YABE, Yasuo[2] ; KAWAKATA, Hironori[3] ; ANTHONY, Ward[6] ; RAY, Durrheim[4] ; OGASAWARA, Hiroshi[3]

[1]Univ. of Tokyo, [2]Tohoku Univ., [3]Ritsumeikan Univ., [4]CSIR, [5]OHMS, [6]SeismoGen

We are monitoring Acoustic Emissions (AEs) down to Mw -4 or less at 1km beneath the ground in the Cooke 4 Mine (previously known as the Ezulwini Mine), where many earthquakes up to Mw 2 are induced by stress concentration due to tabular mining. The network consists of 24 AE sensors and 6 three-component accelerometers. Naoi et al. (2013; Pageoph) made a catalog composed of about 360,000 events by using waveform data obtained for three months, and reported that 90% of them aggregated within 10 m ahead of the mining front at the time.

In this study, we extended the analysis term to 9 months and developed a catalog composed of about one million events. We also applied the double difference algorithm (Waldhauser and Ellsworth, 2000) to them so as to examine spatial distributions of the AEs near the mining front in detail. Travel time differences for relative location were calculated from arrival times automatically read by the program of Horiuchi et al. (2011). To efficiently calculate relative hypocenters for a massive amount of events, we adopted the parallelization method of Hauksson and Shearer (2005), where events in subregions overlapping each other are firstly relocated and then the hypocenters relocated redundantly are averaged to make a single catalog. We succeeded in relocating 96% of the one million events.

The relocated AEs near the mining front exhibited two-dimensional, tabular aggregations with a few tens of meters lateral extent (hereinafter referred to as tabular cluster), rather than a three-dimensional distribution spread more or less uniformly (randomly) over the entire zone of the stope-front activity of 10 m breadth. Each tabular cluster was discernible because they were separated by regions of low AE density. That is, AEs ahead of the mining front basically occur selectively in several discrete tabular zones within a highly stressed volume affected by the mining cavity. The tabular clusters strike parallel to the mining face and dip 60-80^o. This resembles similarly large shear fractures along the plane of maximum shear commonly observed by excavation around the stopes (Gay and Ortlepp, 1979; Adams and Jager, 1980; Adams et al. 1981). Ahead of a panel that advanced by 40 m during the analysis period, 10 such tabular zones formed at intervals of 5 m on average.

By the same AE monitoring network, we also have found extremely aggregated (a few tens of centimeter thickness) planar clusters continuous over the cluster's extent, reminiscent of thoroughgoing fracture surfaces. They often coincide with pre-existing geological faults (Naoi et al. 2013; JpGU). In contrast, the AEs of the tabular clusters regularly forming in the mining front were spread over 1-2 m thickness, lacking a dominant aggregation with good continuity. We interpret that the tabular-cluster AEs are microfractures occurring in a formation process of a large-scale shear crack in macroscopically intact rock subjected to high stress ahead of the advancing mining front. Indeed, the activity of tabular clusters gradually increased as the mining front approached and ceased when passed by the front.

Deformation and acoustic emission of a penetrated granular bed

MATSUYAMA, Kazuhiro[1] ; KATSURAGI, Hiroaki[2*]

[1]Department of Applied Science for Electronics and Materials, Kyushu University, [2]Department of Earth and Environmental Sciences, Nagoya University

In general, the rheological behavior of granular matter can mimic a certain side of the geophysical phenomena. In this experiment, the plunged granular matter is used to model the deformation and/or fracturing of the geophysical materials.

Penetration resistant force and acoustic emission (AE) from a plunged granular bed are experimentally investigated through their power-law distribution forms. The experimental apparatus used in this study is basically similar to that in our previous works [1,2]. In this experiment, AE measurement is used to approach the grain's-level microscopic behavior in a penetrated granular bed. An AE sensor (NF AE-9913) is buried in a glass beads bed. Then, the bed is slowly penetrated by a solid sphere by using a universal testing machine (Shimadzu AG-100NX). The average diameter of glass beads is varied from 0.4 to 2 mm, and the penetrating sphere's diameter ranges from 10 to 40 mm. During the penetration, the resistant force applied to the sphere and the AE signal are simultaneously measured [3]. The penetration speed (in the order of 1 mm/s) is kept slow enough to focus on the quasi-static regime. In this slow-penetration regime, the resistant force is independent of the penetration speed. Moreover, the resistant force shows power-law relation to the penetration depth. The obtained power-law exponent seems to depend on the size of granular column, i.e., the container's size. By comparing the resistant forces obtained by this experiment and other experiments, we confirm the relation between the resistant force and container's size. The smaller the container is, the larger the power-law exponent of resistant force becomes. This might mean that the slow penetration drag is affected by side wall of the container through force chains.

For AE signal, we observe a lot of (more than 1,000) burst-like AE events in each penetration experiment. We define the size of each AE event by its maximum amplitude. Then we find that the size distribution of AE events obeys power-law that is similar to Gutenberg Richter's law of the earthquakes statistics. However, the measured power-law exponent is not universal in this experiment. It rather depends on experimental condition. Particularly, the size of beads composing the penetrated granular bed affects the result significantly. The small glass beads bed shows larger power-law exponent. This tendency of power-law exponent indicates that the deformation of small-grains-bed is rather plastic, and the deformation of large-grains-bed shows brittle-like behavior. Namely, the emitted acoustic signal relates to the mode of deformation or fracturing. Since the grains network constructed in a small grains bed is dissipative, it also influences the statistics of AE events. The large AE events could be dissipated and screened by a lot of contact points in the small grains bed. This effect is also consistent with the current experimental result. In this study, only the AE events are measured and analyzed based on its power-law distribution. Actually, to characterize the mode of fracturing more precisely, electromagnetic emission (EME) should be also measured. Simultaneous measurement of AE and EME would reveal the details of the mechanics of slowly penetrated granular bed. Although this result is still preliminary to directly compare the power-law exponent with actual geophysical phenomena, the systematic behaviors of the power-law exponents are qualitatively informative to understand the deformation of the granular matter which relates to various geophysical phenomena and is quite different from usual continuum.

Variety of memories of clay paste flows which can be visualized as desiccation crack patterns

NAKAHARA, Akio[1*] ; MATSUO, Yousuke[1] ; OOSHIDA, Takeshi[2] ; OTSUKI, Michio[3] ; KITSUNEZAKI, So[4]

[1]College of Science and Technology, Nihon University, [2]Department of Mechanical and Aerospace Engineering, Tottori University, [3]Department of Materials Science, Shimane University, [4]Graduate School of Human Culture, Nara Women's University

Due to its plasticity, a water-poor clay paste can remember the direction of vibration and flow that it suffered. The memory of flow in clay paste can be visialized as a morphology of crack pattern that appears when the clay paste is dried. When the clay paste remembers the flow direction, desiccation cracks run all parallel to the direction of the flow. Recently, we find that there are some different types of memory of flow, as the direction of crack propagation changes from parallel to perpendicular direction. We would like to discuss on the mechanism of the memory effect of flow.

Precursory Signal of Frontal Thrust Formation: Current status of Large Scale High Precision Sand Box Experiments

HORI, Takane[1*] ; SAKAGUCHI, Hide[1] ; YAMADA, Yasuhiro[2] ; DOTARE, Tatsuya[2] ; FUKUMOTO, Yutaka[3]

[1]JAMSTEC, [2]Depertment of Urban Management Engineering, Kyoto University, [3]Graduate School of Agriculture, Kyoto University

In order to find out the mechanism of the three dimensional complex shape formation in sequential thrust and uplift of a accretion prism, we have developed a large scale high precision sand box experimental apparatus since 2011. After a number of modifications in the experimental apparatus and experimental procedure, we finally performed productive runs in July 2013. In specimen preparation, the thickness of a sand layer is controlled with the precision of less than single particle size. As a result, the shape of a frontal thrust became uniformly straight with high reproducibility and no complex shape has been observed since then. However, with such a well-controlled experimental system, we succeeded to detect the precursory signal prior to frontal thrust formation. In this talk, detailed information of the experimental apparatus and our new findings will be given with the scope of applicability of our finding in the field.

New modelling devices to enhance the reproducibility of analogue model experiments

DOTARE, Tatsuya[1*] ; YAMADA, Yasuhiro[1] ; SAKAGUCHI, Hide[2] ; HORI, Takane[2]

[1]Department of Urban Management, Kyoto University, [2]Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

The scaled analogue model experiments have been used for more than 100 years to reproduce the geological development processes in the laboratory scales using the granular material (e.g. dry sand). Recently, we can obtain the small-scale deformation quantitatively by applying digital image analyses. Then, we observed the 'weak shear band' before fault initiation process. However, heterogeneity in the initial model produced by human hand often causes the fluctuation of the experimental results (e.g. fault location, faulting timing and fault geometry).

To solve this problem, we made the experimental device for making the initial model automatically and conducted the experiments to compare the experimental results with the previous method.

We conducted simple convergent experiments. Initial models were made by previous method (human hand) or new method (new device) and experiments were repeated 5 times, respectively.

As a result, while branches of new faults can be seen in the previous method, there are no branches in the new method. In addition, the fluctuation of experimental results was restricted in the new method.

This shows that new experimental device can make the initial model homogeneous and reproduce the same initial model in each experiment.

Relaxation processes of granular layer at seismic slip rates and layer thickness.

KUWANO, Osamu[1*] ; NAKATANI, Masao[2] ; HATANO, Takahiro[2] ; SAKAGUCHI, Hide[1]

[1]IFREE, JAMSTEC, [2]ERI, University of Tokyo

A natural fault has the cataclasite core zone, along which shear deformation concentrates. Rheology of these granular matters thus provides us an important insight in considering the nature of friction on faults from a microscopic point of view. In the past two decades, experiments conducted at sub seismic to seismic slip rates (mm/s to m/s) revealed two remarkable phenomena of high-velocity rock friction; very long critical slip distance (Dc) of the order of 1-10m/s and the considerable weakening due to mechanochemical effects by frictional heating [e.g., Di Toro et al., 2011, Nature]. Recently, Chambon et al.[2006, JGR] conducted friction experiment with very large shear displacement experiment on a thick granular layer, and reported significant slip-weakening behavior active over decimetric slip distances. However, the relation between long Dc observed in a thick granular layer and long Dc in the high-velocity friction is still not clear. Here, we report on laboratory experiments designed to explore transient responses of a thick granular layer following a step change in slip velocity at seismic slip rates. We use simple particle and choose relatively low normal stress to exclude the possible mechanochemical effects caused by frictional heat. We find that friction coefficient and layer thickness show similar response that is symmetry with respect to velocity changes, and Dc is of the order of 10m. It appears that these responses are attributed to dynamics of granular matter. We also report how magnitude of the relaxation and Dc are affected by the layer thickness.

Porosity and permeability under effective pressure for the Quaternary Kazusa Group siltstones

MARUMO, Haruna[1*] ; UEHARA, Shin-ichi[1] ; TAMURA, Yukie[2] ; MITSUHASHI, Shunsuke[2]

[1]Graduate School of Science, Toho University, [2]Faculty of Science, Toho University

The Kazusa group is a geological formation of the middle Pleistocene - Pliocene marine, and widely distributes in middle and northern part of the Boso Peninsula. Mudstones of the Kazusa Group is in the first stage of consolidation (viscous compaction stage), and porosity is 37.9 - 55.5% [1]. In mudstone formations of the Kazusa Group, high porosity anomaly is observed, of which location is consistent with that of natural gas deposits. This high porosity anomaly is suggested to have been generated by an abnormally excess pore pressure. The development process of the high pore pressure is still unknown. Previous studies have discussed the mechanism in connection with production of natural gas, but sufficiently quantitative analyses have not been performed. H igh pore pressure zone may affect many properties and processes in underground, such as porosity and permeability development in accretionary wedge or sedimentary basins during accretion and depositional process, ground water flows or petroleum migrations in underground, and fault mechanisms. Thus, to elucidate the mechanism of developing the high pore pressure zone is important. We are therefore planning to investigate the mechanism of the high pore pressure zone development by using the 1D model of Tanikawa et al. [2], which include simple deposition and compaction processes. In this study, as the first step of this project, the effective pressure dependences of porosity and permeability were determined for laboratory experiments for siltstone of the Kazusa Group, which are necessary for the modeling.

