Review of Earthquake Early Warning Operation in Japan for eight years from 2007

Yuji Nishimae¹, Yuki Kodera¹, Yasuyuki Yamada¹, Shimpei Adachi¹, Masahiko Morimoto¹, Mitsuyuki Hoshiba²

1. Seismology and Volcanoology Department, Japan Meteorological Agency, 2. Meteorological Research Institute, Japan Meteorological Agency

It has been about eight years since the Japan Meteorological Agency (JMA) launched a nationwide Earthquake Early Warning (EEW) service for the general public on October 1, 2007. We describe details of the JMA EEW system and review its performance and improvements.

In the JMA EEW system, JMA seismic intensities in about 200 areas across the nation are predicted with hypocenter and magnitude estimated from several methods. EEW announcements are issued mainly based on predicted JMA seismic intensity. In order to assess EEW prediction accuracy, JMA reports annual EEW scores calculated from a percentage of areas where an error of predicted seismic intensity is within one degree (Figure 1).

The EEW operation started with about 200 seismometers of a JMA network and 800 of a National Research Institute for Earth Science and Disaster Prevention (NIED) network. In fiscal 2007 to 2009, the EEW scores remained at a high level (Note that fiscal year begins in April and ends in March in Japan). On June 14, 2008, JMA issued EEW announcements for the Iwate-Miyagi earthquake (M7.2), which contributed to disaster mitigation in various sites such as an airport and a kindergarten. Until March 1, 2011, 12 new stations, most of which were installed in islands, and five new ocean-bottom seismometers (OBS) in Tonankai were incorporated in the system.

On March 11, 2011, the 2011 off the Pacific coast of Tohoku Earthquake (the Tohoku earthquake) (M9.0) happened. An EEW warning was successfully issued for the Tohoku district, the nearest region from the epicenter, before S-wave arrival. The JMA EEW system worked well in Tohoku district, whereas the EEW system under-predicted seismic intensities of the Kanto district due to large extension of the rupture. After the Tohoku earthquake, highly-active aftershocks occurred and the system issued many warnings including false alarms. The score lowered down to 28% in fiscal 2010. Major causes for the false warnings fell into two factors: (1) confusion of multiple simultaneous earthquakes and a single large earthquake (2) lack of data from seismometers in disaster areas subject to blackout or disconnection of communication lines. JMA conducted improvement of an earthquake identification logic and reinforcement of the JMA seismometer network infrastructure. Owing to the countermeasures and decrease of the number of aftershocks, the number of false alarm decreased and the EEW score turned into an upward trend in fiscal 2011.

In fiscal 2012, JMA introduced site amplification factors estimated from actual observation. The score reached 79%. However, on August 8, 2013, a false warning was issued for very wide range of areas due to contamination of abnormal data from one of the Tonankai OBS. It caused serious impact on economic activities such as stopping trains. JMA took some actions for its measures. The score temporarily fell to 63% in fiscal 2013.

On March 31, 2015, the EEW system started to use 15 deep borehole seismometers (more than about 500 meters depth) of NIED, two OBS in DONET1 of Japan Agency for Marine-Earth Science and Technology (JAMSTEC) and 50 new JMA seismometers. JMA plans to utilize about 180 OBS of JAMSTEC and NIED and about 410 seismic intensity meters of JMA in the future after checking data quality. New prediction methods are going to be implemented within a couple of years for measures of multiple
simultaneous earthquakes and a large rupture. Integrated Particle Filter (IPF) method is a new hypocenter determination algorithm with Bayesian estimation that can recognize occurrence of multiple simultaneous earthquakes more robustly. Propagation of Local Undamped Motion (PLUM) method is a new seismic intensity prediction algorithm based on wave field prediction with real-time observed seismic intensity instead of hypocenter determination.

ShakeAlert: Implementing Public Earthquake Early Warning for the U.S.

*Douglas D Given*

1.USGS Pasadena

The ShakeAlert Earthquake Early Warning (EEW) is a practical use of earthquake science that can reduce injuries, deaths, and property damage by giving people and systems up to a minute to take protective actions before the heaviest shaking arrives. The U.S. Geological Survey (USGS) and its many partners are working to implement ShakeAlert in the three states of the West Coast of the U.S., Washington, Oregon, and California. The partners include Caltech, UC Berkeley, the University of Washington, the University of Oregon, state emergency services organizations, private companies, and the Gordon and Betty Moore Foundation. ShakeAlert is built on the extensive monitoring infrastructure of the USGS Advanced National Seismic System.

The ShakeAlert demonstration system has successfully sent hundreds of test notifications to selected beta users in California since 2012 and began sending messages for Washington and Oregon in 2015. It has alerted on several significant earthquakes and has demonstrated its ability, in some cases, to send alerts less than 4 seconds after an earthquake begins.

On February 1, 2016 the USGS, along with its partners, rolled-out the next-generation ShakeAlert early warning test system in California. This next-generation “production prototype” does not support public warnings but will allow qualified early adopters to develop and deploy pilot implementations that take protective actions triggered by the ShakeAlert warnings in areas with sufficient station coverage.

