確率密度比推定を用いた前震のリアルタイム識別
Real-time Classifier of Foreshocks Using Probability Density Ratio Estimation

野村 俊一 1*

1 Tokyo Institute of Technology

前震は大地震の短期予測において一つの有効な手段である。過去多くの大地震について前震が観測されているが、本震が起こるより前に前震を識別することは困難な課題である。前震を事前に完全に識別することは困難であるものの、前震の位置情報や規模あるいは時間的情報などを利用して、前震であることを確率的に評価する研究はこれまでに多くの研究がなされてきた。

本研究では、確率密度比推定を用いて前震の確率的識別関数を構成する手法を提案する。確率密度比推定は統計的機械学習の一つの枠組みであり、高次元空間上でのクラス判別を確率的に与える手法である。更新されるカタログから随時追加的に学習することができ、リアルタイムでの前震識別を与えることが可能となる。識別関数にはカーネル関数を利用することで、空間的情報や時間的情報などを組み合わせた高次元空間上に非線形な判別境界を設けることができる。

本研究では、気象庁の一元化カタログに本手法を適用して、震源位置、時間、マグニチュードなどの情報から前震確率を評価する識別関数を推定する。また、推定された識別関数を独立した過去のカタログに適用して、予測性能の評価を行う。

Forecast uncertainty in aftershock forecasting

OMI, Takahiro1*; OGATA, Yoshihiko2; HIRATA, Yoshito1; AIHARA, Kazuyuki1

1 The Institute of Industrial Science, The University of Tokyo, 2 Institute of Statistical Mathematics

Aftershock forecasting provides one of the important measures for mitigation of earthquake damages. For this purpose, statistics- and physics- based models have been developed. When forecasting using these models, we usually adopt an optimal single set of parameter values such as the maximum likelihood estimates, which is called as plug-in forecasting. However, for a given small sized and incomplete data shortly after the main shock, the estimation of the model parameters may be accompanied by large uncertainty. In such a case, the plug-in forecasting underestimates the predictive probability range, and sometimes the range significantly biases the actual observations. Alternatively, more robust and unbiased forecasts can be obtained by considering the estimation uncertainty in an appropriate way. Bayesian forecasting provides a consistent statistical framework for this, and enables us to assess the forecast uncertainty. In this talk, we will argue the importance of evaluating the forecast uncertainty in probabilistic forecasting. As an example here, we employ the epidemic type aftershock sequence (ETAS) model as a forecasting model, and we show how the plug-in forecasting can fail and how the Bayesian forecasting can improve the performance. We will argue that the Bayesian predictors should also be tested in CSEP forecasting experiments.

Correlation between Coulomb stress imparted by the 2011 Tohoku-Oki earthquake and seismicity rate change in Kanto, Japan

ISHIBE, Takeo*; SAKAI, Shin'ichi; SHIMAZAKI, Kunihiko; TSURUOKA, Hiroshi; YOKOTA, Yusuke; NAKAGAWA, Shigeki; HIRATA, Naoshi

Earthquake Research Institute, the University of Tokyo, Japan Coast Guard, Hydrographic and oceanographic department

We show that the seismicity rate increase in the Kanto region around Tokyo following the 2011 Tohoku-Oki earthquake (Mw9.0) was well correlated with the static increases in the Coulomb failure function (ΔCFF) transferred from the Tohoku-Oki earthquake sequence. Because earthquakes in the Kanto region exhibit various focal mechanisms, the receiver faults for the ΔCFF were assumed to be reliable focal mechanism solutions of 3,000 earthquakes compiled from three networks (F-net, JMA network, and MeSO-net).

The histograms of ΔCFF showed that more events in the postseismic period had positive ΔCFF values than those in the preseismic period (2008 April 1 - 2011 March 10). Among the 928 receiver faults showing the significant ΔCFF with absolute values ≥ 0.1 bars in the preseismic period, 717 receiver faults (77.3 %) indicated positive ΔCFF. On the contrary, 1,334 (88.2 %) out of 1,513 receiver faults indicated positive ΔCFF in the postseismic period. We confirmed that the result is similar for the longer preseismic period, between 1997 October 1 and 2011 March 10.

To test the significance of the difference in the distribution of ΔCFF between preseismic and postseismic periods, we used a Monte Carlo method with bootstrap resampling. As a result, the ratio of positive ΔCFF randomly resampled from ΔCFF values in the preseismic period never exceeded 83.1%, even after 10,000 iterations. This supports the findings of Toda & Stein [2013]; however, our calculation is more reliable than theirs because we used a much larger number of focal mechanisms compiled from the three networks. It also proves that the static stress changes transferred from the Tohoku-Oki earthquake sequence are responsible for the changes in the seismicity rate in the Kanto region.

