Detailed distribution of microearthquakes along, an oblique spreading center, the northern Reykjanes Ridge

Masashi Mochizuki[1], Bryndis Brandsdottir[2], Hajime Shiobara[3], Gunnar Gudmundsson[4], Ragnar Stefansson[4], Hideki Shimamura[5]

We have obtained a snapshot image of the earthquake activity along the northern Reykjanes Ridge using a dense ocean bottom seismometer array. The earthquakes are narrowly concentrated along the NE-SW trending ridge crest. The seismicity is segmented into clusters by the en-echelon NNE-SSW trending axial volcanic systems which characterize the obliquely spreading ridge. The hypocenters are concentrated at somewhat greater depths (3-7 km) than on the Reykjanes Peninsula, where the crust is thicker. Normal faulting dominates at the ridge crest. The focal planes are oriented more NE-SW than NNE-SSW, i.e., parallel to the ridge crest and its peripheral faults rather than the trend of individual axial volcanic systems and associated faults.