To reach full public operation the system needs about 1,000 more sensors in California, Oregon and Washington, more reliable telecommunications paths, and a campaign to educate the public about earthquake early warning alerts and how to respond to them. Progress is being made in all these areas; however the project is not yet fully funded. The USGS ShakeAlert implementation plan estimates it will cost $38.3 million in capital funding to complete the system on the West Coast to the point of issuing public alerts and $16.1 million each year to operate and maintain it. This is in addition to current support for seismic networks from other sources.

Completion of the system to the point of public alerting will require a whole-community effort which is gaining momentum. The USGS budget is now $8.2 million per year for the project. A recent White House summit focused attention on ShakeAlert and announced new commitments from a variety of stakeholders. There is a bill in the California legislature for $23 million to build that state’s part of the system and the state of Oregon, as well as various utilities, have funded stations. University partners and the USGS are implementing and testing new algorithms that will speed up and improve the system, incorporate high-precision real-time GPS data, and characterize evolving fault ruptures, including megathrusts, in real-time. Use of data from low-cost sensors and cell phones is also being explored. Private partners are co-developing commercial applications to receive and act on ShakeAlert notifications. The telecommunications industry is taking steps to develop the standards and technological enhancements needed to broadcast alerts to cell phones with minimum delay.

While significant progress is being made, a fully functional ShakeAlert system will require additional funding and further collaborative work before full West Coast public alerting will be possible.

1.University of California Berkeley, 2.Deutsche Telekom Silicon Valley Innovation Center

ShakeAlert is the U.S. earthquake early warning system that is now in the process of being rolled out across the U.S. west coast. It uses traditional networks of seismic and geodetic stations to provide seconds to minutes of warning. The newly operational ‘production prototype’ system is now available for pilot projects in which selected users make automated responses and warn personnel of forthcoming shaking. Improved methodologies are also under evaluation for inclusion in the system. New approaches focus on providing better information in the biggest earthquakes by assessing the finite extent of the rupture and updating the warning accordingly.

MyShake is a new experimental approach to earthquake early warning that harnesses the accelerometers in personal smartphones to detect the earthquake and assess the hazard. In the first two days of the public release 50,000 people installed the app on their android phones around the world (see map). We will report on the performance of this system and its potential to contribute to early warning in regions with and without traditional seismic networks.

The Mexican Seismic Alert System, its public service since 1993

*JUAN MANUEL ESPINOSA ARANDA*, Armando Cuellar

1.Centro de Instrumentación y Registro Sísmico A.C. (CIRES)

With the aim to mitigate future seismic disasters in the metropolitan region of Mexico Valley, Mexico City Authorities required from CIRES in 1991 the experimental development of a Sistema de Alerta Sísmica (SAS), originally with 12 strong motion seismic detectors in the Guerrero Gap, capable to detect and forecast danger generated by strong seismic events, and broadcast warning signals in the Mexico City Valley, distant 320 km, bringing the population opportunity to reduce the seismic vulnerability with near to beneficial 60 s, prior to perceive the strong “s” wave effects. With the same objective during 2002 the Oaxaca State Authorities also required from CIRES the development of another EEW system which started operating 36-field seismic sensors in 2003. After the 2010 Haiti Caribbean disaster, with the agree of the Mexico Ministry of Government, the Civil Protection States Authorities decided the integration of the SAS developments and also shared their services, extending the sensors coverage over seismic active regions in the Pacific coast from Jalisco to Oaxaca, also over the South of the Neovolcanic axis in Guerrero and Puebla. Today, integrated as the SASMEX is operating 97 field stations from 130 originally programmed. SASMEX warning performance has been capable to detect and forecast seismic danger issuing 58 public alerts that announced strong seismic effects and 90 preventive ones, when they were estimated moderate. The SASMEX data catalog accumulates more than 9300 seismic records, generated by near than 4700 seismic events. SASMEX warning services broadcasts signals in Acapulco, Chilpancingo, Morelia, Oaxaca, Puebla, Toluca and Mexico City. To reduce any time delay to reach people under seismic risk, SASMEX automatically controls the signals to modulate the carriers broadcasted by the commercial Television and Radio stations integrated in this social service, also the signals of the NWR SAME international NOAA protocol and EAS-Public Alert, now issued to operate especial receivers SARMEX, which have the capability to operate with the SASMEX warning and more natural hazards or emergencies. Mexico City Government and Federal Government Ministry invested to buy little more than 88 thousand SARMEX receivers to provide the SASMEX seismic warning mainly inside the classrooms of public elementary schools as well as other public services: Metro, Hospitals, etc.

The real seismic threaten and good SASMEX results motivated the local governments, and the federal one, to deem relevant expand geographic coverage of the sensors in seismic regions of the south of México, as well as the dissemination capacity of other alert notices trough the SARMEX receivers, useful to mitigate the vulnerability to populations under risk by other natural hazards. The SASMEX performance is notified across such diverse Internet platforms like Web, Blog, E-mail, Facebook, Twitter, RSS and web-socket protocols, emphasizing that due to the uncontrolled delays of these media and Apps, they should not be used to warn seismic alert signals.