The measurements were performed using an intra-vessel deformation fluid-flow apparatus at Toho University. The rock samples used in the experiments were collected from outcrops at Umegase Formation, Ota-dai Formation, Kiwada Formation, Ohara Formation and Katsuura Formation of the Kazusa group. The collected samples were shaped into a cylindrical shape about 40 mm in diameter and about 30 mm in height. Distilled water was used for pore fluid and confining pressure was applied by using oil. Permeability and porosity of siltstones were measured at room temperature and under effective pressures from 0 MPa to 35 MPa. To obtain porosity under effective pressure, we measured a volume of water discharged from the specimen when confining pressure was applied. We measured permeability by monitoring flow rate through the specimen under the condition that pore pressure differences at the both side of the specimen is kept constant.

Permeability and porosity ranged from 10^{-17} - 10^{-18} m^2 and to 34 - 42 %, respectively. Permeability and porosity both decreased with increasing effective pressure, and this pressure dependence varies.Based on the results of the experiment, porosity and permeability was expressed in relation to the effective pressure. We have examined the relationship between permeability and porosity.

Rheological properties of mafic schists: Implications for subduction dynamics

OKAZAKI, Keishi[1*] ; HIRTH, Greg[1]

[1]Department of Geological Sciences, Brown University

To understand the spatial and temporal distribution of deformation (e.g., underplating and exhumation of metamorphic rocks) and earthquakes in subduction zones, it is important to constrain the rheological properties of metamorphic rocks (i.e., altered oceanic crust and sediments), and how they evolve during metamorphic reactions following hydration, carbonation and dehydration of the down-going slab. Metamorphism of oceanic crust has stimulated hypotheses on the relationship between intra-slab earthquakes and slab-wedge coupling along plate boundaries in subduction zones. While it is well known that metamorphism has important effects on material fluxes and arc volcanisms at subduction system, it remains unclear how the formation of metamorphic minerals following fluid release influences rheology. Past experimental studies on mafic metamorphic rocks were mostly concentrated on phase equilibrium, thus there are few reports on the mechanical data for these metamorphic rocks.

We conducted triaxial deformation experiments on two mafic schists sampled from the Sambagawa metamorphic belt (Shikoku Island, Japan), using Griggs-type solid pressure- medium apparatus at Brown University. Both mafic schists are mainly composed of amphible, albite, epidote, and chorlite with small amounts of titanite and phengitic mica However, there are differences in the peak metamorphic condition (i.e., the maximun PT condition), amphibole composition and mineral abundance of minerals in the two schists. One, which was metamorphosed at greenschist facies (pressure of ~0.75 GPa and temperature of ~400 ℃), has a relatively high chlorite content (~12 %) and actinolite is the dominant amphibole phase. The other, metamorphosed at the epidote-amphibolite facies (pressure of ~1 GPa and temperature of ~520 ℃), has a lower chlorite content (<2 %) and hornblende is the dominant amphibole phase. Constant strain rate experiments and strain rate stepping experiments were conducted at confining pressures (P_c) from 0.76-2GPa, temperatures (T) from 300-600 ℃ and strain rates from 10^{-5}-10^{-7} 1/s.

At conditions near the peak conditions of the greenschist (P_c = 1 GPa, T = 400 ℃), differential stresses were higher than 1 GPa. The greenschist samples are weaker than the epidote-amphibolite samples under all experimental conditions. Both types of samples exhibit strain rate strengthening; frictional behavior that inhibits earthquake nucleation. Differential stress increased with increasing confining pressure, while friction coefficient decreased with increasing confining pressure and temperature. At T = 400 ℃, the nominal friction coefficient (μ) for the greeschist samples was μ ~0.34 at P_c = 1 GPa and μ ~0.30 at P_c = 1.5 GPa; for the epidote-amphibolite, μ ~0.48 at P_c = 1 GPa and μ ~0.42 at P_c = 1.5 GPa. Stress exponents (n) for the greenschist samples at P_c = 1 GPa were n ~26 at T = 300 ℃, n ~36 at T =400 ℃ and n ~34 at T = 500 ℃; for the epitote-amphibolite, n ~31 at T = 400 ℃ and n ~21 at T = 500 ℃. Microstructures of recovered samples showed modest buckling and several localized shear zones. These features suggest that the deformation of mafic schist is accommodated by semi-brittle deformation resulting in strain localization on faults.

We also conducted deformation experiments in which temperature was increased above the thermal stability of chlorite (~800 ℃) to simulate a prograde metamorphism in subduction zones. With increasing temperature during deformation, differential stress decreased and reached nearly 0 MPa. This suggests that such reaction-enhanced weakening of metamorphic rocks forms weak fault zones in subducting slab, which might promote detachment of oceanic crust from the subducting slab and allow underplating to forearc crust. The strain-rate strengthening behavior of these materials suggests that such faults would be relatively aseismic.

Effect of iron content on the creep behavior of olivine under hydrous conditions

TASAKA, Miki[1*] ; ZIMMERMAN, Mark[1] ; KOHLSTEDT, David[1]

[1]University of Minnesota

Since iron and hydrogen play important roles in dynamic processes not only in Earth's mantle but also in Mars's mantle, we conducted triaxial compressive creep experiments on polycrystalline samples of olivine, $(Fe_{1-x},Mg_x)_2SiO_4$, with x = 0, 0.53, 0.77, 0.90, and 1.0 under hydrous condition. A Paterson-type gas-medium apparatus was used for these experiments. The water contents, determined from Fourier transform infrared (FTIR) spectroscopy analyses of larger Fo_{90} crystals embedded in the olivine aggregates, demonstrate that the samples are water-saturated both before and after deformation. The grain sizes of initial and deformed samples were determined using electron backscatter diffraction (EBSD).

Creep tests at 300 MPa confining pressure were conducted at temperatures from 1050 to 1200C at constant stresses in the range 25 to 315 MPa. The values of the pre-exponential term, stress and grain size exponents, and activation energy in the constitutive equation were determined for a wide range of iron concentrations. Samples with high Mg contents are finer grained (1-2 μm) than those with low Mg contents (10-20 μm). Furthermore, samples with high Mg contents ($x \geq 0.90$) exhibit a stress exponent of n = 2, whereas samples with low Mg contents (x <0.90) deform with n = 3. This result is consistent with the dislocation-accommodated grain boundary sliding model of Langdon (1994), which predicts that fine-grained samples that do not contain sub-grains should exhibit n = 2 while coarser-grained samples that do contain sub-grains should exhibit n =3. The flow stress decreases with increasing iron content of the olivine samples at constant temperature, strain rate, and grain size. Following the analysis of previous studies (Mackwell *et al*., 2005; Zhao *et al*., 2009), we fit our creep data to the following flow law: strain rate = $A\sigma^n\ d^{-p}\ (1\text{-}x)^m\ {f_{H2O}}^r\ \exp\{-[Q_0 + \alpha(1\text{-}x)] / RT\}$, where A is a material-dependent parameter, σ is stress, d is grain size, p grain size exponent, m iron content exponent, f_{H2O} water fugacity, r water fugacity exponent, Q_0 activation energy at $(1\text{-}x)$ = 0, and α a constant. The dependence of strain rate on iron concentration is characterized by two parameters - directly, through the iron content exponent m and, indirectly, through the term $\alpha(1\text{-}x)$ in the activation energy. The values of m and α are determined by the rate-controlling mechanism of deformation and the charge neutrality condition for Fe-bearing olivine.

High accuracy measurement of activation energy of creep and electrical conductivity of olivine aggregate

NAKAKOJI, Tadashi[1*] ; HIRAGA, Takehiko[1] ; MIBE, Kenji[1]

[1]Earthquake Research Institute, The University of Tokyo

It is believed that creep rate of peridotite being major rock in the Mantle is controlled by diffusion of the slowest ion which is Si^{4+}. However it is suggested that diffusion of the second fastest ion controls the deformation rate in the system of which not only olivine but it including pyroxene also consists (Sundberg and Cooper (2008)). As seen above, the controlling process has not been understood well. Besides the activation energy being indication for deciding the mechanism is often obtained with a large error range. Therefore, in a case of extrapolating the experimental to the Earth's interior value, the large error will produce a large uncertainty. To solving the two problems, we have conducted the compression experiment and electrical conduction test for olivine simultaneously under a continuously changing temperature.

The sample used for the experiment was synthetic olivine composed of forsterite (90vol %) + enstatite (10vol %), which imitates a material in upper Mantle. To inhibit to grain growth during the experiment, the sample was annealed at 1360 ℃ for 24 hours in the furnace before the test conducted. During the experiment, the sample was kept loaded at constant stress, 20MPa, and temperature changed from 1360 ℃ to 1240 ℃ and then increased from 1240 ℃ to 1360 ℃ in order to confirm reproducibility of measurements. Measurement of impedance of the sample was also conducted simultaneously. The sample applied at 20V every ten degree from 1360 ℃ provided us current response, which was used for measurement of impedance of the sample.

The result of the experimental data provided us viscosity and electrical conductivity of the sample. Viscosity was obtained by the relation of stress and strain rate. Arrhenius plot of reciprocal viscosity shows a linear distribution. This indicates that deformation mechanism of the sample did not change at the applied temperature range in the experiment. Electrical conductivity in the sample was obtained by the resistivity derived from the data by impedance measurement. Assuming that the conduction is thermally-activated process, the relation of conductivity times temperature and temperature shows a linear relation in Arrhenius plot. From each these slopes of lines, Activation energy of 627±15 kJ/mol was obtained about creep and that of 297 ±12 kJ/mol was obtained about electrical conduction, respectively. This difference of the activation energies indicates that the creep rate and electrical conduction were controlled by different ion or/and different diffusion in the sample.

Sundberg and Cooper (2008) suggested that deformation mechanism is Mg^{2+} + O^{2-} ion diffusion but not Si^{4+}diffusion in a case of the sample of olivine + pyroxene. Therefore we compare our result with previous works. Activation energy of lattice diffusion of Si^{4+} and O^{2-}in olivine are ≈530 kJ/mol and ≈340 kJ/mol(Dohmen et al. 2002), respectively and that of Mg^{2+}lattice diffusion is about 400±60 kJ/mol (Chakraborty et al. 1994). On other hand, 627±15 kJ/mol was obtained in this study, so that we can infer that lattice diffusion of Si4+ controlled creep rate. ten Grotenhuis et al. (2004) obtained that activation energy of 315±39 kJ/mol by measuring electrical conductivity of olivine aggregate which has the same composition and almost same grain size of ours, and relation of increase electrical conductivity and decrease in grain size. Consequently, from the grain size is the same one of us, we can infer that grain boundary diffusion of Mg^{2+}ion contributed to the conductivity of our sample.

Quantification of grain boundary sliding and grain rotation during diffusion creep of mantle rocks

MARUYAMA, Genta[1*] ; HIRAGA, Takehiko[1]

[1]Department of Earth and Planetary Sciences, Earthquake Research Institute, University of Tokyo

Existence of an anisotropy in the seismic wave velocity in Earth's upper mantle have been known for decades (Tanimoto and Anderson 1984). The seismic anisotropy is often explained by the crystallographic preferred orientation (CPO) of rock-forming minerals, which have anisotropic elasticity. In general, the CPO of olivine produced during dislocation creep is considered to be the primary cause of the anisotropy. Recently, our team showed that the CPO of olivine is produced even during diffusion creep (Miyazaki et al. 2013). However, the mechanism of the CPO development under diffusion creep is still not clear. The purpose of this study is to understand the mechanism in submicron scale by observations of samples surface after the sample deformation where the fine-scale strain markers were imposed.

We used a vacuum sintering technique to synthesize cylindrical samples which were composed of fine-grained forsterite plus 20 vol. % diopside (a combination that we denote Fo80Di20) and forsterite plus 35 vol. % enstatite (En). We polished the lateral side of the sample. Subsequently we imposed grooves on such surface with using a focused ion beam. These marker lines were parallel to the compression axis of sample deformation. We conducted uniaxial compression creep experiments at atmospheric pressure, temperatures of 1300oC and strain rates of 10^{-5} -10^{-4} s^{-1}. After the compression creep experiment, we observed the marker lines under scanning electron microscope (SEM) with field emission gun (JEOL 6500F installed at Nano-Manufacturing Institute, University of Tokyo) to observe how the markers were displaced after the deformation. Such observations allow to quantify the amount of grain boundary sliding and grain rotation due to a plastic deformation of the sample.

We succeeded to observe the marker lines after the deformation. Significant grain boundary sliding was detected from the offsets of the markers at numbers of grain boundaries. No distortion of the markers within the grains was found indicating the absence of intragranular deformation process such as a glide of dislocations. We quantified the grain rotation finding that the rotation angle increases with strain. The average angles in the sample of Fo80Di20 with strain of 3%, 7% and 14% were 1.2^o, 3.9^o, 6.5^o, respectively. We also found larger rotation angle of the grains in Fo80Di20 than in Fo65En35. Fo80Di20 is composed of anisotropic grains of Fo whereas Fo65En35 has isotropic grains, which may explain the difference in the grain rotation between the samples. The shape of anisotropic grains is crystallographically controlled resulting in a development of longer and straight grain boundaries. We assumed that grains were easier to glide at such boundaries resulting in development of CPO during diffusion creep (Miyazaki et al. 2013), which is an modified model of grain rotation during grain boundary sliding creep (Beere 1978). Our present result seems to support our CPO model.

