Planktonic foraminifers have been employed in paleoceanographic studies due to two major characters: wide geographic distributions of species and chemical composition of their calcareous shells, which reflect temperature and chemistry of ambient seawater. Accumulating phylogeographic knowledge, high genetic diversity of planktonic foraminifers has been known today and these genetically isolated species are distributed in narrower geographic area than we expected. The previous studies re-established temperature dependences of genetic types according to the pattern of their geographic distributions in many area. Moreover, genetic differentiation among geographically distant populations examined the role of ocean currents in dispersal of planktonic foraminifers. In order to improve the use of planktonic foraminifers as ocean environmental indicators, understanding ecological characters of genetic types is a crucial issue. In the previous studies for molecular phylogenetic analyses, living specimens of planktonic foraminifers were collected at each site as occasion arises. The present study therefore collected samples every month for 1 and half years at same location, the Tosa Bay, where the branch of the Kuroshio Current reaches. We focused on *Globigerinoides ruber*, the most commonly used species for paleoceanography, and found this morphospecies during the whole years in the study area. Four genetic types are detected throughout our survey, though the frequency of each type varied at each sampling time. We demonstrate the effect of external environment to productivity of planktonic foraminifers by analyzing the relationship among water-temperature, chlorophyll concentration, and frequency of genetic types. We furthermore test whether the distance from the main path of the Kuroshio Current is efficiently caused to transport a population of specific genetic type. These examinations provide us the exact information to address seasonal variation of planktonic foraminifers at genetic-type level.

Planktonic foraminifera are marine single celled eukaryotes that are found globally in the ocean. They construct calcite shells that accumulate in the sediment and are used for micropaleontological studies to reconstruct past climate conditions. Modern planktonic foraminifera have been classified into about 40 species on the basis of morphological characteristics of their calcite shell. Molecular investigations however uncovered an unexpectedly high cryptic genetic diversity within these morphospecies, implying that their biodiversity has been largely underestimated. These cryptic species show distinct biogeographic distribution patterns and ecological adaptations. Therefore, understanding the extent of genetic diversity within a morphospecies as well as the ecological adaptations of its cryptic species is highly important in order to enhance the applicability of foraminifera as proxies in micropaleontological studies. We are applying a single cell approach to survey the extent of cryptic diversity within the SSU rDNA of individual morphospecies and to examine the biogeography, habitats and ecological adaptations of cryptic species. In addition, we are trying to establish a connection between genetic diversity and morphological variability of the calcite shells by morphometric analysis in order to taxonomically revise the morphospecies and to create a connection between living specimens and the fossil record.

Major groups of foraminifers precipitate calcium carbonate and form calcareous shells with unique and complicate structure. One characteristic structure is a spine, covering the exterior surface of the shells. These shells and spines are though to have a function for the protection of the cell from predators or for the prop to extend the pseudopodia. However, in other organisms (e.g., land plants), calcareous crystals play a role for increasing light intensity into the photosynthetic tissue more efficiency by scattering light. Our question is what are ecological functions of the shell and spines of calcareous crystals in foraminifers.

Large benthic foraminifers (e.g., *Calcarina*) are the dominant species in the tropical reef waters, where is under exposure of strong light with nutrient depletion. They harbor a vast amount of photosynthetic symbionts inside the cell and utilize these symbionts for uptake recycle-nutrients to survive in the oligotrophic waters. Morphologically, *Calcarina* have blunt spines, which help to spread the pseudopodia, extended in a single circle round a central axis. Their pseudopodia attach to the basement, and avoid to be flowed over by tidal wave. However, our knowledge to ecological function of calcareous spines of *Calcarina* is still limited. We investigated the crystal orientation of calcareous spines of *Calcarina gaudichaudii* by using Electron Back Scatter Diffraction (EBSD) analysis. Calcareous crystals are arranged horizontally to the axis of the spine in the center and gradually vent to the edge. This orientation of calcareous crystals makes a pathway of light through spines to the interior of the shell. Our finding suggests that calcareous spines of *C. gaudichaudii* have ecological function to focus light into the cell and promote photosynthesis of their harboring symbionts.

For the study of biomineralization, the mollusc *Pinctada fucata* is arguably an attractive genetic model system, with its draft genome sequence having been deciphered recently. It produces two crystallographically different shell layers, including the industrially important nacreous layer. We are interested in developing knock-out pearl oysters to analyze the functions of shell matrix proteins, the key players in biomineralization processes, including the unusually acidic protein Aspein. In this study, the widely used Minos transposon system is applied to generate insertional mutagenesis. The first step in developing transposons as tools for mutagenesis is to demonstrate their mobile elements function efficiently and stably in the target organism. Therefore, green fluorescent protein (GFP) is integrated into the transposon to reflect its efficiency.