The Performance of Earthworm Based Earthquake Alarm Reporting system in Taiwan

*TA-YI CHEN¹, Nai-Chi Hsiao¹, Yih-Min Wu²

1.Central Weather Bureau, Taiwan, 2.Department of Geosciences, National Taiwan University, Taiwan

The Central Weather Bureau of Taiwan has operated an earthquake early warning (EEW) system and issued warnings to schools and government agencies since 2014. Because the real-time seismic data streams are integrated by the Earthworm software, some EEW modules were created under the Earthworm platform. The system is named Earthworm Based Earthquake Alarm Reporting (eBEAR) system, which is currently operating. The eBEAR system consists of new Earthworm modules for managing P-wave phase picking, trigger associations, hypocenter locations, magnitude estimations, and alert filtering prior to broadcasting. Here, we outline the methodology and performance of the eBEAR system. The online performance of the eBEAR system indicated that the average reporting times afforded by the system are approximately 15 and 26 s for inland and offshore earthquakes, respectively. Comparing to the earthquake catalog, the difference of the epicenters are less than 10 km for inland earthquakes; the difference of the magnitude are about 0.3. No false alarms generated by the system, but there were three false alarms issued by human. Due to the wrong operations, the EEW information created by off-line test were sent. However, we have learned from it and improved the standard operation procedure in the EEW system.

Local Tsunami Warnings and the role of high-rate GNSS in Earthquake Early Warning

*Melgar Diego¹, Richard M Allen¹, Sergio Barrientos², Ronni Grapenthin³, Mario Aranha¹

¹.University of California Berkeley, ².Centro Sismologico Nacional, ³.New Mexico Institute of Mining and Technology

Local tsunami warning requires rapid assessment and communication of the tsunami hazard for communities immediately adjacent to large earthquake. Here, the warning times are typically of minutes to tens of minutes. Local warning remains a challenging problem with very few systems worldwide capable of issuing such alerts. Here, we demonstrate a flexible strategy for local tsunami warning that relies on regional geodetic and seismic stations. Through retrospective analysis of four recent tsunamigenic events in Japan and Chile, we show that rapid earthquake source information, provided by methodologies developed for earthquake early warning, can be used to generate timely estimates of maximum expected tsunami amplitude with enough accuracy for tsunami warning. We validate the technique by comparing to detailed models of earthquake source and tsunami propagation as well as field surveys of tsunami inundation. Our approach does not require deployment of new geodetic and seismic instrumentation in many subduction zones, and could be implemented rapidly by national monitoring and warning agencies. We illustrate the potential impact of our method with a detailed comparison to the actual timeline of events during the recent 2015 Mw8.3 Illapel, Chile earthquake and tsunami that prompted the evacuation of 1 million people.

For tsunami warning and for rapid assessment of large events high-rate GNSS observations are a fundamental tool. We will discuss the Geodetic Alarm System (G-larmS) tool. A software system developed in collaboration between the Berkeley Seismological Laboratory (BSL) and New Mexico Tech (NMT) for real-time Earthquake Early Warning (EEW). It currently uses high rate (1Hz), low latency (< ~5 seconds), accurate positioning (cm level) time series data from a regional GPS network and P-wave event triggers from the ShakeAlert EEW system. G-larmS has been in continuous operation at the BSL since 2014 using event triggers from the California Integrated Seismic Network (CISN) ShakeAlert system and real-time position time series. We evaluate the performance of G-larmS for EEW by analyzing the results using a set of well defined test cases to investigate the following: (1) using multiple fault regimes and concurrent processing with the ultimate goal of achieving model generation (slip and magnitude computations) within each 1 second GPS epoch on very large magnitude earthquakes (up to M 9.0) and (2) the use of Precise Point Positioning (PPP) real-time data streams of various operators, accuracies, latencies and formats along with baseline data streams. We will also discuss the recent expansion and performance of the G-larmS algorithm along the U.S. West Coast on a regional network basis for Northern California, Southern California and Cascadia.

We will further highlight ongoing collaboration between the National Seismological Center (CSN) in Chile and the Berkeley Seismological Laboratory. This strategic partnership’s goal is to share data and warning algorithms between the two institutions with the end goal of enabling CSN to issue and disseminate early warning alerts to the country at large.
ShakeAlert: Using early warnings for earthquakes in California and the US West Coast

