

Mantle melting and volatiles: Redox-controlled solution behavior in silicate-COH magmatic systems

The behavior of hydrogen-bearing fluids and magmatic liquids is at the core of understanding formation and evolution of the Earth, its oceans, and atmosphere. To advance this knowledge, infrared and Raman spectroscopy has been employed for melt structural characterization and for determination of hydrogen and carbon isotope partitioning within and between melts and fluids in alkali aluminosilicate-C-O-H systems contained in externally-heated diamond anvil cells. The measurements were carried out in-situ under equilibrium conditions while the samples were at the temperatures, pressures, and redox conditions corresponding to those of the Earth's upper mantle and deep crust.

Hydrogen as H₂O is the major component of the silicate Earth. Its solubility in magma can reach >30 wt% under crustal and upper mantle conditions. The CH₄ and H₂ solubility is in the 0.1-1 wt% range, and CO₂-solubility typically 1-5 wt%. These variations reflect bulk chemical and, therefore, structural control of solubility. Water dissolved in magmatic liquids to form predominantly Si-OH and Al-OH bonding together with molecular H₂O. The OH/H₂O ratio is positively correlated with SiO₂ and Al₂O₃ concentrations in melts. The carbon solution equilibria are, $2\text{CH}_4 + \text{Q}^n = 2\text{CH}_3 + \text{H}_2\text{O} + \text{Q}^{n+1}$ and, $2\text{CO}_2 + \text{H}_2\text{O} + 2\text{Q}^{n+1} = \text{HCO}_3 + 2\text{Q}^n$, under reducing and oxidizing conditions, respectively. In the Qⁿ-notations, the superscript, *n*, in the Qⁿ-species denotes number of bridging oxygen in the silicate species (Q-species). The abundance ratios, CH₃/CH₄ and HCO₃/CO₂, increase with temperature.

The resulting structural changes result in hydrogen and carbon isotope fractionation factors between melt, fluid, and crystalline materials significantly different from 1 even at magmatic temperatures. The D/H and fractionation between aqueous fluid and magma are also temperature dependent with a small enthalpy change near -5 kJ/mol. In silicate-C-O-H systems, the enthalpy-values for ¹³C/¹²C fractionation factors are near -3.2 and 1 kJ/mol under oxidizing and reducing conditions, respectively. These differences reflect different energetics of O-D, O-H, O-¹³C, and O-¹²C bonding environments governed by different solution mechanisms in melts of the individual volatile components.

From experimentally-determined temperature- and pressure-dependent D/H fractionation between fluids and melts, it is suggested suggest that (C-O-H)-saturated partial melts in the upper mantle can have dD-values 100%, or more, lighter than coexisting silicate-saturated fluid. This effect is greater under oxidizing than under reducing conditions. Analogous relationships exist for ¹³C/¹²C with δ¹³C-differences between silicate melts and coexisting CO₂+H₂O (oxidizing) and CH₄+H₂O+H₂ (reducing) fluid and at magmatic temperatures in the Earth's upper mantle increases with temperature from about 40 to > 100% and 80 -120 % under oxidizing and reducing conditions, respectively. The use of hydrogen and carbon isotopes of mantle-derived magma to derive isotopic composition of upper mantle source regions, therefore, is discouraged as these are affected by temperature, bulk composition, and redox conditions during melting, crystallization, and degassing events.