Earthquakes of focal mechanisms with positive ΔCFF values drastically increased, while those with negative ΔCFFs showed no obvious changes except for immediately after the mainshock. This fault-dependent seismicity rate change strongly supports the contribution of the Coulomb stress transferred from the Tohoku-Oki sequence to the seismicity rate change in the Kanto region. Immediately following the mainshock, earthquakes of all types of focal mechanisms were activated, but the increased seismicity rate of earthquakes with negative ΔCFFs returned to the background level within a few months. This suggests that there might be other contributing factors to the seismicity rate change such as dynamic stress triggering or pore-fluid pressure changes.

It is 5 years since we have established the Japanese testing center for the Study of Earthquake Predictability (CSEP) in Earthquake Research Institute, the University of Tokyo. During the period of testing, in 2011 March, Tohoku-oki earthquake with M9.0 occurred and seismic activity changed very much in entire part of Japanese Islands.

The CSEP Japan testing experiment consists of 12 categories, with 4 testing classes with different periods (1 day, 3 months, 1 year and 3 years) and 3 testing regions called “AllJapan,” “Mainland,” and “Kanto.” Starting from 91 models in September 2009, a total of 160 models, as of January 2015, are currently under testing in the CSEP official suite with collaboration of CSEP Testing Center at the Southern California Earthquake Center (SCEC) (Nanjo et al., 2011; Tsuruoka et al., 2012). For 3-month and one-year testing experiments, more than 15 runs of fully prospective experiments have been operated. Probability gains of tested models with respective to a spatially uniform probability model show that some models have always better performances in regions of AllJapan and Kanto, but the best model varies rounds by rounds for the region of Mainland.

In the testing period including the 2011 Tohoku-oki earthquake, a model which has wider spatial smoothing radius of 100km of Relative Intensity Model (RI) shows larger probability gain than those with a narrow smoothing while in other periods a small smoothing radius of 10 km shows better performance. Probability gains of models for 3-month and 1-year testing class for each model are almost same although a magnitude of target events is different. A model of HISTETAS5PA (Ogata, 2011) shows best performance for 1 day class and a region of AllJapan before the 2011 Tohoku-oki event but after the event ETAS (Zhuang, 2011) is better than HISTETAS5PA.

Post-Disaster Damage Mapping as Tool for Risk Testing

SCHORLEMMER, Danijel\(^1\+\) ; BEUTIN, Thomas\(^1\) ; FANSELOW, Florian\(^1\)

\(^1\)GFZ German Research Centre for Geosciences, 14473 Potsdam, Germany

The Post-Disaster Damage Mapping is part of the Global Dynamic Exposure project, in which we interpret and visualize crowd-sourced and open geographic data and provide guidance to what is called the crowd in data collection. We base our work on OpenStreetMap (www.openstreetmap.org) because of the fully open geographic data and the availability of open-source software for processing the data. Because of the immense number and variety of buildings, exposure- and vulnerability-related data cannot be compiled by a small group. Furthermore, the dynamic aspect of risk, namely rapid urbanization, requires monitoring of exposure and vulnerability indicators, again a task that can only be achieved when distributing the work onto many shoulders.

The objective of the Global Dynamic Exposure project is to provide a high-resolution (on the building-by-building level) and dynamic (low-latency) exposure model for the world. It will build upon the Global Exposure Database for the Global Earthquake Model (GED4GEM) and augment it where crowd-sourced and open data exists in high quality and high density. The exposure and vulnerability indicators are derived from geographic data (e. g. building footprint, land use), building properties (e. g. type of building, occupancy), and semantic interpretation (e. g. regional types of architecture, cultural habits). Once a target area is fully captured in OpenStreetMap, further changes in the dataset indicate the change of building stock or the process of urbanization. This dynamic aspect of data collection is used for the Post-Disaster Damage Mapping. Here, the so-called Humanitarian OpenStreetMap Team (hot.openstreetmap.org), a crowd-sourced disaster mapping effort, is providing information about the status of buildings and roads in the aftermath of a disaster. These data is retrieved mainly from aerial imagery but also from mappers on the ground.

Combining the exposure and vulnerability data of buildings prior to a natural disaster with the post-disaster damage status will provide a new dataset for better understanding risk and the societal impact of a catastrophe, but will also for the first time offer an independent dataset for testing risk estimates.