*Hellweg Margaret¹, Richard M Allen¹, Jennifer A Strauss¹

¹ U.C. Berkeley Seismological Lab

With funding from the USGS and the Gordon & Betty Moore Foundation, a prototype production system for earthquake early warning, ShakeAlert, is now operating in California. Earthquake early warning (EEW) is the ability to detect an earthquake quickly and provide a few seconds of warning before destructive shaking starts. Alerts from an EEW system can improve resilience if their recipients have developed plans for responding and act on them. We are working with a suite of perspective users from critical industries and institutions throughout California to identify information they require, as well as delivery mechanisms, procedures and products. Our most effective collaboration has been with the Bay Area Rapid Transit District (BART). Since 2012 the BART system has been using EEW information to automatically slow trains. BART receives alerts via the internet and feeds them into the train operating system. In the 2014 South Napa (Mg) earthquake, the BART operations center received the EEW alert 8 s before shaking began at their site, 5 s after the earthquake started. The automatic processing worked. Had trains been running at 03:21 local time when the quake occurred, they would have slowed automatically. Other recipients of EEW alerts from California's EEW system include the emergency managers of San Francisco and Los Angeles, the California Office of Emergency Services, UC Berkeley's police department, and other organizations like the LA School District, Google, Amgen and the major power companies in California, PG&E and SoCal Edison. These organizations currently receive the alerts to enhance their situational awareness. We are also supporting their efforts to determine and implement appropriate responses to EEW alerts, and to assess possible uses and especially benefits to themselves and to society. More recently, the ShakeAlert system has begun operating in the Pacific Northwest, where our partners are also reaching out to perspective users. With the recent step to the production prototype system in California, we are encouraging our users to develop and implement automated and personal actions suitable to their applications, as further demonstrations of the benefits of EEW toward enhancing society's resilience.

On-Site Earthquake Early Warning System

*Kenichi Takamatsu*

1. Oki Engineering Co., Ltd.

In Japan, Semiconductor industry aimed at a strong factory to an earthquake after the Great Hanshin/Awaji Earthquake in 1995.

We have carried out the correspondence by earthquake-resistant reinforcement of factory, fixing of equipment, shaking stop of the pipes, using expansion joint, etc.

On the other hand, as effective use of JMA-EEW this information is adopted as life safety and factory production continuation.

In our company, an earthquake prediction like JMA-EEW is being carried out using On-Site seismometer. This On-Site system has functioned effectively, when we did not received a prediction of JMA-EEW and we received a wrong prediction.

At present, We use this system combined by JMA-EEW, On-Site EEW and the actual measurement. We pile up much improvement after introduction in 2005 and have obtained many results. The secondary disaster by leakage of dangerous chemicals and special gases is prevented and the reduction in operation loss by early re-operation was achieved.

In 2011 The Great East Japan Earthquake, this function is done effectively and early re-operation was achieved.

Using this outcome, we aimed at practical use expansion of On-Site EEW System.

We developed a MEMS seismometer and the exclusive controller which does the announcement and the external equipment control and use. The Development aiming at effective use of neighborhood information system is expanded by network building of On-Site EEW System as the next stage.

Development of the Earthquake Early Warning System for Railway in Japan

*山本 俊六
*Shunroku Yamamoto

1.Railway Technical Research Institute
1.Railway Technical Research Institute

Since Japan is located in one of the highest seismicity zones, to improve countermeasures against earthquake is a significant issue for railway. An earthquake early warning system is one of those countermeasures, particularly for high-speed trains. The first EEW system was in operation in 1982. This was a front-detection system, in which a seismometer located along coastlines remote from the rail monitors a large shaking from subduction zone earthquakes. The second system called Urgent Earthquake Detection and Alarm System (UrEDAS) had been installed since 1992. UrEDAS estimates magnitude and epicenter of an earthquake in several seconds by the initial phases of P-wave observed at single station, and issues a warning signal when a large shaking is expected along the rail. The present system, which has upgraded algorithms for a warning using single station data, has been operated since 2004. At present all the high-speed trains in Japan use this EEW system. The present EEW system consists of track-side seismometers, front-detection seismometers and a central server. Basically each seismometer can issue warnings by itself, but at the same time it can issue warning by using the information from other seismometers. The seismometer has two kinds of warnings, which are a S-wave warning and a P-wave warning. The S-wave warning is issued by threshold excess of acceleration and the P-wave warning is issued by analyzing the P-wave data. In order to issue the P-wave warning, the seismometer firstly estimates epicentral distance by the B-D method from 2-second P-wave data and also estimates back-azimuth to the epicenter by the Principal Component Analysis from 1.1-second P-wave data. Secondary it determines magnitude by using the epicentral distance and observed amplitude. Finally P-wave warning is issued for the potential damaging area which is determined from an empirical relation using the estimated epicenter and magnitude. The present system is reported to have worked well during large earthquakes. A successful train control by the EEW system during the 2011 Great Tohoku earthquake (Mw=9.0) is one of those examples. However to improve the rapidness, accuracy and reliability of the warnings is expected so as to enhance the safety of railway during earthquakes. Now all the high-speed trains in Japan use EEW information from JMA as an additional EEW source. Further, two other approaches are considered for safety. One is improvement of P-wave warning algorithms, the other is usage of external data such as data from ocean bottom seismometers. For the former approach, the C-D method and variable time window method are developed. These methods shorten the data length for estimation to 0.5-1.0 second and improve the estimation accuracy at the same time. For the latter approach, a simple warning logic using ocean bottom seismometers is proposed though an advanced study to understand the characteristics of OBS data is still necessary. The redundancy of warning logics as well as redundancy of system configurations is essential for a reliable EEW.