The characteristics of the seismic anisotropy vary depending on the types of crystallographic preferred orientation (CPO) of olivine. Therefore, the pattern of the seismic anisotropy has been interpreted by taking into account the water- and pressure-induced fabric transitions of olivine in recent studies (Jung and Karato, 2001; Ohuchi et al., 2011). The fabric strength of olivine aggregates is also important when we evaluate the magnitude of the seismic anisotropy in the upper mantle. In the upper mantle, the steady-state fabric strength of olivine is expected to be achieved due to long time-scales of flows.

The dependency of the fabric strength of olivine aggregates on strain has been evaluated in only limited numbers of experimental studies (e.g., Bystricky et al., 2000). Bystrikcy et al. (2000) showed that total shear strains higher than 4 are needed to achieve the steady-state fabric strength of olivine (D-type fabric) at 0.3 GPa and 1473 K. However, it has been difficult to evaluate the detailed process of the development of fabrics because fabrics of recovered samples have been evaluated. Recently, we have developed experimental techniques for in-situ simple-shear deformation experiments using a D-DIA apparatus. In this paper, we briefly show that our recent experimental results on in-situ observations of stress, strain, and fabric developments in olivine samples.

Simple-shear deformation experiments on olivine aggregates at pressures P = 2-3 GPa, temperatures T = 1290-1490 K, and shear strain rates of 3E-4 s-1 were performed using a deformation-DIA apparatus installed at SPring-8. Shear strain (up to 5) was measured by the rotation of a platinum strain-marker, which was initially placed perpendicular to the shear direction. Differential stress, generated pressure, and CPO patterns of olivine samples were determined from two-dimensional X-ray diffraction patterns using software (IPAnalyzer, PDIndexer, and ReciPro: Seto et al., 2010; Seto, 2012). The CPO patterns of olivine in the recovered samples were also evaluated by the indexation of the electron backscattered diffraction (EBSD) patterns.

A-type olivine fabric was developed under dry conditions. The fabric strength increased with strain ($<$2), and steady-state fabric strength was achieved at shear strains about 2. The [010] axes strongly concentrated to the shear plane normal and its concentration increased with strain. Preferential alignments of the [100] and [001] axes were developed through increase in strain, though concentrations of the [100] and [001] axes were weaker than those of the [010] axes. Development of B-type olivine fabric was observed under wet conditions (˜700 ppm H/Si). The fabric strength of B-type sample continuously increased with strain (up to 3). As same as the case of A-type samples, concentrations of the [010] axes were stronger than those of other axes in the B-type sample. Because the concentration of the [010] axes efficiently increases at strains larger than 1, seismic anisotropy (e.g., VSH/VSV) at shear strains = 1 is quite similar to that under the steady-state conditions.

Using the CPO data of the steady-state A-type fabrics, V_{SH}/V_{SV} of the asthenospheric upper mantle is estimated to be 1.027 (note that 70 vol.% of preferred-orientated olivine grains and 30 vol.% of random-orientated orthopyroxene grains are assumed in the calculation). This value is consistent with the global one-dimensional model reported by Visser et al. (2008). The V_{SH}/V_{SV} of the asthenospheric upper mantle is expected to have higher values in the case of B-type fabric (e.g., 1.035), which is harmonious with the global one-dimensional model reported by Panning and Romaniwics (2006). Our results show that seismic anisotropy in the upper mantle is mostly explained by the steady-state olivine fabrics (A- and B-types), and other effects (e.g., shape-preferred orientation of melt, CPO of other minerals) would be limited.

Simultaneous observations of dehydration and AE activities during the deformation of antigorite at high pressures

IWASATO, Takuya[1*] ; KUBO, Tomoaki[1] ; HIGO, Yuji[2] ; KATO, Takumi[1] ; KANESHIMA, Satoshi[1] ; UEHARA, Seiichiro[1] ; IMAMURA, Masahiro[1]

[1]Kyushu Univ., [2]JASRI

Intermediate-depth earthquakes are seismic activities at depths of 60-300 km, where subducting plates deform plastically rather than brittle failure. Because dehydration embrittlement (Raleigh and Paterson, 1965) may not work for serpentinite at pressures more than ~2 GPa, it is important to understand the mechanisms of shear instability at higher pressure. To conduct simultaneous observation of dehydration reaction, plastic flow and shear instability, we developed an in-situ observation system combined with synchrotron monochromatic X-ray and AE 6-6 system (multiple acoustic emission measurement for multi-anvil 6-6 type system) using Deformation-DIA (D-DIA) apparatus. Using this system, we carried out antigorite deformation experiments up to ~4.5 GPa and ~850 K including the condition of the antigorite dehydration to talc and forsterite.

Deformation experiments were conducted at high pressure and high temperature using a 1500-ton uniaxial press (SPEED Mk. II) with a D-DIA type guide block installed at BL-04B1, SPring-8 (Katsura et al., 2004; Kawazoe et al., 2011). 50 keV monochromatic X-ray were used to measure two-dimensional X-ray diffraction (2D-XRD) patterns and X-ray radiography images, which give reaction kinetics, differential stress, and strain. We developed MA 6-6 type system (Nishiyama et al., 2008) to monitor shear instabilities by AEs from maximum six piezoelectric devices positioned between first and second stage anvils. AE waveforms were recorded in trigger mode using six-channel 8-bit digital oscilloscopes at a sampling rate of 50MHz. Starting material of polycrystalline antigorite cylinder (1.7 mm in diameter and 2.7 mm in length) cored from high-temperature serpetinite (Eigami, Nagasaki, Japan) were first compressed at room temperature, then heated at constant load, and finally deformed with constant strain-rate mode. In some runs, dehydration occurred during heating or deformation. Microstructures of recovered samples were preliminarily observed by optical microscopy.

A total of ten deformation experiments of polycrystalline antigorite were conducted at 1.1~4.5 GPa, 300~850 K, and strain rates of 3.4~6.7 x 10^{-5} s^{-1}. AEs were frequently generated from the sample during the cold compression. Relatively large AEs were also detected when heating the sample to 673 K, while AE activities became zero at higher temperatures. During the constant strain-rate deformation, the flow stress reached steady state at the sample strain of more than 5%, and no stress drops were observed until the final strain of ~30-40%. These flow behaviors and the flow strength are almost consistent with the previous study (Hilairet et al., 2007). We also detected AEs during the deformation stage although the frequency was lower compared to the cold compression and heating stages. The AE activities during the deformation became large at lower temperature and larger stain conditions. Optical microscopic observation revealed that some faults are present in the antigorite samples recovered from each stage. On the other hand, we observed dehydration reaction from antigorite to talc-like phase during the deformation at 800 K. The reaction was very slow and only one AE event was detected at the strain of ~25%. Because the faults were only observed in the relict antigorite region, the AE was possibly originated from antigorite. At higher temperature of 850 K, complete dehydration quickly occurred before the deformation. No AEs were detected during the dehydration and the following deformation of dehydrated materials to more than 30% strain. No faults were observed in the recovered sample. Our simultaneous observations of reaction and AE activities showed that the AE is not generated by dehydration of antigorite at more than ~2 GPa. Instead, the unstable fault slipping that generates AEs occurs during heating and deformation of antigorite without dehydration.

Seismic attenuation measurement by cyclic loading under high pressure and temperature

YOSHINO, Takashi[1*] ; YAMAZAKI, Daisuke[1] ; HIGO, Yuji[2] ; FUNAKOSHI, Ken-ichi[3]

[1]Institute for Study of the Earth's Interior, Okayama Univ., [2]JASRI, [3]CROSS

The estimation of the mantle structure using seismic tomography method has been advanced by understanding of the detailed velocity structure of the Earth interior . On the other hand , Brillouin scattering in the DAC at very high pressure, X-rays inelastic scattering, sound velocity measurement of ultrasonic range in the large press is also improved. These developments can be expected this time as a further declaration of a picture of a more detailed Earth interior. However, as compared to the frequency band of MHz to GHz region, the frequency range of the seismic waves propagating through the earth interior is much lower. We should noted that it is greatly affected by the attenuation of seismic waves. Because the materials are not in a perfectly elastic body, energy loss inside the materials occurs in the wave propagation because of presence of grain boundaries, dislocations, and defects. Thus, seismic attenuation occurs as a function of frequency.

The attenuation of seismic waves (the determination of the Q-1) of mantle material under high pressure has not been reported until recently mostly because it is an experimental quantification is very difficult . Temperature effects and particle size effects were reported for the first time systematically for olivine aggregates at high temperature under low pressure. However, for this system the upper limit of the generated pressure is low because it is a torsion test performed in the gas pressure. So the study of pressure -dependent and high-pressure mineral is difficult . The other group using the D-DIA type press having two differential ram measured $Q^{-}1$ combining an in-situ observation and radiation uniaxial periodic vibration test. This system expands a possibility of experimental determination of Q^{-1} at much higher pressure. In Japan, the DIA type press was installed at SPring8 (D-DIA). Recently we started the measurement of Q^{-1} under high pressure using in situ image acquisition of the high time and spacial resolution at short period of oscillation cycle.

In this paper, some experimental developments for measuring seismic attenuation at high pressure and results of cyclic loading tests are introduced. Time resolved images of the sample and reference material obtained by a synchrotron X-ray radiography provide their strain as a function of time during cyclic loading. Attenuation is determined as the tangent of the angle of phase lag between the strain of the sample and the strain of the reference material. A newly installed short period sinusoidal cyclic loading oil pressure system enable us to determine minimal strain of the sample in a wide frequency range from 2 to 0.01 hertz on olivine aggregates at 1 GPa and up to 1673 K. The detectable minimum strain is around 5×10^{-5}. Several test experiments exhibited resolvable Q^{-1} (10^{-2}) above 1273 K. The results are generally consistent with previously reported data.

Viscoelastic property of antigorite

YAMAZAKI, Daisuke[1*]

[1]Okayama University

Seismological data reveals the structure and dynamics combined with mineral physics. For example, the velocity structures from observations are interpreted using the elastic properties of constituting minerals obtained from the laboratory measurements. Because the minerals in the earth is not perfect single-crystal but they contain a certain amount of defects (vacancy, dislocation, grain boundary), the viscoelastic relaxation is taken place by the viscous motion of the defects during the propagating the seismic waves with the frequency of 10^{-4}-10 Hz. Serpentinite can be considered to be one of the candidate for the source of the fluid in the wedge mantle. In the present study, therefore, we examine the viscoelastic property of serpentine (antigorite) under uppermost mantle conditions by means of high pressure experiments.

Fine-grained polycrystalline antigorite (a few micrometer of grain size) sintered at 3 GPa and 550 degree C for 4 hours was used as a starting material for the attenuation experiment. We conducted the experiments by using D-DIA press with a short-period cyclic loading system, which was recently installed at BL04B1, SPring-8, Japan. D-DIA, which is a single stage of six-anvil compression device, applied pressure by forcing each of the six anvils to advance on the cubic pressure medium with a main ram. After pressure reaching to the target value of 1 GPa by the pumping the main ram, a sinusoidal stress and strain was applied by advancing and withdrawing the upper and lower anvils operated by the short-period cyclic loading system with the frequency between 0.01-2 Hz at 1 GPa and 500-750 degree C. At high temperature (>˜650 degree C), dehydration is expected. The strain was monitored directly from X-ray radiography of sample located in the pressure medium through the anvil gap during cyclic loading. In the present study, single crystal of forsterite was placed next to the sample along the stress axis of the sample and it can be used as the standard to estimate the stress by recording the X-ray radiography images displaying the lengths of standard and sample simultaneously.

The time lag of strain of sample against that of standard provided us the quality factor, Q, to be 5.4, 4.8 and 4.4 for the periods of 5, 10 and 20 s, respectively, at 600 degree C. Present preliminary results shows the temperature dependence of Q-1. At 500 degree C, Q^{-1}s are ˜0.5 log unit lower than those at 600 degree C. The present values is ˜2 order of magnitude lower than that of olivine aggregates. The shear modulus was estimated to be 15-25 GPa in our experimental condition, which is much smaller than the shear modulus without attenuation (38.5 GPa). The large reduction in shear modulus due to attenuation was previously reported in the case of olivine.