\textsuperscript{1}GFZ-Potsdam

Verifying a nationwide seismic hazard assessment using data collected after the assessment has been made (i.e., prospective data) is a direct consistency check of the assessment. We directly compared the predicted rate of ground motion exceedance by the four available versions of the USGS national seismic hazard map (NSHMP, 1996, 2002, 2008, 2014) with the actual observed rate during 2000-2013. The data were prospective to the two earlier versions of NSHMP. We used three sets of somewhat independent data, namely 1) the USGS "Did You Feel It?" (DYFI) intensity reports, 2) ShakeMap gridded ground motions, and 3) instrumental ground motion records extracted from ShakeMap stations. The first two were not strictly observations but models calibrated by observations. The third was true observation but the amount of data is limited.

Our results indicated that for California, the predicted and observed hazards are very comparable. Discrepancy lied generally on the safe side (i.e., predicted hazard not lower than the observed one). The three sets of data gave consistent results, implying robustness. The consistency also encourages the use of DYFI and ShakeMap data for hazard verification in the central and eastern US (CEUS), where instrumental records are lacking. The result showed that the observed ground-motion exceedance was larger than the predicted in CEUS, implying a possible underpredicted hazard.

The primary value of this study is to demonstrate the usefulness of DYFI and ShakeMap data, originally designed for community communication instead of scientific analysis, for the purpose of hazard verification. The large discrepancy between the observed and predicted ground-motion exceedance in CEUS implied that either the ground motions were not described correctly by DYFI and ShakeMap for the region, or the hazard was actually underestimated. Induced seismicity could be the cause of this underestimation.

Detecting spatial variations of earthquake clustering parameters via maximum weighted likelihoods estimates

庄建倉

ZHUANG, Jiancang

1統計数理研究所
1Institute of Statistical Mathematics

The ETAS model has been used to describe the clustering features of seismicity with just several parameters. To see how the clustering parameters and background rates change spatially, in this study, the earthquake data from the JMA catalog are used and these model parameters are estimated by using the maximum weighted likelihood estimate (MWLE) method. Even though this MWLE method is not as sophisticated as the HIST-ETAS model, which is built on a more rigorous basis of the Bayesian procedure with the smoothness prior, MWLE is simpler to implement, in both parallel and non-parallel computing environments, without loss of detecting resolution of the spatial variation of earthquake clustering parameters.

The data analysis shows that the spatial variation of the MWLEs of each parameter shows different features between tectonic regions. Also, applying the MWLE method has the potentials for improving the forecasting performance of the space-time ETAS model in evaluating earthquake probabilities.

前震や余震があることからも明らかのように，地震活動には，互いに相関のある活動が含まれる。そのため，地震数の頻度分布をポアソン分布で表することは難しいと思われるが，実際の近い分布関数について検討した。これは，地震活動の一因を理解する上で必要なことであり，また，正しい頻度分布がわからないと適確な予測の評価を行うことができない。

地震数の頻度分布は，これまでしばしば負の2項分布で表されてきた。しかしこれは，概してデータセットの平均 \( r \) が大きい場合（例えば \( r \gg 1 \) ）であり，希にしか地震が起こらないデータセットについては，疑問に思われる。小さな平均の場合，分布は負のべき分布に近い。そこで筆者たちは，地震発生頻度の分布関数として，離散ガンマ分布を提案した（\( f(x) = c (x-a)^{a-1} \exp(-bx) \)：Yamashina et. al, 2012）。一方，もうひとつの候補として，ここでは負の離散ガンマ分布を取り上げる（\( f(x) = c (x-a)^{a-1} \exp(-b/x) \）両関数は，大きな平均をもつデータセットから小さな平均のものまで，広い範囲でかなりよく実際の分布事例について示すことができるが，特に大きな平均をもつ場合について，後者の方が当てはまりがよい傾向がある。

ここで取り上げた関数は， \( a \) が正のときには \( x = 0 \) で発散するが， \( x = 1 \) 以上について適用する。これは，例えば \( x = 2 \) の頻度は \( x = 1 \) の頻度と関係するものの， \( x = 0 \) の頻度との相関が小さいと思われ， \( x = 0 \), \( 1 \), \( 2 \) を同じ分布関数で表現することは難しいと考えられたからである。\( x = 0 \) の頻度は，他の頻度を合計した残りとする。

CSEPプロジェクトの地震活動予測において，予測値がどのくらい実状に合っていたかどうかを評価する際，現在は，地震発生回数の頻度がポアソン分布だとみなして行っている。しかし，実態を必ずしも反映しない頻度分布を前提にしたのでは，評価した結果が信頼性に欠ける。今後，実態に合う頻度分布を評価に取り入れたときにどのような違いがあるかも知れないが，確かめられることが望まれる。