Numerical shake prediction for Earthquake Early Warning: Introduction of attenuation structure

Mitsuyuki Hoshiba, Masashi Ogiso

1. Meteorological Research Institute

In many strategies of the present EEW systems, hypocenter and magnitude are determined quickly, and then the strengths of ground motions (PGA, PGV, seismic intensity) are predicted based on a ground motion prediction equation (GMPE) using the hypocentral distance and magnitude, which usually leads the prediction of concentric distribution of ground shaking. However, actual ground shaking is not always concentric, even when the difference of site amplification is corrected. Even after correction of site amplification factor, the strengths of shaking may be much different at stations having the same hypocentral distances. For some cases, PGA differs more than 10 times, which leads to imprecise prediction of ground shaking in EEW.

Recently, innovative approach was proposed for EEW (Hoshiba and Aoki, 2015), that is Numerical Shake Prediction. In the method, the present ongoing wavefield of ground shaking is estimated using data assimilation technique, and then future wavefield is predicted based on physics of wave propagation. Information of hypocentral location and magnitude is not required. Because future is predicted from the present condition, it is possible to address the issue of the non-concentric distribution. Once the heterogeneous distribution is actually monitored in ongoing wavefield, future distribution is predicted accordingly to be non-concentric. We will indicate examples of M6 crustal earthquakes occurred at central Japan, in which strengths of shaking were observed to non-concentrically distribute. We will show their predictions using Numerical Shake Prediction method.

The heterogeneous distribution may be explained by inhomogeneity of attenuation/velocity. If attenuation/velocity structure is introduced, we can predict the future shaking more rapidly and precisely. The information of attenuation/velocity structure leads to more precise and rapid prediction in Numerical Shake Prediction method for EEW. We will show examples of precise predictions of the M6 crustal earthquakes at central Japan using the attenuation structure.

Keywords: Earthquake early warning, ground motion, real-time, prediction
We have developed a near-field tsunami forecast system based on an automatic centroid moment tensor (CMT) estimation using regional broadband seismic observation networks in the regions of Indonesia, the Philippines, and Chile. The automatic procedure of the CMT estimation has been implemented to work for tsunamigenic earthquakes. A tsunami propagation simulation model is used for the forecast and hindcast. A rectangular fault model based on the estimated CMT is employed to figure the initial condition of the tsunami height. The forecast system considers uncertainties due to two possible fault planes and two possible scaling laws, and shows four possible scenarios with the uncertainties for each estimated CMT. The system requires approximately 15 minutes to estimate the CMT after earthquake occurrence, and approximately another 15 minutes to make tsunami forecast results available, including the maximum tsunami height and its arrival time at the epicentral region and near-field coasts. The retrospectively forecasted tsunamis were evaluated by the deep-sea pressure and tide gauge observations, for the eight past tsunamis (Mw7.5-8.6) that occurred around the regional seismic networks. The forecasts were shown to range from half to double the amplitudes of the deep-sea pressure observations, and range mostly in the same order of magnitude of the maximum heights of the tide gauge observations. It was found that the forecast uncertainties become larger for greater earthquakes because the tsunami source is no longer approximated as a point source for greater earthquakes (e.g., Mw>8). The forecast results for the coasts nearest to the epicenter should be carefully used because the coasts often experience the highest tsunami with the shortest arrival time (e.g., <30 minutes).

実用早期地震検知警報システムの開発概史
Brief History of Effective EEW Systems

*中村 豊¹
*yutaka nakamura¹

1.株式会社 システムアンドデータリサーチ
1.System and Data Research Co., Ltd.

最初のEEW構想（1868年11月3日付のSan Francisco Daily Evening Bulletin紙上）によると、きっかけは江戸時代に日本で考案された地震予知器が1868年10月の地震を予知できなかったことにあるらしい。そこで、J.D.クーパー医学博士は、震源近傍で地震の発生を検知し、電信を使って人手を介さず自動的に地震警報であることを周知させる特別な鐘を鳴らすことで、大きな揺れが来る前に、人々に地震の発生を知らせるという構想を提案したが、残念ながら実現できなかった。およそ100年後の1972年、全く独立に伯野元彦博士らにより、東京を対象にした地震“10秒前検知システム”が提案された。ある大学研究室における雑談から生まれたこの構想も、気象庁や防災研など多くの国立研究機関で研究されたが、実用化には成功しなかった。一方、当時の国鉄では高速鉄道の普及拡大に際して、新しい地震警報システムの必要性が強く認識され、明確な目標と具体的な減災イメージをもって10秒前検知システムの実用化が進められていた。

それまでの地震警報は、JMA震度5以上の地震動が被害をもたらすことが多いという経験に基づき、JMA震度5より小さい段階で、しかし地震以外の振動で不用意に警報しないように、JMA震度4相当の加速度で警報を出そうとするものである。しかし、被害をもたらす強震動到来までの先行時間は多くなかった。先行時間を延ばそうと警報加速度を小さくすると過剰警報となるジレンマを抱え、監視加速度の周波数帯域の適切な制限や、大地震の発生地域近傍での地震検知などの工夫を重ねていた。