Experimental study of anelasticity of a polycrystalline material near the melting temperature

YAMAUCHI, Hatsuki[1*] ; TAKEI, Yasuko[1]

[1]Earthquake Research Institute, University of Tokyo

Rock anelasticity is important to interpret seismic wave velocity and attenuation structures in the upper mantle. By using organic polycrystalline borneol ($C_{10}H_{18}O$, melting temperature =204.5 ℃) as an analog to mantle rock, McCarthy et al.(2011) measured Young's modulus and attenuation Q^{-1} as functions of frequency f (=10^{-4} - 2 Hz), temperature T (20-50 ℃) and grain size d (3.3 - 22 micrometer). They also measured viscosity, and calculated the Maxwell frequency fm. When the obtained Q^{-1} spectra were plotted as functions of the frequency normalized by the Maxwell frequency fm, all Q^{-1} spectra obtained for various temperatures and grain sizes collapsed onto a nearly single curve. Moreover, data from olivine aggregates (Gribb and Cooper, 1998; Tan et al. 2001; Jackson et al. 2002) collapsed onto the same master curve as borneol, demonstrating the universality of anelastic behavior. However, experimental frequencies normalized by the Maxwell frequency of the samples were lower than $5*10^4$, which is considerablly lower than those of seismic waves in the upper mantle (f/fm= 10^6-10^9). Therefore, whether the Maxwell frequency scaling is applicable to the seismic waves or not is an open question.

Takei et al. (in preparation) measured anelasticity of organic polycrystalline borneol at lower temperatures (0-20 ℃) and higher frequencies (10^{-4}-50 Hz) than McCarthy et al. (2011). They also investigated the effect of chemical composition on anelasticity, by using the samples made of high-purity borneol and borneol + diphenylamine ($(C_6H_5)_2NH$) (eutectic temperature = 43 ℃). Before obtaining these data, our experimental methodology and data quality were much improved. When the obtained Q^{-1} spectra were plotted as functions of the frequency normalized by the Maxwell frequency, the Q^{-1} spectra collapsed onto a nearly single curve at f/fm $<10^4$, but significantly scattered at f/fm $>10^4$, where the spectra have a broad peak and the scattering is caused by the variation of the peak amplitude and width with temperature, grain size and chemical composition. Therefore, the simple Maxwell frequency scaling is not applicable to the seismic waves in the upper mantle. They found that seismic attenuation predicted from the data of high purity samples and those of the borneol + diphenylamine samples under low temperature conditions is too low to explain the seismic attenuation in the upper mantle (~ 0.01). In other words, enhancement of attenuation near the melting temperature is important to understand high Q^{-1} in the upper mantle.

In this study, we measured anelasticity of borneol + diphenylamine system at various frequencies ($2*10^{-4}$ -50 Hz) and temperatures (20 - 46 ℃), and obtained the detailed behavior of anelasticity near the melting temperature (43 ℃). The result obtained so far show that the change of viscosity and anelasticity near the melting temperature is not discrete but continuous. This result is somewhat different from our previous understanding that physical properties abruptly change when melting starts beyond the solidus. We will further obtain systematic data for various grain sizes and melt fractions.

Experimental study of bulk and shear viscosities of partially molten rock analogue

SUZUKI, Ayako[1*] ; TAKEI, Yasuko[1] ; WATANABE, Shun-ichi[2]

[1]Earthquake Research Institute, University of Tokyo, [2]Hydrographic & Oceanographic Dept, Japan Coast Guard

Deformation of partially molten rock is controlled by two independent viscosities: shear viscosity for shear deformation and bulk viscosity for compaction/decompaction. Bulk viscosity and its ratio to shear viscosity, h_b/h_s , play an important role in melt segregation dynamics in the upper mantle (Katz, 2008). However, that value has not been well constrained theoretically nor experimentally especially at small melt fractions. Most numerical studies have used the theoretically predicted value of h_b/h_s = ~f^{-1}, where f is the melt fraction. Takei and Holtzman (2009a) theoretically obtained a constant value of h_b/h_s by taking into account a diffusion creep mechanism. The discrepancy between two models is significant at small melt fractions. There has not been experimentally determined value of h_b/h_s because very few experimental studies have been done about bulk viscosity although shear viscosity has been measured extensively. To discuss the validity of these models based on the experimental data, it is highly important to measure both bulk and shear viscosities by using the equivalent samples. In this study, we measured experimentally these two viscosities as functions of melt fraction using a partially molten rock analogue.

Samples were polycrystalline aggregates of borneol-diphenylamine binary with eutectic temperature of 316K, which has a quite similar equilibrium microstructure to olivine + basalt system (Takei, 2000). Initial melt fraction can be controlled precisely by the concentration of diphenylamine because of its simple eutectic reaction. Before deformation experiments, samples were annealed at 320K for ~100 hours in a sealed capsule to make those grain size large enough (~0.030 mm), resulted in negligible grain growth during the successive deformation tests at the same temperature.

To measure bulk and shear viscosities, we carried out two separate experiments. For bulk viscosity, compaction experiments were performed under the diffusion creep regime. A cylindrical sample was compacted uniaxially in a rigid sleeve (e_{zz} <0, e_{xx} = e_{yy} = 0, where e is the strain). Melt was squeezed out from the partially molten sample into porous metals which contact with the sample at the top and bottom ends until melt fraction becomes nearly zero. Evolution of melt fraction in the sample was calculated from the sample length measured with digital gauge. Apparent viscosities as a function of melt fraction were proportional to exp(-af) with a = ~30 at f >4 %, which is quite consistent with the olivine + melt systems (Renner et al., 2003). At f <3 %, deviation of the viscosity from the exponential curve occurs, suggesting the possible effects of permeability and change of rate limiting process of the volumetric creep (Takei & Holtzman, 2009b). For shear viscosity, uniaxial deformation experiments were performed without a horizontal confining pressure (s_{zz} <0, s_{xx} = s_{yy} = 0, where s is the stress). Melt fraction was nearly constant during the test. Deformation tests were conducted with some constant load steps under the diffusion creep regime. Apparent viscosity is evaluated from the stress and the strain rate at steady state.

From the two apparent viscosities obtained independently, we can calculate each bulk and shear viscosities as functions of melt fraction. We will test the predictions of models and discuss the possible viscosity ratio of the partially molten rocks in the upper mantle.

Role of Mg-O grain-boundary diffusion in rheology and grain-growth in the Earth's mantle

NISHIHARA, Yu[1*] ; NISHI, Masayuki[1] ; MARUYAMA, Genta[2]

[1]Geodynamics Research Center, Ehime University, [2]Earthquake Research Institute, University of Tokyo

Material and heat transports in the Earth highly depends on rheology and grain-growth kinetics of the constituent materials. Although rheology and grain-growth in single phase aggregate have been studied extensively, knowledge of those in multi-phase system is still limited. Sundberg and Cooper (2008) pointed out the importance of a creep mechanism in which strain is produced by Mg-O grain-boundary diffusion accompanied with reaction at olivine-orthopyroxene phase boundary in the Earth's upper mantle. Tasaka and Hiraga (2013) showed that grain-growth in forsterite-enstatite two-phase system is rate-limited by growth of secondary phase through Mg-O grain-boundary diffusion. These reports suggest that Mg-O grain-boundary diffusion plays important role both in rheology and grain-growth. Recently, our group reported Mg-O grain-boundary diffusion coefficients in forsterite and $MgSiO_3$ perovskite (Maruyama et al., 2013; Nishi et al., 2013). In this study, theoretical model using our Mg-O grain-boundary diffusion data are compared with available rheological and grain-growth data, and importance of these mechanisms are discussed.

Flow-law were calculated for Mg-O grain-boundary diffusion creeps accompanied by reaction at forsterite-enstatite phase boundary (upper mantle) or accompanied by grain-growth of periclase (lower mantle) using Coble's (1963) equation and results by Maruyama et al. (2013) and Nishi et al. (2013). The derived flow-law for the upper mantle shows ˜3 orders of magnitude faster strain-rate than that of creep experiments by Tasaka et al. (2013) which suggests this mechanism is not realistic. Although no comparable creep data was reported for the lower mantle, the derived flow-law shows faster strain-rate than that by Si lattice diffusion creep that was assumed in Xu et al. (2011) and the mechanism is a possible candidate deformation mechanism in the most part of lower mantle.

Grain-growth in the forsterite-enstatite two phase system was studied by Tasaka and Hiraga (2013) experimentally and it is already shown that grain-growth in this system is rate-limited by growth of secondary phase through Mg-O grain-boundary diffusion. Based on the same manner as Tasaka and Hiraga (2013), grain-growth law was calculated for the lower mantle assemblage $MgSiO_3$ perovskite-periclase system using Ardell's (1972) theory and Nishi et al.'s (2013) results. Derived grain-growth law was generally consistent with the grain-growth data in $MgSiO_3$ + MgO system reported by Yamazaki et al. (1996). Yamazaki et al.'s results can be explained by initial rapid growth from metastable texture and subsequent normal grain-growth which is rate-limited by Mg-O grain-boundary diffusion. Based on this interpretation, grain-size in the lower mantle is estimated to reach several hundred micro meter by 10^6 years.

Relationship between Skempton's coefficient and diagenesis of the Quaternary Kazusa Group siltstones

MITSUHASHI, Shunsuke[1*] ; UEHARA, Shin-ichi[1] ; MARUMO, Haruna[2] ; TAMURA, Yukie[1]

[1]Faculty of Science, Toho University, [2]Graduate School of Science, Toho University

Skempton's coefficient B is one of fundamental properties of sediments and rocks. B is defined as the change in pore pressure per unit change in total stress applied under undrained conditions. To reveal the evolution of B of sediments and sedimentary rocks during diagenesis is critical for some processes relating to geophysics and geology, such as mechanisms of developing abnormal pore pressure in sedimentary basins (Tanikawa et al., 2008). However, how B depends on diagenesis is still not clear. To understand the dependency, we evaluated B based on porosity measurements under effective stress for siltstones collected from various formations in the Quaternary Kazusa Group. We also tried to measure B directly, and compared the results with B values obtained from measurements of porosity.

We used siltstones of Umegase, Otadai, Kiwada, Ohara and Katsuura Formations of the Kazusa Group as the samples for the experiments. The specimens from the samples were 30 mm in diameter and 40 mm in length. The laboratory experiments were performed using an intra-vessel deformation fluid-flow apparatus at Toho University, at room temperature and under confining pressures from 2 MPa to 35 MPa. Distilled water was used for pore fluid. From the results of the porosity measurements under effective pressure, we estimated the compressibilites of the rock on the assumption that volume change of the rock at effective stress change equals to the pore volume change, and calculated B from the results. In the direct measurements of B, we measured pore pressure changes when confining pressure were applied under undrained conditions.

The results of B estimations from porosity measurements indicated that B tends to decrease with increasing burial depth. But, B of Ohara siltstones was somewhat higher than other samples despite Ohara Formation is relatively lower in the Kazusa Group. This is probably because siltstones at Ohara Formation were not consolidated enough as compared with those at other formations due to some reasons such as developing abnormal pore pressure. Results indicated that the dependency of B on effective pressure is not simple. B was not simply decreased with effective pressure increases, but B was increased at some range of effective pressure, which mostly reflected that the compressibility was increased at the transition from overconsolidation to normal consolidation state. B depends on both compressibility and porosity, and in the case of the Kazusa Group siltstones, the behavior of compressibility has greater effect on B. Thus, B is decreased as a grade of diagenesis increases because compressibility is decreased. The values of B measured directly tended to be higher than B estimated from measurements of porosity. This is probably because a period between step changes of effective stress was not enough for the rocks to reach steady state.

Effects of pore pressure changes on frictional behaviors of talc

UEHARA, Shin-ichi[1*] ; OKAZAKI, Keishi[2] ; SHIMIZU, Ichiko[3]

[1]Faculty of Science, Toho University, [2]Department of Geological Science, Brown University, [3]Faculty of Science, The University of Tokyo

Since the discovery of low frequency earthquake, several classes of physical mechanisms have been proposed to explain this events. Several models and geophysical observations have suggested that the overpressurized fluid along the subducting plate interface have an important role in triggering such events. In addition, the existence of hydrous minerals along the plate boundary at fore-arc wedge may also be important for the seismogenic properties of the slab-mantle interface. Especially, serpentine minerals are generally expected to be the main hydrous mineral present in the fore-arc minerals, and the existence of serpentine in the wedge mantle has suggested by seismological studies. However, talc may also be important in fault mechanism at the plate boundary in the fore-arc wedge mantle, because slab-derived fluids are likely to lead replacement of serpentine by talc at the slab-mantle interface in the fore-arc wedge mantle, and talc is one of the weakest minerals that constitute natural fault zones. However the quantitative influences of pore pressure on the frictional properties of talc are not well constrained. We conducted friction experiments using pre-cut samples of talc with controlling pore pressure P_p and confining pressure P_c adopting several kinds of stress paths during an experiment.

