A technique for EBSD analyses of phyllosilicates in petrographic sections and determination of polytypes in lepidolite

Applications of Electron backscatter diffraction (EBSD) to obtain crystallographic information of minerals in petrographic thin sections are increasing in mineralogy and petrology. However, platy phyllosilicates that mostly appear with their silicate layers terminated by the surface of the thin section generally do not show sharp EBSD patterns in spite of gentle mechanical polishing using colloidal silica. Transmission electron microscopy (TEM) examination indicated that this is due to crystal bending of phyllosilicates from the surface to a few micrometers in depth, caused by the polishing process (Fig. a). Ion beam etching commonly used to prepare TEM specimens was found to be applicable to remove the surface region with crystal bending (Fig. b and c). As a result, clear and sharp EBSD patterns were acquired from the phyllosilicates (micas, chlorite, etc.) in petrographic thin sections, by which their crystal orientations and polytypes were unambiguously determined. This technique was applied to the determination of polytypes of lepidolite, a lithium-rich aluminous mica whose general composition is expressed as K(Li, Al)2−3(Si,Al)4O10(OH,F)2.

The mica structure generates six standard polytypes expressed as 1M, 2M1, 2M2, 2O, 3T and 6R. They are divided into two subfamilies: subfamilies A and B. 1M, 2M1 and 3T are classified into subfamilies A, and 2M2, 2O and 6R are classified into subfamilies B (Backhaus and Durovic 1984). Using EBSD pattern, it is possible to distinguish the two subfamilies (Kogure 2002). We investigated lepidolite from a lithium pegmatite in Myoken-san, Ibaraki, where various polytypes have been reported (Kogure and Bunno 2004). EBSD analyses of lepidolite crystals in petrographic thin sections showed that polytypes with different subfamilies coexist within a single crystal: The outside was 1M (subfamilies A) and inside was 2M2 (subfamilies B).