1983年に初めて開発に成功し、改良を重ねながら1992年に東海道新幹線で実用化されたユレダスは、地震動のP波初動を検知し、破壊断層の大きさに関わる初動周期から地震の規模を推定して、初動振幅と推定地震規模から距離を推定、波動の入射状況から震央方位と震源深さを推定している。推定された震源情報を基に被害地域を予想し警報するのである。用いられた地震学の知識は初歩的なものであるが、それだけに物理的な裏付けも明確で、地震の遠近や規模の大小に関係なく適用できるという特長を有する。ユレダスでは、単一観測点の三成分波形の地震動情報を使って、サンプルタイム周期1/100秒毎に連続的に推定する。多くの推定量は、地震動の検知とともに同時に得られるが、初動周期については、10km以上の断層地震を対象に、検知後3秒間（1周期）で推定することとし、その後、1/4周期分の時間をで確定できることを確認し、1秒間で初動周期を確定している。

1995年阪神大震災に遭遇して、ユレダスは的確に警報を発信したが、通信網トラブルで警報が対象まで届かなかったという事態を経験し、また警報処理に3秒かかるのは問題であることを現実問題として強く認識した。直後の地震に対しては少なくとも検知後1秒後には警報を出せるように、1997年には新たな警報発信方法を考案した。これが、初動と最大動の関係に着目したコンパクトユレダス警報であり、JR東日本の新幹線で1998年に実用化された。地震動をリアルタイム震度（RI：SDR特許技術、最大値はほぼJMA震度に一致）で監視し、P波初動を検出すると同時に、最大震度を想定して必要警報を出すというもので、当初最短1秒から現在最短0.1秒まで短縮している。

このコンパクトユレダスは、必要な地震に対して的確にP波警報を発信してきたが、2004年10月に発生した新潟県中越地震では、直上で地震を捕獲、1秒後にP波警報して、震源直上を高速走行中の新幹線列車に非常制動を掛けさせ、脱線はしたものの154人の乗客乗員の安全を無傷で確保することに成功している。その後、ユレダスとコンパクトユレダスはフレックルに融合され、先進的な超小型地震警報器が誕生した。これは、現在、在来鉄道のみならず、原子力発電所、球場、工場などに採用されるとともに、ハイパーキュー隊の装備品として活躍中である。なお、ユレダスやコンパクトユレダスは2007年以後新幹線では使われていない。

2011年東北太平洋沖地震に対して、新幹線の警報システムが一次警報システムや、原子力発電所における警報システムの発生を脅かすと、地震動の発生を検知するフレックルは的確にP波警報を発し最大震度RI5.5を記録した。
している。この地震後、フレックル警報の迅速性と信頼性をさらに向上させる技術が開発されている。最後に、EEWのような実用システムの開発には工学的センスが重要であることと、EEWの防災効果を過大評価することのないようにEEWは主たる地震防災対策である耐震補強を補完するもののひとつに過ぎないことを強調しておきたい。
Proposal of earthquake early warning system estimating damage assessment of buildings and structures in metropolitan area

*Shigeki Horiuchi*, Kenichi Hanyu, Yuko Sato, Toshimi Aoki

1. Home Seismometer Corporation, 2. Japan Disaster corporation

An earthquake of magnitude 5.2 with focal depth of 57 km occurred beneath Tokyo bay on September 12, 2015. Shaking intensities by this earthquake are ranging from 2 to 5- in a small areas of nearly same hypocentral distances. This observation suggests that it is almost impossible to predict accurate shaking intensity by the present EEW system operated by JMA, which determines hypocenters and magnitude and transmits them for the estimation of shaking intensity at user’s location, because the spatial large change in observed shaking intensity is originated to the existence of very strong lateral heterogeneity in the site amplification factors and the complexed deep structure but not in the estimation errors of hypocenter location or magnitude. We proposed to install a new EEW system specialized for the metropolitan areas.

2. Why we need a new EEW system specialized for metropolitan areas

1) The present EEW system has about 30 km of blind zone in focal areas where most of earthquake damages occur, owing to the limitation of the number of seismic stations. 2) There are large estimation errors of seismic intensity owing to the large lateral heterogeneity of site amplifications. It is shown that estimated values of site amplifications with 250m mesh do not able to greatly decrease estimation errors. 3) Each building has different strength and the natural period. Estimation of earthquake damage should be done based on the response of building to the earthquake shaking. 4) Because the earthquake damages are huge in metropolitan areas, which is limited in a small area in general, specialized earthquake early warning system for urban area seems to be effective.

3. Proposed EEW system in metropolitan areas

1) Install seismometers with an interval of several hundred meters which send observed real-time waveform data to their data center. 2) Register data of user’s buildings or structures to the data center, such as the location, dumping factor, and strength of buildings. 3) At a time of strong shaking, the data center predicts shaking intensity using real-time P wave data transmitted from the closest station. It also calculates response of buildings associated with the ground shaking and estimates damage assessment of individual buildings. 4) The data center sends these computed results to each owner of building or users so as to do something for the mitigation of earthquake damage. Since there are seismic stations closed to each building in the proposed EEW system, we can consider that shaking at each building are approximated by the shaking recorded at the closest station. Therefore, we can consider that the proposed system can issue accurate EEW information to individual users. It is also pointed out that shaking intensity is predicted by the use of near-by stations, there are almost no blind zone.