Cylindrical samples of talc (Gvangjsih, China), 20 mm in diameter, were cut at an angle of 30^o to the sample axis. The sliding surfaces were ground with carborundum (#400). A small hole (3 mm in diameter) through the center of each piece ensured adequate communication of the water between the precut surfaces with the rest of the pore pressure system. The specimen was loaded by a triaxial apparatus and sheared under an axial displacement rate of 1 μm/s. We used water as a pore fluid. All measurements were performed at room temperature. Experiments were conducted under several paths of P_c (up to 110 MPa) and P_p (up to 100 MPa). During steady axial loading, either P_c or P_p was changed stepwise.

The stepwise changes of effective normal stress σ (= σ_t - P_p, where σ_t is total normal stress) resulted in a linear elastic response of shear stress followed by a transient evolution of friction. In the case that σ was decreased, friction coefficient μ was temporally increased and then decreased back to steady state, and the normalized transient change of μ to the logarithm of normalized amplitude of σ change ranged from 0.2 to 0.28, which is comparable to that for quartz and Westerly granite reported by previous studies (Linker and Dieterich, *J. Geophys. Res.*, 1992; Hong and Marone, *Geochem. Geophys. Geosyst.*, 2005). While in the case that σ was increased (μ was temporally decreased then increased), the values were smaller (less than 0.12, and negative in some cases), which means that a transient change of μ was less dependent on a change of σ than that for quartz and granite, which may reflect ductile deformation of contacts on fault surfaces during the evolutional transition.

This frictional property might cause slow slip phenomena. After an initiation of a fault slip, possibly triggered by an increase of pore pressure, partially undrained conditions on the slip surface may cause dilatancy hardening, and therefore σ may be increased during the slip. The results of this study suggest that, in the case that a fault plane is covered by talc, the temporal decrease of μ following an increase of σ might be smaller than the case that fault planes are covered by other ordinary minerals. Consequently, a frictional resistance might act more effectively than faults covered by other ordinary minerals and an acceleration of fault slip rate might be mitigated, and therefore a slip rate might be smaller than regular earthquakes.

This research is supported by Grant-in-Aid for Scientific Research on Innovative Areas, KAKENHI.

Sintering experiments on fine-grained polycrystalline orthoclase

OHIRA, Akane[1*] ; ISHIKAWA, Masahiro[1]

[1]Graduate school of Environment and Information Sciences, Yokohama National University

K-feldspar is one of the major mineral components of granitic rocks and a wide variety of metamorphic rocks. Its deformational behavior is important for establishing the overall rheology of continental crust. The creep strength is influenced by various factors such as mineral species, grain size and pores. Therefore control of these factors in polycrystalline minerals is essential for rheological experiments. In order to make dense polycrystalline orthoclase, we have carried out sintering experiments.

We prepared submicron mineral powders from a single crystal of orthoclase ($K_{0.83}Na_{0.17}Al_{1.04}Si_{2.96}O_8$). As a result of X-ray fluorescence (XRF) analysis, ZrO2 (<5.65wt.%) which is considered to be contamination from a mill was detected. We formed cylindrical compacts from fine-grained mineral powders by uniaxial dry pressing at room temperature and pressure of 20MPa. Sintering was carried out using a tube furnace at temperature of 970 ℃ for 4 hours, achieving a vacuum condition of $\sim 4.1 \times 10$Pa. We also compared the sintered body with a sample sintered at atmospheric pressure using muffle furnace at the same temperature and the time. Sintered bodies were observed using scanning electron microscope (SEM), and analyzed by XRF and X-ray diffraction (XRD).

As the result of vacuum and atmospheric pressure sintering, we obtained sintered bodies with volume reduction of 52.2% and 44.5%, and porosity of 0.15 and 0.17, respectively. SEM images showed that densification process was advanced by both vacuum and atmospheric pressure sintering. We confirmed that crystal structures (Al/Si order-disorder) were not changed from compacts by XRD patterns.

In this study, we found that dense submicron polycrystalline orthoclase can be made from fine-grained powders by either of vacuum and atmospheric pressure sintering, and confirmed that orthoclase does not cause order-disorder phase transition by a sintering for 4 hours.

Doping effect on high-temperature creep of polycrystalline anorthite

YABE, Kosuke[1*] ; KOIZUMI, Sanae[1] ; HIRAGA, Takehiko[1]

[1]Earthquake Research Institute, The University of Tokyo

Rheological properties of lower crust are considered to play important roles on the cause of inland earthquakes. Previous studies on creep properties of polycrystalline anorthite indicate that the polycrystalline anorthite will deform under diffusion creep at temperature condition of 400 to 1000C and grain size of <100 um where such conditions are identified in mylonites which are of lower crust origin. Therefore, it is important to know a precise strength of polycrystalline anorthite during diffusion creep.

Previous studies have shown the influence of grain size, temperature, stress, and water content on the strength of polycrystalline anorthite. It is well known that a small amount of impurities segregated at grain boundaries has a significant effect on the strength of polycrystalline oxides. We have shown that our pure anorthite aggregate, which was synthesized using the technique that could minimize the contamination of impurities, had two orders of magnitude larger strength than anorthite aggregates used in previous studies. In this study, we examine the effect of doping a small amount of MgO on high-temperature creep of anorthite aggregates.

MgO-doped anorthite aggregates were fabricated from nano-sized powders of $CaCO_3$, Al_2O_3, SiO_2 ,and $Mg(OH)_2$, all of which have <50 nm in diameter, and vacuum sintering of the powders. We controlled the amount of $Mg(OH)_2$ powders to obtain anorthite doped with 1wt% of MgO. Constant load tests were performed at temperatures ranging from 1150 to 1380C, stresses from 10 to 120 MPa, and confining pressure of 0.1 MPa. We measured Arithmetic mean grain size of specimens by microstructural observations using scanning electron microscopy (SEM) before and after creep tests.

Grain sizes of the specimens were 1˜2um before and after the creep test. Log stress versus log strain rate showed a linear relationship where its slope gave a stress exponent, n of 1, indicating that samples were deformed under diffusion creep. MgO-doped anorhite aggregates exhibited more than one order of magnitude weaker than pure anorthite. We obtained activation energy, Q of 702 kJ/mol which was higher than that of our pure anorthite. The difference in strength between pure and MgO-doped anorthite was attributed to the presence of a small amount of MgO which was probably segregated at grain boundaries.

Synthesis of textural polycrystalline forsterite using colloidal processing in a strong magnetic field.

KOIZUMI, Sanae[1*] ; HIRAGA, Takehiko[1] ; SUZUKI S., Tohru[2] ; SAKKA, Yoshio[2]

[1]Earthquake Research Institute, University of Tokyo, [2]National Institute for Material Science

It is well known that the crystallographic preferred orientation (CPO) of minerals is commonly produced in the Earth's interior. Thus, it is important to understand the physical properties of the mineral aggregates that exhibit CPO. However, silicate minerals are often feeble magnetic and have small anisotropic susceptibilities so that it is difficult to apply a magnetic field effectively to rotate the mineral particles. Tendency of finer particles to spontaneously agglomerate due to strong attractive interactions (van der Waals forces) add further difficulty. We used a technique of slip casting in a high magnetic field (12T) to align certain crystallographic axis of mineral particles. For the particles to rotate easily in the solvent under a strong magnetic field, we improve the method of deflocculating. To control the surface potential of the particles, we applied various types of polymer modification. Vacuum sintering of the powders that were composed of the aligned particles was expected to produce a polycrystalline material aggregate that exhibits CPO. The resultant materials were characterized by X-ray powder diffraction (XRD), secondary electron microscope (SEM) and Electron Backscatter Diffraction (EBSD).

The specimen exposed to a strong magnetic field exhibits preferential A-axis alignment to the magnetic direction. Those synthetic specimens allow us to examine the effect of CPO on the physical properties of the earth's materials in future room experiments.

Grain growth experiment on pyrolite materialunder lower mantle conditions

IMAMURA, Masahiro[1*] ; KUBO, Tomoaki[1] ; KATO, Takumi[1]

[1]Kyushu Univ.

Grain size is a key parameter for understanding viscosity of Earth's mantle. Grain growth rate is one of important factors controlling the grain size. Especially, it is indispensable to examine grain growth kinetics in multiple phases because the grain growth rate of major phase drastically changes with the proportion of secondary phases (e.g., Hiraga et al., 2010). In the lower mantle, Mg-perovskite is major phase, and ferro-periclase, Ca-perovskite, and majoritic garnet are present as secondary phases (e.g., Irifune, 1994; Nishiyama and Yagi, 2003). The previous grain growth experiment (Yamazaki et al., 1996) in the two-phase system of $MgSiO_3$ perovskite and MgO periclase using Mg_2SiO_4 forsterite as a starting material suggests that the grain growth rate is too slow to explain the lower mantle viscosity constrained by geophysical observations. This inconsistency may arise from effects of the eutectoid transformation prior to the grain growth process (e.g., Solomatov et al., 2002). It is also necessary to examine effects of the chemical composition that affects the proportion of secondary phases and diffusivity. Here, we report preliminary results of the grain growth experiment on pyrolite material under lower mantle conditions.

High-pressure and temperature experiments were conducted using a Kawai-type multi-anvil apparatus (QDES) installed at Kyushu University. Starting material is a powder with pyrolite composition that was used in the previous phase equilibrium study (e.g., Irifune, 1994). We conducted annealing experiments at 25-28 GPa and 1600-1800 ℃ for 6-600 min. Chemical compositions, microstructures and grain sizes of recovered samples were examined using a FE-SEM with an energy-dispersive analytical system.

Four phases of Mg-perovskite, Ca-perovskite, ferro-periclase and majoritic garnet were present in recovered samples annealed at 25 GPa and 1600-1800 ℃. The normalized grain size distribution in the recovered samples showed Gaussian-like shape and the largest grain size is smaller than three times of the mean grain size, suggesting that normal grain growth occurred. The grain growth rate is faster than that of the previous study (Yamazaki et al., 1996). Preliminary analysis of the kinetic data of Mg-perovskite obtained showed the smaller grain growth exponent of 4.3 than that reported in the previous study. On the other hand, three phases of Mg-perovskite, Ca-perovskite and ferro-periclase were present at higher pressure of 28 GPa and 1800 ℃, in which the volume fraction of Mg-perovskite increased compared to the four-phases experiment. While the microstructure and the grain size distribution in the three-phase assemblage was similar to those of the four-phase assemblage, the grain size was larger probably due to the smaller proportion of the secondary phases. Our preliminary results provide some insights into the grain-size evolution in the lower mantle and suggest that further quantitative grain growth data with possible lower mantle conditions are needed.

Grain boundary diffusion of noble metal elements in mantle composites

MATSUO, Naoya[1*] ; HIRAGA, Takehiko[1]

[1]Eartuquake Research Institute, The University of Tokyo

So far, it is not clear whether Earth's core and mantle have been chemically isolated through geological time. It has been believed that highly incompatible elements such as siderophile elements in the mantle minerals have not been moved from the core to the mantles so that the elemental abundance of highly siderophile elements (HSEs) in the core and mantle were determined when both were separated. Although HSEs are refractory, amounts of HSEs are very little in the mantle (Wood, 2006) so that these elements are expected to be highly concentrated in the core relative to the silicate mantle. However, a recent study has shown that incompatible elements can be concentrated and quickly diffuse at grain boundaries (Hiraga et al., 2004). If HSEs can diffuse from the core to the mantle, the concentration of HSEs in the mantle can change through Earth's history. Therefore, HSEs can be a good tracer to detect the chemical interaction of the core and the mantle.

We conducted grain growth experiments on Au particles in forsterite (Fo) aggregates at 1 atmosphere pressure and temperature of 1360 ℃. We prepared several sintered bodies which were made by dispersing 10vol% Au particles in Fo aggregates and then annealed for several hours. We observed these bodies using a scanning electronic microscope. In the result, Au particles changed their shape from spherical to polygonal. This is due to a balance of interfacial tensions between Au and Fo phases. Further, average grain size of Au particles was found to increase with time. Based on these observations, we conclude that Ostwald ripening of grains, by which Au atoms move from small particles to larger ones to minimize entire interfacial energies of the system, occurred in our experiment. Grain boundaries as diffusion paths should be responsible for Au diffusion. In this case, grain growth of Au particles will follow the relationship of $d^4-d_0^4=kt$, where d is the average grain size of Au particles after annealing, d_0 is the initial average grain size, k is the grain growth coefficient, and t is annealing time. Using the average grain size of each body, we calculated k. In addition, we estimated the interfacial energy of the system from the shape of Au particles and calculated the product of concentration of Au particles at grain boundaries, c, and diffusivity of Au atoms at grain boundaries, D.