共焦点顕微鏡による大型有孔虫の細胞質形態と小胞内 pH の可視化 Morphological observation of cytoplasm with acidic and alkaline vesicles in large foraminifera cell by confocal imaging

Algal symbiont-bearing large benthic foraminifers are primary and carbonate producers as well as paleoenvironmental indicators in tropical and subtropical reef environments. Despite their importance, their cellular physiology is not well known. In the present study, we have developed methods to observe in vivo images of a living symbiotic porcelaneous large foraminifer, *Amphisorus kudakajimensis*. The Nikon A1 confocal laser scanning microscope with Calcein-AM was used as a fluorescent indicator for visualizing the morphology and streaming of cytoplasm in living *A. kudakajimensis*. The observations indicated that the cytoplasmic density decreased and reticulopodia were formed at the aperture in the marginal part of intrashell cytoplasm. We also observed vesicles with elevated pH (pH 9.0) and lowered pH (pH 6.0) in reticulopodia-like cytoplasm using a pH-sensitive probe molecule, 8-hydroxypyrene-1,3,6-trisulfonic acid (HPTS). The present study demonstrates the use of confocal microscopy in studying cytoplasmic dynamics and the initial calcification processes such as seawater endocytosis and alkalization of seawater vacuoles.

Calcifying organisms, such as pteropods, bivalves, corals and foraminifera provide a rich resource for pale-oceanographers and climatologists because their geochemical make-up (proxies) can be used to reconstruct past ocean history and evolution during and after natural carbon perturbations. However, it has been shown for all geochemical proxies that the main assumption of only one environmental variable controlling a target proxy is too simple. Empirical calibrations introduce a lot of uncertainty because the mechanisms of proxy incorporation are not well understood. The major problem is that the calcification mechanisms are still a black box. In this presentation I will review our current understanding of calcification and proxy incorporation in foraminifera, specifically with respect to the impact of carbonate chemistry and the new opportunities arising from this.

Specimens of the patellogastropod limpet *Patella caerulea* were collected within and outside a CO₂ vent site at Ischia, Italy. The shells were sectioned transversally and scanned for polymorph distribution by means of confocal Raman microscopy. Minor element to calcium ratios were measured using laser-ablation-inductively-coupled-plasma-mass-spectroscopy (LA-ICPMS). Mg/Ca, Sr/Ca, and Li/Ca ratios were determined in calcitic as well as aragonitic parts of the shells. This approach allows for investigating the effects of the polymorph and the seawater carbonate chemistry on minor element partitioning separately.

海洋性単細胞生物である有孔虫は、今日の海洋の炭酸カルシウムのおよそ 50%を生成しており、海洋における炭素サイクルの重要な部分を担っている。しかしながらその石灰化過程がどのようなメカニズムで進行し、どのように環境を変えているのかは未だ理解されていない。

今回我々は、有孔虫の石灰化過程を理解するために行った pH 分析の結果を報告する。まず pH を可視化することにより、石灰化過程にともなって有孔虫のまわりの pH が急速に低下することが確かめられた。これは有孔虫が石灰化時にプロトンを能動的に外界に輸送していることを意味している。次に可視化した pH 分布からプロトンの流束を見積もり、その流束と釣り合うような内部へのカルシウム輸送を仮定して、そのカルシウムの流入総量と新しいチャンバーを作るために必要な炭酸カルシウム量と比較した。これら結果を用いて、プロトンとカルシウムとの交換が石灰化過程に重要な役割を果たしていることを提唱する。

Planktic foraminifers are marine heterotrophic protists. Of about 50 species of modern planktic foraminifers, about 10 species that especially dominate in warm and low-nutrient surface water harbor autotrophic algae as endosymbionts (photosymbiosis). It is generally considered that foraminifers benefit from photosynthates of symbionts, and in return, they provide nutritious environment for symbionts to live. At the same time, however, the host's degree of dependence on symbionts is still enigmatic. This is because growth of the host primarily depends on food (prey) availability. In this context, a common assumption that photosymbiosis is an advantageous ecology for host foraminifers to live in oligotrophic oceans still has room to discuss. To understand trophic interaction between host and symbionts, we conducted culture experiments and analyzed vitality of host-symbiont consortia under controlled nutrient conditions.