4. Effectiveness of the proposed system

We checked the accuracy of shaking intensity estimation by the proposed system. We estimated values of shaking intensity using 1800 P wave data recorded by K-net station and found that the average estimation error of shaking intensity is 0.5. Since the shaking intensity is predicted by the use
of waveform data at near-by station in the proposed system, we are able to consider that the 
average estimation error obtained by K-net data is approximated to that by the proposed system. We 
also calculated estimated errors of shaking intensity estimation from the attenuation equation with 
putting parameters of hypocenter location and magnitude used in the present EEW system. The average 
error in this case is 0.91, which is much larger than the value of 0.51. The proposed system 
compute the response of each building associated with ground shaking. it may be possible to issue 
warning about the fall down of unfixed furniture.

Most of the damages by shallow inland earthquakes are concentrated on the fault and surrounding areas. For instance, the highest level of intensity by an event of M7 class is often located within an area of 50-60 km from the source area. It is also noted that the shaking duration in the source area is approximately of 20-30 s. However, the current Earthquake Early Warning (EEW) in Japan has the difficulty to reach the strong motion prediction information in this area. In this study, we argue the possibility of using the peak ground accelerations (PGAs) and peak ground velocities (PGVs) obtained from P-wave amplitude for EEW. We investigated PGAs and PGVs in time step of 0.1 s (10 samples) of P-waves using 100,000 records from 2,000 events. The data were obtained from K-NET of National Research Institute for Earth Science and Disaster Prevention (NIED) from 1996 to 2016. Events were located in inland and coast regions, and records with a maximum epicenter distances of 20 km were included. In our results, the amplitude ratio of PGAs and PGVs obtained from S-wave to those obtained from P-wave has approximately a value of 5.9, which is close to the theoretical value (i.e., value of 5). The amplitude ratio shows a strong correlation with the time step when reach 0.5 s and follows, measured from the onset of P-wave. The PGAs and PGVs amplitude obtained from short period of P-waves are likely proportional to the scale of destruction, which it makes possible to estimate the microscopic seismic source parameters such as the inhomogeneity, strong motion generation area (i.e., asperity size), and the stress drop in the source area. We discuss the changes of the apparent velocity with different azimuthal angles of the source and surrounding areas. We also discuss the optimum network distribution for EEW using the proposed method. This study shows the potential of strong motion prediction obtained from short-period amplitudes by densely distributed seismic networks.
Rapid Magnitude Estimation in Earthquake Early Warning with Seismogeodesy

Earthquake early warning (EEW) is critical to reducing injuries and casualties in case of a large magnitude earthquake. Fault systems often coincide with populous cities, thus we require a P-wave detection method for effective early warning. Such a system must rely on near-source data to minimize the time between event onset and issuance of a warning. Current early warning systems typically rely on seismic instruments (seismometers and accelerometers). Global Navigation and Satellite System (GNSS) instruments are starting to be deployed, but are not yet fully exploited. Seismic instruments experience difficulty maintaining reliable data within close epicentral distance of large events. Large motions can exceed the dynamic range of broadband seismometers, and accelerometers conflate rotations and translations, causing spurious translational recordings that obscure the true nature of shaking. Moreover, the relation between ground motion amplitude and earthquake magnitude “saturates” for large earthquakes, causing magnitude underestimation that proved catastrophic for the 2011 M₉.₀ Great East Japan earthquake and resulting tsunami [Hoshiba and Ozaki, 2014; Yun and Hamada, 2014]. GNSS instruments capture the long period motions and have been shown to produce robust estimates of the true size of the earthquake source. However, GNSS alone is not precise enough to record first seismic wave arrivals, which is an important consideration for issuing an early warning. Our approach is to optimally combine direct measurements from collocated GNSS and accelerometer stations using a Kalman filter [Bock et al., 2011] to estimate broadband coseismic displacement and velocity waveforms with complete spectral recovery from the static offset to the accelerometer Nyquist frequency, regardless of the intensity of shaking. This approach, referred to as seismogeodesy, includes the long period and static offset without interference from accelerometer errors or saturation for large magnitude events and, unlike GNSS alone, is precise enough to detect P-wave arrivals. We demonstrate the advantages of seismogeodesy for earthquake early warning via retrospective simulated real time examples for earthquakes in the western U.S., Japan and Chile. For event detection and location we use the seismogeodetic velocity. We also discuss the sensitivity of hypocenter location as a function of the distribution of monitoring stations near the source and demonstrate rapid magnitude scaling relationships [Crowell et al., 2013; Melgar et al., 2015]. The prototype early warning system developed at Scripps is being applied to local tsunami warning by the U.S. National Oceanic and Atmospheric Administration’s Tsunami Warning Centers. The critical input for tsunami warning is a rapid estimate of magnitude.

Left: Seismogeodetic velocity waveforms at 11 GPS/seismic stations sorted by order of P-wave detection. Continuous blue vertical line denotes current epoch. Preceding red lines indicate when P-wave was detected from seismogeodetic velocity at each station.