The effect of partial melting on the mantle viscosity and electrical

SUEYOSHI, Kenta[1*] ; HIRAGA, Takehiko[1]

[1]Earthquake Research Institute, University of Tokyo

In this study, in order to know the change in mantle viscosity and electrical conductivity during partial melting, which corresponds to decompression melting of ascending mantle beneath mid-ocean ridge, mantle analogue sample was synthesized and used to measure its viscosity and electrical conductivity under atmospheric pressure and high temperature conditions. The sample has lherzolite composition of olivine (50%), orthopyroxene(40%) and clinopyroxene(10%) with addition of 0.5 vol% spinel. Constant force was applied to the sample under increasing the temperature where its range includes sample solidus. Sample viscosity and the electrical conductivity by the impedance measurement were calculated for every temperature. We particularly examined how viscosity and conductivity change when the sample transforms from melt-free to melt-bearing system. Temperature ranged from 1100 to 1390 ℃, which resulted in the change of melt fraction (ϕ) from 0 to 0.09, where the melt composition becomes enriched in clinopyroxene component as the temperature increases.

We observed a continuous and gradual reduction of sample viscosity with increasing temperature. The effect of the increasing melt fraction on the sample viscosity should have been added to the viscosity change simply due to thermally activation process. There is a linear relationship between measured 1/T and $\log(1/\eta)$,which goes well with the previous proposed empirical expression of flow law that, which is an function of melt fraction.

Analyzing the observed viscosity change with temperature with this law, the apparent activation energy of 970 kJ/mol is obtained at a temperature range of 1220 ℃ to 1340 ℃ and the effect of increasing melt fraction on sample viscosity roughly corresponds to the activation energy of ˜+35 kJ/mol. The activation energy on the melt ?free system is estimated to be 935 kJ/mol. This value is close to the activation energy of the dislocation creep of orthopyroxene and clinopyroxene indicating that the sample viscosity was essentially controlled by deformation of pyroxenes.

Electrical conductivity did not change dramatically when the experimental temperature reached and exceeded the sample solidus. Grain size dependency on the conductivity was observed at all temperature conditions indicating that the conductivity is simply determined by grain boundary conductivity even at higher melt fraction condition, probably due to fine grain size of the samples. Compared with previously reported grain boundary conductivity in the melt-fee forsterite system, grain boundaries in our sample have 3 to 4 times higher conductivity indicating that the pyroxene grain boundaries have a large effect on the bulk sample conductivity in our experiment.

In this study, it was demonstrated that previously proposed empirical flow law as a function of melt fraction can approximate the viscosity change of the mantle during its transition from melt-free to melt-bearing Taking into account of the incremental rate of melt fraction with temperature and the connectivity of intergranular melt in the mantle highly depend on the volume fraction of the pyroxenes and spinel phases, mineral mode in the mantle should have substantial effects on the mantle rheology and electrical conductivity during mantle melting.

Stress calibration of Griggs-type deformation apparatus with solid salt assemblies

KIDO, Masanori[1*] ; MUTO, Jun[1] ; NAGAHAMA, Hiroyuki[1]

[1]Department of Earth Sciences, Tohoku University

Mechanical properties of rocks and minerals can be quantitatively studied by deformation experiments under high-temperature and high-pressure conditions relevant to the Earth's interior. There are several types of deformation apparatus using different confining media such as gases, liquids or weak solids (e.g., Tullis and Tullis, 1986). Liquid medium apparatus have the disadvantage that they cannot be used for temperatures above 500 ℃ because of prevention from alteration of oil at high temperature. Solid medium apparatus can provide us high pressure safely and stably for a long time. However, stress accuracy is not high due to frictional forces between pressure medium and load piston or samples (e.g., Tullis and Tullis, 1986). Gas apparatus has most accurate stress measurement because of the usage of internal load cell; thus measured stresses do not include frictional forces. However, experiments are restricted to confining pressures less than 200 MPa in Japan due to safety issues on the usage of high-pressure gas. Therefore, solid medium apparatus is necessary for generating high temperature and high pressure required to investigate rheological behaviors of rocks and minerals in lower crust or uppermost mantle.

Recently, comparisons of mechanical results obtained for metals at the same confining pressure, temperatures and strain rates deformed in a Griggs apparatus with solid salt assemblies (SSA) and a gas apparatus provide calibration for Griggs apparatus with SSA (Holyoke and Kronenberg, 2010). This calibration law allowed differential stresses to be measured accurately to within $\pm$30 MPa. However, we have not been able to reproduce elastic, yielding and post-yield behaviors because the calibration law was obtained by the comparison of strengths at 5% strain of mechanical results. Calibration law for measured stresses using Griggs apparatus in all deformation behaviors are required for revealing detailed rheological behavior of rocks and minerals.

In this study, we performed axial compression experiments on high-purity nickels to measure differential stresses using a Griggs apparatus with SSA at Tohoku University. Samples were given by Drs. Holyoke and Kronenberg. Experimental conditions were confining pressures of 300 and 1200 MPa, temperatures of 600, 700, and 800 ℃ and strain rates of 2×10^{-4}, 2×10^{-5} and 2×10^{-6} /s. Measured differential stresses agreed with results of the former study within $\pm$30 MPa under the identical confining pressure of 300 MPa. However, differential stresses were larger with confining pressure. We analyzed obtained mechanical data of nickels based on the high temperature viscoelastic constitutive law developed by Shimamoto (1987). We made the master curve which normalized temperature and strain conditions. In the same way, we also made the master curve from mechanical data of nickels using a gas apparatus (mechanical data are from Holyoke and Kronenberg, 2010). Master curves were made of mechanical data of the identical material between Griggs apparatus and gas apparatus under normalized temperature and strain conditions. Therefore, difference in master curves is thought to be derived from apparatus and assembly. We derived calibration law for Griggs apparatus from difference in master curves. Applying this calibration law to differential stresses of nickels obtained using Griggs apparatus with SSA, it became possible to reproduce gas apparatus's differential stresses not only steady state but also elastic, yield and post-yield behaviors within the systematic error of $\pm$30 MPa. However, the error was $\pm$70 MPa when the calibration law was applied to the mechanical data of carbonate rock. Moreover, unlike gas apparatus, measured differential stresses using Griggs apparatus tend to become larger with confining pressures. Therefore, it is necessary to investigate the effect of confining pressures on measured stresses in the calibration law.

Preliminary experiments on in-situ stress-strain measurements of Ca-Pv and Mg-Pv up to 23 GPa

TSUJINO, Noriyoshi[1*] ; YAMAZAKI, Daisuke[1] ; YOSHINO, Takashi[1] ; SAKURAI, Moe[2] ; NISHIHARA, Yu[3] ; HIGO, Yuji[4]

[1]ISEI, Okayama Univ., [2]Tokyo tech., [3]GRC, Ehime Univ., [4]JASRI

In order to discuss mantle dynamics in the Earth's interior, knowledge of viscosity of the Earth's lower mantle, which is the highest of the whole mantle, is important. Viscosity models of the Earth's lower mantle were reported by geophysical observations. However, observation values of viscosity have large variety (2˜3 order magnitude). Although determination of viscosity of lower mantle minerals by high pressure experiments is needed to understand mantle dynamics, stress-strain relationship for $MgSiO_3$-perovskite (Mg-Pv) and $CaSiO_3$-perovskite (Ca-Pv), which are principal minerals of the Earth's lower mantle, are not reported due to difficulty of high pressure deformation experiments. In this study, we tried in-situ stress-strain measurements of Ca-Pv and Mg-Pv up to 23.0 GPa.

In-situ uniaxial deformation experiments were conducted using a deformation DIA apparatus (SPEED-Mk.II) as Kawai-type apparatus at SPring-8 BL04B1. Experimental conditions of Ca-Pv and Mg-Pv are 13.8 GPa, 1473 K and 23.0 GPa, 1273 K, respectively. cBN anvils, which was transparent material against X-ray, was used along X-ray path. Two-dimensional X-ray diffraction patterns were taken for 120-180 s using CCD detector. To calculate the stress magnitude from the X-ray diffraction data, we used a model of stress-lattice strain relationship (Singh et al. 1998),

$d_{hkl}(\psi) = d_{0hkl}\,[1+(1-3\cos^2\psi)\,\sigma/6\,G_{hkl}]$ (1)

where d_{hkl} is the d-spacing measured as a function of azimuth angle ψ, d_{0hkl} is the d-spacing under the hydrostatic pressure, G_{hkl} is the appropriate shear modulus for a given hkl, and σ is the uniaxial stress. Pressure and stress were estimated using Ca-Pv (110) (200) and Au (111) diffraction in Pressure marker (Au : Fo = 1 : 2 volume ratio) at deformation experiments of Ca-Pv and Mg-Pv, respectively. An X-ray radiograph of the strain markers was taken using an imaging system composed of a YAG crystal and a CCD camera with an exposure time of 60 s.

Uniaxial stress of Ca-Pv at 13.8 GPa, 1473 K and ˜1.2×10^{-5} /s and Mg-Pv at 23.0 GPa, 1273 K and ˜1.5×10^{-5} /s were estimated as ˜2GPa and ˜0.25 GPa , respectively. Stress of Mg-Pv was significantly smaller than that of Ca-Pv though temperature condition of Mg-Pv was lower than that of Ca-Pv. This fact is doubtful. This reason is thought that stress estimated by Au was much smaller than that of Mg-Pv because of framework made by Ringeoodite, which was polymorphic phase of Fo in pressure marker.

A new form of the dynamics equation of Maxwellian visco-elastic media

MATSUNO, Taroh[1*]

[1]Japan Agency for Marine-Earth Science and Technology

Dynamical property of the earth's interior down to the core-mantle boundary has so far been considered to be a Maxwellian visco-elastic medium. It behaves as an elastic body for short time-scale phenomena, while on a very long time-scale it shows fluid-like behavior. So the Navier-Stokes equation for viscous fluids is considered to be appropriate for describing mantle convection, and numerical simulations have been made based on the equation.

As a phenomenon for which both elastic body property and viscous fluid property are essential post-glacial uplift has been discussed based on the constitutive equation proposed by Maxwell. However, so far most of studies apply Laplace transform to expressing time evolution, so it is not possible to treat this problem by use of finite difference method, just like general circulation models of atmosphere and oceans. Thus it is not possible to extend numerical simulation of mantle convection to include elastic property of the plate near the earth's surface.

With intention to overcome this difficulty to enable us to conduct numerical simulations of mantle-plate general circulation, a new formulation of dynamics equations for Maxwellian visco-elastic media is attempted in this study

Effects of Al content on water partitioning between Opx and Ol: Implications for lithosphere-asthenosphere boundary

SAKURAI, Moe[1*] ; TSUJINO, Noriyoshi[2] ; SAKUMA, Hiroshi[3] ; KAWAMURA, Katsuyuki[4] ; TAKAHASHI, Eiichi[1]

[1]Earth and Planet. Sci., Tokyo Inst. Tech., [2]ISEI, Okayama, [3]NIMS, [4]Enviromental Sci., Okayama Univ.

Most minerals in the Earth's upper mantle contain small amounts of hydrogen (i.e. "water"), structurally bound as hydroxyl. Water has an important influence on the behavior of rock system. This small amount of water has an important influence on the behaviours of rock systems. A large viscosity contrast of more than two orders of magnitude was detected at depths of 70 km to 100 km beneath ocean and was defined as the lithosphere-asthenosphere boundary [1]. The origin of the lithosphere-asthenosphere boundary remains an enigma. The water distribution in the Earth is critical to the nature of the boundary. For example, Mierdel et al. (2007)[2] indicated that a high water solubility in aluminous orthopyroxene among mantle geotherm in the Earth's upper mantle would effectively contribute to a stiffening of the lithosphere. Therefore, precise knowledge on the distribution of water among mantle minerals is very important for understanding the Earth's dynamics. The Earth's uppermost mantle is composed mainly of olivine (Ol), orthopyroxene (Opx), clinopyroxene (Cpx), spinel, and garnet. In particular, Ol accounts for a large proportion (60 vol.%) of the Earth's uppermost mantle. In addition, Opx, which contains significantly more water than does Ol in the mantle xenolith, is the second phase of the Earth's uppermost mantle. The FeO content in mantle Ol shows very limited variation in range, whereas the Al content of Opx in the Earth's upper mantle decreases significantly with increasing pressure [3] Therefore, the variation of Al content in mantle minerals can be important for the solubility of water in mantle minerals.