We cultured dinoflagellate-bearing species *Globigerinoides sacculifer* for two weeks. Assuming the two sources of nutrients for symbionts, i.e., from the host's metabolites and from the ambient seawater, we controlled feeding regime (fed *Artemia* every other day or unfed) and nutrient concentration of culture media (0.22- μm filtered seawater [SW] or nutrients-added filtered seawater [NSW]). Four experimental groups are set; (a) fed and SW, (b) unfed and SW, (c) fed and NSW, and (d) unfed and NSW. Nutrient concentrations of SW and NSW were respectively 0.2 and 16 $\mu\text{mol L}^{-1}$ of NO_3+NO_2 , and 0.07 and 1.0 $\mu\text{mol L}^{-1}$ of PO_4 . Temperature was set to 26.5-27.5 °C. Photosynthetic active radiation was set to 170-220 $\mu\text{mol quanta m}^{-2} \text{s}^{-1}$, and its light/dark cycle was 14/10 hours. Test growth of the host, chlorophyll content, and photo-physiology of the symbionts were used as criteria of their vitality. We measured maximum test length of host foraminifers and chlorophyll fluorescence of individual host-symbiont consortium during the culture period almost every day. For fluorometric analysis, we used fast repetition rate (FRR) fluorometry. From FRR measurement, F_m (an index of chlorophyll content), and F_v/F_m (an index of potential photosynthetic activity) were obtained and analyzed for each individual consortium.

During the culture period, foraminifers grew and formed new chambers in the fed groups (a, c). On the contrary, specimens in the unfed groups (b, d) gradually decreased their cytoplasm volume, and in accordance with the decrease they often shed chambers one by one. The chlorophyll content, thus the biomass of symbionts per foraminifer, tended to increase in the fed groups (a, c), whereas it decreased or kept nearly constant in the unfed groups (b, d). Despite the apparent diminishment of the unfed groups, F_v/F_m was significantly higher in the unfed groups (b, d) than that in the fed groups (a, c). It indicates that symbionts in starved foraminifers photosynthesized more actively. Nutrient concentration in the culture media (SW or NSW) did not necessarily affect on F_v/F_m .

Considering the fact that foraminifers maintained their life and symbionts were capable of photosynthesis in starved condition, it can be said that foraminifers have survived only by photosynthates derived from the symbionts or digesting the symbionts themselves for about two weeks of the culture period. If this relationship is true in natural environment, photosymbiotic interaction should help foraminifers to survive for certain duration even if they cannot capture any prey. This should be an advantage for them to live in low-nutrient and well-lit environment.

The giant clam (*Tridacnidae*) widely distributes over the coral reefs in Indo-Pacific oceans and forms the largest shells in bivalves. The giant clam has symbiotic algae, facilitating fast growth rate and forming daily shell growth patterns. By measuring and counting the daily growth lines, we can know exactly when the daily growth lines were deposited. This growth pattern analysis is useful for reconstruction of the past environments at daily resolution. The aim of this study was to validate whether the shell of the giant clam (*Tridacna maxima*) in Okinotori Island, the southern edge island in Japan, could record daily environmental events such as typhoons.

The shell samples were collected alive in Okinotori Island on 5th Jun 2006. The shells were cut into two slices along the maximum growth axis. The number and interval width of microgrowth lines were measured under a digital microscope (KYENCE VHX-2000). Sub-sampling for oxygen stable isotope measurements were performed along the growth direction on another slice of the shell by using dental drill. The powder samples were introduced to carbonate preparation device (Kiel Device IV), and the produced CO₂ was analyzed by a stable isotope ratio mass spectrometer (Thermo Scientific MAT253). Stable oxygen isotope ratios ($\delta^{18}\text{O}$) were compared with sea surface temperature (SST) and maxima values were assigned the lowest SST in February. The correspondence between reconstructed SST and daily observed SST indicated that the microgrowth lines were formed daily basis. Growth disturbances were observed as v-shaped breaks in the shell outer layers. The high $\delta^{18}\text{O}$ peaks corresponded with these growth disturbances suggested that this specimen recorded the strong typhoon in Okinotori Island on 3th September 2005. Trace element analysis using laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) (Agilent 7700) with 100 μm and 30 μm spots (Mg, Ca, Mn, Sr, Ba) revealed that the specimen has Ba/Ca positive peaks as an after-signature of strong typhoons. Moreover, the significant positive peaks observed in Ba/Ca profile suggested the upwelling events due to typhoons in Okinotori Island.

These results indicated that sclerochronological and geochemical record in giant clam shells could be useful for reconstruction of past typhoon events.