Right: Once 4 stations have triggered, an estimate of the hypocenter can be made, denoted by the yellow star with one-sigma error ellipse on map. Hypocenter is updated with P-wave arrivals at additional stations. Propagation of P- and S-waves are shown by the partial circles (red and green, respectively), with the S-wave trailing the P-wave. In this scenario, it would take the S-wave front about 80-90s before arriving in the heavily populated areas of Riverside and Los Angeles Counties. Magnitude is estimated through Peak Ground Displacement (PGD) scaling relation using seismogeodetic displacement. Shown here is a frame 30s after P-wave detection at the first station.
地震波検知手法の改良：kurtosis（尖度）を利用したリアルタイムP波検知

Improvement of the P-wave detection method in real time by using kurtosis statistics

現在の緊急地震速報では、主にSTA/LTA（Allen, 1978）を用いてP波検知を行っているが、ノイズに強くロバストな検知方法として、kurtosisを用いたP波ピッキングが近年提案された（Saragiotis et al, 2002）。この手法は、オフラインでの処理を想定しており、緊急地震速報に利用するにはリアルタイム処理が必要である。そこで本手法を工夫してリアルタイム処理を可能にし、使用するデータ長やノイズ除去について検討を行った。また2005年4月から2015年7月までの中期間において震度5強以上を記録した地震の中から、震源距離が100km以内の観測点の記録に対して、STA/LTA（Allen, 1978）とkurtosis(Baillard et al, 2014)とkurtosis(realtime)の3つの方法によるP波検知を行った。こうして得られた各アルゴリズムのP波到達時刻とトリガ時刻を、波形を目で見て手動で決定したP波到達時刻と比較し、kurtosis(realtime)の性能を検証した。

その結果、地震波検知手法にkurtosisを用いると、従来の方法よりも地震波を早く検知でき、かつ地震波到達時刻をより正確に決定できることがわかった。

このことよりkurtosisを用いて地震波検知する手法を緊急地震速報に適応すると、従来の方法よりもはやく速報を得ることが可能となることがわかった。

Reduce False Alarm Due to Non-Earthquake Events for On-Site Earthquake Early Warning System in Schools

*Ting-Yu Hsu¹, Shieh-Kung Huang¹, Hung-Wei Chiang¹, Pei-Yang Lin¹, Kung-Chung Lu²

¹.Researcher, ².Assistant Researcher

An on-site earthquake early warning system (EEWS) can provide more lead-time at regions that are close to the epicentre of an earthquake since only seismic information of a target site is required. The on-site system extracts some P-wave features from the first few seconds of vertical ground acceleration of a single station and then predicts the intensity of the forthcoming earthquake at the same station according to these features. However, the system may be triggered by some vibration signals that are not caused by an earthquake or by interference from electronic signals, which may consequently result in a false alarm at the station. In order to reduce false alarms caused by non-earthquake events and at the same time keep earthquake alarms, an approach based on Support Vector Classification (SVC) and Singular Spectrum Analysis (SSA) is proposed. The established SVC model are employed to classify the vibration signals and then a SSA criterion is added for identifying earthquake events that are classified as non-earthquake events by the SVC model with increased accuracy. The proposed approach is verified by using data collected from earthquake early warning stations of the National Center for Research on Earthquake Engineering (NCREE). The results indicate that the proposed approaches effectively reduce the possibility of false alarms caused by unknown vibration events.

The earthquake early warning (EEW) concept is getting increasingly prevalent and somewhat replacing the expectation for earthquake prediction. An extensive real-time monitoring and EEW system installed in a wide region can detect an earthquake within seconds, and immediately issue alerts to affected areas through public media. On-site EEW systems developed for specific facilities may also detect an event and enable the facilities to take necessary actions before strong hits. Having timely warnings come accurate, EEWs can mitigate economy losses and save many lives. However, there are issues regarding EEWs provided by a big network and on-site monitoring systems that specialists in seismology know clearly, for which the general public has to be educated.

A big EEW system estimates seismic intensities using a conventional ground motion prediction equation (GMPE) as a function of distance that are not always in agreement with observed intensities. The actual intensity distributions in felt earthquakes show short-wavelength variation. The frequency band in which seismic intensities are determined is from about 0.5 to 10 Hz, and thus the response of subsurface structure is significant in the estimation. The ground motion at a specific site should be evaluated not only by a GMPE and a site amplification factor, but also accounting for the incident azimuth of incoming seismic waves. We have some exploratory studies to illustrate the local subsurface effects using data recorded by the dense network of strong motion instruments (with a station interval of less than 1.5 km) in Yokohama City. We used several small earthquakes of a similar magnitude (M~4.5) that are located at an epicentral distance of ~60 km from the network and provide different incident azimuths of incoming waves to the network. The observed ground motions at the stations show variations among the events reflecting 3D structural effects along the propagation paths. We also show the variation of amplification from a borehole to the surface using Kik-net data, and suggest that on-site calibrations are necessary for better intensity estimates. Should an earthquake occur directly beneath a crowded metropolitan area, e.g. Tokyo, the warning time is very short and cannot be extended by increasing the station density of a big network.