To investigate the partitioning coefficient of water between Opx and Ol ($D_{(Opx/Ol)}$) under low-water concentrations (3 ~ 387 wt. ppm) similar to the Earth's mantle conditions, high-pressure experiments have been conducted at pressures of 1.5-6 GPa and a temperature of 1573 K. The experiments were performed with Kawai-type multi-anvil and piston-cylinder apparatus by using starting materials of natural Ol and synthetic Opx with various Al contents. The water contents were obtained with a vacuum type Fourier transform infrared spectrometer (*Jasco*: FT-IR6100, IRT5000). Water content of minerals was calculated based on Paterson's calibration [4]. IR-spectra of Ol and Al-bearing Opx in this study are similar to those obtained by high-pressure experiments [5] and natural rocks [6], respectively. It is believed that broad bands in IR spectra of natural Opx are due to effect of crystal distortion by large Al substitution. On the contrary, IR-spectra of Al-free Opx are not consistent with those reported by Rauch and Keppler (2002) [7] likely because of the large difference of water fugacity. $D_{(Al-freeOpx/Ol)}$ is ~ 1 at all pressure conditions. However, the water contents of Al-bearing Opx are significantly larger than those of Ol at the same conditions. In addition, the effect of Al concentration in Opx on $D_{(Opx/Ol)}$ becomes larger with increasing pressure. The high Al content in Opx significantly increases $D_{(Opx/Ol)}$ and the trend increases with increasing pressure. $D_{(Opx/Ol)}$ drops sharply at the pressure at which the Al concentration of Opx becomes nearly 0 in the Earth's mantle conditions.

These results imply that viscosity of the upper mantle decreases sharply at depths deeper than those in which orthopyroxene contains no Al. The dramatic change of $D_{(Opx/Ol)}$ may explain the lithosphere-asthenosphere boundary beneath oceans and continents.

Acoustic velocities of MgGeO3 gel at high pressure by Brillouin scattering

KAWADAI, Tomofumi[1*] ; MURAKAMI, Motohiko[1] ; OHTANI, Eiji[1]

[1]Tohoku University

Properties of silicate melts are essential for understanding evolution and dynamic behavior of the Earth and terrestrial planets. In the shallow mantle melting processes the density contrast between melts and crystals is well studied, but studies on the deep melting near the core-mantle boundary are still limited due to technical difficulties. The studies of amorphous material, analogs of melt, at high pressure can provide valuable insights about melts in the deep mantle. The Brillouin scattering method is suitable for velocity measurements of amorphous materials. It has been suggested that the change in coordination in the melt or glass structure reflects to the change in acoustic velocity. Thus we conducted sound velocity measurement using the Brillouin scattering method in diamond anvil cell at high pressure. We report in situ high-pressure acoustic velocity measurements of $MgGeO_3$ gel, an analogue of the $MgSiO_3$ melt, revealing the gradual coordination change of Ge from four- to six at least up to 80 GPa. We will conduct experiments at higher pressure in order to confirm the possible Ge coordination change in the gel expected to exist in the terrestrial and extraterrestrial planets.

Measurement of differential P-wave travel time between two BBOBSs with Correction for crustal reverberation

OBAYASHI, Masayuki[1*] ; YOSHIMITSU, Junko[1] ; ISHIHARA, Yasushi[1] ; SUETSUGU, Daisuke[1]

[1]JAMSTEC

Seismic observations under the ocean are very important to investigate three-dimensional structure of the whole mantle. However, it is difficult to pick up arrival times of P-waves because noise level of broadband ocean bottom seismometer (BBOBS) is in general high in the period range more than 5 sec. Instead of picking arrival times, differential travel times between two BBOBSs have been measured by cross-correlating the waveforms at a period of around 10 sec or more (e.g. Toomey et al. 1998, Tanaka et al., 2009).

The resolution of P-wave tomography become high effectively by taking dispersion of P-wave travel time into account with the finite frequency theory (e.g. Obayashi et al. 2013 JpGU meeting), and its effect is expected to be significant under the ocean where the observations have been sparse. Obayashi et al. (2004) showed dispersion of PP is generated by interference of crustal reverberations under its bounce point. The reverberation under the station also affects a direct P-wave. Especially the effect of the seawater reverberation is significant.

Obayashi et al. (2013) proposed a method of correction for such reverberations to measure differential travel times between any two stations. In this method a waveform is convolved by the response calculated for the crustal structure under the other station.

We applied this method to the BBOBS array at French Polynesia. In the case of the measurement between a BBOBS and a island station, the waveforms of the two stations become similar each other after the correction, suggesting the correction is effective. We report the characteristics of the observed dispersions and the very first result of P-wave tomography using the new observations.

Small shear modulus of cubic CaSiO3 perovskite

KAWAI, Kenji[1*] ; TSUCHIYA, Taku[2]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [2]Geodynamics Research Center, Ehime University

Ca-perovskite (CaPv) is considered to be one of the most abundant minerals in the Earth's lower mantle (LM) and was suggested to have distinctly larger shear modulus than MgPv from static calculations and mean-field theory (Karki and Stixrude 1999; Stixrude et al. 2007). In this study the elasticity of cubic CaPv is reinvestigated using density functional constant-temperature first principles molecular dynamics simulations with strict calculation conditions. First, we computed the stable structure of CaPv and found that the cubic phase is more stable than the tetragonal and orthorhombic in the LM P,T condition. The thermal equation of state of CaPv was analyzed using the MD data set, which indicates its thermal properties including Gruneisen parameter quite similar to those of MgPv. Along the adiabatic temperature, CaPv was found to have higher density than the PREM and 12.5% iron-bearing MgPv. Next, we calculated elastic constants of cubic CaPv. Our new results clearly demonstrate that cubic CaPv does not have anomalously large shear modulus suggested by previous calculations with a small computation cell. This is because the cell applied in the previous studies is too small to allow the rotational phonon motion of SiO6 octahedra related to the zone boundary optic phonon instability. Acoustic wave velocities were finally determined from the elastic moduli, indicating no significant differences in velocities between CaPv and iron-bearing MgPv.

Seismic Constraints on an Enstatite Chondrite Earth

HOUSER, Christine[1*] ; GREAUX, Steeve[2] ; DU, Wei[2]

[1]Earth-Life Science Institute, Tokyo Tech, [2]Geodynamics Research Center, Ehime University

Recently, Javoy et al., EPSL, 2010 suggested the possibility that Earth had an initial enstatite chondrite composition due to their similar oxygen isotopes. Currently, the calculations of the bulk silicate Earth (BSE) are based on the assumption that the initial Earth began with a composition very close to that of a carbonaceous chondrite. Thus, it is necessary to evaluate whether the 1D seismic properties of the Earth are more consistent with an initial enstatite or chondritic composition. The BSE of an enstatite chondrite Earth (ECE) is different from that of a carbonaceous chondrite since the magnesium/silicon ratio is much lower for the former, resulting in a lower mantle that is almost devoid of Mg. Hence, the primitive lower mantle of an ECE consists mostly of iron-rich perovskite and pure silica. The seismic velocities of these phases are much slower than Mg-perovskite which, by itself, is faster than PREM (the slower MgO phase is necessary to match PREM velocities). However, the present-day lower mantle would be a mix of the primitive upper mantle (ie. pyrolite) and the Mg-depleted lower mantle. The latest mineral physics results are used to calculate possible 1-D seismic profiles of the Earth associated with these two scenarios and to compare with those observed for the Earth today.

Thermal property modeling of the core-mantle boundary

TSUCHIYA, Taku[1*] ; DEKURA, Haruhiko[1]

[1]Ehime Univ

Lattice thermal conductivity of minerals under pressure and temperature is a key property to understanding dynamics and evolution of the Earth's interior. We recently established an efficient ab initio technique for calculating the thermal conductivity of silicate minerals with complex structure and chemistry (Dekura, Tsuchiya, Tsuchiya, PRL, 2013). Calculated lattice thermal conductivity of MgSiO3 perovskite agreed satisfactorily with experimental values at room temperature, and post-perovskite was found to have thermal conductivity quite different from perovskite's, indicating that the D" discontinuity is not only the phase transition boundary but also the conductivity boundary. Using the obtained results, we determine the effective conductivity of the lower mantle and estimate the energy flow across the core-mantle boundary (CMB). Our results demonstrate that the CMB heat flux could change significantly from place to place by reflecting temperature heterogeneity located atop the core. A large CMB heat flow recently suggested from the outer core side can be reconciled only by considering polycrystalline assemblages yielding high-thermal conductivity.

Waveform inversion for localized 3-D seismic velocity structure in the lowermost mantle beneath the Western Pacific

KONISHI, Kensuke[1] ; KAWAI, Kenji[2] ; GELLER, Robert J.[3*] ; FUJI, Nobuaki[4]

[1]School of Earth and Environmental Sciences, Seoul National University, [2]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [3]Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo, [4]Institut de Physique du Globe de Paris

We infer 3-D localized shear velocity structure in the lowermost 400 km of the mantle at the western edge of the Pacific large low shear velocity province (LLSVP) by applying waveform inversion to transverse component body-wave waveforms from the F-net seismic array in Japan. Our dataset consists of relatively long period (12.5-200 s) broad-band seismic waveforms of Tonga-Fiji deep focus and intermediate deep earthquakes. We conduct several tests to confirm the robustness of the inversion results. We find two low velocity zones at the bottom of the target region, with a high velocity zone in the middle, and a low velocity zone above the high velocity zone and contiguous with the two deeper low velocity zones at a depth of 200-300 km above the CMB. This supports the idea that the Pacific LLSVP may be an aggregation of small upwelling plumes rather than a single large thermochemical pile.

Compressional sound velocity and density measurements of hcp-Fe under core conditions

SAKAMAKI, Tatsuya[1*] ; OHTANI, Eiji[1] ; FUKUI, Hiroshi[2] ; KAMADA, Seiji[1] ; TAKAHASHI, Suguru[1] ; SAKAIRI, Takanori[1] ; TAKAHATA, Akihiro[1] ; SAKAI, Takeshi[4] ; TSUTSUI, Satoshi[5] ; BARON, Alfred[3]

[1]Tohoku University, [2]University of Hyogo, [3]RIKEN, [4]Ehime University, [5]SPring-8/JASRI

Sound velocity measurements of Fe and Fe-alloy at high temperature and high pressure are necessary to understand the Earth's inner core. Despite seismological observations providing density-sound velocity data of Earth's core, there are few experimental reports about sound velocity of hcp-Fe at ultrahigh pressure and temperature conditions. In order to push forward with research, we have developed a portable laser-heating system for diamond anvil cell, which is called COMPAT (Fukui et al., 2013). We have succeeded in measuring the sound velocity of hcp-iron up to 160 GPa and 3000 K by inelastic X-ray scattering measurements combining with a laser-heated diamond anvil cell. The obtained pressure and temperature dependence of the sound velocity suggest that compressional sound velocity of hcp-Fe at inner core boundary (330 GPa and 5500 K) is higher than that of Earth's inner core. Thus, we can conclude that the light elements or combination of the light elements and nickel in the inner core decreases both density and compressional sound velocity of hcp-Fe simultaneously under the inner core conditions.

The P-V-T equation of state of liquid pure Fe and Fe-light elements alloys by ab initio molecular dynamics simulations

ICHIKAWA, Hiroki[1*] ; TSUCHIYA, Taku[1] ; OSUMI, Masanao[2]

[1]GRC, Ehime University and ELSI, Tokyo Institute of Technology, [2]Geodynamics Research Center, Ehime University

The equation of state (EoS) of pure Fe and Fe-light elements alloy liquids were calculated by means of ab initio molecular dynamics simulations at the outer core P-T conditions. In the outer core, many light elements, such as carbon, nitrogen, oxygen, hydrogen, sulfur, and silicon, have been proposed as possible constituents. The concentrations of these elements have been strongly debated for years. In this study, internally consistent thermodynamic and elastic properties of pure Fe and Fe-light elements alloys, in particular density, adiabatic bulk modulus, and P-wave velocity were analyzed in order to clarify the effect of light elements incorporation on seismically observable data. Then the results were compared with the seismological data of the Earth's outer core to confine the plausible compositions of the outer core. The new EoS model of liquid iron alloys as a function of pressure, temperature and fraction of light elements may serve as fundamental data for the composition model of the Earth's core.