An important characteristic of any seismic network is its detection completeness, which should be considered a function of space and time. Many researchers rely on robust estimates of detection completeness, especially when investigating statistical parameters of earthquake occurrence like earthquake rates. Contrary to traditional approaches, we do not estimate completeness using methods in which the completeness magnitude is defined as the deviation of the frequency-magnitude distribution from the linear Gutenberg-Richter relation. Here, we present a method based on empirical data only: phase data, station information, and the network-specific attenuation relation. For each station of the network we estimate a time-dependent distribution function describing the detection capability depending on magnitude and distance to the earthquake. For each point in time, maps of detection probabilities for certain magnitudes or overall completeness levels are compiled based on these distributions. Therefore, this method allows for inspection of station performances and their evolution as well as investigations on local detection probabilities even in regions without seismic activity.

We present a full history of network detection completeness for Japan and discuss details of this evolution. These results are compared with estimated completeness levels of other methods and with completeness levels in other regions of the World. We present scenario computations showing the impact of different possible network failures. All presented results are published on the CompletenessWeb (www.completenessweb.org) from which the user can download completeness data from all investigated regions, software codes for reproducing the results, and publication-ready and customizable figures.

Assessment of optimal short-term earthquake forecasts based on ULF seismo-magnetic data

Han Peng\textsuperscript{1,*}; Hattori Katsumi\textsuperscript{1}; Zhuang Jiancang\textsuperscript{2}

1\textsuperscript{Graduate School of Science, Chiba University, 2\textsuperscript{Institute of Statistical Mathematics, Tokyo, Japan}

Our previous statistical studies have indicated that the ULF seismo-magnetic phenomena contain precursory information and can be useful in short-term forecasting of sizable earthquakes. In practice, for given series of precursory signals and related earthquake events, the efficiency of forecast is a function of the leading time of alarms (\(\Delta\)) and the length of alarm window (L). To find out the best prediction strategies, Molchan’s error diagram has been employed. The same as our previous study, we utilized geomagnetic data and earthquake events registered in Kakioka (KAK), Japan during 2001-2010. Ratios of observed energy to modeled background are applied to indentify precursory signals. A modified area skill score, which measures the area between actual prediction curve and random prediction line, is introduced to assess the efficiency of different prediction strategies. The results indicate that ULF magnetic data at KAK contains higher precursory information when \(\Delta\) is around 1 week and L is less than 4 days or \(\Delta\) is 13-14 days and L is less than 1 week; the optimal strategy of short-term forecasts is: \(\Delta = 8\) days and L = 1 day. The methodology proposed in this study could help to evaluate the prediction policy and find out the optimal solution of other different measurements for short-term earthquake forecasting.

Earthquake mechanism in post-megathrust intraplate stress

HONG, Tae-kyung¹*, LEE, Junhyung¹; HOUNG, Soung eil¹
HONG, Tae-kyung¹*, LEE, Junhyung¹; HOUNG, Soung eil¹

¹Yonsei University, Department of Earth System Sciences, Seoul 120-749, South Korea

Megathrusts produce large permanent lithospheric displacements as well as strong transient ground shaking up to regional distances. The lateral permanent displacements construct stress shadows in a wide backarc region. The Korean Peninsula is placed in the far-eastern Eurasian plate that belongs to a stable intraplate region with a low earthquake occurrence rate and diffused seismicity, and is located in the backarc at ~1300 km in the west from the epicenter of the 11 March 2011 M9.0 Tohoku-Oki earthquake. The seismicity around the Korean Peninsula was increased significantly after the 2011 M9.0 Tohoku-Oki earthquake, which is not consistent with the expected seismic-quiescence. Strong seismic waves cause large dynamic stress changes, incurring fluid migration and increasing pore fluid pressure in the media. The lithospheric displacements directing to the epicenter on the convergent plate boundary develop transient radial tension field over the backarc lithospheres, which is subparallel with the preseismic ambient compressional field. The pore pressure growth and radial tension field decrease the Coulomb failure stress, increasing episodic increases of seismicity in both fault zones and intact media. The ambient stress field is recovered gradually as the induced stress field diminishes with time by tectonic loading. The seismicity changes with the temporal evolution of stress field. A series of moderate-size earthquakes and earthquake swarms occur as a consequence of medium response to the temporal evolution of stress field. The long-term evolution of seismicity is expected to continue until the preseismic ambient stress field is fully recovered.
