The hydrometric and tracer approaches were applied to investigate subsurface water flow processes of the soil and bedrock in a small headwater catchment underlain by sandstone, Karasawasan University Forest, Tokyo University of Agriculture and Technology, Tochigi prefecture, eastern Japan.

During the observation period (June 19, 2010 - December 29, 2010), 862 mm precipitation were observed and the runoff ratio of the monitored spring discharge was 32\%, that suggesting a large amount of groundwater infiltrate into the bedrock.

Groundwater level changed in the boreholes drilled into the bedrock with a similar trend of hydrograph at spring. The lag time from rainfall peak to the runoff peak shows a good correlation with that of groundwater level. This suggests that the groundwater flow hydraulically connects with the spring discharge.

End-member mixing analysis was applied to evaluate the runoff components using SiO\textsubscript{2} and HCO\textsubscript{3}\textsuperscript{−} concentrations as tracers. Contribution ratio of the bedrock groundwater to the runoff was estimated to be more than 60\% during a secondary runoff peak. The CFCs concentrations show an average residence time of the spring water to be approximately 20 years.