Simultaneous measurement of liquid Fe-C density and sound velocity at high pressure

SHIMOYAMA, Yuta[1*] ; TERASAKI, Hidenori[1] ; TAKUBO, Yusaku[1] ; URAKAWA, Satoru[2] ; KUWABARA, Souma[1] ; KATAYAMA, Yoshinori[3]

[1]Graduate School of Science, Osaka University, [2]Department of Earth Sciences, Okayama University, [3]Japan Atomic Energy Agency

The cores of terrestrial planets, such as Mercury, Mars and Moon are considered to contain some light elements. The effect of light elements on density and bulk modulus of liquid iron is necessary for estimating of these core compositions. Sound velocity of liquid iron alloys is also important for identifying light elements in the core by comparison with observed seismic data.

In this study, we have measured density and sound velocity of liquid Fe-C at SPring-8 beamline BL22XU. Density was measured using X-ray absorption method (Katayama et al., 1993) and sound velocity was measured using pulse-echo overlapping method (Higo et al., 2009). Experimental conditions were 1.2-2.9 GPa and 1650-1850 K. Obtained density values of this study were consistent with our previous results (Shimoyama et al., 2013). In sound velocity measurement, we could observe clear sample wave signal. Measured compressional wave velocity of liquid Fe-C was found to increase with pressure.

Sound velocity and density measurement of liquid FeSi alloy by laser-shock compression

HOSOGI, Ryota[1*] ; YOKOYAMA, Naoya[1] ; SAKAIYA, Tatsuhiro[1] ; KONDO, Tadashi[1] ; TERASAKI, Hidenori[1] ; SHIGEMORI, Keisuke[2] ; HIRONAKA, Yoichiro[2]

[1]Graduate School of Science, Osaka University, [2]Institute of Laser Engineering, Osaka University

The internal structure of the earth is estimated by observing seismic wave. Comparing seismic wave observations and experimental data of sound velocity of iron(Fe), the composition of the Earth's core is not pure Fe. Several light elements (hydrogen, carbon, oxygen, silicon, sulphur, etc.) have been considered as the candidate of the composition of the Earth's core, but its composition is still unclear. In order to constrain the core composition, it is important to measure the sound velocity of iron alloys because it can be directly compared with the seismic wave. Silicon (Si) has been proposed as a major light element in the inner core [Mao et al., 2012]. So we measured the sound velocity of laser-shocked FeSi alloy in order to investigate the effect of Si for sound velocity of liquid Fe in the outer core condition.

The starting sample was prepared by synthesizing from mixture of Fe (99.98% purity) and Si (99.9% purity) slugs at arc furnace. The compositions of Fe and Si are 66.5 wt.% and 33.5 wt.%, respectively. We measured sound velocities and densities of FeSi at high pressure and high temperature conditions at the large laser facility in Institute of Laser Engineering, Osaka University. The sound velocities were measured by the x-ray radiography [Shigemori et al., 2012].

We obtained the sound velocity and density of FeSi at pressures around 700 GPa. It is seen that Si has the effect of increasing the sound velocity of liquid Fe. Comparing our experimental results and PREM model [Dziewonski and Anderson, 1981], Si may be contained up to 13.1 wt.% at 135 GPa, and up to 5.5 wt.% at 330 GPa in the outer core.

Effects of hydrous rocks on behaviors of subducting slabs

NAKAO, Atsushi[1*] ; IWAMORI, Hikaru[2] ; NAKAKUKI, Tomoeki[3]

[1]Department of Earth and Planetary Sciences, Tokyo Institute of Technology, [2]Institute for Research on Earth Evolution, JAMSTEC, [3]Department of Earth and Planetary Systems Science, Hiroshima University

Introduction: It is widely accepted that Earth's deep mantle contains water in several tens to several hundreds ppm, and that the water causes plate tectonics, volcanoes in subduction zones, deep earthquakes, and large-scale transportation of hydrophilic elements. A number of previous numerical studies on water transportation in the deep mantle are performed. In theses simulations, constant plate velocities and/or fixed plate shapes are synthetically imposed. In this study, we systematically investigated water transportation into the deep mantle and how the water changes the spontaneous behavior of the slab using a numerical model of whole mantle convection without external forces.

Numerical Model: Based on 2-D fluid mechanics simulation (Tagawa *et al*., 2007, *EPS*), the motion of mantle rocks is calculated. Advection of hydrous rocks is calculated using a Marker-And-Cell method, and dehydration/hydration reactions are evaluated by experimentally determined phase diagrams of the hydrous basalt and peridotite (Iwamori, 2007, *Chem. Geol.*). Effects of the hydrous rocks are formularized in constitutive laws (*e.g*. Karato and Wu, 1993, *Science*) and a state equation; therefore, the water transportation and the motion of solid phase are interactive. Only two parameters r (= 0, 0.7, 1.0, 1.93) in constitutive laws (viscosity reduction by hydration) and β (= 0, 1.0, 2.0) in a state equation (density reduction by hydration) are treated as variable, and other settings are equalized.

Results and Discussion: The reaction path (p-T path) of subducting hydrous rocks in each result is the same as that of southwest Japan (Iwamori, 2007), and a hydrous ultramafic layer along the slab surface ($\sim$2000 ppmH_2O in NAMs) is formed beneath $\sim$200-km depth. Large hydration weakening seems essential for back arc spreading because the subducting slab causes tensile stress within the overlying continental plate, and then the expansive deformation is concentrated on the hydrous weak area. Comparing the results with each other, at large r, the subduction rate increases. This is because a hydrous layer reduces viscous resistance above the slab. In contrast, at large β, the subduction rate decreases. This is because the positive buoyancy of the hydrous layer partially canceled to the gravitational instability of the slab. The subduction rate significantly controls the velocity field of the corner flow in the mantle wedge. A rapid corner flow causes strong suction force along the slab surface, which determines the angle of subduction. This also causes effective heat advection from the deep mantle to the back arc, and that contributes rapid, sustainable back arc spreading. The analytical discussion enables us to understand why scenarios differ when r and β are changed. In east Asia, stagnant slabs and back arcs are widely distributed. To realize both, large r and small β are needed. This is because they require strong corner flow, but β declines it. Thus the slab shapes and the period of back arc spreading may constrain scales of hydrous buoyancy and hydrous weakening in the mantle wedge comparing with those in nature.

Regional scale variation of splitting intensity observed in Japanese islands by Hi-net II

OGAWA, Naoto[1*] ; KAWAKATSU, Hitoshi[1] ; TAKEUCHI, Nozomu[1] ; SHIOMI, Katsuhiko[2]

[1]Earthquake Research Institute, the University of Tokyo, [2]National Research Institute for Earth Science and Disaster Prevention

To systematically investigate the spatial variation of seismic anisotropy around the Japanese islands, we measured the splitting intensity (SI) of teleseismic SKS and SKKS phases by Hi-net (Ogawa et al., 2013, SSJ). SI is first introduced by Chevrot (2000) as a method of measuring seismic anisotropy; it is based on cross-correlation of polarized waveforms, and can be modeled like the delay time of seismic tomography considering the effect of finite frequency (e.g., Favier and Chevrot, 2003). In this study, we extend our previous work by measuring SI for a large number of dataset recorded by the dense seismic station network, Hi-net. We use data from tilt-meters of Hi-net from October in 2000 to September in 2013. We have selected the recordings of SKS phases for epicentral distances between 90 and 135 degrees and SKKS beyond 105 degrees, and Mw larger than 6.0, resulting in a total number of events to be 189 that is much larger than the previous case. For the actual analysis, we apply a band-pass filter between 0.05 and 0.125 Hz, and the measurement error of each SI will be carefully estimated using a new formulation, as there appears an error in the Chevrot (2000)'s original treatment. The preliminary analysis indicates regional scale variations of SI patterns that apparently depend on the back azimuth of seismic event, which may be influenced by the subducting slabs.

Comparison of phase relations in pyrolite, MORB and harzburgite across 660-km discontinuity

ISHII, Takayuki[1*] ; KOJITANI, Hiroshi[1] ; AKAOGI, Masaki[1]

[1]Depertment of chemistry, Gakushuin University

Pyrolite is the model rock which composes the average upper mantle. It is accepted that 660-km seismic discontinuity is formed by post-spinel transition of pyrolite. MORB (mid-ocean ridge basalt) and harzburgite in slabs subduct to 660-km seismic discontinuity due to their higher densities than pyrolitic average mantle. It has been considered that the density cross-over between pyrolite and slab materials occurs due to post-spinel transition in pyrolite at the 660-km discontinuity, and MORB and harzburgite are trapped around the depth (e.g. Ringwood and Irifune, 1988). Therefore, the phase transition pressures of these mantle rocks are the important parameters to elucidate the dynamics around 660-km seismic discontinuity. We investigated detailed phase relations of pyrolite, MORB and harzburgite with multi-sample cell technique.

The starting materials were prepared from the oxide mixtures of pyrolite, MORB and harzburgite composition after McDonugh and Sun (1995) (excluding MnO, K_2O and P_2O_5), Melson et al. (1976) (P_2O_5) and Michael and Bonatti (1975), respectively. High-pressure and high-temperature experiments by quench method were performed at about 20-28 GPa and 1600-2200C for 2-10 hours using a Kawai-type 6-8 multianvil high-pressure apparatus at Gakushuin University. These samples were packed with pressure calibrants ($MgSiO_3$ or pyrope) in a Re multi-sample capsule with four holes. Temperature was controlled with a LaCrO3 heater and measured with a W5%Re-W26%Re thermocouple inserted in a Cr_2O_3-doped MgO pressure medium. Phases of recovered samples were identified with microfocus-Xray diffractometer and SEM-EDS.

In pyrolite at 1600-2200C, the mineral assemblage of $MgSiO_3$-rich perovskite (Mpv) + magnesiowustite (Mw) + garnet (Gt) + $CaSiO_3$-perovskite (Cpv) is stable at pressure range of 22-24 GPa, and changes to that of Mpv + Mw + Cpv above 24 GPa. The mineral assemblage of ringwoodite (Rw) + Gt + Cpv at 1600C transforms to that of Rw + Mw + Gt + Cpv due to transition of Rw to Gt + Mw at 1800-2000C, and Rw disappears perfectly above 2200C. In MORB, the mineral assemblage of Gt + stishovite (St) + Cpv changes to that of Mpv + St + Al-rich phase + Cpv with continuous post-garnet transition. In harzburgite at 1600C, the mineral assemblage of akimotoite (Ak) + Rw + Gt changes to that of Mpv + Mw by post-spinel transition after the Ak to Mpv transition. Above 1800C, no Ak was observed.

At 1600C, post-spinel transition in pyrolite occurred by about 0.5 GPa and 2 GPa lower pressure than that of harzburgite and post-garnet transition in MORB, respectively. The Clapeyron slope of post-spinel transition in harzburgite is larger than that of pyrolite, and both boundaries intersect at 2000C. From the comparisons of density profiles at 1600C, MORB and harzburgite have lower densities than pyrolite by post-spinel transition in pyrolite.

Melting experiments in the system Fe-Xe and Earth's missing xenon

MORI, Yuko[1*] ; HIROSE, Kei[2] ; TATENO, Shigehiko[1] ; OZAWA, Haruka[3] ; OHISHI, Yasuo[4]

[1]Dept. of Earth & Planetary Sciences, Tokyo Institute of Technology, [2]Earth-Life Science Institute, Tokyo Institute of Technology, [3]Japan Agency for Marine-Earth Science and Technology, [4]Japan Synchrotron Radiation Research Institute,

The abundances of noble gases in the Earth's atmosphere should be consistent with those in CI chondrite. However, xenon in the atmosphere is depleted relative to chondritic abundance, while lighter rare gases, Ne,Ar, and Kr, are less depleted. This is the so-called "missing xenon" problem and its reservoir has been discussed for a long time. Since xenon is too heavy to escape toward outer space, the missing xenon (Xe) might be hidden in the deep Earth.

The potential reservoirs are the mantle and core because xenon has a good reactivity under high pressure. Although extensive studies on the reactions of Xe and various mantle materials have been performed, none of those found a Xe reservoir (e.g., Sanloup et al., 2005; 2011; Brock et al., 2011). On the other hand, the alloying of iron with xenon has been expected based on the fact that Xe becomes metallic above 130 GPa (e.g., Eremets et al., 2000). While first-principle calculations suggested that the solubility of xenon in hcp iron is 0.8 mol% at Earth's core conditions (Lee et al., 2006), experimental study showed that the solid Fe-Xe reaction did not occur at least up to 155 GPa and 3000 K (Nishio-Hamane et al., 2010). Here we performed melting experiments in the Fe-Xe system to 86 GPa and 6450 K.