人間活動の結果大気へと放出された二酸化炭素の約3分の1は海洋表層水によって吸収されたと考えられている。その結果、海水 pH は例にない速さで低下しており（海洋酸性化）、産業革命以降、すでに 0.1 低下したと考えられている。海水 pH の低下は炭酸塩飽和度を低下させるため、造礁サンゴに対して重大な影響をもたらすと考えられている。これまで、海洋酸性化が造礁サンゴに与える影響の評価は一般に飼育実験を通じて行われてきており、野外において影響を評価した研究はほとんどない。環境変化に対してサンゴそしてサンゴ礁生態系がどのように適応するか、或いは影響を被るかをより良く理解するためにも野外観測は必要不可欠である。そこで本研究では、北西太平洋・小笠原諸島父島で得られた塊状ハマサンゴに対して、表面電離型質量分析器を用いて過去 100 年間のホウ素同位体比 ($\delta^{11}\text{B}$) の分析を行った。測定結果は、1960 年以降のホウ素同位体比が顕著に低下していること ($-0.17 \pm 0.07 \text{‰/decade}$)、すなわち石灰化流体の pH が低下していることを示唆している。さらに、ハマサンゴの飼育実験の予想よりも早く石灰化流体の pH が低下していること（感度が高い）も分かった。このことは、石灰化流体の pH の上方調整機構にもかかわらず、アラゴナイト飽和度が予想よりも早く低下する可能性を示唆するものである（2050 年頃に海水の pH が 8.0 程度になった時には石灰化流体の pH は 8.3 程度）。従って、海洋酸性化は、温暖化に代表される種々の環境ストレスに既に晒されている造礁サンゴに対してさらなる悪影響を既にもたらしている可能性が高いと考えられる。

Marine calcification plays an important role in the global carbon cycle. Currently, approximately half of all carbon buried in the seafloor is the result of biogenic calcium carbonate production. Perforate foraminifera are a prime example of marine carbonate producers and responsible for a large portion of today's production. The physiological processes involved in calcification, however, are still unclear. Here we present some results on the intra- and extracellular pH changes in benthic perforate foraminifera during calcification. These observations allow for calculating the budgets of ion fluxes that are taken up and removed from the calcification space, which are placed in the context of previously obtained results and published calcification models to construct a unifying model for perforate foraminiferal calcification. This model also accounts for general patterns in observed fractionation factors of various elements.

無機的環境下における炭酸カルシウム多形の形成過程とその前駆物質 Inorganic precipitation mechanism of calcium carbonate polymorphs and their precursors

川野 潤^{1*}
KAWANO, Jun^{1*}

¹ 北海道大学 創成研究機構

¹ Creative Research Institution, Hokkaido University

Calcium carbonate, CaCO_3 , occurs in six different forms: three crystalline polymorphs (calcite, aragonite, and vaterite), two hydrate phases, and amorphous calcium carbonate (ACC). These polymorphs are important both in life and material sciences, especially the occurrence of CaCO_3 in living organisms has received considerable attention. As a basis for understanding biomineralization, inorganic precipitation mechanism of these polymorphs has been extensively investigated for over a hundred years. Recently, crystallization pathway through non-classical mechanism such as stable prenucleation cluster aggregation has been proposed, which give a new picture of the early stages of calcium carbonate growth. However our knowledge of formation process of CaCO_3 , especially that of the mechanism of polymorph selection, is far from complete.

We have investigated experimentally and theoretically the metastable formation of CaCO_3 polymorphs and their precursors. In particular, the effect of Mg^{2+} on the nucleation and growth of CaCO_3 polymorphs has been focused and the quantum chemical calculations of Mg-containing CaCO_3 surfaces and clusters appearing in the early stages of CaCO_3 formation have been performed. As a result, Mg^{2+} substituted for Ca^{2+} affects the structure of surfaces and clusters, and may have significant effect on the polymorph selection of CaCO_3 . In this presentation, we will report our results in detail based on the recent progress in this field.

The mesoscale granular textures having a single crystalline feature are generally observed on the continuous body of various biogenic and biomimetic calcite crystals. The distribution of the organic phase and lattice strain in the textured crystals vary with organism species or the growth conditions. The prismatic layer of a fan mussel, *A. pectinata*, exhibits a relatively homogeneous, low-strain texture consisting of the nanoscale grains with discrete organic inclusions; the prism structure of a pearl oyster, *P. fucata*, and an avian eggshell have a high-strain granular texture with localized organic phases. A variety of the mesoscopic textures similar to the biogenic calcite crystals are artificially produced in a supersaturated solution containing specific organic molecules. The high-strain textures were produced through mesoscopic dendritic growth of calcite by physical impedance of a rigid gel matrix and subsequent thickening of the branches. Continuous growth of the crystal involving nanoscale segregation of soluble polymers would result in the formation of the low-strain body having mesoscopic textures. The chemical durability of the low-strain biogenic and biomimetic textured calcites are enhanced by the combination of the inorganic crystal and the organic molecules.
